- *Ischemic heart disease and cerebrovascular disease are the leading causes of death in developed countries*. In these countries the main risk factors associated with loss of healthy life are smoking, high blood pressure, obesity, high cholesterol, and alcohol abuse.
- *In developing countries, infectious diseases constitute 5 of the 10 leading causes of death:* respiratory infections, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), diarrheal diseases, tuberculosis, and malaria.[2] HIV/AIDS contributes 18% to the loss of healthy life in sub-Saharan Africa and 13% in South Asia.
- *About 70% of all child deaths are attributed to only five conditions, all of them preventable*: pneumonia, diarrheal diseases, malaria, measles, and perinatal/neonatal problems (mostly prematurity and neonatal infections).
- *Worldwide mortality of children under 5 years of age has declined* from 110 deaths per 1000 in 1980 to 72 per 1000 in 2005. Though impressive, the 27% decline in mortality under 5 years of age, expected to occur between 1990 and 2015, falls short of the United Nations Millennium Development Goal of achieving a 67% decline. To be noted is that under-5 mortality in Central and West Africa (about 210/1000) is almost 50 times higher than that in Western Europe[3] (Fig. 9-1) and has shown no significant decline.
- *Emerging infectious diseases (EIDs)* constitute one of the most important components of the global burden of disease. EIDs are correlated with environmental, and socioeconomic conditions, and include (1) *diseases caused by newly evolved strains or organisms*, such as rifampin/isoniazid-resistant and multidrug-resistant (XDR) tuberculosis, chloroquine-resistant malaria, and methicillin-resistant *Staphylococcus aureus;* (2) *diseases caused by pathogens endemic in other species (e.g., wild mammals and birds) that recently entered human populations*, such as HIV and severe acute respiratory syndrome (SARS); (3) *diseases caused by pathogens that have been present in human populations but show a recent increase in incidence*, such as dengue fever.
- Bacteria and rickettsia caused approximately 54% of worldwide emerging infectious diseases during the last 60 years (viruses represented ~25%). Drug-resistant bacteria were the most important group of pathogens. Their appearance relates to therapeutic use of antibiotics, and in agriculture as well as urban living in densely populated areas. During the last decade, vector-borne diseases constituted approximately 29% of emerging infectious disease, an increase that may be related to environmental changes such as global warming.[4]

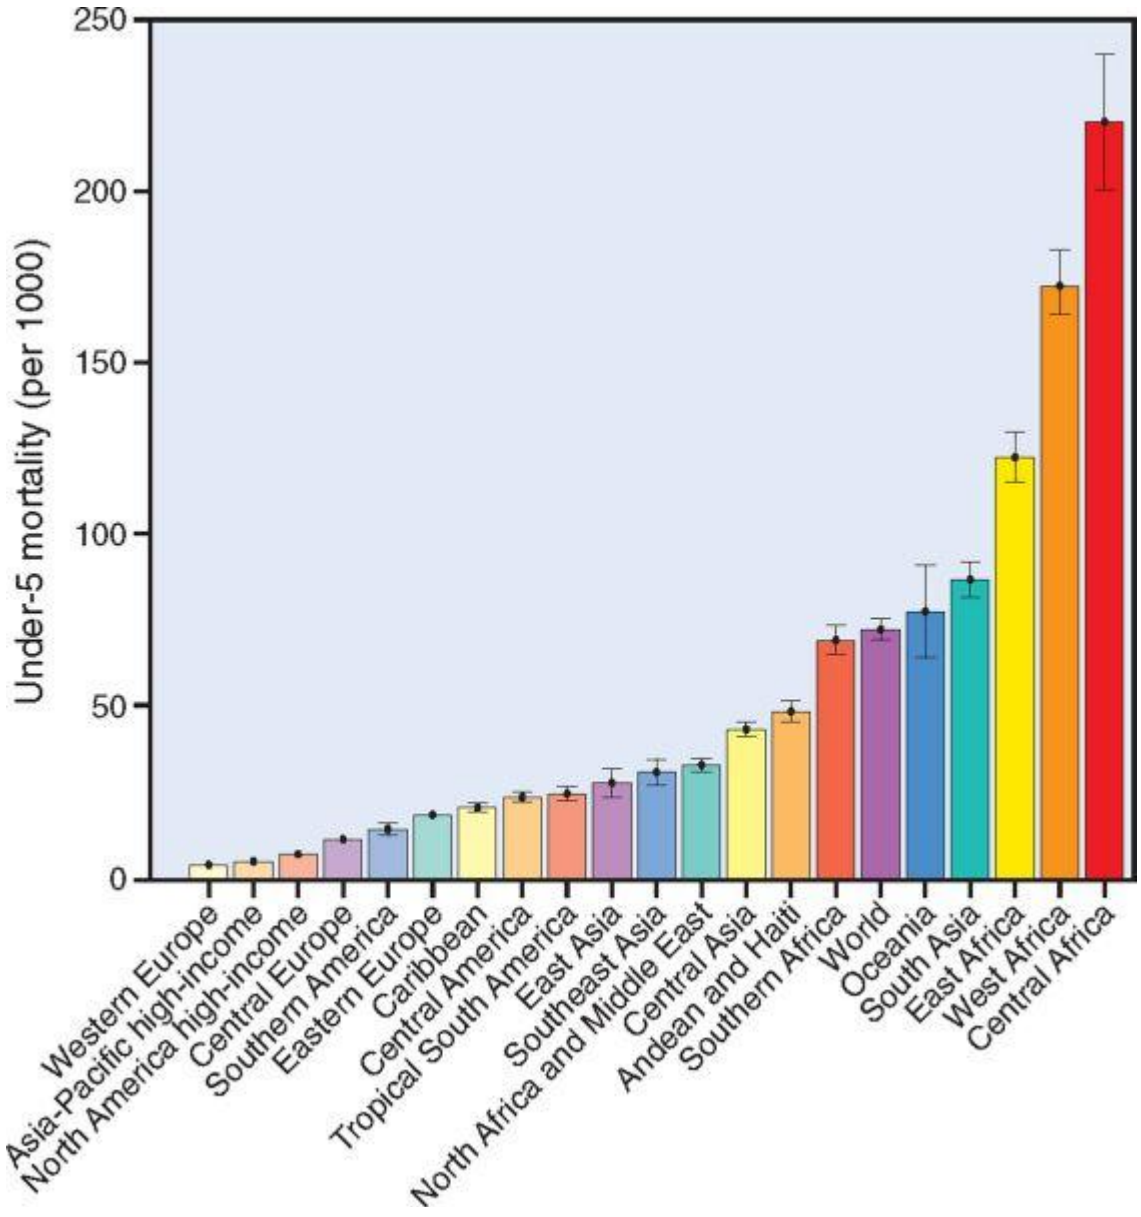

FIGURE 9-1 Worldwide mortality of children under 5 years of age. Note the more than 50-fold difference between areas with the lowest and highest mortality. Malnutrition and infections are major causes of the high mortality in East, Central, and West Africa.

2.9.2 Health Effects of Climate Change

There is general agreement that the earth has been warming at an accelerating pace during the last 40 years, and that the rate of warming is more rapid than at any other period in perhaps 1000 years.[5] Since 1960 the global average surface temperature increased by 0.6°C; the increase is not uniform, being greatest at latitudes between 40° N and 70° N.[6] Glacier melting has accelerated, and in polar regions, snow cover and ice thickness have diminished. At the same time, the sea level has risen 1 to 2 mm/year as a result of thermal expansion.[6] The importance of climate change was highlighted by the awarding of the 2007 Nobel Peace Prize to individuals and organizations concerned with the impact of these changes on human health.

The causes of global climate change are the subject of debate, but human activity is a major contributor, through increases of *carbon dioxide* (CO_2), *methane*, and *ozone* (discussed later), the main agents of the *greenhouse effect*. These gases (along with water vapor) act like a blanket by absorbing energy radiated from the earth's surface that would otherwise be lost into space. Recent increases in levels of greenhouse gases, particularly CO_2 and ozone produced by the combustion of hydrocarbons in automobiles and energy plants, are strongly correlated with warming of the earth (Fig. 9-2). The present concentration of atmospheric CO_2, estimated to be 370 ppm (highest in about 1 million years), is expected to increase to 500 to 1200 ppm at the end of this century. Also contributing to the increase in atmospheric CO_2 is large-scale deforestation (present estimates are that the Amazon forest will lose 50% of the original area by 2050), which decreases carbon sequestration by trees. Beyond certain levels of warming of the land and seas, it is predicted that positive-feedback loops will amplify the process further. Examples include increases in heat absorption due to the loss of reflective snow and ice; increases in water vapor in the atmosphere due to greater evaporation from bodies of water and transpiration from trees; large releases of stored CO_2 and methane from thawing arctic tundra; and decreased sequestration of CO_2 in the oceans, due to diminished growth of diatoms, which serve as an important CO_2 sink. Depending on the model used, these changes are predicted to cause the global temperature to rise 2° to 5°C by the year 2100 (see Fig. 9-2).

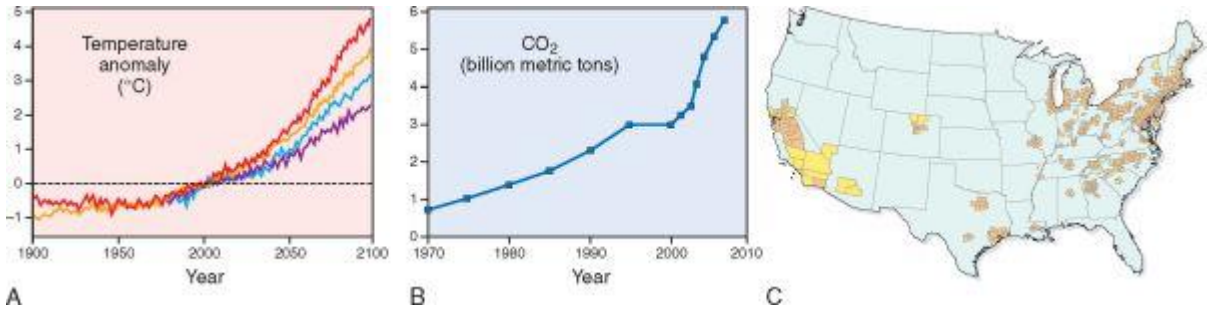

FIGURE 9-2 Sources and consequences of increased greenhouse gases. **A**, Predicted temperature increases during the twenty-first century. Different computer models plot anticipated rises in temperature of 2° to 5°C by the year 2100. **B**, Release of carbon dioxide (CO_2) from combustion sources in China, 1970 to 2005. China has now surpassed the United States as the world's largest producer of CO_2. **C**, Regions of the United States in which ozone levels are above existing accepted standards (80 ppb during an 8-hour period). These areas include about 500 counties located predominantly in the East Coast corridor, the Los Angeles basin, and areas with large coal-burning plants.

The future impact of global warming on health will depend on the extent and rapidity of climate change, the severity of the ensuing consequences, and humankind's ability to adapt to or otherwise mitigate the damaging effects. Even in the best-case scenario, however, it is expected that climate change will seriously impact human health by increasing the incidence of several diseases.[7]

- *Cardiovascular, cerebrovascular, and respiratory diseases*, caused by heat waves and air pollution (e.g., the European summer of 2003, the warmest in 500 years, resulted in more than 25,000 heat- and pollution-related deaths)
- *Gastroenteritis and infectious disease epidemics*, caused by water and food contamination as a consequence of floods, and disruption of clean water supplies and sewage treatment, after heavy rains and other environmental disasters
- *Vector-borne infectious diseases*, such as dengue fever, malaria, West Nile virus infection, and hantavirus pulmonary syndrome, as a consequence of changes in vector number and geographic distribution caused by increased temperatures, crop failures, and more frequent El Nino climate cycles
- *Malnutrition*, caused by disruption of crops, mostly in tropical locations in which average temperatures are near or above crop tolerance levels; it is estimated that by 2080 agricultural productivity may decline by 10% to 25% in some developing countries as a consequence of warming, while it may decrease or even increase by up to 6% in developed countries with more moderate climates

Despite recognition of these dangers, climate change is just one of multiple factors that contribute to the incidence of a disease at a particular geographic location, making it difficult to establish precise risk estimates for effects which are specifically caused by global warming.[8]

Both developed and developing countries will suffer the consequences of climate change, but the burden will be heaviest in developing nations. Wealthy countries are the main producers of the emissions that cause global warming, but rapidly developing countries such as China and India are using increasingly large amounts of energy to sustain their growth. The urgent challenge ahead is to develop new methods of energy production that do not harm the environment and do not contribute to global warming.

2.9.3 Toxicity of Chemical & Physical Agents

Toxicology is defined as the science of poisons. It studies the distribution, effects, and mechanisms of action of toxic agents. More broadly, it also includes the study of the effects of physical agents such as radiation and heat. Approximately 4 billion pounds of toxic chemicals, including 72 million pounds of recognized carcinogens, are released per year in the United States. Of about 100,000 chemicals in commercial use in the United States, only a very small proportion has been tested experimentally for health effects. Several agencies in the United States set permissible levels of exposure to known environmental hazards (e.g., the maximum level of carbon monoxide in air that is noninjurious or the tolerable levels of radiation that are harmless or "safe"). But factors such as the complex interaction between various pollutants, and the age, genetic predisposition, and the different tissue sensitivities of exposed persons, create wide variations in individual sensitivity to toxic agents, limiting the value of establishing rigid "safe levels" for entire populations. Nevertheless, such levels are useful for comparative studies of the effects of harmful agents between specific populations, and for estimating risk of disease in heavily exposed individuals.

We now consider some basic principles relevant to the effects of toxic chemicals and drugs.

- The *definition of a poison* is not straightforward. It is basically a quantitative concept strictly dependent on *dosage*. The quote from Paracelsus in the sixteenth century that "all substances are poisons; the right dosage differentiates a poison from a remedy" is even more valid today, given the proliferation of pharmaceutical drugs with potentially harmful effects.
- *Xenobiotics* are exogenous chemicals in the environment in air, water, food, and soil that may be absorbed into the body through inhalation, ingestion, and skin contact (Fig. 9-3).
- Chemicals may be excreted in urine, feces, or eliminated in expired air, or may accumulate in bone, fat, brain, or other tissues.
- Chemicals may act at the site of entry or at other sites following transport through the blood.
- *Most solvents and drugs are lipophilic*, which facilitates their transport in the blood by lipoproteins and their penetration through the plasma membrane into cells.
- Some agents are not modified after entry in the body, but most solvents, drugs, and xenobiotics are metabolized to form inactive water-soluble products *(detoxification)*, or are *activated to form toxic metabolites*. The reactions that metabolize xenobiotics into nontoxic products, or activate xenobiotics to generate toxic compounds (Figs. 9-3 and 9-4), occur in two phases. In *phase I* reactions, chemicals undergo hydrolysis, oxidation, or reduction. Products of phase I reactions are often metabolized into water-soluble compounds through *phase II* reactions, which include glucuronidation, sulfation, methylation, and conjugation with glutathione. Water-soluble compounds are readily excreted. Enzymes that catalyze the biotransformation of xenobiotics and drugs are known as *drug-metabolizing enzymes*.
- The most important catalyst of phase I reactions is the *cytochrome P-450 enzyme system* (*abbreviated as CYP*) located primarily in the endoplasmic reticulum of the liver but also present in skin, lungs, and gastrointestinal mucosa, and practically every organ.[9] CYPs are a large family of heme-containing enzymes with preferential affinity toward different substrates. The system catalyzes reactions that either *detoxify xenobiotics or activate xenobiotics into active compounds that cause cellular injury*. Both types of reactions may produce, as a byproduct, *reactive oxygen species (ROS)*, which can cause cellular damage (Chapter

1). Examples of metabolic activation of chemicals through CYPs are the production of the toxic trichloromethyl free radical from carbon tetrachloride in the liver, and the generation of a DNA-binding metabolite from benzo[*a*]pyrene, a carcinogen present in cigarette smoke. CYPs participate in the metabolism of a large number of common therapeutic drugs such as acetaminophen, barbiturates, and anticonvulsants, and also in alcohol metabolism (discussed later in this chapter).

There is great variation in the activity of CYPs among individuals. The variation may be a consequence of *genetic polymorphisms in specific CYPs*, but more commonly it is due to exposure to drugs or chemicals that induce or diminish CYP activity. Known CYP inducers include environmental chemicals, drugs, smoking, alcohol, and hormones. In contrast, fasting or starvation can decrease CYP activity.

Inducers of CYP do so by binding to nuclear receptors, which then heterodimerize with the retinoic X receptor (RXR) to form a transcriptional activation complex that associates with promoter elements located in the 5′-flanking region of CYP genes.[10] Nuclear receptors participating in CYP induction responses include the *aryl hydrocarbon receptor*, the *peroxisome proliferator–activated receptors (PPAR)*, and two orphan nuclear receptors, constitutive androstane receptor (CAR), and pregnane X receptor (PXR).

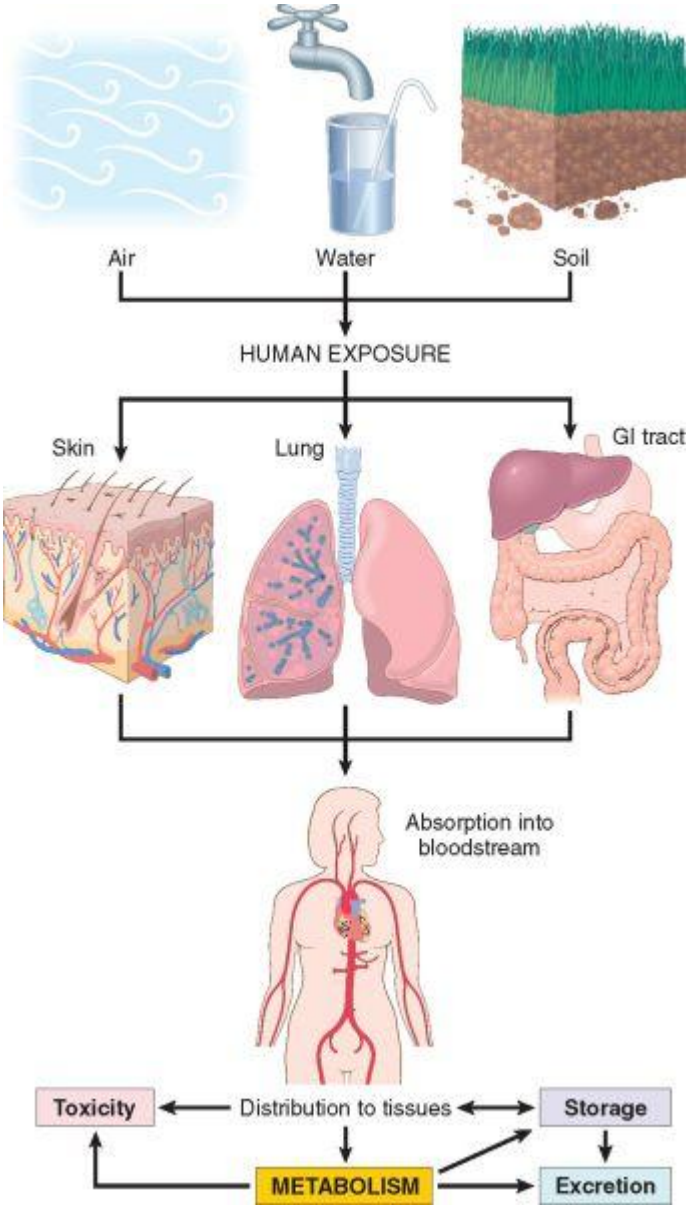

FIGURE 9-3 Human exposure to pollutants. Pollutants contained in air, water, and soil are absorbed through the lungs, gastrointestinal tract, and skin. In the body they may act at the site of absorption but are generally transported through the bloodstream to various organs where they may be stored or metabolized. Metabolism of xenobiotics may result in the formation of water-soluble compounds that are excreted, or in activation of the agent, creating a toxic metabolite.

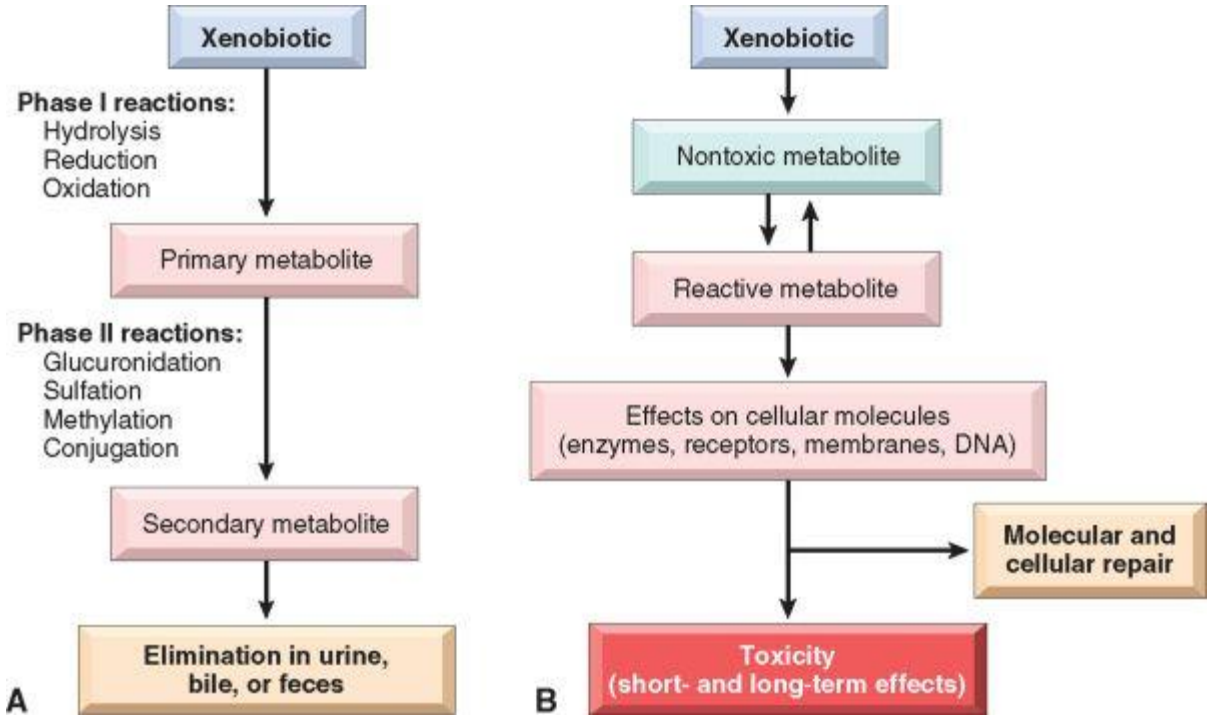

FIGURE 9-4 Xenobiotic metabolism. **A**, Xenobiotics can be metabolized to nontoxic metabolites and eliminated from the body (detoxification). **B**, Xenobiotic metabolism may also result in the formation of a reactive metabolite that is toxic to cellular components. If repair is not effective, short- and long-term effects develop. *(Based on Hodgson E: A Textbook of Modern Toxicology, 3rd ed. Hoboken, NJ, Wiley, 2004.)*

This brief overview of the general mechanisms of toxicity provides the background for the discussion of environmental diseases presented in this chapter.

2.9.4 Environmental Pollution

AIR POLLUTION

Precious as air is—especially to those deprived of it—it is often loaded with many potential causes of disease. Airborne microorganisms contaminating food and water have long been major causes of morbidity and mortality, especially in developing countries. More widespread are the chemical and particulate pollutants found in the air, especially in industrialized nations. Here, we consider these hazards in outdoor and indoor air.

Outdoor Air Pollution

The ambient air in industrialized nations is contaminated with an unsavory mixture of gaseous and particulate pollutants, more heavily in cities and in proximity to heavy industry. In the United States the Environmental Protection Agency monitors and sets allowable upper limits for six pollutants: sulfur dioxide, carbon monoxide, ozone, nitrogen dioxide, lead, and particulate matter. Collectively, these agents produce the well-known *smog* (smoke and fog) that sometimes stifles large cities such as Beijing, Los Angeles, Houston, Cairo, New Delhi, Mexico City, and São Paulo. It may seem that air pollution is a modern phenomenon. This is not so, since John Evelyn wrote in 1661 that inhabitants of London suffered from “Catharrs, Phthisicks and Consumptions” (bronchitis, pneumonia, and tuberculosis) and

breathed “nothing but an impure and thick mist, accompanied by a fuliginous and filthy vapour, which renders them obnoxious to a thousand inconveniences, corrupting the lungs, and disordering the entire habit of their bodies.” The first environmental control law, proclaimed by Edward I in 1306, was straightforward in its simplicity: “whoever should be found guilty of burning coal shall suffer the loss of his head.” Thus, what has changed in modern times is the nature and sources of air pollutants, and the types of regulations that control their emission.

Although the lungs bear the brunt of the adverse consequences, air pollutants can affect many organ systems (see, for instance, the discussion of lead poisoning and carbon monoxide effects in this chapter). Except for some comments on smoking, pollutant-caused lung diseases are discussed in Chapter 15 . Major health effects of outdoor pollutants are described in Table 9-1 . Here we discuss ozone, sulfur dioxide, particulates, and carbon monoxide.

TABLE 9-1 -- Health Effects of Outdoor Air Pollutants

Pollutant	Populations at Risk	Effects
Ozone	Healthy adults and children	Decreased lung function
		Increased airway reactivity
		Lung inflammation
	Athletes, outdoor workers	Decreased exercise capacity
	Asthmatics	Increased hospitalizations
Nitrogen dioxide	Healthy adults	Increased airway reactivity
	Asthmatics	Decreased lung function
	Children	Increased respiratory infections
Sulfur dioxide	Healthy adults	Increased respiratory symptoms
	Individuals with chronic lung disease	Increased mortality
	Asthmatics	Increased hospitalization
		Decreased lung function
Acid aerosols	Healthy adults	Altered mucociliary clearance
	Children	Increased respiratory infections
	Asthmatics	Decreased lung function
		Increased hospitalizations
Particulates	Children	Increased respiratory infections
	Individuals with chronic lung or heart disease	Decreased lung function
	Asthmatics	Excess mortality
		Increased attacks

Data from Bascom R, et al.: Health effects of outdoor air pollution. Am J Respir Crit Care Med 153:477, 1996.

Ozone. The interaction of ultraviolet (UV) radiation and oxygen (O_2) in the stratosphere leads to the formation of *ozone* (O_3), which accumulates in the so-called ozone layer 10 to 30 miles above the earth's surface. This layer protects life on earth by absorbing the most dangerous UV radiation emitted by the sun. During the last 30 years, the stratospheric ozone layer decreased in both thickness and extent due to the widespread use of aerosols, which drift up into the upper atmosphere and participate in chemical

reactions that destroy ozone. The resulting depletion has been most profound over polar regions, particularly Antarctica, during the winter months. Recognition of the problem led to the ban of chlorofluorocarbons as aerosol propellants and their replacement by hydrofluoroalkanes, resulting in a decrease in the extent of stratospheric ozone "holes."

In contrast to the "good" ozone in the stratosphere, *ozone that accumulates in the lower atmosphere (ground-level ozone) is one of the most pernicious air pollutants* (see Fig. 9-2). Ground-level ozone is a gas formed by the reaction of nitrogen oxides and volatile organic compounds in the presence of sunlight. These chemicals are released by industrial emissions and motor vehicle exhaust. Ozone toxicity is in large part mediated by the production of free radicals, which injure epithelial cells along the respiratory tract and type I alveolar cells, and cause the release of inflammatory mediators. Healthy individuals exposed to ozone experience upper respiratory tract inflammation and mild symptoms (decreased lung function and chest discomfort), but exposure is much more dangerous for people with asthma or emphysema. Ozone-induced asthma is associated with airway hyper-reactivity and neutrophilia.[11]

Even low levels of ozone may be detrimental to the lung function of normal individuals when combined with other air pollutants. Unfortunately, air pollutants often combine to create a veritable "witches' brew" of ozone and other agents such as *sulfur dioxide* and particulates. Sulfur dioxide is produced by power plants burning coal and oil, from copper smelting, and as a byproduct of paper mills. Released into the air, it may be converted into sulfuric acid and sulfuric trioxide, which cause a burning sensation in the nose and throat, difficulty in breathing, and asthma attacks in susceptible individuals.

Particulate matter (known as "soot") is emitted by coal- and oil-fired power plants, by industrial processes burning these fuels, and by diesel exhaust. Exposure to particulates was the main cause of morbidity and mortality in the air pollution episodes that occurred in London in 1952 and 1962. Although the particles have not been well characterized chemically or physically, *fine or ultrafine particles that are less than 10 μm in diameter are the most harmful*. They are readily inhaled into the alveoli, where they are phagocytosed by macrophages and neutrophils, which release inflammatory mediators such as macrophage inflammatory protein 1α and endothelin. Acute exposure to diesel exhaust that contains fine particles may cause irritation to the eyes, throat, and lungs, induce asthma attacks,[12] and promote myocardial ischemia.[13] In contrast, exposure to particles that are greater than 10 μm in diameter is of lesser consequence, because these particles are generally removed in the nose, or trapped by the mucociliary epithelium of the airways.

Carbon monoxide (CO). CO is a nonirritating, colorless, tasteless, odorless gas produced by the incomplete oxidation of carbonaceous materials. Its sources include automotive engines, industrial processes using fossil fuels, wood and charcoal burning with an inadequate supply of oxygen, and cigarette smoke. The low levels often found in ambient air may contribute to impaired respiratory function, but of themselves they are not life-threatening. However, chronic poisoning can occur in individuals working in confined environments with high exposure to fumes, such as tunnels, underground garages, and in highway toll workers. *CO is included here as an air pollutant, but it is also an important cause of accidental and suicidal death*. In a small, closed garage, the average car exhaust can induce lethal coma within 5 minutes. CO is a systemic asphyxiant that kills by inducing central nervous system (CNS) depression, which appears so insidiously that victims are often unaware of their plight and fail to help themselves. Hemoglobin has 200-fold greater affinity for CO than for oxygen, and the resultant carboxyhemoglobin does not carry oxygen. Systemic hypoxia develops when the hemoglobin is 20% to 30% saturated with CO; unconsciousness and death are likely with 60% to 70% saturation.

Morphology. Chronic poisoning by CO develops because carboxyhemoglobin, once formed, is remarkably stable. Even with low-level, but persistent, exposure to CO, carboxyhemoglobin may rise to life-threatening levels in the blood. The slowly developing hypoxia can insidiously evoke widespread ischemic changes in the central nervous system; these are particularly marked in the basal ganglia and lenticular nuclei. With cessation of exposure to CO, the patient usually recovers, but often there are permanent neurologic sequelae such as impairment of memory, vision, hearing, and speech. The diagnosis is made by measuring carboxyhemoglobin levels in the blood.

Acute poisoning by CO is generally a consequence of accidental exposure or suicide attempt. In light-skinned individuals, **acute poisoning is marked by a characteristic generalized cherry-red color of the skin** and mucous membranes, which result from high levels of carboxyhemoglobin. If death occurs rapidly morphologic changes may not be present; with longer survival the brain may be slightly edematous, with punctate hemorrhages and hypoxia-induced neuronal changes. The morphologic changes are not specific and stem from systemic hypoxia.

Indoor Air Pollution

As we increasingly "button up" our homes to exclude the environment, the potential for pollution of the indoor air increases. The commonest pollutant is *tobacco smoke* (discussed later), but additional offenders are CO, nitrogen dioxide (both already mentioned as outdoor pollutants), and asbestos (discussed in Chapter 15). Volatile substances containing polycyclic aromatic hydrocarbons generated by cooking oils and coal burning are important indoor pollutants in some regions of China. Only a few comments about other agents will be made here.

Wood smoke, containing various oxides of nitrogen and carbon particulates, may not only be an irritant but also predisposes to lung infections and may contain the far more dangerous carcinogenic polycyclic hydrocarbons. *Bioaerosols* range from microbiologic agents capable of causing infectious diseases such as Legionnaires' disease, viral pneumonia, and the common cold, to less threatening but nonetheless distressing allergens derived from pet dander, dust mites, and fungi and molds responsible for rhinitis, eye irritation, and asthma. *Radon*, a radioactive gas derived from uranium widely present in soil and in homes, can cause lung cancer in uranium miners. However, it does not seem that low-level chronic exposures in the home increase lung cancer risk, at least for nonsmokers. Exposure to *formaldehyde*, used in the manufacture of building materials (cabinetry, furniture, adhesives, etc.) has become a common health problem in refugees from environmental disasters living in poorly ventilated trailers. Many of these cases occurred in trailers occupied by families displaced from their homes after Hurricane Katrina, which hit the southeastern United States in 2005. At concentrations of 0.1 ppm or higher, it causes breathing difficulties and a burning sensation in the eyes and throat, and can trigger asthma attacks. Formaldehyde is classified as a carcinogen for humans and animals. Finally, the so-called *sick building syndrome* remains an elusive problem, since it may be a consequence of exposure to one or more of the indoor pollutants already mentioned or be caused by poor ventilation.

METALS AS ENVIRONMENTAL POLLUTANTS

Lead, mercury, arsenic, and cadmium are the heavy metals most commonly associated with harmful effects in humans.

Lead

Lead exposure occurs through contaminated air and food and water. For most of the twentieth century the major sources of lead in the environment were lead-containing house paints and gasoline. Although limits have been set for the amounts of lead contained in residential paints, and leaded gasoline has

practically disappeared in the United States, lead contamination remains an important health hazard, particularly for children. The large-scale recall of toys containing lead in 2007 alerted the general public to the dangers of lead exposures. There are many sources of lead in the environment, such as from mining, foundries, batteries, and spray painting, which constitute occupational hazards. However, *flaking lead paint* in older houses and soil contamination pose major hazards to youngsters, and ingestion of up to 200 mg/day can occur. During the last 30 years the median blood level of lead in preschool children in the United States decreased from 15 µg/dL to the present level of less than 2 µg/dL. However, lead blood levels in children living in older homes containing lead-based paint or lead-contaminated dust, often exceed the maximal allowed level of 10 µg/dL. *Subclinical lead poisoning* may occur in children exposed to levels of lead below 10 µg/dL, causing low intellectual capacity, behavioral problems such as hyperactivity, and poor organizational skills.[14,][15] Lead poisoning, although less common in adults, occurs mainly as an occupational hazard in those involved in the manufacturing of batteries, pigments, car radiators, and tin cans. The main clinical features of lead poisoning in children and adults are shown in Figures 9-5 and 9-6 .

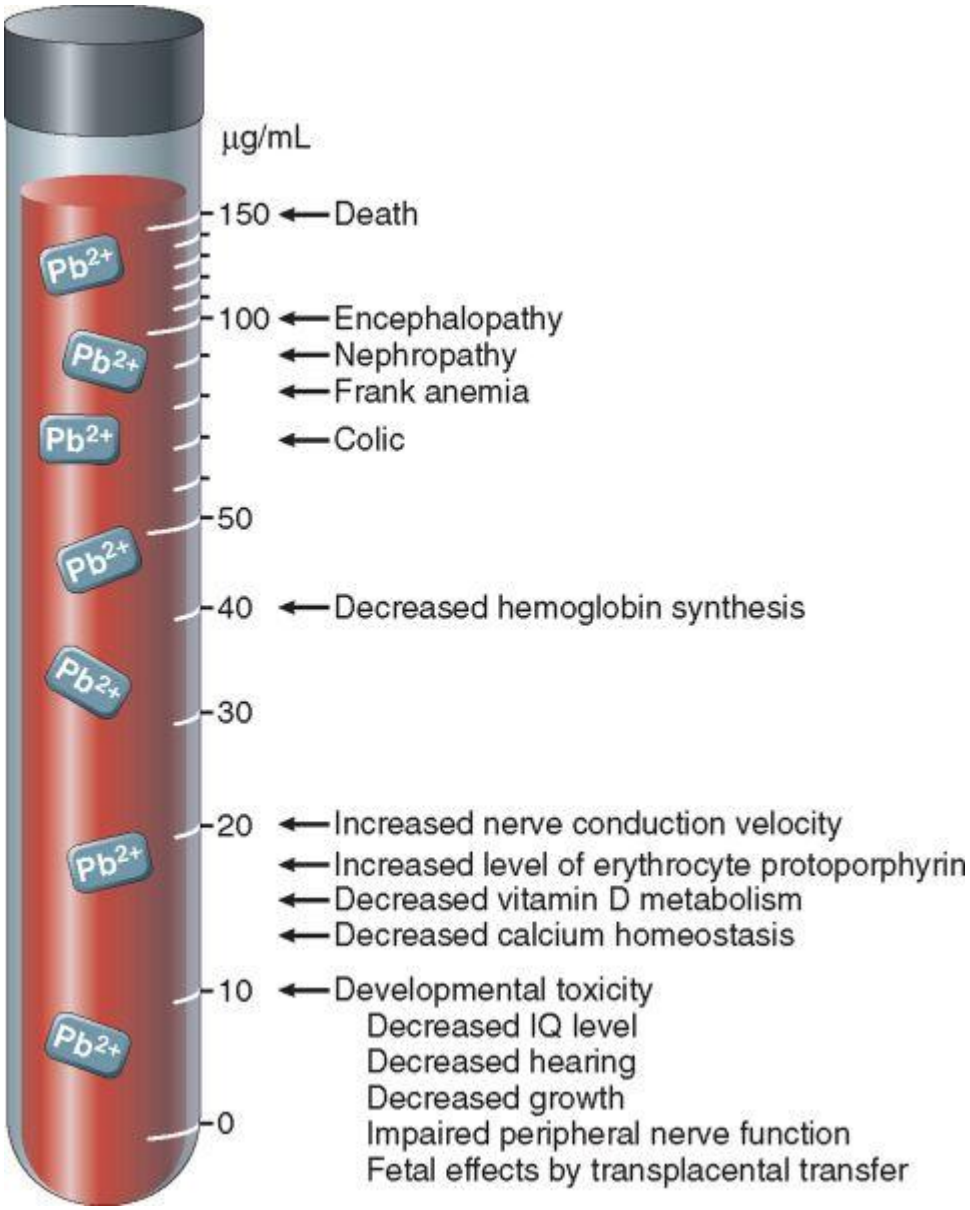

FIGURE 9-5 Effects of lead poisoning in children related to blood levels. *(Modified from Bellinger DC, Bellinger AM: Childhood lead*

poisoning: the tortuous path from science to policy. J Clin Invest 116:853, 2006.)

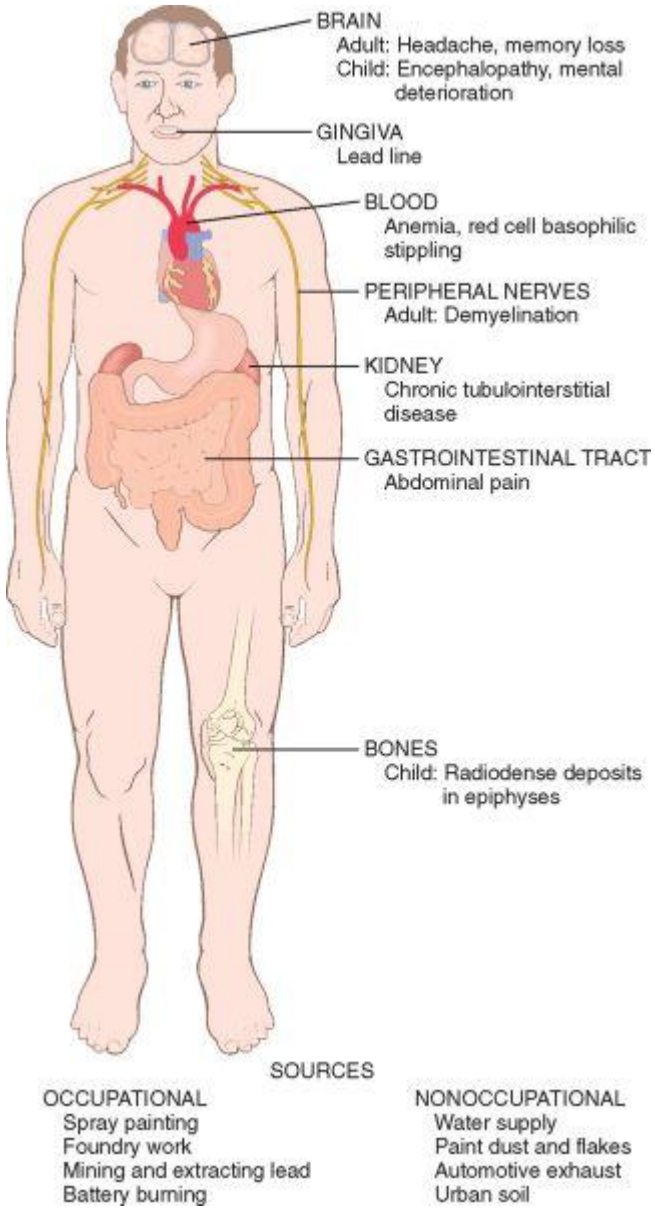

FIGURE 9-6 Pathologic features of lead poisoning in adults.

Most of the absorbed lead (80% to 85%) is incorporated into bone and developing teeth, where it competes with calcium; its half-life in bone is 20 to 30 years. *High levels of lead cause disturbances in the CNS in adults and children*, but peripheral neuropathies predominate in adults. Children absorb more than 50% of ingested lead (as compared with ≤15% in adults); the higher intestinal absorption and the more permeable blood-brain barrier of children create a high susceptibility to brain damage. The neurotoxic effects of lead are attributed to the inhibition of neurotransmitters caused by the disruption of calcium homeostasis. Other effects of lead exposure are listed below.

- *Lead interferes with the normal remodeling of cartilage* and primary bone trabeculae in the epiphyses in children. This causes increased bone density detected as radiodense “lead lines” (Fig. 9-7 ; another type of lead line appears in the gums as a result of hyperpigmentation). Lead *inhibits the healing of fractures* by increasing chondrogenesis and delaying cartilage mineralization.
- Lead inhibits the activity of two enzymes involved in heme synthesis, δ-aminolevulinic acid dehydratase and ferrochelatase. Ferrochelatase catalyzes the incorporation of iron into protoporphyrin, and its inhibition causes a rise in protoporphyrin levels. The resulting heme deficiency causes various abnormalities, but the most obvious is a *microcytic, hypochromic anemia* stemming from the suppression of hemoglobin synthesis.

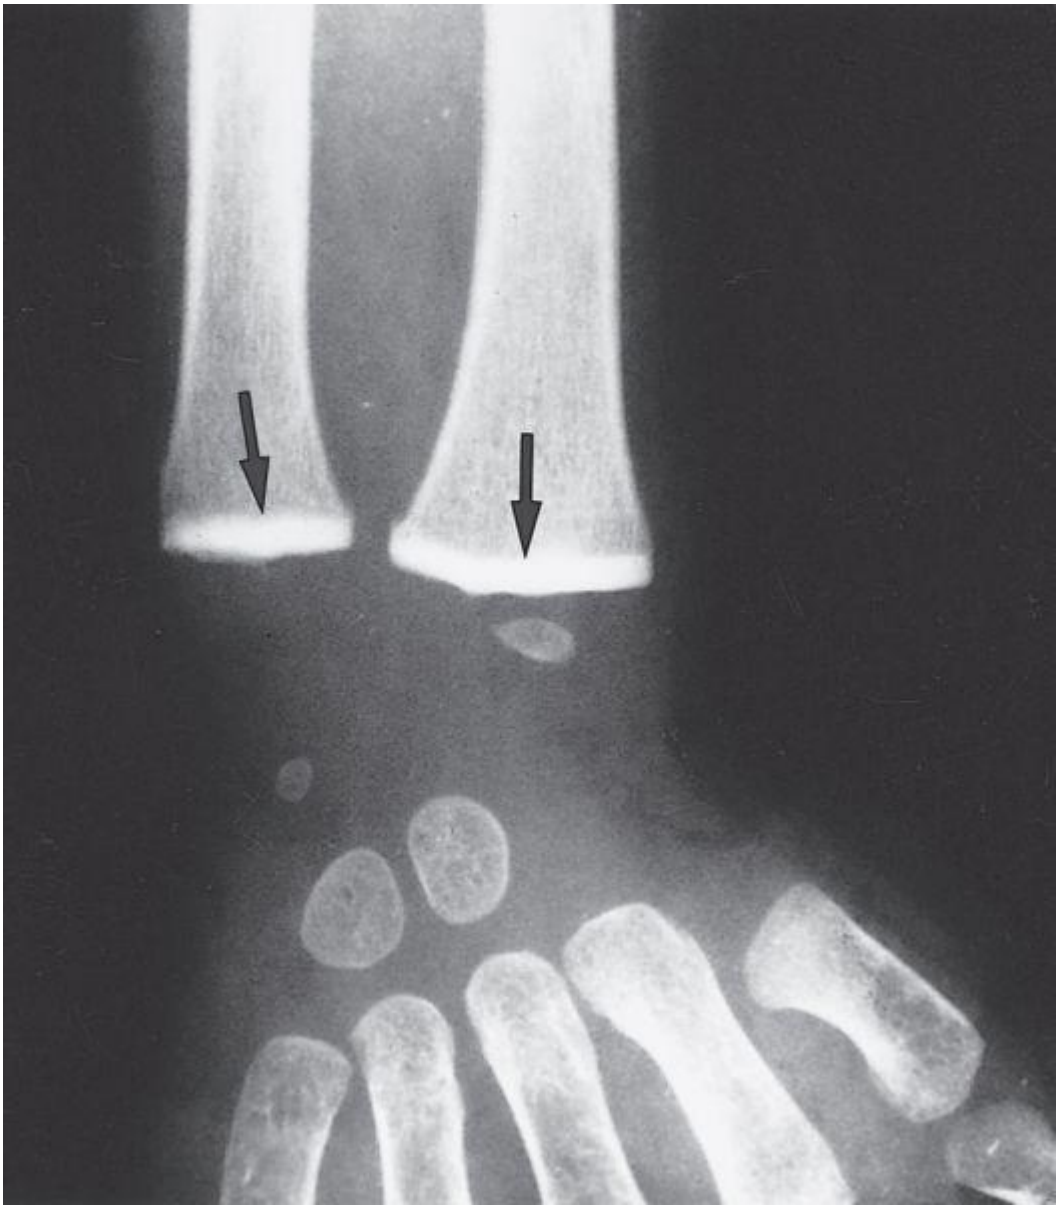

FIGURE 9-7 Lead poisoning. Impaired remodeling of calcified cartilage in the epiphyses *(arrows)* of the wrist has caused a marked increase in their radiodensity, so that they are as radiopaque as the cortical bone. *(Courtesy of Dr. G.W. Dietz, Department of Radiology, University of Texas Southwestern Medical School, Dallas, TX.)*

The diagnosis of lead poisoning requires constant awareness of its prevalence. In children it may be suspected on the basis of neurologic and behavioral changes, or by unexplained anemia with basophilic

stippling in red cells. Definitive diagnosis requires the detection of elevated blood levels of lead and free (or zinc-bound) red cell protoporphyrin.

Morphology. The major anatomic targets of lead toxicity are the bone marrow and blood, nervous system, gastrointestinal tract, and kidneys (see Fig. 9-6).

Blood and marrow changes occur fairly early and are characteristic. The inhibition of ferrochelatase by lead results in the appearance of scattered **ringed sideroblasts**, red cell precursors with iron-laden mitochondria that are detected with a Prussian blue stain. In the peripheral blood the defect in hemoglobin synthesis appears as a **microcytic, hypochromic anemia** that is often accompanied by mild **hemolysis**. Even more distinctive is a **punctate basophilic stippling of the red cells**.

Brain damage is prone to occur in children. It can be very subtle, producing mild dysfunction, or it can be massive and lethal. In young children, sensory, motor, intellectual, and psychologic impairments have been described, including reduced IQ, learning disabilities, retarded psychomotor development, blindness, and, in more severe cases, psychoses, seizures, and coma (see Fig. 9-5). Lead toxicity in the mother may impair brain development in the prenatal infant. The anatomic changes underlying the more subtle functional deficits are ill-defined, but there is concern that some of the defects may be permanent. At the more severe end of the spectrum are marked brain edema, demyelination of the cerebral and cerebellar white matter, and necrosis of cortical neurons accompanied by diffuse astrocytic proliferation. In adults the CNS is less often affected, but frequently **a peripheral demyelinating neuropathy** appears, typically involving the motor nerves of the most commonly used muscles. Thus, the extensor muscles of the wrist and fingers are often the first to be affected (causing wristdrop), followed by paralysis of the peroneal muscles (causing footdrop).

The **gastrointestinal tract** is also a major source of clinical manifestations. Lead "colic" is characterized by extremely severe, poorly localized abdominal pain.

Kidneys may develop proximal tubular damage with intranuclear lead inclusions. Chronic renal damage leads eventually to interstitial fibrosis and possibly renal failure. Decreases in uric acid excretion can lead to gout ("saturnine gout").

Mercury

Mercury has had many uses throughout history such as a pigment in cave paintings, a cosmetic, a remedy for syphilis, and a component of diuretics. Alchemists tried (without much success) to produce gold from mercury. Poisoning from inhalation of mercury vapors has long been recognized and is associated with tremor, gingivitis, and bizarre behavior, such as that displayed by the Mad Hatter in *Alice in Wonderland*. There are three forms of mercury: metallic mercury (also referred to as elemental mercury), inorganic mercury compounds (mostly mercuric chloride), and organic mercury (mostly methyl mercury). Today, the main sources of exposure to mercury are contaminated fish (methyl mercury) and mercury vapors released from metallic mercury in dental amalgams, a possible occupational hazard for dental workers. In some areas of the world, mercury used in gold mining has contaminated rivers and streams.

Inorganic mercury from the natural degassing of the earth's crust or from industrial contamination is converted to organic compounds such as methyl mercury by bacteria. Methyl mercury enters the food chain, and in carnivorous fish such as swordfish, shark, and bluefish, mercury may be concentrated to levels a million-fold higher than in the surrounding water. Disasters caused by the consumption of fish

contaminated by the release of methyl mercury from industrial sources in Minamata Bay and the Agano River in Japan caused widespread mortality and morbidity. Acute exposure through consumption of bread made from grain treated with a methyl mercury–based fungicide in Iraq in 1971 resulted in hundreds of deaths and thousands of hospitalizations. The medical disorders associated with the Minamata episode became known as *"Minamata disease"* and include cerebral palsy, deafness, blindness, mental retardation, and major CNS defects in children exposed in utero. For unclear reasons, *the developing brain is extremely sensitive to methyl mercury*. The lipid solubility of methyl mercury and metallic mercury facilitate their accumulation in the brain, disturbing neuromotor, cognitive, and behavioral functions.[16] Mercury binds with high affinity to thiol groups, a property that contributes to its toxicity. *Intracellular glutathione, acting as thiol donor, is the main protective mechanism against mercury-induced CNS and kidney damage*.

Mercury continues to be released into the environment by power plants and other industrial sources, and there are serious concerns about the effects of chronic low-level exposure to methyl mercury in the food supply. To protect against potential fetal brain damage, the Centers for Disease Control and Prevention has recommended that pregnant women reduce their consumption of fish known to contain mercury to a minimum. There has been much publicity about a possible relationship between thimerosal (a compound that contains ethyl mercury, used until recently as a preservative in some vaccines) and the development of autism, but multiple studies have failed to find evidence of a causal relationship.[17]

Arsenic

Arsenic was the poison of choice in Renaissance Italy, with members of the Borgia and Medici families being highly skilled practitioners of the art. Because of its favored use as a murder weapon among royal families, arsenic has been called "the poison of kings and the king of poisons."[18] Deliberate poisoning by arsenic is exceedingly rare today, but exposure to arsenic is an important health problem in many areas of the world. Arsenic is found naturally in soils and water and is used in products such as wood preservers, as well as herbicides and other agricultural products. It may be released into the environment from mines and smelting industries. Arsenic is present in Chinese and Indian herbal medicine, and arsenic trioxide is used in the treatment of relapsing acute promyelocytic leukemia. Large concentrations of inorganic arsenic are present in ground water used for drinking in countries such as Bangladesh, Chile, and China. Between 35 and 77 million people in Bangladesh drink water contaminated by arsenic, constituting the highest environmental cancer risk ever found.

The most toxic forms of arsenic are the trivalent compounds arsenic trioxide, sodium arsenite, and arsenic trichloride.[19] If ingested in large quantities, arsenic causes acute toxic effects consisting of severe disturbances of the *gastrointestinal, cardiovascular, and central nervous systems* that are often fatal. These effects may be attributed to interference with mitochondrial oxidative phosphorylation, since trivalent arsenic can replace the phosphates in adenosine triphosphate. *Neurologic effects* usually occur 2 to 8 weeks after exposure and consist of a sensorimotor neuropathy that causes paresthesias, numbness, and pain. The most serious consequence of chronic exposure is the *increased risk for the development of cancers* in almost all tissues, but particularly in the lungs and skin. Chronic exposure to arsenic causes *skin changes* consisting of hyperpigmentation and hyperkeratosis, which may be followed by the development of basal and squamous cell carcinomas. Arsenic-induced skin tumors differ from those induced by sunlight; they are often multiple and usually appear on the palms and soles. The mechanisms of arsenic carcinogenesis in skin and lung have not been elucidated but may involve defects in nucleotide excision repair mechanisms that protect against DNA damage.[18] Recent studies suggest that chronic exposure to arsenic in drinking water can also cause non-malignant respiratory disease.[20]

Cadmium

In contrast to the other metals discussed in this section, cadmium toxicity is a relatively modern problem. It is an occupational and environmental pollutant generated by mining, electroplating, and production of nickel-cadmium batteries, which are usually disposed of as household waste. Cadmium can contaminate the soil and plants directly or through fertilizers and irrigation water. Food is the most important source of cadmium exposure for the general population. *The toxic effects of excess cadmium consist of obstructive lung disease caused by necrosis of alveolar macrophages, and kidney damage, initially consisting of tubular damage that may progress to end-stage renal disease*. Cadmium exposure can also cause skeletal abnormalities associated with calcium loss. Cadmium-containing water used to irrigate rice fields in Japan caused a disease in postmenopausal women known as "Itai-Itai" (ouch-ouch), a combination of osteoporosis and osteomalacia associated with renal disease. Cadmium exposure is also associated with elevated risk of lung cancer, which has been demonstrated in workers exposed occupationally and in populations living near zinc smelters.[21] Cadmium is not directly genotoxic and most likely produces DNA damage through the generation of reactive oxygen species (see Chapter 1). A recent survey showed that 5% of the US population age 20 years and older have urinary cadmium levels that may produce subtle kidney injury and calcium loss.

2.9.5 Occupational Health Risks: Industrial & Agricultural Exposures

More than 10 million injuries and about 100,000 deaths occur yearly in the United States as a consequence of work-related accidents and illnesses. Work-related accidents are the biggest problem in developing countries, while work-related diseases are more frequent in industrialized countries. The fraction of global disease attributed to occupational exposures includes 13% of all cases of chronic obstructive pulmonary disease, 9% of lung cancers, and 2 % of leukemias. Industrial exposures to toxic agents are as varied as the industries themselves. They range from mere irritation of the respiratory mucosa by formaldehyde or ammonia fumes; to lung cancer induced by exposure to asbestos, arsenic, or uranium mining; to leukemia caused by chronic exposure to benzene. Human diseases associated with occupational exposures are listed in Table 9-2 . Here we provide a few examples of important agents that contribute to occupational diseases. Toxicity caused by metals has already been discussed in this chapter.

- *Organic solvents* are widely used in huge quantities worldwide. Some, such as *chloroform and carbon tetrachloride*, are found in degreasing and dry cleaning agents and paint removers. Acute exposure to high levels of vapors from these agents can cause dizziness and confusion, leading to central nervous system depression and even coma. Lower levels are toxic for the liver and kidneys. Occupational exposure of rubber workers to *benzene* and *1,3-butadiene* increases the risk of leukemia. Benzene is oxidized by hepatic CYP2E1 to toxic metabolites that disrupt the differentiation of hematopoietic cells in the bone marrow, leading to dose-dependent marrow aplasia and an increased risk of acute myeloid leukemia.
- *Polycyclic hydrocarbons* may be released during the combustion of fossil fuels, particularly when coal and gas are burned at high temperatures (such as in steel foundries), and are also present in tar and soot (Pott identified soot as the cause of scrotal cancers in chimney sweeps in 1775, as mentioned in Chapter 7). Polycyclic hydrocarbons are among the most potent carcinogens, and industrial exposures have been implicated in the development of lung and bladder cancer.
- *Organochlorines*. Organochlorines (and halogenated organic compounds in general) are synthetic lipophilic products that resist degradation. Important organochlorines used as pesticides include *DDT (dichlorodiphenyltrichloroethane)*, Lindane, Aldrin, and Dieldrin. Nonpesticide organochlorines include *polychlorinated biphenyls (PCBs) and dioxin* (TCDD; 2,3,7,8-tetrachlorodibenzo-*p*-dioxin). DDT was banned in the United States in 1973, but more than half of the U.S. population has detectable levels of *p*, *p'*-DDE, a long-lasting DDT metabolite. This substance was even found in 12- to 19-year-olds born after the ban on DDT. PCB (another banned substance), dioxin, and PBDEs (polybrominated diphenyl ethers used as flame retardants) are also detectable in a large proportion of the U.S. population. *Most organochlorines are endocrine disruptors* with anti-estrogenic or anti-androgenic activity.
- *Dioxins and PCBs* can cause skin disorders such as folliculitis and a dermatosis known as *chloracne* that is characterized by acne, cyst formation, hyperpigmentation, and hyperkeratosis, generally around the face and behind the ears. These toxins can also cause abnormalities in the liver and central nervous system. Because

PCBs induce CYPs, workers exposed to these substances may show abnormal drug metabolism. Environmental disasters in Japan and China in the late 1960s caused by the consumption of rice oil contaminated by PCBs during its production, poisoned about 2000 people in each episode. The primary manifestation of the disease (Yusho in Japan; Yu-Cheng in China) was chloracne and hyperpigmentation of the skin and nails. A bizarre case of intentional dioxin poisoning, which made international headlines and was a front-page illustration of chloracne, involved a future president of Ukraine. This individual developed extensive chloracne and systemic symptoms, as a consequence of eating a meal spiked with dioxin that was offered by one of his political "friends."

- *Inhalation of mineral dusts causes chronic, non-neoplastic lung diseases known as pneumoconioses*. This term also includes diseases induced by organic and inorganic particulates, and chemical fume- and vapor-induced non-neoplastic lung diseases. The most common pneumoconioses are caused by exposures to *coal dust* (from mining of hard coal), *silica* (sandblasting, stone cutting, etc.), *asbestos* (mining, fabrication, insulation work), and *beryllium* (mining, fabrication). Exposure to these agents nearly always occurs in the workplace. However, the increased risk of cancer as a result of asbestos exposure extends to the family members of asbestos workers and to other individuals exposed outside the workplace. Pneumoconioses and their pathogenesis are discussed in Chapter 15 .
- Exposure to *vinyl chloride* used in the synthesis of polyvinyl resins leads to the development of angiosarcoma of the liver, an uncommon type of hepatic tumor.
- Exposure to *phthalates* in laboratory animals causes endocrine disruption and a testicular dysgenesis syndrome involving hypospadias, cryptorchidism, and testicular cell abnormalities that are similar to conditions of generally unknown origin found in humans. Phthalates are widely used plasticizers found in flexible plastics (as in food wraps) and in medical containers, such as blood and serum bags. A matter of concern is that critically ill infants may receive large doses of phthalates from bags holding intravenous fluids, although the toxicity in humans has not been firmly established.

TABLE 9-2 -- Human Diseases Associated with Occupational Exposures

Organ/System	Effect	Toxicant
Cardiovascular system	Heart disease	Carbon monoxide, lead, solvents, cobalt, cadmium
Respiratory system	Nasal cancer	Isopropyl alcohol, wood dust
	Lung cancer	Radon, asbestos, silica, bis(chloromethyl)ether, nickel, arsenic, chromium, mustard gas, uranium
	Chronic obstructive lung disease	Grain dust, coal dust, cadmium
	Hypersensitivity	Beryllium, isocyanates
	Irritation	Ammonia, sulfur oxides, formaldehyde
	Fibrosis	Silica, asbestos, cobalt
Nervous system	Peripheral neuropathies	Solvents, acrylamide, methyl chloride, mercury, lead, arsenic, DDT
	Ataxic gait	
	Central nervous system depression	Chlordane, toluene, acrylamide, mercury
	Cataracts	Alcohols, ketones, aldehydes, solvents
		Ultraviolet radiation
Urinary system	Toxicity	Mercury, lead, glycol ethers, solvents
	Bladder cancer	Naphthylamines, 4-aminobiphenyl, benzidine, rubber products
Reproductive system	Male infertility	Lead, phthalate plasticizers, cadmium
	Female infertility/stillbirths	Lead, mercury
	Teratogenesis	Mercury, polychlorinated biphenyls
Hematopoietic system	Leukemia	Benzene
Skin	Folliculitis and acneiform dermatosis	Polychlorinated biphenyls, dioxins, herbicides

Organ/System	Effect	Toxicant
	Cancer	Ultraviolet radiation
Gastrointestinal tract	Liver angiosarcoma	Vinyl chloride

In Rom WN (ed): Environmental and Occupational Medicine, 2nd ed. Boston, Little, Brown, 1992, p 1275; and Levi PE: Classes of toxic chemicals. In Hodgson E, Levi PE (eds): A Textbook of Modern Toxicology. Stamford, CT, Appleton & Lange, 1997, p 229.

2.9.6 Effects of Tobacco

Tobacco is the most common exogenous cause of human cancers, being responsible for 90% of lung cancers. *The main culprit is cigarette smoking, but smokeless tobacco (snuff, chewing tobacco, etc.) is also harmful to health and an important cause of oral cancer*. The use of tobacco products not only creates personal risks, but passive tobacco inhalation from the environment *("second-hand smoke")* can cause lung cancer in nonsmokers.[22] Cigarette smoking causes, worldwide, more than 5 million deaths annually, mostly from cardiovascular disease, various types of cancers, and chronic respiratory problems, that result in a total of more than 35 million years of life lost. These figures are expected to rise to 8 million tobacco-related deaths by 2020, the major increase occurring in developing countries. It has been estimated that of people alive today, approximately 500 million will die from tobacco-related illnesses. In the United States alone, tobacco is responsible for over 400,000 deaths annually, one third of these attributable to lung cancer. Two thirds of smokers live in 10 countries, led by China, which accounts for nearly 30%, and India with about 10%, followed by Indonesia, Russia, the United States, Japan, Brazil, Bangladesh, Germany, and Turkey.

Smoking is the most preventable cause of human death. It reduces overall survival through dose-dependent effects. For instance, while 80% of a population of nonsmokers is alive at age 70, only about 50% of smokers survive to that age (Fig. 9-8). The prevalence of smoking has decreased in US teenagers, a hopeful trend. However, recent surveys estimate that 7%, 14%, and 22% of students in grades 8, 10, and 12, respectively, had used tobacco products during the month before the survey. Delaying the age at which smoking is initiated reduces the future risk of lung and other types of cancers, but, unfortunately, initiation seems to be occurring at younger ages. *Cessation of smoking greatly reduces, within 5 years, the overall mortality and the risk of death from cardiovascular diseases. Lung cancer mortality decreases by 21% within 5 years, but the excess risk lasts for 30 years*.[22]

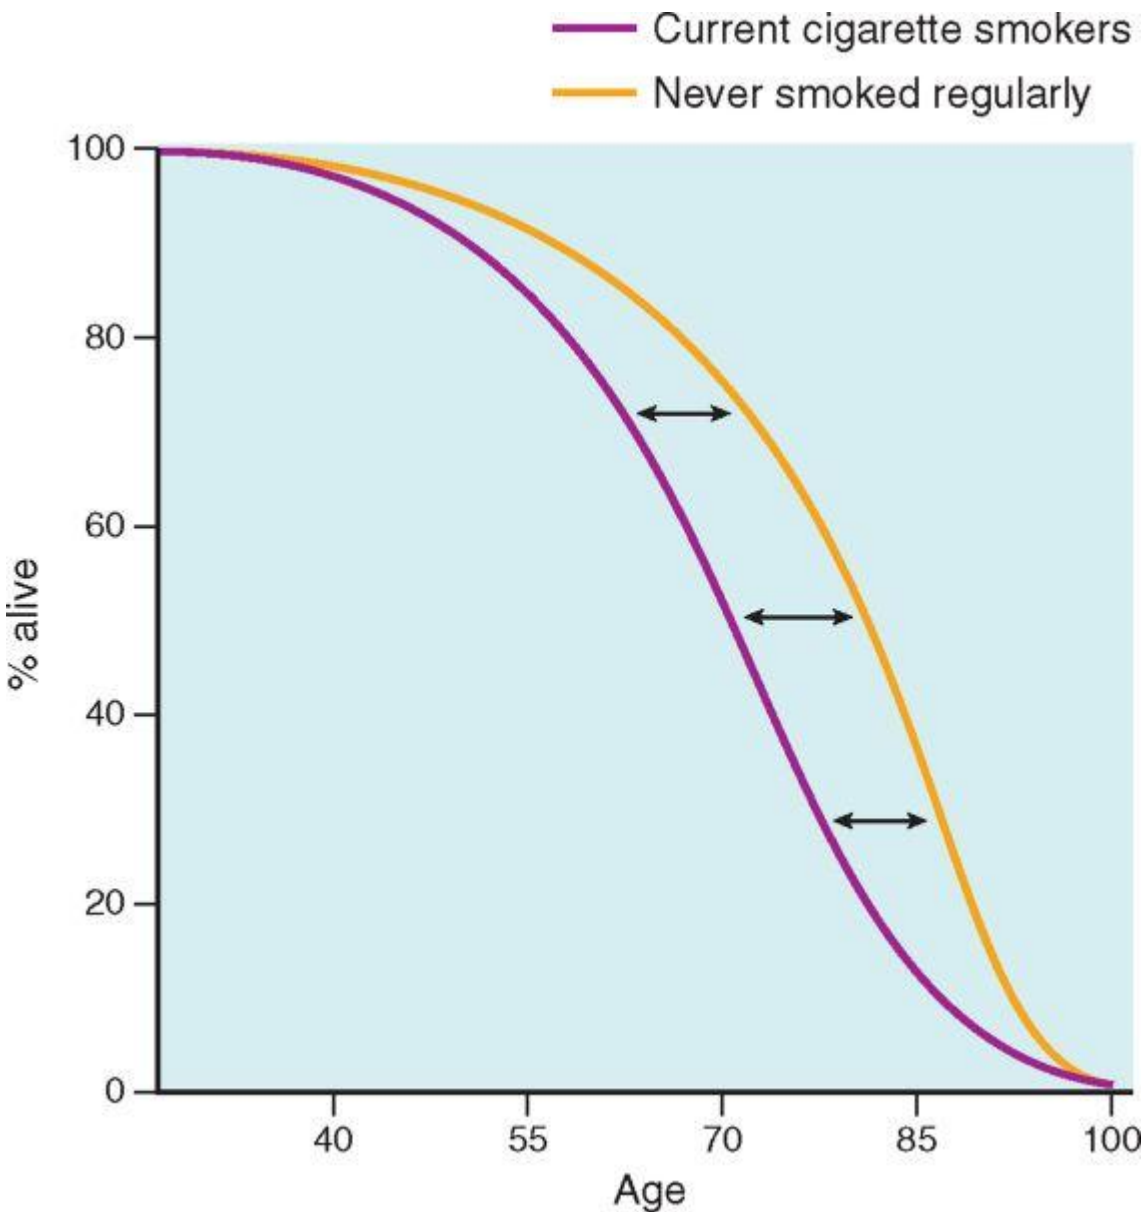

FIGURE 9-8 The effects of smoking on survival. The study compared age-specific death rates for current cigarette smokers with that of individuals who never smoked regularly (British Doctors Study). Measured at age 75, the difference in survival between smokers and nonsmokers is 7.5 years. *(Modified from Stewart BW, Kleihues P (eds): World Cancer Report. Lyon, IARC Press, 2003.)*

The number of potentially noxious chemicals in tobacco smoke is extraordinary. Tobacco contains between 2000 and 4000 substances, more than 60 of which have been identified as carcinogens. Table 9-3 provides only a partial list and includes various types of injuries produced by these agents. *Nicotine*, an alkaloid present in tobacco leaves, is not a direct cause of tobacco-related diseases, but is addictive. Without it, it would be easy for smokers to stop the habit. Nicotine binds to receptors in the brain, and through the release of catecholamines, is responsible for the acute effects of smoking, such as the increase in heart rate and blood pressure, and the elevation in cardiac contractility and output. The *most common diseases caused by cigarette smoking involve the lung and include emphysema, chronic bronchitis, chronic obstructive pulmonary disease, and lung cancer*, conditions that are discussed in

Chapter 15 . *Cigarette smoking is also strongly associated with the development of atherosclerosis, myocardial infarcts, and cancers of the lip, mouth, pharynx, esophagus, pancreas, bladder, kidney, and cervix*. Adverse effects of smoking in various organs systems are shown in Figure 9-9 .

TABLE 9-3 -- Effects of Selected Tobacco Smoke Constituents

Substance	Effect
Tar	Carcinogenesis
Polycyclic aromatic hydrocarbons	Carcinogenesis
Nicotine	Ganglionic stimulation and depression; tumor promotion
Phenol	Tumor promotion; mucosal irritation
Benzopyrene	Carcinogenesis
Carbon monoxide	Impaired oxygen transport and utilization
Formaldehyde	Toxicity to cilia; mucosal irritation
Oxides of nitrogen	Toxicity to cilia; mucosal irritation
Nitrosamine	Carcinogenesis

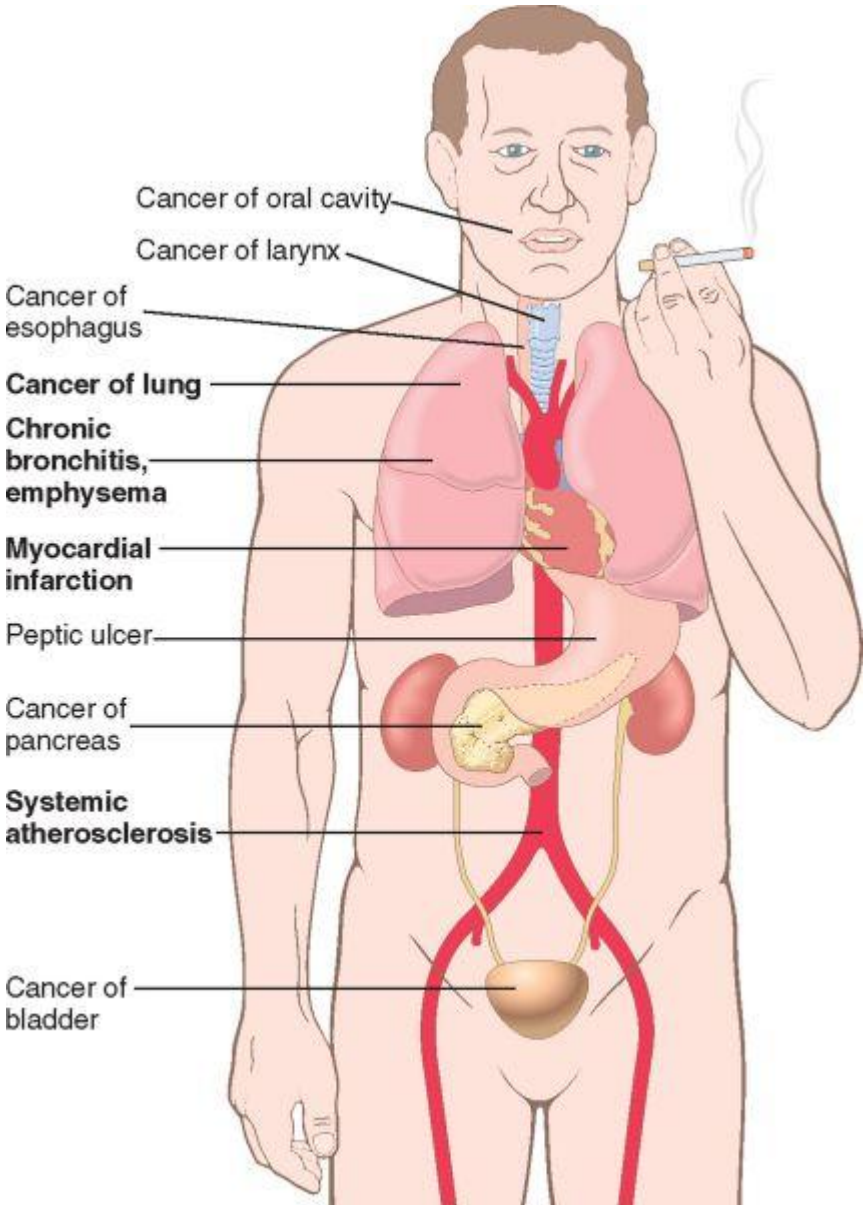

FIGURE 9-9 Adverse effects of smoking: those that are more common are in boldface.

Smoking and Lung Cancer.

Agents in smoke have a direct irritant effect on the tracheobronchial mucosa, producing *inflammation and increased mucus production (bronchitis).* Cigarette smoke also causes the recruitment of leukocytes to the lung, with increased local elastase production and subsequent injury to lung tissue, leading to *emphysema. Components of cigarette smoke, particularly polycyclic hydrocarbons and nitrosamines* (Table 9-4), *are potent carcinogens in animals and likely to be directly involved in the development of lung cancer in humans* (see Chapter 15). CYPs (cytochrome P-450 phase I enzymes) and phase II enzymes increase the water solubility of the carcinogens, facilitating their excretion. However, some intermediates produced by CYPs are electrophilic and form DNA adducts. If such adducts persist, they can cause mutations in oncogenes and tumor suppressors such as *K-Ras* and *p53*,[23] respectively. The risk of developing lung cancer is related to the intensity of exposure, frequently expressed in terms of "pack years" (e.g., one pack smoked daily for 20 years equals 20 pack years) or in cigarettes smoked

per day (Fig. 9-10). Moreover, *smoking multiplies the risk of other carcinogenic influences*. Witness the ten-fold higher incidence of lung carcinomas in asbestos workers and uranium miners who smoke over those who do not smoke, and the interaction between tobacco consumption and alcohol in the development of oral cancers (mentioned below).

TABLE 9-4 -- Organ-Specific Carcinogens in Tobacco Smoke

Organ	Carcinogen
Lung, larynx	Polycyclic aromatic hydrocarbons 4-(Methylnitrosoamino)-1-(3-pyridyl)-1-buta-none (NNK), polonium 210
Esophagus	*N′*-Nitrosonornicotine (NNN)
Pancreas	NNK (?)
Bladder	4-Aminobiphenyl, 2-naphthylamine
Oral cavity (smoking)	Polycyclic aromatic hydrocarbons, NNK, NNN
Oral cavity (snuff)	NNK, NNN, polonium 210

Data from Szczesny LB, Holbrook JH: Cigarette smoking. In Rom WH (ed): Environmental and Occupational Medicine, 2nd ed. Boston, Little, Brown, 1992, p 1211.

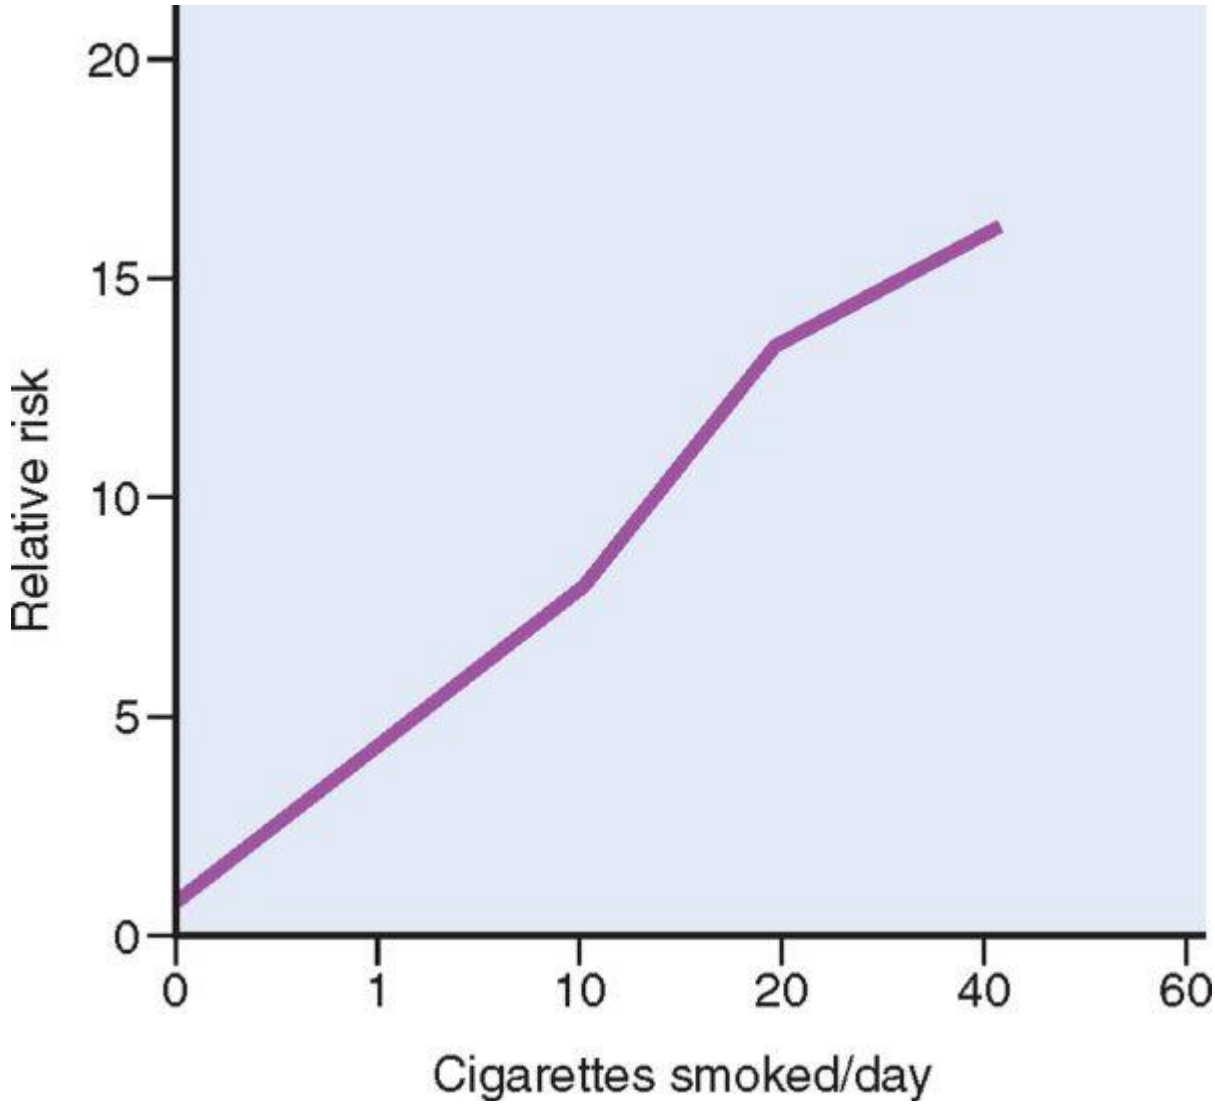

FIGURE 9-10 The risk of lung cancer is determined by the number of cigarettes smoked. *(Modified from Stewart BW, Kleihues P (eds): World Cancer Report. Lyon, IARC Press, 2003.)*

Smoking and Other Diseases.

In addition to lung cancers, *tobacco contributes to the development of cancers of the oral cavity, esophagus, pancreas, and bladder*. Smoke and smokeless tobacco interact with alcohol in the development of laryngeal cancer. The combination of these agents has a multiplicative effect on the risk of developing this tumor (Fig. 9-11).

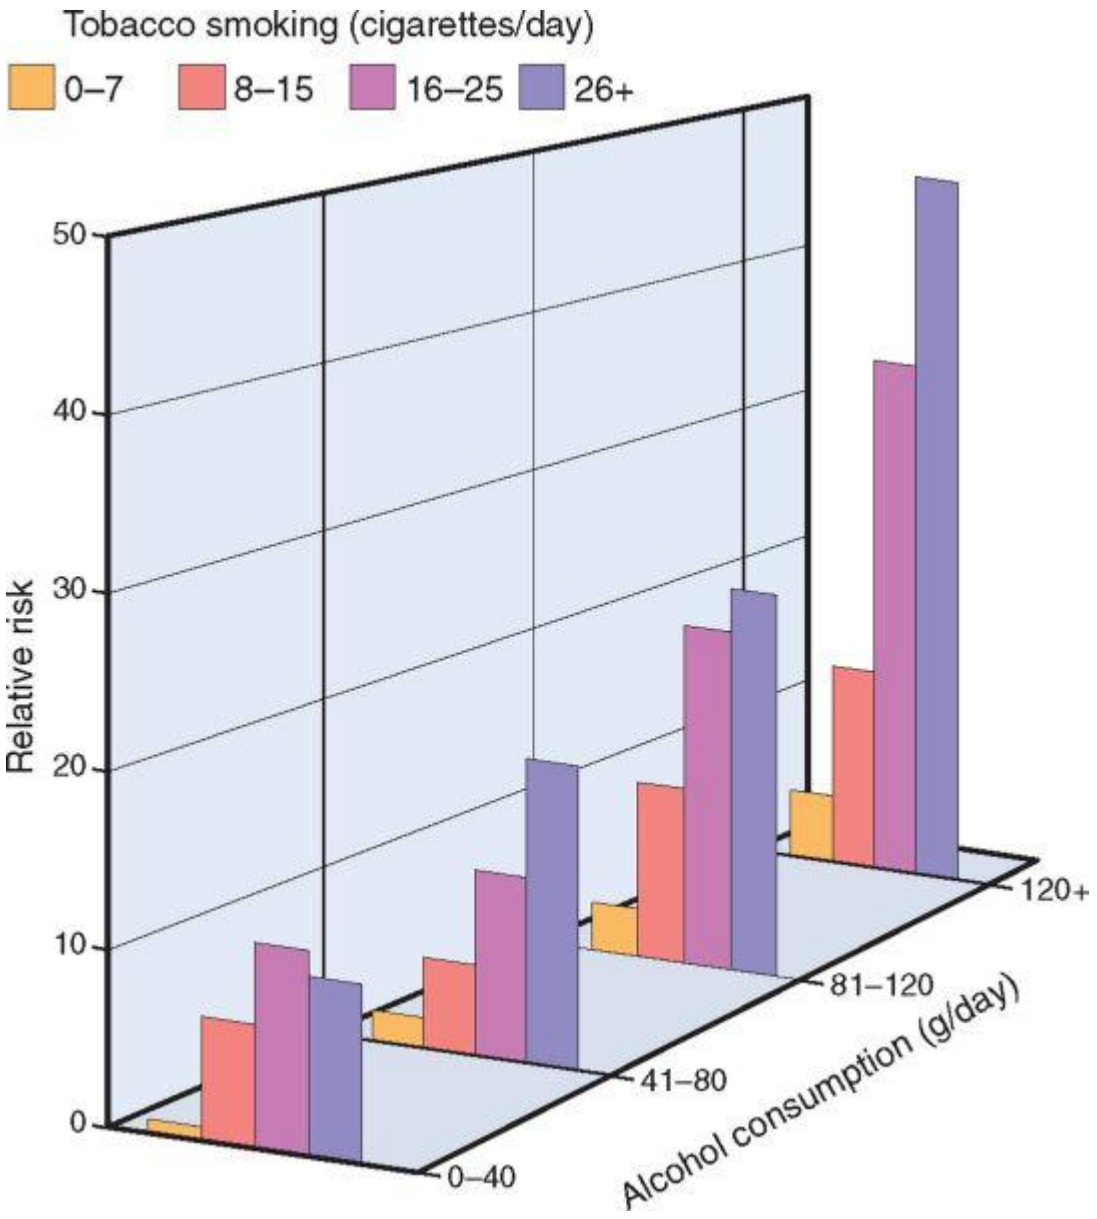

FIGURE 9-11 Multiplicative increase in the risk of laryngeal cancer from the interaction between cigarette smoking and alcohol consumption. *(Modified from Stewart BW, Kleihues P (eds): World Cancer Report. Lyon, IARC Press, 2003.)*

Cigarette smoking is strongly linked to the development of atherosclerosis and its major complication, myocardial infarction. The causal mechanisms probably relate to several factors, including increased platelet aggregation, decreased myocardial oxygen supply (because of significant lung disease coupled with the hypoxia related to the CO content of cigarette smoke) accompanied by an increased oxygen demand, and a decreased threshold for ventricular fibrillation. Smoking has a multiplicative effect on the incidence of myocardial infarction when combined with hypertension and hypercholesterolemia.

Maternal smoking increases the risk of spontaneous abortions and preterm births and results in intrauterine growth retardation (Chapter 10). Birth weights of infants born to mothers who stopped smoking before pregnancy are, however, normal.

Exposure to *environmental tobacco smoke (passive smoke inhalation)* is also associated with some of the same detrimental effects that result from active smoking. It is estimated that the relative risk of lung cancer in nonsmokers exposed to environmental smoke is about 1.3 times higher than that of nonsmokers who are not exposed to smoke. In the United States, approximately 3000 lung cancer deaths in nonsmokers over the age of 35 years can be attributed each year to environmental tobacco smoke. Even more striking is the increased risk of coronary atherosclerosis and fatal myocardial infarction. Studies report that every year 30,000 to 60,000 cardiac deaths in the United States are associated with exposure to passive smoke. Passive smoke inhalation in nonsmokers can be estimated by measuring the blood levels of *cotinine*, a metabolite of nicotine. Median cotinine levels in nonsmokers have decreased by more than 60% during the last 10 years, but exposure to environmental tobacco smoke in the home remains a major public health concern, particularly for children who may develop respiratory illnesses and asthma. It is clear that the transient pleasure a puff may give comes with a heavy long-term price.

2.9.7 Effects of Alcohol

Ethanol consumption in moderate amounts is generally not injurious, but in excessive amounts alcohol causes serious physical and psychologic damage. In this section we describe the steps of alcohol metabolism and the major health consequences associated with alcohol abuse.

Despite all the attention given to illicit drugs such as cocaine and heroin, alcohol abuse is a more widespread hazard and claims many more lives. Fifty percent of adults in the Western world drink alcohol, and about 5% to 10% have chronic alcoholism. It is estimated that *there are more than 10 million chronic alcoholics in the United States and that alcohol consumption is responsible for more than 100,000 deaths annually*. More than 50% of these deaths result from accidents caused by drunken driving and alcohol-related homicides and suicides, and about 15,000 annual deaths are a consequence of cirrhosis of the liver. Worldwide, alcohol accounts for approximately 1.8 million deaths per year (3.2% of all deaths). After consumption, ethanol is absorbed unaltered in the stomach and small intestine. It is then distributed to all the tissues and fluids of the body in direct proportion to the blood level. Less than 10% is excreted unchanged in the urine, sweat, and breath. The amount exhaled is proportional to the blood level and forms the basis of the breath test used by law enforcement agencies. A concentration of 80 mg/dL in the blood constitutes the legal definition of drunk driving in the United States. For an average individual, this alcohol concentration may be reached after consumption of three standard drinks, contained in about 3 (12 ounce) bottles of beer, 15 ounces of wine, or 4–5 ounces of 80 proof distilled spirits. Drowsiness occurs at 200 mg/dL, stupor at 300 mg/dL, and coma, with possible respiratory arrest, at higher levels. The rate of metabolism affects the blood alcohol level. Chronic alcoholics can tolerate levels of up to 700 mg/dL, a situation that is partially explained by accelerated

ethanol metabolism caused by a five- to ten-fold induction of liver CYPs discussed below. The effects of alcohol also vary by age, sex, and body fat.

Most of the alcohol in the blood is biotransformed to acetaldehyde in the liver by three enzyme systems consisting of alcohol dehydrogenase (ADH), the microsomal ethanol-oxidizing system (MEOS), and catalase (Fig. 9-12). The *main enzyme system involved in alcohol metabolism is ADH*, located in the cytosol of hepatocytes. *At high blood alcohol levels, the microsomal ethanol-oxidizing system participates in its metabolism*. Catalase, which uses hydrogen peroxide as substrate, is of minor importance, since it metabolizes no more than 5% of ethanol in the liver. Acetaldehyde produced by alcohol metabolism through ADH or MEOS is converted to *acetate* by acetaldehyde dehydrogenase (ALDH), which is then utilized in the mitochondrial respiratory chain.

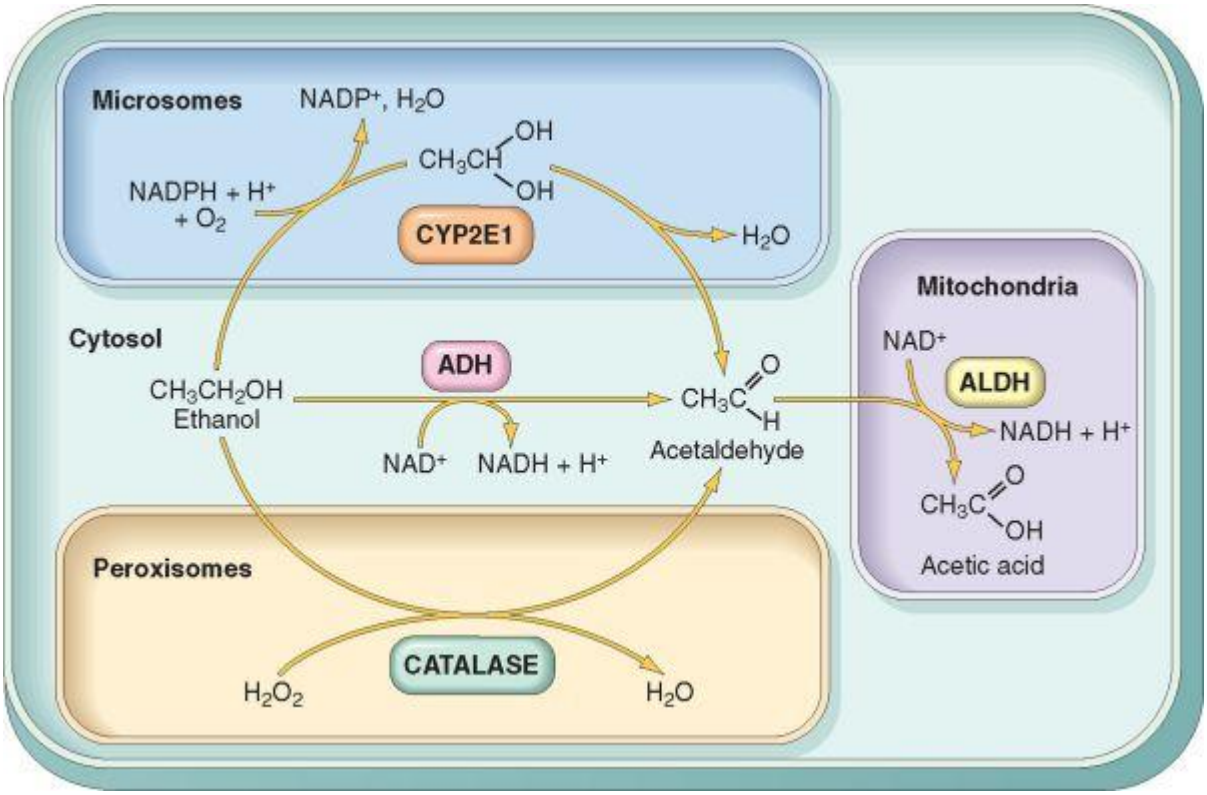

FIGURE 9-12 Metabolism of ethanol: oxidation of ethanol to acetaldehyde by three different routes, and the generation of acetic acid. Note that oxidation by ADH (alcohol dehydrogenase) takes place in the cytosol; the cytochrome P-450 system and its CYP2E1 isoform are located in the endoplasmic reticulum (microsomes), and catalase is located in peroxisomes. Oxidation of acetaldehyde by ALDH (aldehyde dehydrogenase) oc-curs in mitochondria. ADH oxidation is the most important route; catalase is involved in only 5% of ethanol metabolism. Oxidation through CYPs may also generate reactive oxygen species (not shown). *(From Parkinson A: Biotransformation of xenobiotics. In Klassen CD [ed]: Casarett and Doull's Toxicology: The Basic Science of Poisons, 6th ed. New York, McGraw-Hill, 2001, p 133.)*

The microsomal oxidation system involves CYPs, particularly CYP2E1 located in the smooth endoplasmic reticulum. Induction of CYPs by alcohol explains the increased susceptibility of alcoholics to other compounds metabolized by the same enzyme system, which include drugs, anesthetics, carcinogens, and industrial solvents. Note, however, that when alcohol is present in the blood at high concentrations, it competes with other CYP2E1 substrates and delays drug catabolism, potentiating the depressant effects of narcotic, sedative, and psychoactive drugs in the central nervous system. The oxidation of ethanol produces toxic agents and disrupts metabolic pathways. Here we mention only the most important of these changes.

- *Acetaldehyde* has many toxic effects and is responsible for some of the acute effects of alcohol and for the development of oral cancers. The efficiency of alcohol metabolism varies between populations, depending on the expression levels of ADH and ALDH isozymes, and the presence of genetic variants that alter enzyme activity. About 50% of Asians have very low ALDH activity, due to the substitution of lysine for glutamine at residue 487 (the normal allele is termed ALDH2*1 and the inactive variant is designated as ALDH2*2). The ALDH2*2 protein has dominant-negative activity, such that even one copy of the ALDH2*2 allele reduces ALDH activity significantly. *Individuals homozygous for the ALDH2*2 allele are completely unable to oxidize acetaldehyde and cannot tolerate alcohol*, experiencing nausea, flushing, tachycardia, and hyperventilation after its ingestion.[24]
- Alcohol oxidation by ADH causes the reduction of nicotinamide adenine dinucleotide (NAD) to NADH, with a consequent decrease in NAD and increase in NADH. NAD is required for fatty acid oxidation in the liver and for the conversion of lactate into pyruvate. Its deficiency is a main cause of the accumulation of fat in the liver of alcoholics. The increase in the NADH/NAD ratio in alcoholics also causes lactic acidosis.
- *Metabolism of ethanol in the liver by CYP2E1 produces reactive oxygen species and causes lipid peroxidation of cell membranes*. However, the precise mechanisms that account for alcohol-induced cellular injury in the liver have not been well defined. Alcohol also causes the release of endotoxin (lipopolysaccharide) from gram-negative bacteria in the intestinal flora, which stimulates the production of TNF (tumor necrosis factor) and other cytokines from macrophages and Kupffer cells, leading to hepatic injury.

The adverse effects of ethanol can be classified as acute or chronic.

Acute alcoholism exerts its effects mainly on the CNS, but it may induce hepatic and gastric changes that are reversible if alcohol consumption is discontinued. Even with moderate intake of alcohol, multiple fat droplets accumulate in the cytoplasm of hepatocytes *(fatty change or hepatic steatosis)*. The gastric changes are acute *gastritis and ulceration*. In the CNS, alcohol is a depressant, first affecting subcortical structures (probably the high brain stem reticular formation) that modulate cerebral cortical activity. Consequently, there is stimulation and disordered cortical, motor, and intellectual behavior. At progressively higher blood levels, cortical neurons and then lower medullary centers are depressed, including those that regulate respiration. Respiratory arrest may follow.

Chronic alcoholism affects not only the liver and stomach, but virtually all other organs and tissues as well. Chronic alcoholics suffer significant morbidity and have a shortened life span, related principally to damage to the liver, gastrointestinal tract, CNS, cardiovascular system, and pancreas.

- The *liver* is the main site of chronic injury. In addition to fatty change mentioned above, chronic alcoholism causes alcoholic hepatitis and cirrhosis, as described in Chapter 18 . Cirrhosis is associated with portal hypertension and an increased risk for the development of hepatocellular carcinoma.
- In the *gastrointestinal tract*, chronic alcoholism can cause massive bleeding from gastritis, gastric ulcer, or esophageal varices (associated with cirrhosis), which may prove fatal.
- Thiamine (vitamin B_1) deficiency is common in chronic alcoholics. The principal lesions resulting from this deficiency are *peripheral neuropathies* and the *Wernicke-Korsakoff syndrome* (see Table 9-9 in this chapter, and Chapter 28); cerebral atrophy, cerebellar degeneration, and optic neuropathy may also occur.
- Alcohol has diverse effects on the cardiovascular system. Injury to the myocardium may produce dilated congestive cardiomyopathy (*alcoholic cardiomyopathy*, discussed in Chapter 12). Chronic alcoholism is also associated with an increased incidence of hypertension. Moderate amounts of alcohol (about 20–30 gm of daily intake, corresponding to approximately 250 mL of wine) have been reported to increase high-density lipoprotein (HDL) levels and inhibit platelet aggregation, thus protecting against coronary heart disease. However, heavy alcohol consumption, with attendant liver injury, results in decreased levels of HDL, increasing the likelihood of coronary heart disease.
- Excessive alcohol intake increases the risk of *acute and chronic pancreatitis* (Chapter 19).
- The use of ethanol during pregnancy—reportedly in very low amounts—can cause *fetal alcohol syndrome*.[25] It consists of microcephaly, growth retardation, and facial abnormalities in the newborn, and reduction in mental functions as the child grows older. It is difficult to establish the minimal amount of alcohol consumption that can cause fetal alcohol syndrome, but consumption during the first trimester of pregnancy is particularly harmful. It has been estimated that the prevalence of frequent and binge drinking among

pregnant women is approximately 6% and that fetal alcohol syndrome affects 1 to 4.8 per 1000 children born in the United States.

- Chronic alcohol consumption is associated with an *increased incidence of cancer* of the oral cavity, esophagus, liver, and, possibly, breast in females. Acetaldehyde is considered to be the main agent associated with alcohol-induced laryngeal and esophageal cancer, in that acetaldehyde-DNA adducts have been detected in some tumors from these tissues. Individuals with one copy of the ALDH2*2 allele who drink are at a higher risk of developing cancer of the esophagus.
- Ethanol is a substantial source of energy (empty calories). Chronic alcoholism leads to malnutrition and nutritional deficiencies, particularly of the B vitamins.

TABLE 9-9 -- Vitamins: Major Functions and Deficiency Syndromes

Vitamin	Functions	Deficiency Syndromes
FAT-SOLUBLE		
Vitamin A	A component of visual pigment	Night blindness, xerophthalmia, blindness
	Maintenance of specialized epithelia	Squamous metaplasia
	Maintenance of resistance to infection	Vulnerability to infection, particularly measles
Vitamin D	Facilitates intestinal absorption of calcium and phosphorus and mineralization of bone	Riskets in children
		Osteomalacia in adults
Vitamin E	Major antioxidant; scavenges free radicals	Spinocerebellar degeneration
Vitamin K	Cofactor in hepatic carboxylation of procoagulants—factors II (prothrombin), VII, IX, and X; and protein C and protein S	Bleeding diathesis (Chapter 14)
WATER-SOLUBLE		
Vitamin B_1 (thiamine)	As pyrophosphate, is coenzyme in decarboxylation reactions	Dry and wet beriberi, Wernicke syndrome, Korsakoff syndrome (Chapter 28)
Vitamin B_2 (riboflavin)	Converted to coenzymes flavin mononucleotide and flavin adenine dinucleotide, cofactors for many enzymes in intermediary metabolism	Ariboflavinosis, cheilosis, stomatitis, glossitis, dermatitis, corneal vascularization
Niacin	Incorporated into nicotinamide adenine dinucleotide (NAD) and NAD phosphate, involved in a variety of redox reactions	Pellagra—"three Ds": dementia, dermatitis, diarrhea
Vitamin B_6 (pyridoxine)	Derivatives serve as coenzymes in many intermediary reactions	Cheilosis, glossitis, dermatitis, peripheral neuropathy (Chapter 28)
Vitamin B_{12}	Required for normal folate metabolism and DNA synthesis	Megaloblastic pernicious anemia and degeneration of posterolateral spinal cord tracts (Chapter 14)
	Maintenance of myelinization of spinal cord tracts	
Vitamin C	Serves in many oxidation-reduction (redox) reactions and hydroxylation of collagen	Scurvy
Folate	Essential for transfer and use of one-carbon units in DNA synthesis	Megaloblastic anemia, neural tube defects (Chapter 14)
Pantothenic acid	Incorporated in coenzyme A	No nonexperimental syndrome recognized
Biotin	Cofactor in carboxylation reactions	No clearly defined clinical syndrome

And now, a bit of good news: red wine contains *resveratrol*, a polyphenolic compound that increases life span in worms and flies, promotes longevity in mice, and protects mice against diet-induced obesity and insulin resistance. Resveratrol contributes to the protective effect against cardiovascular disease in moderate wine drinkers and possibly provides the clue to the "French paradox," a wine- and food-loving population with a low incidence of obesity and cardiovascular disease. The effects of resveratrol on

longevity have been attributed to its activation of protein deacetylases of the *Sir2 (sirtuin)* family of enzymes, which include histone deacetylases (Chapter 1). However, because resveratrol also interacts with various other proteins, ongoing studies seek to identify the precise mechanisms of its protective effects.[26,][27]

2.9.8 Injury by Therapeutic Drugs & Drugs of Abuse

INJURY BY THERAPEUTIC DRUGS (ADVERSE DRUG REACTIONS)

Adverse drug reactions (ADRs) refer to untoward effects of drugs that are given in conventional therapeutic settings. These reactions are extremely common in the practice of medicine (Fig. 9-13) and affect almost 10% of patients admitted to a hospital. It is estimated that in about 10% of these patients, ADRs are fatal. Table 9-5 lists common pathologic findings in ADRs and the drugs most frequently involved. As can be seen in the table, many of the drugs that produce ADRs, such as antineoplastic agents, are highly potent, and the adverse reactions are expected risks of the treatment. In this section, we examine the adverse reactions to some commonly used drugs. We first discuss the adverse effects of *hormonal replacement therapy (HRT), oral contraceptives (OCs), and anabolic steroids. This is followed by a discussion of the effects of the drugs acetaminophen and aspirin, because all of these are used very commonly*.

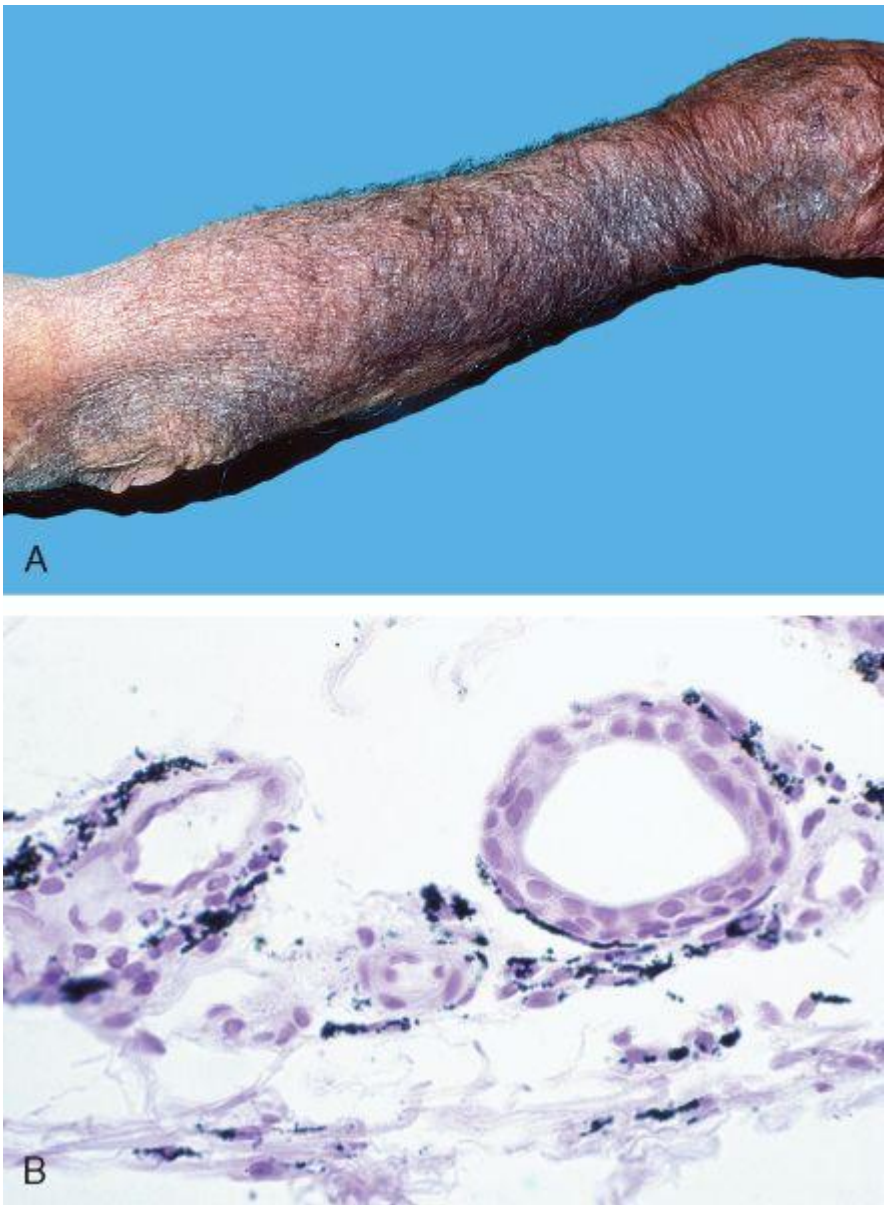

FIGURE 9-13 Adverse drug reaction. Skin pigmentation caused by minocycline, a long-acting tetracycline derivative. **A**, Diffuse blue-gray pigmentation of the forearm; **B**, Deposition of drug metabolite/iron/melanin pigment particles in the dermis. *(Courtesy of Dr. Zsolt Argenyi, Department of Pathology, University of Washington, Seattle, WA.)*

TABLE 9-5 -- Some Common Adverse Drug Reactions and Their Agents

Reaction	Major Offenders
BONE MARROW AND BLOOD CELLS[*]	
Granulocytopenia, aplastic anemia, pancytopenia	Antineoplastic agents, immunosuppressives, and chloramphenicol
Hemolytic anemia, thrombocytopenia	Penicillin, methyldopa, quinidine, heparin
CUTANEOUS	
Urticaria, macules, papules, vesicles, petechiae, exfoliative	Antineoplastic agents, sulfonamides, hydantoins,

Reaction	Major Offenders
dermatitis, fixed drug eruptions, abnormal pigmentation	some antibiotics, and many other agents
CARDIAC	
Arrhythmias	Theophylline, hydantoins, digoxin
Cardiomyopathy	Doxorubicin, daunorubicin
RENAL	
Glomerulonephritis	Penicillamine
Acute tubular necrosis	Aminoglycoside antibiotics, cyclosporin, amphotericin B
Tubulointerstitial disease with papillary necrosis	Phenacetin, salicylates
PULMONARY	
Asthma	Salicylates
Acute pneumonitis	Nitrofurantoin
Interstitial fibrosis	Busulfan, nitrofurantoin, bleomycin
HEPATIC	
Fatty change	Tetracycline
Diffuse hepatocellular damage	Halothane, isoniazid, acetominophen
Cholestasis	Chlorpromazine, estrogens, contraceptive agents
SYSTEMIC	
Anaphylaxis	Penicillin
Lupus erythematosus syndrome (drug-induced lupus)	Hydralazine, procainamide
CENTRAL NERVOUS SYSTEM	
Tinnitus and dizziness	Salicylates
Acute dystonic reactions and parkinsonian syndrome	Phenothiazine antipsychotics
Respiratory depression	Sedatives

* Affected in almost half of all drug-related deaths.

Hormonal Replacement Therapy (HRT)

The most common type of HRT consists of the administration of estrogens together with progesterone. Because of the risk of uterine cancer, estrogen therapy alone is used only in hysterectomized women. Once prescribed primarily for distressing menopausal symptoms (e.g., hot flashes), HRT had been widely used in postmenopausal women to prevent or slow the progression of osteoporosis (Chapter 26) and to reduce the likelihood of myocardial infarction. However, the results of the Women's Health Initiative published in 2002, stunned the scientific community by failing to find support for some of the presumed beneficial effects of the therapy. This large epidemiologic study involved approximately 17,000 women who were taking a combination of estrogen (equine estrogen) and progesterone (medroxyprogesterone acetate). Although the study found that HRT caused a reduction in the number of fractures, it also reported that after 5 years of treatment, HRT increased the risk of breast cancer (as discussed in Chapter 23) and thromboembolism, and had no effect on preventing cardiovascular disease. The wide dissemination of these findings led to a drastic decrease in the use of HRT, from 16 million prescriptions in 2001 to 6 million in 2006, which was accompanied by an apparent drop in the incidence of newly diagnosed breast cancers. During the last few years there has been a reappraisal of the risks and benefits of HRT.[28] The new analyses showed that HRT effects depend on the type of

estrogen/progesterone used, the mode of drug administration, the age of the person at the start of treatment, the duration of the treatment, and the presence of associated diseases.

- *HRT increases the risk of breast cancer after a median time of 5 to 8 years*. The risk is highest and the latency times shorter for the development of lobular carcinomas and ductal-lobular cancer.[29]
- HRT has a protective effect on the development of atherosclerosis and coronary disease in women under age 60, but there is no protection in women who started HRT at an older age.[30] These data support the notion that there is a critical therapeutic window for HRT effects on the cardiovascular system. Protective effects in younger women depend in part on the response of estrogen receptors that regulate calcium homeostasis in blood vessels.
- *HRT increases the risk of venous thromboembolism*, including deep vein thrombosis, pulmonary embolism, and stroke. The increase is more pronounced during the first 2 years of treatment and in women who have other risk factors such as immobilization, and hypercoagulable states caused by prothrombin or factor V Leiden mutations (Chapter 4).

Oral Contraceptives (OCs)

Worldwide, more than 100 million women use hormonal contraception. OCs nearly always contain a synthetic estradiol and a variable amount of a progestin, but some preparations contain only progestins. They act by inhibiting ovulation or preventing implantation. Currently prescribed OCs contain a much smaller amount of estrogens (as little as 20 μg of ethinyl estradiol) than the earliest formulations approved for use in the United States in 1960, and are associated with fewer side effects. Transdermal and implantable formulations have also become available. Hence, the results of epidemiologic studies should be interpreted in the context of the dosage and the delivery system. Nevertheless, there is good evidence that the use of OCs is associated with the following conditions[31]:

Thromboembolism. Most studies indicate that OC use results in an approximately three-fold increased risk of venous thrombosis and pulmonary thromboembolism. This risk is increased further in carriers of prothrombin and factor V Leiden mutations. The increased thrombotic risk seems to be a consequence of the generation of an acute-phase response, with increases in C-reactive protein and coagulation factors (factors VII, IX, X, XII, and XIII), and reduction in anticoagulants (protein S and anti-thrombin III).

Cardiovascular disease. OCs increase the risk of myocardial infarction in smoking women at all ages and in nonsmoking women over age 35. In women over 35 years of age, the effect is more than ten-fold higher in smokers than nonsmokers.

Cancers. OCs reduce the incidence of endometrial and ovarian cancers. They do not increase the lifetime risk for development of breast cancers, although a small increase in incidence has been detected during the first 5 years of use.

Hepatic adenoma. There is a well-defined association between the use of OCs and this hepatic tumor (Chapter 18), particularly in older women who have used OCs for prolonged periods of time. The tumor appears as a large, solitary, and well-encapsulated mass.

Anabolic Steroids

The use of steroids to increase performance by baseball players, track-and-field athletes, and wrestlers has received wide publicity during the last few years. Anabolic steroids are synthetic versions of testosterone, and for performance enhancement they are used at doses that are about 10 to 100 times higher than therapeutic indications. The high concentration of testosterone and its derivatives inhibits production and release of luteinizing hormone and follicle-stimulating hormone by a feedback mechanism, and increases the amount of estrogens, which are produced from anabolic steroids. Anabolic steroids have multiple adverse effects including stunted growth in adolescents, acne, gynecomastia and testicular atrophy in males, and growth of facial hair and menstrual changes in women. Other effects include psychiatric problems and premature heart attacks. Hepatic cholestasis may develop in individuals receiving orally administered anabolic steroids.

Acetaminophen

Acetaminophen is the most commonly used analgesic in the United States. It is present in over 300 products, alone or in combination with other agents. Hence, acetaminophen toxicity is common, being responsible for more than 50,000 emergency room visits per year. In the United States, it is the cause of about 50% of cases of acute liver failure, with 30% mortality. Intentional overdosage (suicide attempts) is the most common cause of acetaminophen toxicity in Great Britain, but unintentional overdosage is the most frequent cause in the United States, representing almost 50% of the total intoxication cases.

At therapeutic doses about 95% of acetaminophen undergoes detoxification in the liver by phase II enzymes and is excreted in the urine as glucuronate or sulfate conjugates (Fig. 9-14). About 5% or less is metabolized through the activity of CYPs (primarily CYP2E) to NAPQI (*N*-acetyl-*p*-benzoquinoneimine), a highly reactive metabolite.[32,][33] NAPQI is normally conjugated with glutathione (GSH), but when taken in larger doses unconjugated *NAPQI accumulates and causes hepatocellular injury leading to centrilobular necrosis and liver failure*. The injury produced by NAPQI involves two mechanisms: (1) covalent binding to hepatic proteins, which causes damage to cellular membranes and mitochondrial dysfunction, and (2) depletion of GSH, making hepatocytes more susceptible to reactive oxygen species–induced injury. It should be noted that because alcohol induces CYP2E in the liver, toxicity can occur at lower doses in chronic alcoholics.

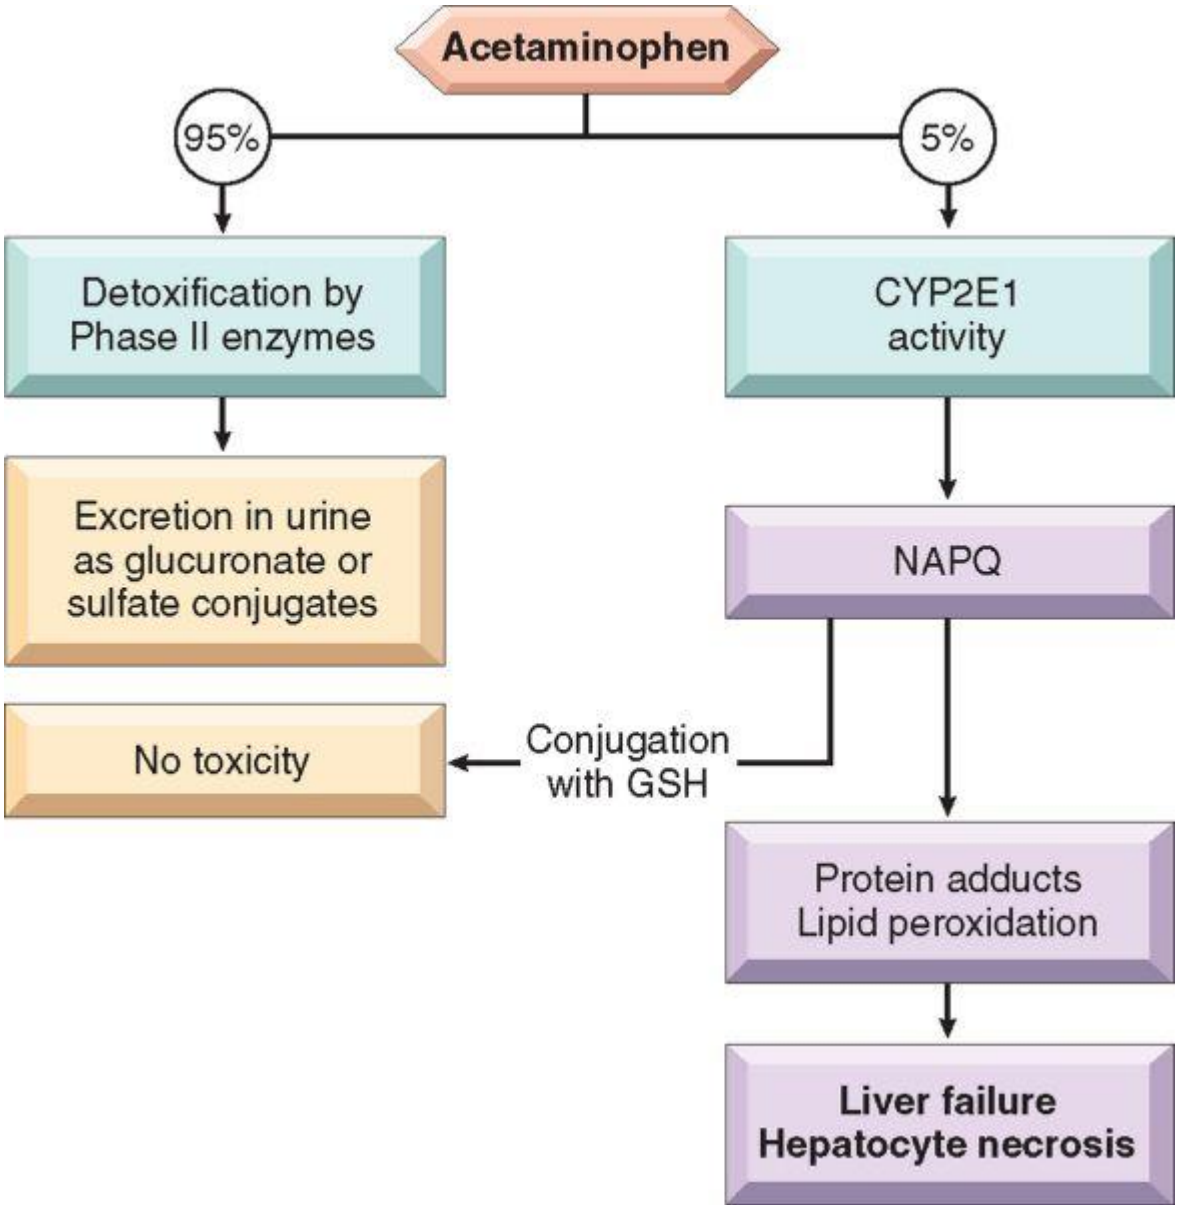

FIGURE 9-14 Acetaminophen metabolism and toxicity. (See text for details.) *(Courtesy of Dr. Xavier Vaquero, Department of Pathology, University of Washington, Seattle, WA.)*

The window between the usual dose (0.5 gm) and the toxic dose (15 to 25 gm) is large, and the drug is ordinarily very safe. Toxicity begins with nausea, vomiting, diarrhea, and sometimes shock, followed in a few days by evidence of jaundice. Overdoses of acetaminophen can be treated at its early stages (within 12 hours) by administration of *N-acetylcysteine, which restores GSH*. In serious overdose liver failure ensues, starting with centrilobular necrosis that may extend to entire lobules, requiring liver transplantation for survival. Some patients show evidence of concurrent renal damage.

Aspirin (Acetylsalicylic Acid)

Overdose may result from accidental ingestion of a large number of tablets by young children; in adults overdose is frequently suicidal. A source of salicylate poisoning is the excessive use of ointments containing oil of wintergreen (methyl salicylate). Acute salicylate overdose causes alkalosis as a consequence of the stimulation of the respiratory center in the medulla. This is followed by metabolic acidosis and accumulation of pyruvate and lactate, caused by uncoupling of oxidative phosphorylation and inhibition of the Krebs cycle. Metabolic acidosis enhances the formation of non-ionized forms of salicylates, which diffuse into the brain and produce effects from nausea to coma. Ingestion of 2 to 4 gm by children or 10 to 30 gm by adults may be fatal, but survival has been reported after ingestion of doses five times larger.

Chronic aspirin toxicity (salicylism) may develop in persons who take 3 gm or more daily for long periods of time for treatment of chronic pain or inflammatory conditions. Chronic salicylism is manifested by headaches, dizziness, ringing in the ears (tinnitus), hearing impairment, mental confusion, drowsiness, nausea, vomiting, and diarrhea. The CNS changes may progress to convulsions and coma. The morphologic consequences of chronic salicylism are varied. Most often there is an acute erosive gastritis (Chapter 17), which may produce overt or covert gastrointestinal bleeding and lead to gastric ulceration. A bleeding tendency may appear concurrently with chronic toxicity, because aspirin acetylates platelet cyclooxygenase and irreversibly blocks the production of thromboxane A_2, an activator of platelet aggregation. Petechial hemorrhages may appear in the skin and internal viscera, and bleeding from gastric ulcerations may be exaggerated. With the recognition of gastric ulceration and bleeding as an important complication of ingestion of large doses of aspirin, its chronic toxicity is now quite uncommon.

Proprietary analgesic mixtures of aspirin and phenacetin or its active metabolite, acetaminophen, when taken over several years, can cause tubulointerstitial nephritis with renal papillary necrosis, referred to as *analgesic nephropathy* (Chapter 20).

INJURY BY NONTHERAPEUTIC AGENTS (DRUG ABUSE)

Drug abuse generally involves the use of mind-altering substances, beyond therapeutic or social norms. Drug addiction and overdose are serious public health problems. Common drugs of abuse are listed in Table 9-6 . Here we consider cocaine, heroin, amphetamines, and marijuana, and briefly mention a few others.

TABLE 9-6 -- Common Drugs of Abuse

Class	Molecular Target	Example
Opioid narcotics	Mu opioid receptor (agonist)	Heroin, hydromorphone (Dilaudid)
		Oxycodone (Percodan, Percocet, Oxycontin)
		Methadone (Dolophine)
		Meperidine (Demerol)
Sedative-hypnotics	$GABA_A$ receptor (agonist)	Barbiturates
		Ethanol
		Methaqualone (Quaalude)
		Glutethimide (Doriden)
		Ethchlorvynol (Placidyl)
Psychomotor stimulants	Dopamine transporter (antagonist)	Cocaine
	Serotonin receptors (toxicity)	Amphetamines

Class	Molecular Target	Example
		3,4-methylenedioxymethamphetamine (MDMA, ecstasy)
Phencyclidine-like drugs	NMDA glutamate receptor channel (antagonist)	Phencyclidine (PCP, angel dust)
		Ketamine
Cannabinoids	CBI cannabinoid receptors (agonist)	Marijuana
		Hashish
Hallucinogens	Serotonin 5-HT_2 receptors (agonist)	Lysergic acid diethylamide (LSD)
		Mescaline
		Psilocybin

Data from Hyman SE: A 28-year-old man addicted to cocaine. JAMA 286:2586, 2001.

GABA, γ-aminobutyric acid; 5-HT_2, 5-hydroxytryptamine; NMDA, *N*-methyl D-aspartate.

Cocaine

The use of cocaine and crack continues to increase. According to a 2006 survey, approximately 35.3 million Americans aged 12 or older have tried cocaine, with 6.1 million having used cocaine in the past year. Cocaine is extracted from the leaves of the coca plant, and is usually prepared as a water-soluble powder, cocaine hydrochloride. Sold on the street, it is liberally diluted with talcum powder, lactose, or other look-alikes. Cocaine can be snorted or dissolved in water and injected subcutaneously or intravenously. Crystallization of the pure alkaloid yields nuggets of *crack*, so called because of the cracking or popping sound it makes when heated to produce vapors that are inhaled. The pharmacologic actions of cocaine and crack are identical, but crack is far more potent.

Cocaine produces an intense euphoria and stimulation, making it one of the most addictive drugs. Experimental animals will press a lever more than 1000 times and forgo food and drink to obtain it. In the cocaine user, although physical dependence generally does not occur, the psychologic withdrawal is profound and can be extremely difficult to treat. Intense cravings are particularly severe in the first several months after abstinence and can recur for years. Acute overdose can produce seizures, cardiac arrhythmias, and respiratory arrest.

- *Cardiovascular effects*. The most serious physical effects of cocaine relate to its acute action on the cardiovascular system, where it behaves as a sympathomimetic (Fig. 9-15). It facilitates neurotransmission both in the CNS, where it blocks the reuptake of dopamine, and at adrenergic nerve endings, where it blocks the reuptake of both epinephrine and norepinephrine while stimulating the presynaptic release of norepinephrine. The net effect is the accumulation of these two neurotransmitters in synapses, resulting in excess stimulation, manifested by *tachycardia*, *hypertension*, and *peripheral vasoconstriction*. Cocaine also induces *myocardial ischemia*, by causing *coronary artery vasoconstriction*, and enhancing platelet aggregation and thrombus formation. Cigarette smoking potentiates cocaine-induced coronary vasospasm. Thus, the dual effect of cocaine, causing increased myocardial oxygen demand by its sympathomimetic action, and, at the same time, decreasing coronary blood flow, sets the stage for myocardial ischemia that may lead to myocardial infarction. Cocaine can also precipitate *lethal arrhythmias* by enhanced sympathetic activity as well as by disrupting normal ion (K^+, $Ca^{[2]+}$, Na^+) transport in the myocardium. These toxic effects are not necessarily dose-related, and a fatal event may occur in a first-time user with what is a typical mood-altering dose.
- *CNS*. The most common CNS effects are hyperpyrexia (thought to be caused by aberrations of the dopaminergic pathways that control body temperature) and seizures.

- *Effects on pregnancy*. In pregnant women, cocaine may cause decreased blood flow to the placenta, resulting in fetal hypoxia and spontaneous abortion. Neurologic development may be impaired in the fetus of pregnant women who are chronic drug users.
- *Other effects*. Chronic cocaine use may cause (1) perforation of the nasal septum in snorters, (2) decreased lung diffusing capacity in those who inhale the smoke, and (3) the development of dilated cardiomyopathy.

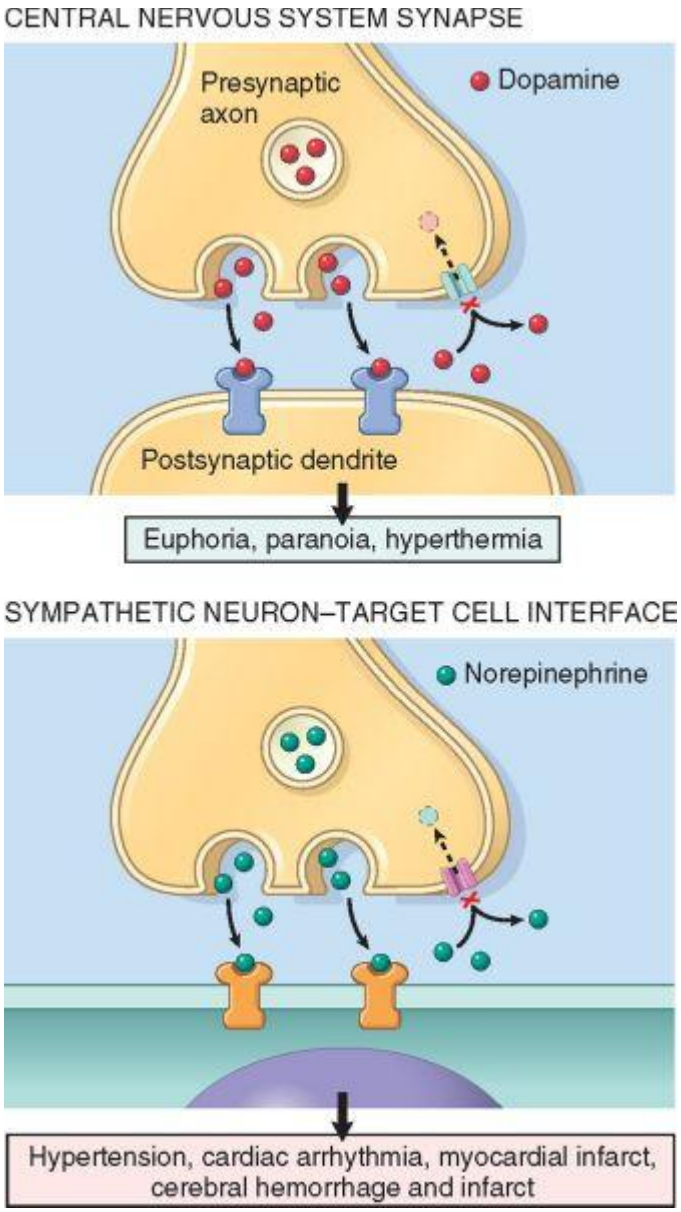

FIGURE 9-15 The effect of cocaine on neurotransmission. The drug inhibits reuptake of the neurotransmitters dopamine and norepinephrine in the central and peripheral nervous systems.

Heroin

Heroin is an addictive opioid derived from the poppy plant that is closely related to morphine. Its use is even more harmful than that of cocaine. As sold on the street, it is cut (diluted) with an agent (often talc or quinine); thus, the size of the dose is not only variable but also usually unknown to the buyer. Heroin, along with any contaminating substances, is usually self-administered intravenously or subcutaneously. Effects are varied and include euphoria, hallucinations, somnolence, and sedation. Heroin has a wide

range of adverse physical effects related to (1) the pharmacologic action of the agent, (2) reactions to the cutting agents or contaminants, (3) hypersensitivity reactions to the drug or its adulterants (quinine itself has neurologic, renal, and auditory toxicity), and (4) diseases contracted incident to the use of infected needles. Some of the most important adverse effects of heroin are the following:

- *Sudden death*. Sudden death, usually related to overdose, is an ever-present risk, because drug purity is generally unknown (it may range from 2% to 90%). The yearly mortality among heroin users in the United States is estimated to be between 1% and 3%. Sudden death can also occur if heroin is taken after tolerance for the drug, built up over time, is lost (as during a period of incarceration). The mechanisms of death include profound respiratory depression, arrhythmia and cardiac arrest, and severe pulmonary edema.
- *Pulmonary injury*. Pulmonary complications include moderate to severe edema, septic embolism from endocarditis lung abscess, opportunistic infections, and foreign-body granulomas from talc and other adulterants. Although granulomas occur principally in the lung, they are sometimes found in the mononuclear phagocyte system, particularly in the spleen, liver, and lymph nodes that drain the upper extremities. Examination under polarized light often highlights trapped talc crystals, sometimes enclosed within foreign-body giant cells.
- *Infections*. Infectious complications are common. The four sites most commonly affected are the skin and subcutaneous tissue, heart valves, liver, and lungs. In a series of addicted patients admitted to the hospital, more than 10% had endocarditis, which often takes a distinctive form involving right-sided heart valves, particularly the tricuspid. Most cases are caused by *S. aureus*, but fungi and a multitude of other organisms have also been implicated. Viral hepatitis is the most common infection among addicted persons and is acquired by the sharing of dirty needles. In the United States, this practice has also led to a very high incidence of AIDS in intravenous drug abusers.
- *Skin*. Cutaneous lesions are probably the most frequent telltale sign of heroin addiction. Acute changes include abscesses, cellulitis, and ulcerations due to subcutaneous injections. Scarring at injection sites, hyperpigmentation over commonly used veins, and thrombosed veins are the usual sequelae of repeated intravenous inoculations.
- *Renal problems*. Kidney disease is a relatively common hazard. The two forms most frequently encountered are amyloidosis (generally secondary to skin infections) and focal glomerulosclerosis; both induce heavy proteinuria and the nephrotic syndrome.

Methadone, originally used in the treatment of heroin addiction, is increasingly being prescribed as a painkiller. Unfortunately, its careless use has contributed to more than 800 deaths per year in the United States.

Amphetamines

Methamphetamine.

This addictive drug, known as *"speed"* or *"meth, "* is closely related to amphetamine but has stronger effects in the CNS. It is estimated that there are approximately 500,000 current users in the United States. Approximately 2.5% of youths in grade 8 and 6.5% in grade 12 have tried methamphetamine at least once. It acts by releasing dopamine in the brain, which inhibits presynaptic neurotransmission at corticostriatal synapses, slowing glutamate release.[34] Metamphetamine produces a feeling of euphoria, which is followed by a "crash." Long-term use leads to violent behaviors, confusion, and psychotic features that include paranoia and hallucinations.

MDMA.

MDMA (3,4 methylenedioxymethamphetamine) is popularly known as *ecstasy*. MDMA is generally taken orally. Its effects, which include euphoria and hallucinogen-like feelings that last for 4 to 6 hours, are mainly due to an increase in serotonin release in the CNS. This is coupled with interference in serotonin synthesis, causing a reduction in serotonin that is only slowly replenished. MDMA use also reduces the number of serotonergic axon terminals in the striatum and the cortex, and it may increase

the peripheral effects of dopamine and adrenergic agents. MDMA tablets may be spiked with other drugs, including methamphetamine and cocaine, which greatly enhance the effects on the CNS.

Marijuana

Marijuana, or "pot," is made from the leaves of the *Cannabis sativa* plant, which contain the psychoactive substance Δ^9-tetrahydrocannabinol (THC). About 5% to 10% of THC is absorbed when it is smoked in a hand-rolled cigarette ("joint"). Despite numerous studies, the central question of whether the drug has persistent adverse physical and functional effects remains unresolved.[35] Some of the untoward anecdotal effects may be allergic or idiosyncratic reactions or possibly related to contaminants in the preparations rather than to the pharmacologic effects of marijuana. Among the beneficial effects of marijuana is its potential use to treat nausea secondary to cancer chemotherapy, and as an agent capable of decreasing pain in some chronic conditions that are otherwise difficult to treat. The functional and organic CNS consequences of marijuana smoking have received most scrutiny. Its use distorts sensory perception and impairs motor coordination, but these acute effects generally clear in 4 to 5 hours. With continued use these changes may progress to cognitive and psychomotor impairments, such as inability to judge time, speed, and distance, a frequent cause of automobile accidents. Marijuana increases the heart rate and sometimes blood pressure, and it may cause angina in a person with coronary artery disease.

The respiratory system is also affected by chronic marijuana smoking; laryngitis, pharyngitis, bronchitis, cough and hoarseness, and asthma-like symptoms have all been described, along with mild but significant airway obstruction. Marijuana cigarettes contain a large number of carcinogens that are also present in tobacco. Smoking a marijuana cigarette, compared with a tobacco cigarette, is associated with a three-fold increase in the amount of tar inhaled and retained in the lungs, presumably because of the larger puff volume, deeper inhalation, and longer breath holding.

Regardless of the use of THC as a recreational drug, a large number of studies have characterized the *endogenous cannabinoid system*, which consists of the *cannabinoid receptors CB1 and CB2*, and the endogenous lipid ligands known as *endocannabinoids*.[36] This system participates in the regulation of the hypothalamic-pituitary-adrenal axis, and modulates the control of appetite, food intake, and energy balance, as well as fertility and sexual behavior.[37]

Other Drugs

The variety of drugs that have been tried by those seeking "new experiences" (e.g., "highs," "lows," "out-of-the-body experiences") defies belief. Overall, there has been a decrease in the use of most illegal drugs, but large increases have occurred in prescription and nonprescription drug abuse, and in the inhalation of potentially toxic household products. These drugs include various stimulants, depressants, analgesics, and hallucinogens (see Table 9-6). Among these are PCP (phenylcyclidine, an anesthetic agent), analgesics such as oxycontin and vicodin, and ketamine, an anesthetic agent used in animal surgery. Chronic inhalation of vapors of spray paints, paint thinners, and some glues that contain toluene ("glue sniffing") can cause cognitive abnormalities and magnetic resonance imaging–detectable brain damage that ranges from mild to severe dementia. Because they are used haphazardly and in various combinations, not much is known about the long-time deleterious effects of most of these agents. However, their acute effects are clear: they cause bizarre and often aggressive behavior that leads to violence, or depressed mood and suicidal ideation.

2.9.9 Injury by Physical Agents

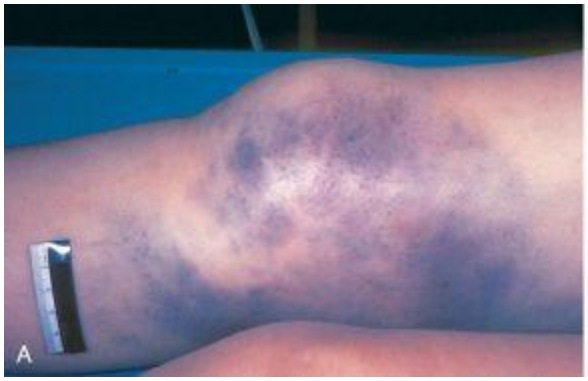
Injury induced by physical agents is divided into the following categories: mechanical trauma, thermal injury, electrical injury, and injury produced by ionizing radiation. Each type is considered separately.

MECHANICAL TRAUMA

Mechanical forces may inflict a variety of forms of damage. *The type of injury depends on the shape of the colliding object, the amount of energy discharged at impact, and the tissues or organs that bear the impact*. Bone and head injuries result in unique damage and are discussed elsewhere (Chapter 28). All soft tissues react similarly to mechanical forces, and the patterns of injury can be divided into abrasions, contusions, lacerations, incised wounds, and puncture wounds. This is just a small sampling of the various forms of trauma encountered by forensic pathologists, who deal with wounds produced by shooting, stabbing, blunt force, traffic accidents, and other causes. In addition to morphologic analyses, forensic pathology now includes molecular methods for identity testing and sophisticated methods to detect the presence of foreign substances. Details about the practice of forensic pathology can be found in specialized textbooks.

Morphology. An **abrasion** is a wound produced by scraping or rubbing, resulting in removal of the superficial layer. Skin abrasions may remove only the epidermal layer. A **contusion**, or bruise, is an injury usually produced by a blunt object characterized by damage to blood vessels and extravasation of blood into tissues (Fig. 9-16A). A **laceration** is a tear or disruptive stretching of tissue caused by the application of force by a blunt object (Fig. 9-16B). In contrast to an incision, most lacerations have intact bridging blood vessels and jagged, irregular edges. An **incised wound** is one inflicted by a sharp instrument. The bridging blood vessels are severed. A **puncture wound** is caused by a long, narrow instrument and is termed **penetrating** when the instrument pierces the tissue and **perforating** when it traverses a tissue to also create an exit wound. Gunshot wounds are special forms of puncture wounds that demonstrate distinctive features important to the forensic pathologist. For example, a wound from a bullet fired at close range leaves powder burns, whereas one fired from more than 4 or 5 feet away does not.

One of the most common causes of mechanical injury is vehicular accident. The typical injuries result from (1) hitting a part of the interior of the vehicle or being hit by an object that enters the passenger compartment during the crash, such as the motor; (2) being thrown from the vehicle; or (3) being trapped in a burning vehicle. The pattern of injury relates to whether one or all three of these mechanisms are operative. For example, in a head-on collision, a common pattern of injury sustained by a driver who is not wearing a seat belt includes trauma to the head (windshield impact), chest (steering column impact), and knees (dashboard impact). Under these conditions, common chest injuries include sternal and rib fractures, heart contusions, aortic lacerations, and (less commonly) lacerations of the spleen and liver. Thus, in caring for an automobile injury victim, it is essential to remember that internal wounds often accompany superficial abrasions, contusions, and lacerations. Indeed, in many cases external evidence of serious internal damage is completely absent.



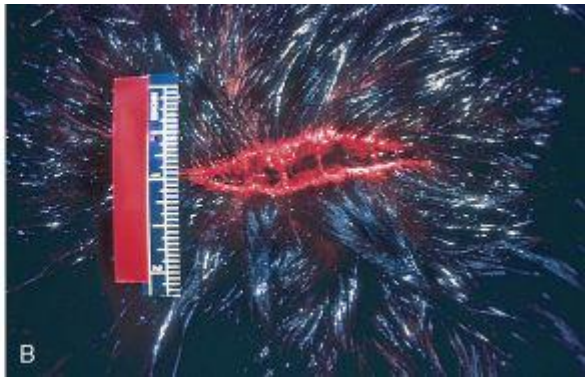


FIGURE 9-16 **A**, Contusion resulting from blunt trauma. The skin is intact, but there is hemorrhage of subcutaneous vessels, producing extensive discoloration. **B**, Laceration of the scalp; the bridging strands of fibrous tissues are evident. *(From the Department of Pathology, Southwestern Medical School, Dallas, TX.)*

THERMAL INJURY

Both excessive heat and excessive cold are important causes of injury. Burns are the most common cause of thermal injury and are discussed first; a brief discussion of hyperthermia and hypothermia follows.

Thermal Burns

In the United States, approximately 500,000 persons per year receive medical treatment for burn injuries. It is estimated that approximately 4000 persons per year die as a consequence of injuries caused by fire and smoke inhalation, mostly originating in homes. Fortunately, since the 1970s, marked decreases have been seen in both mortality rates and the length of hospitalizations of burn patients. In 2007 there were 40,000 hospitalizations in specialized burn centers, with a 90% survival. Eighty percent of the burns were caused by fire or scalding, the latter being a major cause of injury in children. Improvements in burn treatment have been achieved by a better understanding of the systemic effects of massive burns, the prevention of wound infection, and improvements in treatments that promote the healing of skin surfaces.

The clinical significance of a burn injury depends on the following factors:

- Depth of the burns
- Percentage of body surface involved
- Internal injuries caused by the inhalation of hot and toxic fumes
- Promptness and efficacy of therapy, especially fluid and electrolyte management and prevention or control of wound infections

Burns used to be classified as first to fourth degree, according to the depth of the injury (first-degree burns being the most superficial). This classification has been replaced by the terms *superficial, partial thickness, and full-thickness burns*.

- *Superficial burns* (formerly known as first-degree burns) are confined to the *epidermis*.
- *Partial thickness burns* (formerly known as second-degree burns) involve *injury to the dermis*.
- *Full-thickness burns* (formerly known as third-degree burns) extend to the *subcutaneous tissue*. Full-thickness burns may also involve *damage to muscle tissue* underneath the subcutaneous tissue (these were known formerly as fourth-degree burns).

Shock, sepsis, and respiratory insufficiency are the greatest threats to life in burn patients. Particularly in burns of more than 20% of the body surface, there is a rapid (within hours) shift of body fluids into the interstitial compartments, both at the burn site and systemically, which can result in *hypovolemic shock* (Chapter 4). Because protein from the blood is lost into interstitial tissue, generalized edema, including pulmonary edema, can be severe. An important pathophysiologic effect of burns is the development of a *hypermetabolic state* associated with excess heat loss and an increased need for

nutritional support. It is estimated that when more than 40% of the body surface is burned, the resting metabolic rate may double.

The burn site is ideal for the growth of microorganisms; the serum and debris provide nutrients, and the burn injury compromises blood flow, blocking effective inflammatory responses. The most common offender is the opportunist *Pseudomonas aeruginosa*, but antibiotic-resistant strains of other common hospital-acquired bacteria, such as *S. aureus*, and fungi, particularly *Candida* species, may also be involved. Furthermore, cellular and humoral defenses against infections are compromised, and both lymphocyte and phagocyte functions are impaired. Direct bacteremic spread and release of toxic substances such as endotoxin from the local site have dire consequences. Pneumonia or septic shock with renal failure and/or the acute respiratory distress syndrome (Chapter 15) are the most common serious sequelae.

Organ system failure resulting from burn sepsis has greatly diminished during the last 30 years, because of the introduction of techniques for early excision and grafting of the burn wound. Removal of the burn wound decreases infection and reduces the need for reconstructive surgery.[38] Grafting is done with split-thickness skin grafts; dermal substitutes, which serve as a bed for cell repopulation, may be used in large full-thickness burns.

Injury to the airways and lungs may develop within 24 to 48 hours after the burn and may result from the direct effect of heat on the mouth, nose, and upper airways or from the inhalation of heated air and noxious gases in the smoke. Water-soluble gases, such as chlorine, sulfur oxides, and ammonia, may react with water to form acids or alkalis, particularly in the upper airways, producing inflammation and swelling, which may lead to partial or complete airway obstruction. Lipid-soluble gases, such as nitrous oxide and products of burning plastics, are more likely to reach deeper airways, producing pneumonitis.

In burn survivors the development of hypertrophic scars, both at the site of the original burn and at donor graft sites, and itching may become long-term, difficult-to-treat problems. Hypertrophic scars after burn injury may be a consequence of continuous angiogenesis in the wound caused by excess neuropeptides, such as substance P, released from injured nerve endings.[39]

Morphology. Grossly, full-thickness burns are white or charred, dry, and anesthetic (because of destruction of nerve endings), whereas, depending on the depth, partial-thickness burns are pink or mottled with blisters and are painful. Histologically, devitalized tissue reveals coagulative necrosis, adjacent to vital tissue that quickly accumulates inflammatory cells and marked exudation.

Hyperthermia

Prolonged exposure to elevated ambient temperatures can result in heat cramps, heat exhaustion, and heat stroke.

- *Heat cramps* result from loss of electrolytes via sweating. Cramping of voluntary muscles, usually in association with vigorous exercise, is the hallmark. Heat-dissipating mechanisms are able to maintain normal core body temperature.
- *Heat exhaustion* is probably the most common hyperthermic syndrome. Its onset is sudden, with prostration and collapse, and it results from a failure of the cardiovascular system to compensate for hypovolemia, secondary to water depletion. After a period of collapse, which is usually brief, equilibrium is spontaneously re-established.
- *Heat stroke* is associated with high ambient temperatures, high humidity, and exertion. Thermoregulatory mechanisms fail, sweating ceases, and the core body temperature rises to more than 40°C, leading to multi-organ dysfunction that can be rapidly fatal. The underlying mechanism is marked generalized vasodilation,

with peripheral pooling of blood and a decreased effective circulating blood volume. Hyperkalemia, tachycardia, arrhythmias, and other systemic effects are common. *Necrosis of the muscles* (*rhabdomyolysis) and myocardium may occur as a consequence of the nitrosylation of the ryanodine receptor type 1 (RYR1) in skeletal muscle*.[40] RYR1 is located in the sarcoplasmic reticulum and regulates the release of calcium into the cytoplasm. Inherited mutations in *RYR1* occur in the condition called *malignant hyperthermia*, characterized by a rise in core body temperature and muscle contractures in response to exposure to common anesthetics. *RYR1* mutations may also increase the susceptibility to heat stroke. Elderly persons, individuals undergoing intense physical stress (including young athletes and military recruits), and persons with cardiovascular disease are potential candidates for heat stroke.

Hypothermia

Prolonged exposure to low ambient temperature leads to hypothermia, a condition seen all too frequently in homeless persons. High humidity, wet clothing, and dilation of superficial blood vessels resulting from the ingestion of alcohol hasten the lowering of body temperature. At a body temperature of about 90°F, loss of consciousness occurs, followed by bradycardia and atrial fibrillation at lower core temperatures.

Hypothermia causes injury by two mechanisms:

- *Direct effects* are probably mediated by physical disruptions within cells by high salt concentrations caused by the crystallization of intra- and extracellular water.
- *Indirect effects* resulting from circulatory changes, which vary depending on the rate and duration of the temperature drop. Slowly developing chilling may induce vasoconstriction and increased vascular permeability, leading to edema and hypoxia. Such changes are typical of “trench foot.” This condition developed in soldiers who spent long periods of time in water-logged trenches during the First World War (1914–1918), frequently causing gangrene that necessitated amputation (the only protection was to cover the feet with whale-oil grease as insulation). With sudden, persistent chilling, the vasoconstriction and increased viscosity of the blood in the local area may cause ischemic injury and degenerative changes in peripheral nerves. In this situation, the vascular injury and increased permeability with exudation become evident only after the temperature begins to return to normal. However, during the period of ischemia, hypoxic changes and infarction of the affected tissues may develop (e.g., gangrene of toes or feet).

ELECTRICAL INJURY

Electrical injuries, which are often fatal, can arise from contact with low-voltage currents (i.e., in the home and workplace) or high-voltage currents carried by high-power lines or lightning. Injuries are of two types: (1) burns and (2) ventricular fibrillation or cardiac and respiratory center failure, resulting from disruption of normal electrical impulses. The type of injury and the severity and extent of burns depend on the strength (amperage), duration, and path of the electric current within the body.

Voltage in the household and workplace (120 or 220 V) is high enough that with low resistance at the site of contact (as when the skin is wet), sufficient current can pass through the body to cause serious injury, including *ventricular fibrillation*. If current flow continues long enough, it generates enough heat to produce burns at the site of entry and exit as well as in internal organs. An important characteristic of alternating current, the type available in most homes, is that it induces tetanic muscle spasm, so that when a live wire or switch is grasped, irreversible clutching is likely to occur, prolonging the period of current flow. This results in a greater likelihood of developing extensive electrical burns and, in some cases, spasm of the chest wall muscles, producing death from asphyxia. Currents generated from high-voltage sources cause similar damage; however, because of the large current flows generated, these are more likely to produce paralysis of medullary centers and extensive burns. Lightning is a classic cause of high-voltage electrical injury.

Earlier studies had linked exposure to high-voltage magnetic fields to an increased risk of cancer, mainly leukemias, among workers on electric high-power lines and children living near power transmission lines. However, further analyses have failed to find a consistent association between these

exposures and cancer development. Electric and magnetic fields and microwave radiation, when sufficiently intense, may produce burns, usually of the skin and subjacent connective tissue, and both forms of radiation can interfere with cardiac pacemakers.

INJURY PRODUCED BY IONIZING RADIATION

Radiation is energy that travels in the form of waves or high-speed particles. Radiation has a wide range of energies that span the electromagnetic spectrum; it can be divided into non-ionizing and ionizing radiation. The energy of non-ionizing radiation such as UV and infrared light, microwave, and sound waves, can move atoms in a molecule or cause them to vibrate, but is not sufficient to displace bound electrons from atoms. By contrast, *ionizing radiation has sufficient energy to remove tightly bound electrons*. Collision of electrons with other molecules releases electrons in a reaction cascade, referred to as ionization. The main sources of ionizing radiation are *x-rays and gamma rays* (electromagnetic waves of very high frequencies), *high-energy neutrons, alpha particles* (composed of two protons and two neutrons), and *beta particles*, which are essentially electrons. At equivalent amounts of energy, alpha particles induce heavy damage in a restricted area, whereas x-rays and gamma rays dissipate energy over a longer, deeper course, and produce considerably less damage per unit of tissue. About 25% of the total dose of ionizing radiation received by the US population is human-made, mostly originated in medical devices and radioisotopes.

Ionizing radiation is a double-edged sword. It is indispensable in medical practice, being used in the treatment of cancer, in diagnostic imaging, and in therapeutic or diagnostic radioisotopes, but it also produces adverse short- and long-term effects such as *fibrosis*, *mutagenesis, carcinogenesis, and teratogenesis*.[41]

Radiation Units.

Several somewhat confusing terms are used to describe the radiation doses. This is because radiation is measured in three different ways. These are, the amount of radiation emitted by a source, the radiation dose absorbed by a person, and the biologic effect of the radiation. These are described below:

- *Curie* (Ci) represents the disintegrations per second of a radionuclide (radioisotope). One Ci is equal to 3.7×10^{10} disintegrations per second. This is an expression of the amount of radiation emitted by a source.
- *Gray* (Gy) is a unit that expresses the energy absorbed by the target tissue per unit mass. It corresponds to the absorption of 10^4 erg/gm of tissue. The centigray (cGy), which is the absorption of 100 erg/gm of tissue, is equivalent to the exposure of tissue to 100 Rads (radiation absorbed dose), abbreviated as R. The cGy terminology has now replaced R.
- *Sievert* (Sv) is a unit of equivalent dose that depends on the biologic rather than the physical effects of radiation (it replaced a unit called “rem”). For the same absorbed dose, various types of radiation differ in the extent of damage they produce. The equivalent dose controls for this variation and thereby provides a uniform measure of biologic dose. *The equivalent dose (expressed in Sieverts) corresponds to the absorbed dose (expressed in Grays) multiplied by the relative biologic effectiveness of the radiation*. The relative biologic effectiveness depends on the type of radiation, the type and volume of the exposed tissue, the duration of the exposure, and some other biologic factors (discussed below). The effective dose of x-rays in radiographs and computed tomography is commonly expressed in millisieverts (mSv). For x-radiation, 1 mSv = 1 mGy.

Main Determinants of the Biologic Effects of Ionizing Radiation.

In addition to the physical properties of the radiation, its biologic effects depend heavily on the following factors.

- *Rate of delivery*. The rate of delivery significantly modifies the biologic effect. Although the effect of radiant energy is cumulative, divided doses may allow cells to repair some of the damage between exposures.

Thus, fractionated doses of radiant energy have a cumulative effect only to the extent that repair during the "recovery" intervals is incomplete. Radiation therapy of tumors exploits the general capability of normal cells to repair themselves and recover more rapidly than tumor cells, and thus not sustain as much cumulative radiation damage.

- *Field size*. The size of the field exposed to radiation has a great influence on its consequences. The body can sustain relatively high doses of radiation when delivered to small, carefully shielded fields, whereas smaller doses delivered to larger fields may be lethal.
- *Cell proliferation*. Because ionizing radiation damages DNA, rapidly dividing cells are more vulnerable to injury than are quiescent cells (Fig. 9-17). Except at extremely high doses that impair DNA transcription, DNA damage is compatible with survival in nondividing cells, such as brain and myocardium. However, in dividing cells, certain types of mutations and chromosomal abnormalities are recognized by cell cycle checkpoints, which initiate events that lead to growth arrest and apoptosis. Understandably, therefore, *tissues with a high rate of cell division*, *such as gonads, bone marrow*, *lymphoid tissue*, *and the mucosa of the gastrointestinal tract*, *are extremely vulnerable to radiation*, and the injury is manifested early after exposure.
- *Oxygen effects and hypoxia*. The production of reactive oxygen species from the radiolysis of water is the most important mechanism of DNA damage by ionizing radiation. Poorly vascularized tissues with low oxygenation, such as the center of rapidly growing tumors, are generally less sensitive to radiation therapy than nonhypoxic tissues.
- *Vascular damage*. Damage to endothelial cells, which are moderately sensitive to radiation, may cause narrowing or occlusion of the blood vessel leading to impaired healing, fibrosis, and chronic ischemic atrophy. These changes may appear months or years after exposure (Fig. 9-18). Late effects in tissues with a low rate of cell proliferation such as brain, kidney, liver, muscle, and subcutaneous tissue, may include diverse lesions such as cell death, atrophy, and fibrosis. These effects are associated with vascular damage and the release of pro-inflammatory cytokines in irradiated areas.

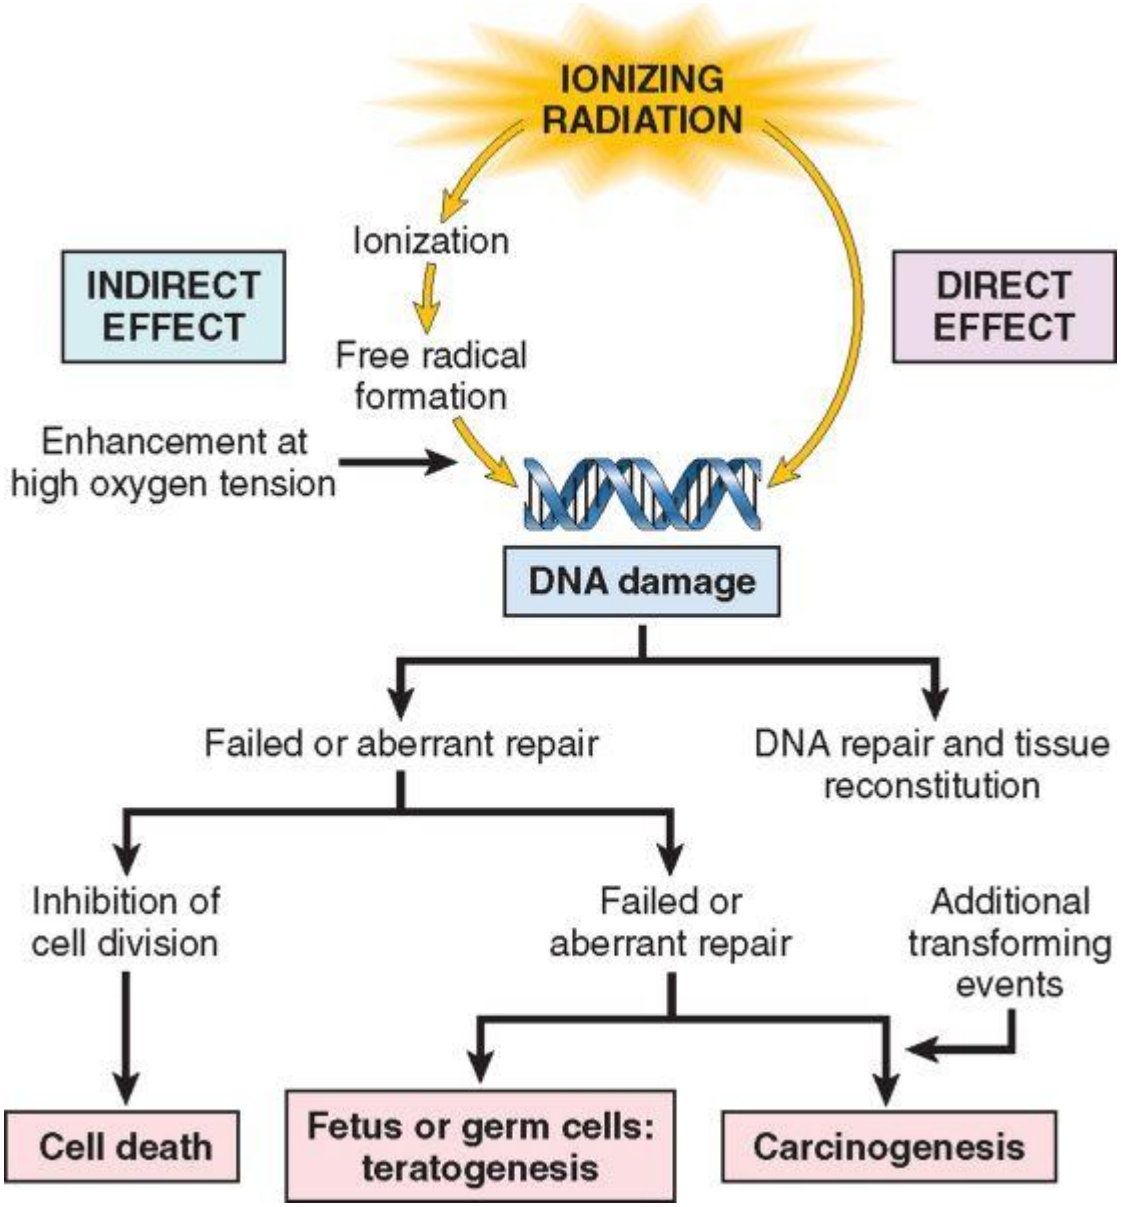

FIGURE 9-17 Effects of ionizing radiation on DNA and its consequences. The effects on DNA can be direct, or most importantly, indirect, through free radical formation.

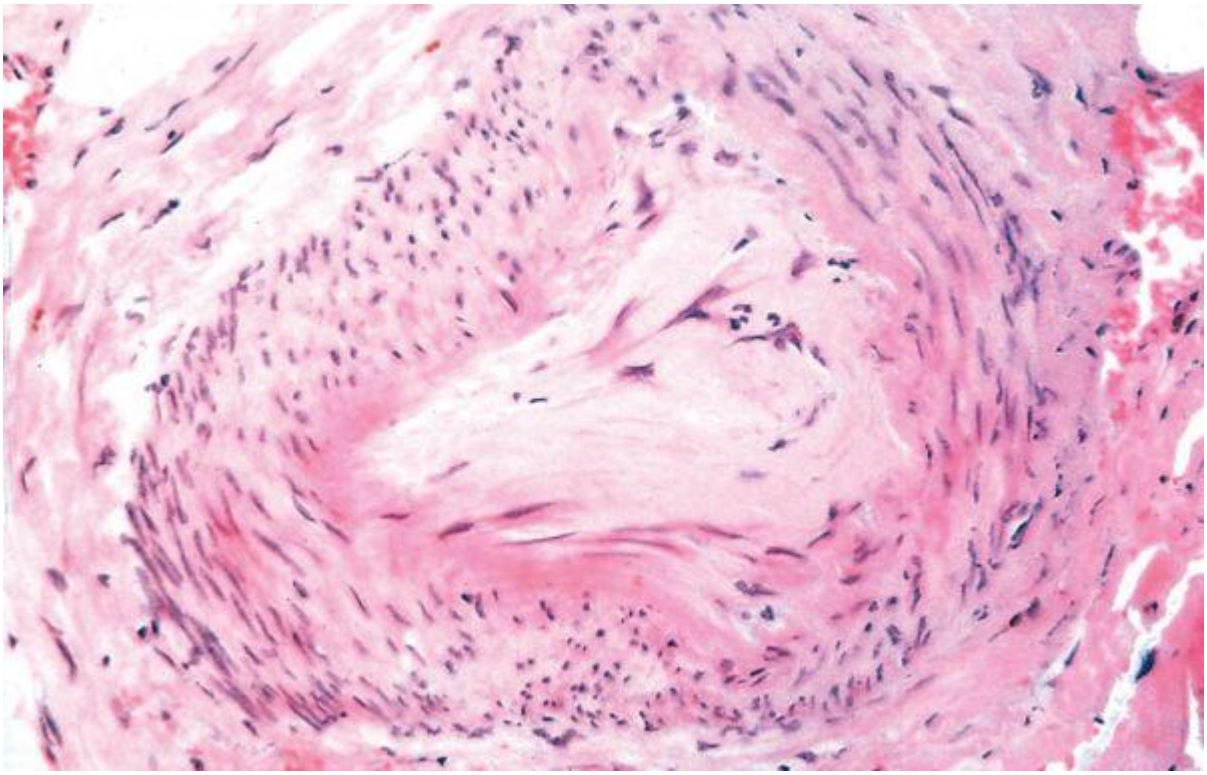

FIGURE 9-18 Chronic vascular injury with subintimal fibrosis occluding the lumen. *(American Registry of Pathology © 1990.)*

Figure 9-19 shows the overall consequences of radiation exposure. These consequences may vary according to the dose of radiation and the type of exposure. Table 9-7 lists the estimated threshold doses for acute effects of radiation aimed at specific organs; Table 9-8 shows the syndromes caused by exposure to various doses of total-body radiation.

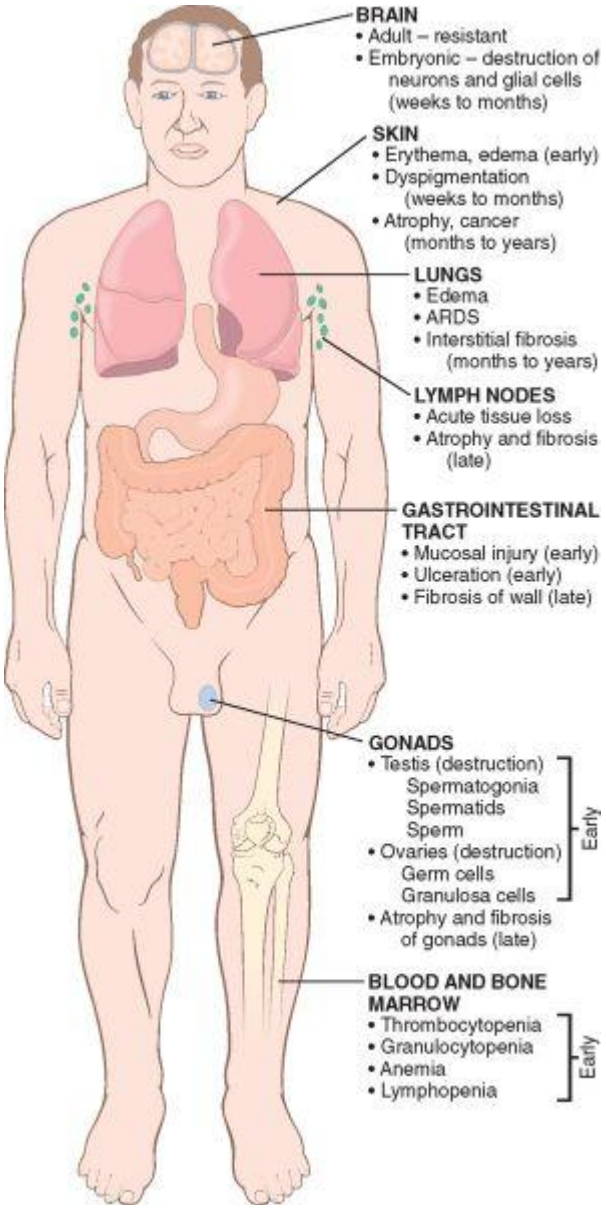

FIGURE 9-19 Overview of the major morphologic consequences of radiation injury. Early changes occur in hours to weeks; late changes occur in months to years. ARDS, acute respiratory distress syndrome.

TABLE 9-7 -- Estimated Threshold Doses for Acute Radiation Effects on Specific Organs

Health Effect	Organ	Dose (Sv)
Temporary sterility	Testes	0.15
Depression of hematopoiesis	Bone marrow	0.50
Reversible skin effects (e.g., erythema)	Skin	1.0–2.0
Permanent sterility	Ovaries	2.5–6.0
Temporary hair loss	Skin	3.0–5.0
Permanent sterility	Testis	3.5
Cataract	Lens of eye	5.0

TABLE 9-8 -- Effects of Total-Body Ionizing Radiation

	0–1 Sv	1–2 Sv	2–10 Sv	10–20 Sv	>50 Sv
Main site of injury	None	Lymphocytes	Bone marrow	Small bowel	Brain
Main signs and symptoms	None	Moderate granulocytopenia	Leukopenia, hemorrhage, hair loss, vomiting	Diarrhea, fever, electrolyte imbalance, vomiting	Ataxia, coma, convulsions, vomiting
		Lymphopenia			
Time of development	–	1 day to 1 week	2–6 weeks	5–14 days	1–4 hours
Lethality	None	None	Variable (0% to 80%)	100%	100%

Morphology. Cells surviving radiant energy damage show a wide range of structural changes in chromosomes, including deletions, breaks, translocations, and fragmentation. The mitotic spindle often becomes disorderly, and polyploidy and aneuploidy may be encountered. Nuclear swelling and condensation and clumping of chromatin may appear; sometimes the nuclear membrane breaks down. Apoptosis may occur. All forms of abnormal nuclear morphology may be seen. Giant cells with pleomorphic nuclei or more than one nucleus may appear and persist for years after exposure. At extremely high doses of radiant energy, markers of cell death, such as nuclear pyknosis, and lysis appear quickly.

In addition to affecting DNA and nuclei, radiant energy may induce a variety of **cytoplasmic changes**, including cytoplasmic swelling, mitochondrial distortion, and degeneration of the endoplasmic reticulum. Plasma membrane breaks and focal defects may be seen. The histologic constellation of cellular pleomorphism, giant-cell formation, conformational changes in nuclei, and abnormal mitotic figures creates a more than passing similarity between radiation-injured cells and cancer cells, a problem that plagues the pathologist when evaluating post-irradiation tissues for the possible persistence of tumor cells.

At the light microscopic level, vascular changes and interstitial fibrosis are prominent in irradiated tissues (Fig. 9-20). During the immediate post-irradiation period, vessels may show only dilation. With time, or with higher doses, a variety of degenerative changes appear, including endothelial cell swelling and vacuolation, or even dissolution with total necrosis of the walls of small vessels such as capillaries and venules. Affected vessels may rupture or thrombose. Still later, endothelial cell proliferation and collagenous hyalinization with thickening of the media are seen in irradiated vessels, resulting in marked narrowing or even obliteration of the vascular lumens. At this time, an increase in interstitial collagen in the irradiated field usually becomes evident, leading to scarring and contractions.

Total-Body Irradiation.

Exposure of large areas of the body to even very small doses of radiation may have devastating effects. Dosages below 1 Sv produce minimal or no symptoms. However, higher levels of exposure cause health effects known as acute radiation syndromes, which at progressively higher doses involve the hematopoietic, gastrointestinal, and central nervous systems. The syndromes associated with total-body exposure to ionizing radiation are presented in Table 9-8 .

Acute Effects on Hematopoietic and Lymphoid Systems.

The hematopoietic and lymphoid systems are extremely susceptible to radiation injury and deserve special mention. With high dose levels and large exposure fields, severe lymphopenia may appear within hours of irradiation, along with shrinkage of the lymph nodes and spleen. Radiation directly destroys lymphocytes, both in the circulating blood and in tissues (nodes, spleen, thymus, gut). With sublethal doses of radiation, regeneration from viable precursors is prompt, leading to restoration of a normal lymphocyte count in the blood within weeks to months. *Hematopoietic precursors in the bone marrow* are also quite sensitive to radiant energy, which produces a dose-dependent marrow aplasia. Very high doses of radiation kill marrow stem cells and induce permanent aplasia (aplastic anemia), whereas with lower doses the aplasia is transient. The circulating *granulocyte count* may first rise but begins to fall toward the end of the first week. Levels near zero may be reached during the second week. If the patient survives, recovery of the normal granulocyte count may require 2 to 3 months. *Platelets* are similarly affected, with the nadir of the count occurring somewhat later than that of granulocytes; recovery is similarly delayed. Red cell counts fall and anemia appears after 2 to 3 weeks and may persist for months.

Fibrosis.

A common consequence of radiation therapy for cancer is the development of fibrosis in the tissues included in the irradiated field (see Fig. 9-20). Fibrosis may occur weeks or months after irradiation as

a consequence of the replacement of dead parenchymal cells by connective tissue, leading to the formation of scars and adhesions (see Chapter 3). Vascular damage, the killing of tissue stem cells, and the release of cytokines and chemokines that promote an inflammatory reaction and fibroblast activation are the main contributors to the development of radiation-induced fibrosis (Figs. 9-21 and 9-22). Common sites of fibrosis after radiation treatment are the lungs, the salivary glands after radiation therapy for head and neck cancers, and colorectal and pelvic areas after treatment for prostate cancer.

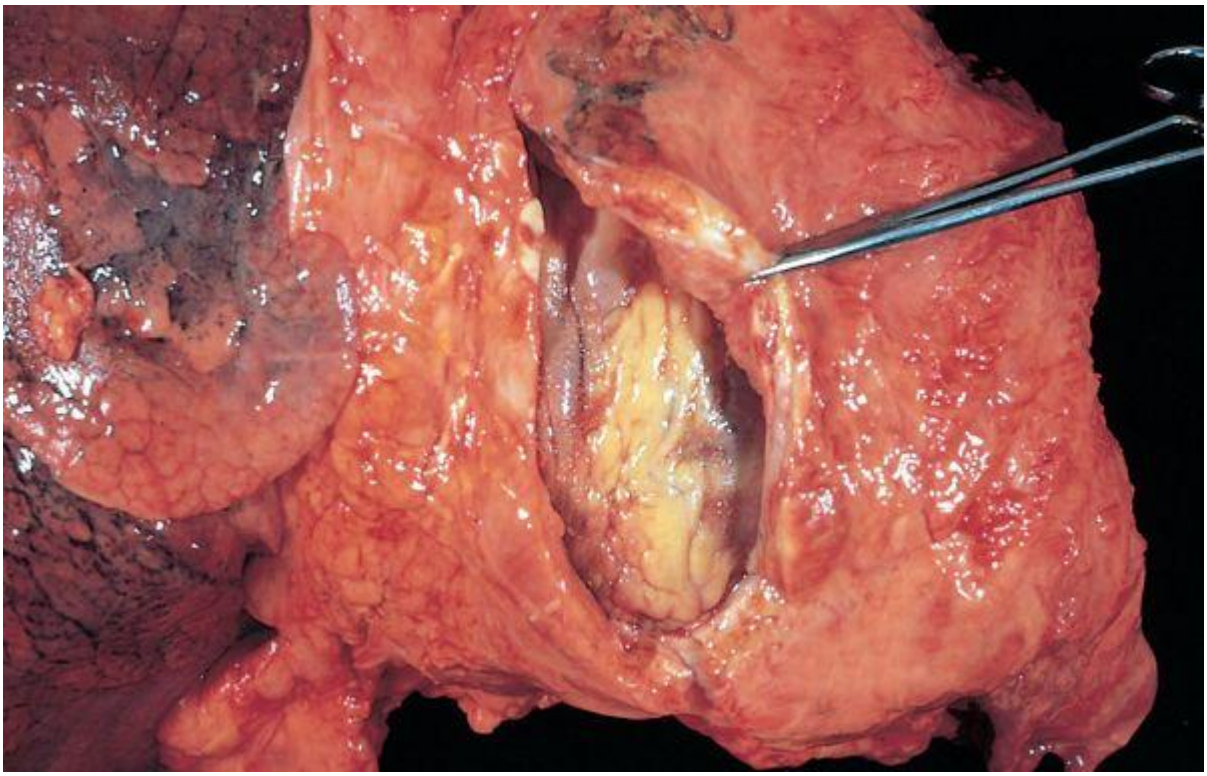

FIGURE 9-22 Extensive mediastinal fibrosis after radiotherapy for carcinoma of the lung. Note the markedly thickened cardium. *(From the teaching collection of the Department Pathology, Southwestern Medical School, Dallas, TX.)*

DNA Damage and Carcinogenesis.

Ionizing radiation can cause multiple types of damage in DNA, including single-base damage, single- and double-stranded breaks, and DNA-protein cross-links. In surviving cells, simple defects may be repaired by various enzyme systems present in most mammalian cells (see Chapter 7). However, *the most serious damage to DNA is caused by double-stranded breaks (DSBs)*. Two types of mechanisms can repair DSBs in mammalian cells: *homologous recombination and nonhomologous end joining (NHEJ)*, with NHEJ being the most common repair pathway. DNA repair through NHEJ often produces mutations, including short deletions or duplications, or gross chromosomal aberrations such as translocations and inversions. If the replication of cells containing DSBs is not stopped by cell cycle checkpoint controls (Chapter 3), cells with chromosomal damage persist and may initiate carcinogenesis many years later. More recently it has been recognized that these abnormal cells may also have a "bystander effect," that is, they may promote growth of non-irradiated surrounding cells through the production of growth factors and cytokines.[42,][43] Bystander effects are referred to as non-target effects of radiation.

Cancer Risks from Exposures to Low-level Radiation.

Any cell capable of division that has sustained a mutation has the potential to become cancerous. Thus, an increased incidence of neoplasms may occur in any organ after exposure to ionizing radiation. The level of radiation required to increase the risk of cancer development is difficult to determine, but there is little doubt that acute or prolonged exposures that result in doses of greater than 100 mSv cause serious consequences including cancer.[44] This is documented by the increased incidence of leukemias

and tumors at various sites (such as thyroid, breast, and lungs) in survivors of the atomic bombings of Hiroshima and Nagasaki; the high number of thyroid cancers in survivors of the Chernobyl accident; the high incidence of thyroid tumors, and the elevated frequency of leukemias and birth defects in inhabitants of the Marshall Islands exposed to nuclear fallout; and the development of "second cancers," such as acute myeloid leukemia, myelodysplastic syndrome, Hodgkin lymphoma and solid tumors, in individuals who received radiation therapy for childhood cancers. The long-term cancer risks caused by radiation exposures in the range of 5 to 100 mSv are much more difficult to establish, because accurate measurements of risks require large population groups ranging from 50,000 to 5 million people.

Estimation of cancer risks at low levels of exposure to ionizing radiation relies in part on models that extrapolate from higher doses. Nevertheless, for x-rays and gamma rays there is good evidence for a statistically significant increase in the risk of cancer at acute doses of greater than 50 mSv and "reasonable" evidence for acute doses of greater than 5 mSv. For protracted exposures, the approximate values suggested are greater than 100 mSv (good evidence for a statistically significant increase of risk) and 50 mSv (reasonable evidence for increased risk). As a comparison, a single posterior-anterior chest radiograph, a lateral chest film chest radiograph, and a computed tomography of the chest deliver effective dosages to the lungs of 0.01, 0.15, and 10 mSv, respectively.[45]

Increased risk of cancer development may also be associated with occupational exposures. Radon gas is a ubiquitous product of the spontaneous decay of uranium. Its carcinogenic effects are largely attributable to two decay products, *polonium 214 and 218* (or "radon daughters"), which emit alpha particles. Polonium 214 and 218 produced from inhaled radon tend to deposit in the lung, and chronic exposure in uranium miners may give rise to lung carcinomas. Risks are also present in homes in which the levels of radon are very high, comparable to those found in mines. However, there is little or no evidence to suggest that radon contributes to the risk of lung cancer in the average household. Among other polonium isotopes, *polonium 210* came to the public attention in November 2006 with the highly publicized use of this isotope to kill an individual in England. For historical reasons, we also mention here the development of osteogenic sarcomas after radium exposure in radium dial painters, chemists, radiologists, and patients exposed to radium as a treatment for various ailments, during the first part of the twentieth century.

2.9.10 Nutritional Diseases

Malnutrition, also referred to as *protein energy malnutrition or PEM*, is a consequence of inadequate intake of proteins and calories, or deficiencies in the digestion or absorption of proteins, resulting in the loss of fat and muscle tissue, weight loss, lethargy, and generalized weakness. Millions of people in developing nations are malnourished and starving, or living on the cruel edge of starvation. In the industrial world and, more recently, also in developing countries, *obesity* has become a major public health problem, associated with the development of diseases such as diabetes and atherosclerosis.

The sections that follow barely skim the surface of nutritional disorders. Particular attention is devoted to PEM, anorexia nervosa and bulimia, deficiencies of vitamins and trace minerals, obesity, and a brief overview of the relationships of diet to atherosclerosis and cancer. Other nutrients and nutritional issues are discussed in the context of specific diseases.

DIETARY INSUFFICIENCY

An appropriate diet should provide (1) sufficient energy, in the form of carbohydrates, fats, and proteins, for the body's daily metabolic needs; (2) amino acids and fatty acids to be used as building blocks for synthesis of structural and functional proteins and lipids; and (3) vitamins and minerals, which function as coenzymes or hormones in vital metabolic pathways or, as in the case of calcium and phosphate, as important structural components. In *primary malnutrition*, one or all of these components are missing

from the diet. By contrast, in *secondary malnutrition*, the supply of nutrients is adequate, but malnutrition results from insufficient intake, malabsorption, impaired utilization or storage, excess loss, or increased need for nutrients.

There are several conditions that may lead to dietary insufficiencies.

- *Poverty*. Homeless persons, aged individuals, and children of the poor often suffer from PEM as well as trace nutrient deficiencies. In poor countries, poverty, crop failures, livestock deaths, and drought, often in times of war and political upheaval, create the setting for the malnourishment of children and adults.
- *Infections*. PEM increases the susceptibility to many common infectious diseases. Conversely, infections have a negative effect on nutrition,[46] thus establishing a vicious cycle.
- *Acute and chronic illnesses*. The basal metabolic rate becomes accelerated in many illnesses resulting in increased daily requirements for all nutrients. Failure to recognize these nutritional needs may delay recovery. *PEM is often present in patients with wasting diseases such as advanced cancers and AIDS* (discussed later).
- *Chronic alcoholism*. Alcoholic persons may sometimes suffer PEM but more frequently have deficiency of several vitamins, especially thiamine, pyridoxine, folate, and vitamin A, as a result of dietary deficiency, defective gastrointestinal absorption, abnormal nutrient utilization and storage, increased metabolic needs, and an increased rate of loss. A failure to recognize the likelihood of thiamine deficiency in persons with chronic alcoholism may result in irreversible brain damage (e.g., Wernicke encephalopathy, discussed in Chapter 28).
- *Ignorance and failure of diet supplementation*. Even the affluent may fail to recognize that infants, adolescents, and pregnant women have increased nutritional needs. Ignorance about the nutritional content of various foods is also a contributing factor. Some examples are: iron deficiency in infants fed exclusively artificial milk diets; polished rice used as the mainstay of a diet may lack adequate amounts of thiamine; lack of iodine from food and water in regions removed from the oceans, unless supplementation is provided.
- *Self-imposed dietary restriction. Anorexia nervosa, bulimia*, and less overt eating disorders affect many individuals who are concerned about body image and are obsessed with body weight (anorexia and bulimia are discussed later).
- *Other causes*. Additional causes of malnutrition include gastrointestinal diseases and malabsorption syndromes, genetic diseases, specific drug therapies (which block uptake or utilization of particular nutrients), and total parenteral nutrition.

PROTEIN-ENERGY MALNUTRITION (PEM)

Severe PEM is a serious, often lethal disease affecting children. It is common in low-income countries, where up to 25% of children may be affected, and where it is a major factor in the high death rates among children younger than 5 years. In the West Africa country of Niger, which suffered a severe famine in 2005, United Nations reports estimate that there were, respectively, 150,000 and 650,000 children with severe and moderate malnutrition. In that country, malnutrition was a direct or indirect cause of mortality in 60% of children under age 5. Decreased food intake can also occur due to sharp increases in prices, as was seen in the first half of 2008. In developed countries, PEM occurs in elderly and debilitated patients in nursing homes and hospitals.

Malnutrition is determined according to the body mass index (BMI, weight in kilograms divided by height in meters squared). *A BMI less than 16 kg/m^2 is considered malnutrition* (normal range 18.5 to 25 kg/m^2). In more practical ways, a child whose weight falls to less than 80% of normal (provided in standard tables) is considered malnourished. However, loss of weight may be masked by generalized edema, as discussed later. Other helpful parameters are the evaluation of fat stores (thickness of skin folds), muscle mass (reduced circumference of mid-arm), and serum proteins (albumin and transferrin measurements provide a measure of the adequacy of the visceral protein compartment).

Marasmus and Kwashiorkor.

In malnourished children, PEM presents as a range of clinical syndromes, all characterized by a dietary intake of protein and calories inadequate to meet the body's needs. The two ends of the spectrum of PEM syndromes are known as *marasmus* and *kwashiorkor*. From a functional standpoint, there are two differentially regulated protein compartments in the body: the somatic compartment, represented by proteins in skeletal muscles, and the visceral compartment, represented by protein stores in the visceral organs, primarily the liver. As we shall see, the somatic compartment is affected more severely in marasmus, and the visceral compartment is depleted more severely in kwashiorkor.

A child is considered to have *marasmus* when weight falls to 60% of normal for sex, height, and age. A *marasmic child suffers growth retardation and loss of muscle*, the latter resulting from catabolism and depletion of the somatic protein compartment. This seems to be an adaptive response that provides the body with amino acids as a source of energy. The visceral protein compartment, which is presumably more precious and critical for survival, is only marginally depleted, and hence *serum albumin levels are either normal or only slightly reduced*. In addition to muscle proteins, subcutaneous fat is also mobilized and used as fuel. The production of leptin (discussed in "Obesity") is low, which may stimulate the hypothalamic-pituitary-adrenal axis to produce high levels of cortisol that contribute to lipolysis. With such losses of muscle and subcutaneous fat, the *extremities are emaciated;* by comparison, the head appears too large for the body (Fig. 9-23A). Anemia and manifestations of multiple vitamin deficiencies are present, and there is evidence of *immune deficiency*, particularly T cell–mediated immunity. Hence, concurrent infections are usually present, which impose additional nutritional demands. Unfortunately, images of children dead or near death with marasmus, have become almost commonplace in television and newspaper reports of famine and disasters in various areas of the world.

FIGURE 9-23 Childhood malnutrition. **A**, Marasmus. Note the loss of muscle mass and subcutaneous fat; the head appears to be too large for the emaciated body. **B**, Kwashiorkor. The infant shows generalized edema, seen as ascites and puffiness of the face, hands, and legs. *(**A**, From Clinic Barak, Reisebericht Kenya.)*

Kwashiorkor occurs when protein deprivation is relatively greater than the reduction in total calories (Fig. 9-23B). This is the most common form of PEM seen in African children who have been weaned too early and subsequently fed, almost exclusively, a carbohydrate diet (the name kwashiorkor is from the Ga language in Ghana describing a disease of a baby due to the arrival of another child). The prevalence of kwashiorkor is also high in impoverished countries of Southeast Asia. Less severe forms may occur worldwide in persons with chronic diarrheal states in which protein is not absorbed or in those with chronic protein loss due to conditions such as protein-losing enteropathies, the nephrotic syndrome, or after extensive burns. Cases of kwashiorkor resulting from fad diets or replacement of milk by rice-based beverages have been reported in the United States.

In kwashiorkor, marked protein deprivation is associated with severe loss of the visceral protein compartment, and the resultant hypoalbuminemia gives rise to *generalized or dependent edema* (Fig. 9-23B). The loss of weight in these patients is masked by the increased fluid retention. In further contrast to marasmus, there is relative sparing of subcutaneous fat and muscle mass. Children with kwashiorkor have characteristic *skin lesions*, with alternating zones of hyperpigmentation, areas of desquamation, and hypopigmentation, giving a "flaky paint" appearance. *Hair changes* include overall loss of color or alternating bands of pale and darker hair. Other features that differentiate kwashiorkor from marasmus include an enlarged, *fatty liver* (resulting from reduced synthesis of the carrier protein component of lipoproteins), and the development of apathy, listlessness, and loss of appetite. Vitamin deficiencies are likely to be present, as are *defects in immunity* and *secondary infections*. *As already stated, marasmus and kwashiorkor are two ends of a spectrum, and considerable overlap exists between these conditions*.

Secondary PEM often develops in chronically ill, elderly, and bedridden patients. An 18-item questionnaire known as the Mininutritional Assessment (MNA) is often used to measure the nutritional status of elderly persons. It is estimated that more than 50% of elderly residents in nursing homes in the United States are malnourished. Weight loss of more than 5% associated with PEM increases the risk of mortality in nursing home patients by almost five-fold. The most obvious signs of secondary PEM include: (1) depletion of subcutaneous fat in the arms, chest wall, shoulders, or metacarpal regions; (2) wasting of the quadriceps femoris and deltoid muscles; and (3) ankle or sacral edema. Bedridden or hospitalized malnourished patients have an increased risk of infection, sepsis, impaired wound healing, and death after surgery.

Morphology. The central anatomic changes in PEM are (1) growth failure, (2) peripheral edema in kwashiorkor, and (3) loss of body fat and atrophy of muscle, more marked in marasmus.

The **liver** in kwashiorkor, but not in marasmus, is enlarged and fatty; superimposed cirrhosis is rare.

In kwashiorkor (rarely in marasmus) the **small bowel** shows a decrease in the mitotic index in the crypts of the glands, associated with mucosal atrophy and loss of villi and microvilli. In such cases concurrent loss of small intestinal enzymes occurs, most often manifested as disaccharidase deficiency. Hence, infants with kwashiorkor initially may not respond well to full-strength, milk-

based diets. With treatment, the mucosal changes are reversible.

The **bone marrow** in both kwashiorkor and marasmus may be hypoplastic, mainly as a result of decreased numbers of red cell precursors. The peripheral blood commonly reveals mild to moderate anemia, which often has a multifactorial origin; nutritional deficiencies of iron, folate, and protein, as well as the suppressive effects of infection (anemia of chronic disease) may all contribute. Depending on the predominant factor, the red cells may be microcytic, normocytic, or macrocytic.

The **brain** in infants who are born to malnourished mothers and who suffer PEM during the first 1 or 2 years of life has been reported by some to show cerebral atrophy, a reduced number of neurons, and impaired myelinization of white matter.

Many **other changes** may be present, including (1) thymic and lymphoid atrophy (more marked in kwashiorkor than in marasmus), (2) anatomic alterations induced by intercurrent infections, particularly with all manner of endemic worms and other parasites, and (3) deficiencies of other required nutrients such as iodine and vitamins.

Cachexia.

PEM is a common complication in patients with AIDS or advanced cancers, and in these settings it is known as cachexia. Cachexia occurs in about 50% of cancer patients, most commonly in individuals with gastrointestinal, pancreatic, and lung cancers, and is responsible for about 30% of cancer deaths. It is a highly debilitating condition characterized by extreme weight loss, fatigue, muscle atrophy, anemia, anorexia, and edema. Mortality is generally the consequence of atrophy of the diaphragm and other respiratory muscles. The precise causes of cachexia are not known, but it is clear that agents secreted by tumors and host responses contribute to its development (Fig. 9-24). Cachetic agents produced by tumors include:

- *PIF (proteolysis-inducing factor*), which is a glycosylated polypeptide excreted in the urine of weight-losing patients with pancreatic, breast, colon, and other cancers
- *LMF* (*lipid-mobilizing factor*), which increases fatty acid oxidation, and pro-inflammatory cytokines such as TNF (originally known as cachetin), interleukin-2 (IL-2), and IL-6. TNF and IL-6 trigger an acute-phase response from the host, increasing the secretion of C-reactive protein and fibrinogen, and decreasing plasma concentrations of albumin.

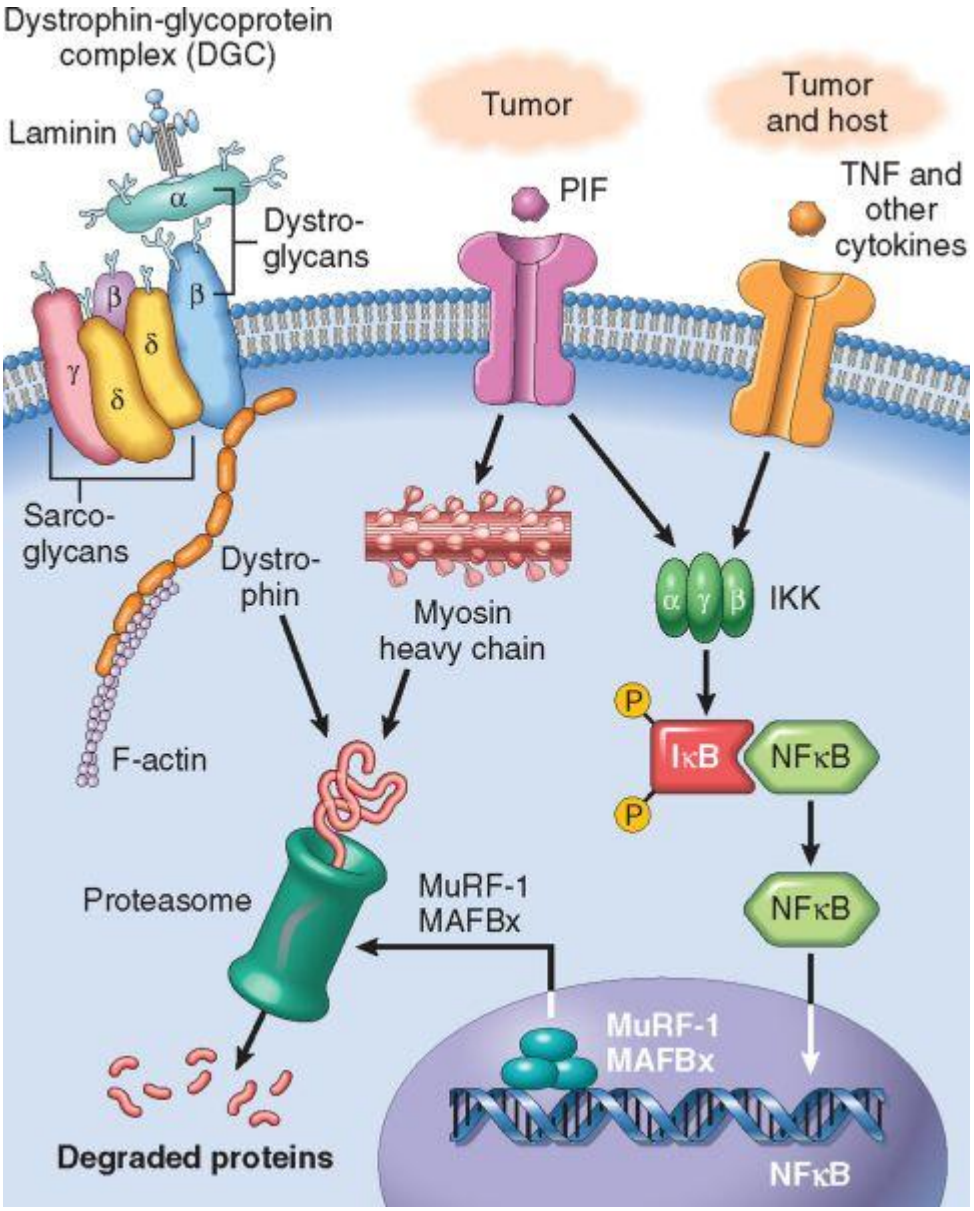

FIGURE 9-24 Mechanisms of cancer cachexia. The figure illustrates three mechanisms that cause muscle atrophy and muscle degradation leading to cachexia. (1) Proteolysis-inducing factor (PIF) produced by tumors degrades myosin heavy chain through the proteasome, causing muscle atrophy; (2) TNF and other cytokines produced by tumors and the host activate NF-κB and initiate the transcription of the ubiquitin ligases MAFBx and MuRF1, contributing to protein breakdown; (3) alterations in the dystrophin-glycoprotein complex leading to dystrophin-degradation by the proteasome also participate in the muscle atrophy of cachexia.

Proteolysis-inducing factor (PIF) and pro-inflammatory cytokines cause skeletal muscle breakdown through the NFκB-induced activation of the ubiquitin proteasome pathway, leading to the degradation of myosin heavy chain.[47] The induction of the ubiquitin proteasome pathway involves the production of two muscle-specific ubiquitin ligases, MuRF1 (muscle RING finger-1) and MAFBx (muscle atrophy F-box, or atroglin-1). More recent data also implicate alterations in the myofibrillar membrane of skeletal muscle with *loss of dystrophin caused by alterations in the dystrophin-glycoprotein complex* (Fig. 9-24) as contributors to muscle atrophy, through a mechanism similar to that which occurs in some muscular dystrophies.[48]

ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa is self-induced starvation, resulting in marked weight loss; *bulimia* is a condition in which the patient binges on food and then induces vomiting. Anorexia nervosa has the highest death rate of any psychiatric disorder. Bulimia is more common than anorexia nervosa, and generally has a better prognosis; it is estimated to occur in 1% to 2% of women and 0.1% of men, with an average onset at 20 years of age. These eating disorders occur primarily in previously healthy young women who have developed an obsession with body image and thinness. The neurobiologic underpinnings of these diseases are unknown, but it has been suggested that altered serotonin metabolism may be an important component.[49]

The clinical findings in anorexia nervosa are generally similar to those in severe PEM. In addition, effects on the endocrine system are prominent. *Amenorrhea*, resulting from decreased secretion of gonadotropin-releasing hormone, and subsequent decreased secretion of luteinizing hormone and follicle-stimulating hormone, is so common that its presence is a diagnostic feature for the disorder. Other common findings, related to decreased thyroid hormone release, include cold intolerance, bradycardia, constipation, and changes in the skin and hair. In addition, dehydration and electrolyte abnormalities are frequently present. The skin becomes dry and scaly. Bone density is decreased, most likely because of low estrogen levels, which mimics the postmenopausal acceleration of osteoporosis. Anemia, lymphopenia, and hypoalbuminemia may be present. A major complication of anorexia nervosa (and also bulimia) is an increased susceptibility to cardiac arrhythmia and sudden death, resulting from hypokalemia.

In bulimia, binge eating is the norm. Large amounts of food, principally carbohydrates, are ingested, only to be followed by induced vomiting. Although menstrual irregularities are common, amenorrhea occurs in less than 50% of bulimic patients, probably because weight and gonadotropin levels are maintained near normal. The major medical complications relate to continual induced vomiting, and the chronic use of laxatives and diuretics. They include (1) electrolyte imbalances (hypokalemia), which predispose the patient to cardiac arrhythmias; (2) pulmonary aspiration of gastric contents; and (3) esophageal and gastric cardiac rupture. Nevertheless, there are no signs and symptoms that are specific for bulimia; the diagnosis must rely on a comprehensive psychologic assessment of the person. A recent trend in bulimic patients has been the combination of binge eating with high ingestion of alcohol. Needless to say, the combined effects of bulimia and alcoholism are devastating.

VITAMIN DEFICIENCIES

Thirteen vitamins are necessary for health; vitamins A, D, E, and K are fat-soluble, and all others are water-soluble. The distinction between fat- and water-soluble vitamins is important. Fat-soluble vitamins are more readily stored in the body, but they may be poorly absorbed in fat malabsorption disorders, caused by disturbances of digestive functions (discussed in Chapter 17). Certain vitamins can be synthesized endogenously—vitamin D from precursor steroids, vitamin K and biotin by the intestinal microflora, and niacin from tryptophan, an essential amino acid. Notwithstanding this endogenous synthesis, a dietary supply of all vitamins is essential for health.

A deficiency of vitamins may be primary (dietary in origin) or secondary because of disturbances in intestinal absorption, transport in the blood, tissue storage, or metabolic conversion. In the following sections, vitamins A, D, and C are presented in some detail because of their wide-ranging activities and the morphologic changes of deficient states. This is followed by presentation in tabular form of the main consequences of deficiencies of the remaining vitamins (E, K, and the B complex) and some essential minerals. However, it should be emphasized that deficiency of a single vitamin is uncommon, and that single or multiple vitamin deficiencies may be associated with PEM.

Vitamin A

Vitamin A is the name given to a group of related compounds that include *retinol* (vitamin A alcohol), *retinal* (vitamin A aldehyde), *and retinoic acid* (vitamin A acid), which have similar biologic activities. Retinol is the chemical name given to vitamin A. It is the transport form and, as retinol ester, also the storage form. The generic term *retinoids* encompasses vitamin A in its various forms and both natural and synthetic chemicals that are structurally related to vitamin A, but may not necessarily have vitamin A–like biologic activity.[50] Animal-derived foods such as liver, fish, eggs, milk, and butter are important dietary sources of preformed vitamin A. Yellow and leafy green vegetables such as carrots, squash, and spinach supply large amounts of carotenoids, which are provitamins that can be metabolized to active vitamin A in the body. Carotenoids contribute approximately 30% of the vitamin A in human diets; the most important of these is β-carotene, which is efficiently converted to vitamin A. The Recommended Dietary Allowance for vitamin A is expressed in retinol equivalents, to take into account both preformed vitamin A and β-carotene.

Vitamin A is a fat-soluble vitamin, and its absorption requires bile, pancreatic enzymes, and some level of antioxidant activity in the food. Retinol (generally ingested as retinol ester) and β-carotene are absorbed in the intestine, where β-carotene is converted to retinol (Fig. 9-25). Retinol is then transported in chylomicrons to the liver for esterification and storage. Uptake in liver cells takes place through the apolipoprotein E receptor. More than 90% of the body's vitamin A reserves are stored in the liver, predominantly in the perisinusoidal stellate (Ito) cells. In healthy persons who consume an adequate diet, these reserves are sufficient to meet the body's demands for at least 6 months. Retinol esters stored in the liver can be mobilized; before release, retinol binds to a specific retinol-binding protein (RBP), synthesized in the liver. The uptake of retinol/RBP in peripheral tissues is dependent on cell surface receptors specific for RBP.[51] After uptake, retinol binds to a cellular RBP, and the RBP is released back into the blood. Retinol may be stored in peripheral tissues as retinol ester or be oxidized to form retinoic acid. Retinoic acid has important effects in epithelial differentiation and growth.

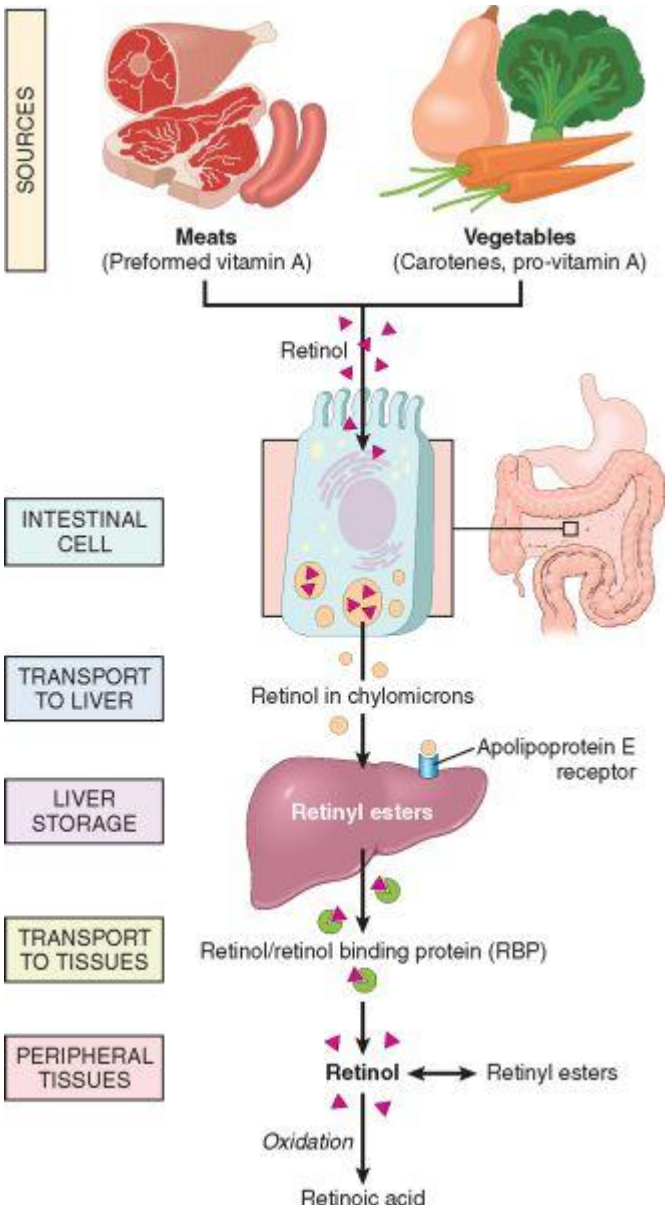

FIGURE 9-25 Vitamin A metabolism.

Function.

In humans the main functions of vitamin A are the following:

- *Maintenance of normal vision*. The *visual process* involves four forms of vitamin A–containing pigments: rhodopsin in the rods, the most light-sensitive pigment and therefore important in reduced light, and three iodopsins in cone cells, each responsive to specific colors in bright light. The synthesis of rhodopsin from retinol involves (1) oxidation to all-*trans*-retinal, (2) isomerization to 11-*cis*-retinal, and (3) covalent association with the 7-transmembrane rod protein opsin to form rhodopsin. A photon of light causes the isomerization of 11-*cis*-retinal to all-*trans*-retinal, which dissociates from rhodopsin. This induces a conformational change in opsin that triggers a series of downstream events and generates a nerve impulse, which is transmitted via neurons from the retina to the brain. During dark adaptation, some of the all-*trans*-retinal is reconverted to 11*cis*-retinal, but most is reduced to retinol and lost to the retina, dictating the need for continuous supply.

- *Cell growth and differentiation*. Vitamin A and retinoids play an important role in the orderly differentiation of mucus-secreting epithelium; *when a deficiency state exists, the epithelium undergoes squamous metaplasia, differentiating into a keratinizing epithelium*. Activation of retinoic acid receptors (RARs) by their ligands causes the release of corepressors and the obligatory formation of heterodimers with another retinoid receptor, known as the retinoic X receptor (RXR). Both RAR and RXR have three isoforms, α, β, and γ. The RAR/RXR heterodimers bind to retinoic acid response elements located in the promoter region of genes that encode receptors for growth factors, tumor suppressor genes, and secreted proteins. Through these effects, retinoids participate in cell growth and differentiation, cell cycle control, and other biologic responses. *All-trans-retinoic acid*, a potent acid derivative of vitamin A, has the highest affinity for RARs compared with other retinoids.[51]
- *Metabolic effects of retinoids*. The retinoic X receptor (RXR), believed to be activated by 9-*cis* retinoic acid, can form heterodimers with other nuclear receptors, such as (as we have seen) nuclear receptors involved in drug metabolism, the peroxisome proliferator-activated receptors (PPARs), and vitamin D receptors. PPARs are key regulators of fatty acid metabolism, including fatty acid oxidation in fat tissue and muscle, adipogenesis, and lipoprotein metabolism. The association between RXR and PPARγ provides an explanation for the metabolic effects of retinoids on adipogenesis and obesity.[52]
- *Host resistance to infections*. Vitamin A supplementation can reduce morbidity and mortality from some forms of diarrhea, and in preschool children with measles, supplementation can quickly improve the clinical outcome. The beneficial effect of vitamin A in diarrheal diseases may be related to the maintenance and restoration of the integrity of the epithelium of the gut. The effects of vitamin A on infections also derive in part from its ability to stimulate the immune system, although the mechanisms are not entirely clear. Infections may reduce the bioavailability of vitamin A by inhibiting retinol binding protein synthesis in the liver through the acute-phase response associated with many infections. The drop in hepatic retinol binding protein causes a decrease in circulating retinol, which reduces the tissue availability of vitamin A.

In addition, the retinoids, β-carotene, and some related carotenoids can function as photoprotective and antioxidant agents.

Retinoids are used clinically for the treatment of skin disorders such as severe acne and certain forms of psoriasis, and also in the treatment of acute promyelocytic leukemia. In this leukemia, a (15 : 17) translocation (Chapter 13) results in the fusion of a truncated *RAR*α gene on chromosome 17 with the *PML* gene on chromosome 15. The fusion gene encodes an abnormal RAR that blocks myeloid cell differentiation. Pharmacologic doses of all-*trans* retinoic acid overcome the block, causing leukemia cells to differentiate into neutrophils, which subsequently die by apoptosis. This “differentiation therapy” induces remission in most individuals with acute promyelocytic leukemia and in combination with other chemotherapeutic agents can be curative. A different isomer, 13-*cis* retinoic acid, has been used with some success in the treatment of neuroblastomas in children.

Vitamin A Deficiency.

Vitamin A deficiency occurs worldwide either as a consequence of general undernutrition or as a secondary deficiency in individuals with conditions that cause malabsorption of fats. In children, stores of vitamin A are depleted by infections, and the absorption of the vitamin is poor in newborn infants. Adult patients with malaborption syndromes, such as celiac disease, Crohn's disease, and colitis, may develop vitamin A deficiency, in conjunction with depletion of other fat-soluble vitamins. Bariatric surgery and, in elderly persons, continuous use of mineral oil as a laxative may lead to deficiency. The pathologic effects of vitamin A deficiency are summarized in Figure 9-26 .

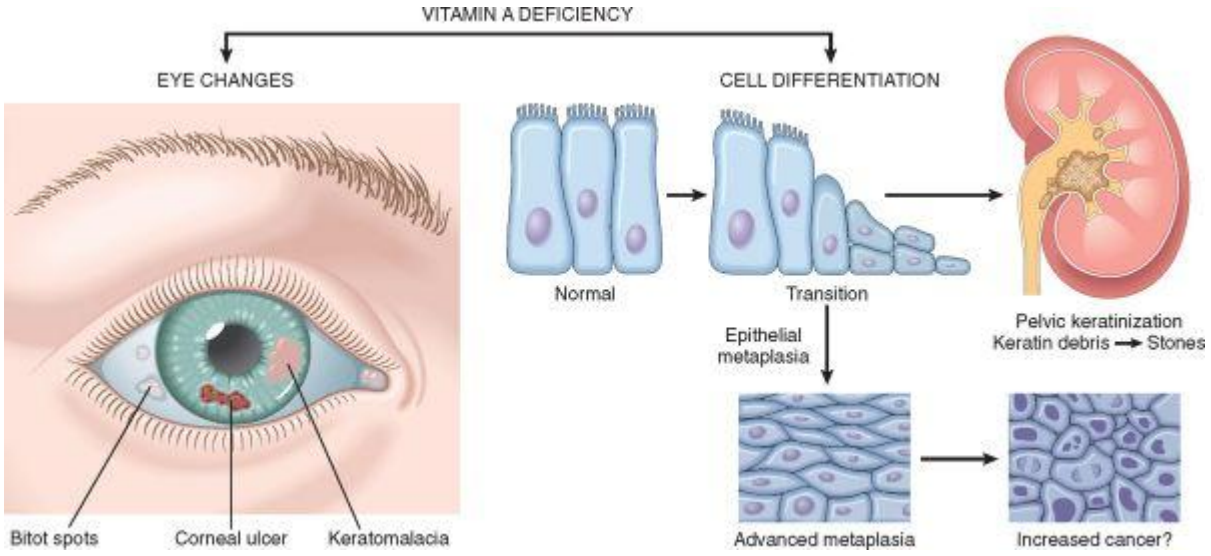

FIGURE 9-26 Vitamin A deficiency: its major consequences in the eye and in the production of keratinizing metaplasia of specialized epithelial surfaces, and its possible role in epithelial metaplasia. Not depicted are night blindness and immune deficiency.

As already discussed, vitamin A is a component of rhodopsin and other visual pigments. Not surprisingly, one of the earliest manifestations of vitamin A deficiency is impaired vision, particularly in reduced light *(night blindness)*. Other effects of deficiency are related to the role of vitamin A in maintaining the differentiation of epithelial cells. Persistent deficiency gives rise to a series of changes involving epithelial metaplasia and keratinization. The most devastating changes occur in the eyes and are referred to as *xerophthalmia* (dry eye). First, there is dryness of the conjunctiva (xerosis conjunctivae) as the normal lacrimal and mucus-secreting epithelium is replaced by keratinized epithelium. This is followed by buildup of keratin debris in small opaque plaques *(Bitot spots)* and, eventually, erosion of the roughened corneal surface with softening and destruction of the cornea *(keratomalacia)* and total blindness.

In addition to the ocular epithelium, the epithelium lining the upper respiratory passage and urinary tract is replaced by keratinizing squamous cells *(squamous metaplasia)*. Loss of the mucociliary epithelium of the airways predisposes to secondary pulmonary infections, and desquamation of keratin debris in the urinary tract predisposes to renal and urinary bladder stones. Hyperplasia and *hyperkeratinization of the epidermis* with plugging of the ducts of the adnexal glands may produce follicular or papular dermatosis. Another very serious consequence is immune deficiency, which is responsible for higher mortality rates from common infections such as measles, pneumonia, and infectious diarrhea. In parts of the world where a deficiency of vitamin A is prevalent, dietary supplements reduce mortality by 20% to 30%.

Vitamin A Toxicity.

Both short- and long-term excesses of vitamin A may produce toxic manifestations, a point of concern because of the megadoses touted by certain sellers of supplements. The consequences of acute hypervitaminosis A were first described by Gerrit de Veer in 1597, a ship's carpenter stranded in the Arctic, who recounted in his diary the serious symptoms that he and other members of the crew developed after eating polar bear liver. With this cautionary tale in mind, the adventurous eater should be aware that acute vitamin A toxicity has also been described in individuals who ingested the livers of whales, sharks, and even tuna! The symptoms of acute vitamin A toxicity include headache, dizziness,

vomiting, stupor, and blurred vision, symptoms that may be confused with those of a brain tumor (pseudotumor cerebri). Chronic toxicity is associated with weight loss, anorexia, nausea, vomiting, and bone and joint pain. Retinoic acid stimulates osteoclast production and activity, which lead to increased bone resorption and high risk of fractures. Although synthetic retinoids used for the treatment of acne are not associated with these types of conditions, their use in pregnancy should be avoided because of the well-established teratogenic effects of retinoids.

Vitamin D

The major function of the fat-soluble vitamin D is the maintenance of adequate plasma levels of calcium and phosphorus to support metabolic functions, bone mineralization, and neuromuscular transmission.[53] Vitamin D is required for the prevention of bone diseases known as *rickets* (in children whose epiphyses have not already closed), *osteomalacia* (in adults), and hypocalcemic tetany. This latter condition is a convulsive state caused by an insufficient extracellular concentration of ionized calcium, which is required for normal neural excitation and the relaxation of muscles. Rickets was nearly endemic in large European cities and poor areas of New York and Boston at the end of the nineteenth century. Although cod liver oil was recognized for its anti-rachitic properties in the early part of that century, it took almost 100 years for it to be accepted by the medical profession as an effective preventive agent (it did not help that cod liver oil consumed in fishing villages in Northern Europe, Scandinavia, and Iceland was a dark, foul-smelling liquid).[54] In addition to its effects on calcium and phosphorus homeostasis, vitamin D has effects in non-skeletal tissues (so called “nonclassical” effects).

Metabolism of Vitamin D.

The major source of vitamin D for humans is its endogenous synthesis in the skin by photochemical conversion of a precursor, 7-dehydrocholesterol, via the energy of solar or artificial UV light in the range of 290 to 315 nm (UVB radiation). Irradiation of 7-dehydrocholesterol forms *cholecalciferol, known as vitamin* D_3. For the sake of simplicity we will use the term vitamin D to refer to this compound. Under usual conditions of sun exposure, about 90% of the vitamin D requirement is endogenously derived from 7-dehydrocholesterol present in the skin. However, individuals with dark skin generally have a lower level of vitamin D production because of melanin pigmentation. Dietary sources, such as deep-sea fish, plants, and grains, contribute about 10% of required vitamin D and depend on adequate intestinal fat absorption. In plants, vitamin D is present in its precursor form (ergosterol), which is converted to vitamin D in the body.

The main steps of vitamin D metabolism are summarized below[53] and shown in Figure 9-27 .

1. Photochemical synthesis of vitamin D from 7-dehydrocholesterol in the skin and absorption of vitamin D from foods and supplements in the gut
2. Binding of vitamin D from both of these sources to plasma α1-globulin *(D-binding protein or DBP)* and transport into the liver
3. Conversion of vitamin D into 25-hydroxycholecalciferol (25-OH-D) in the liver, through the effect of 25-OHases (25-hydroxylases that include CYP27A1 and other CYPs)
4. Conversion of 25-OH-D *into 1,25-dihydroxyvitamin D*, [*1*α, *25(OH)*$_2$*D*$_3$] in the kidney, the most active form of vitamin D, through the activity of α1-hydroxylase

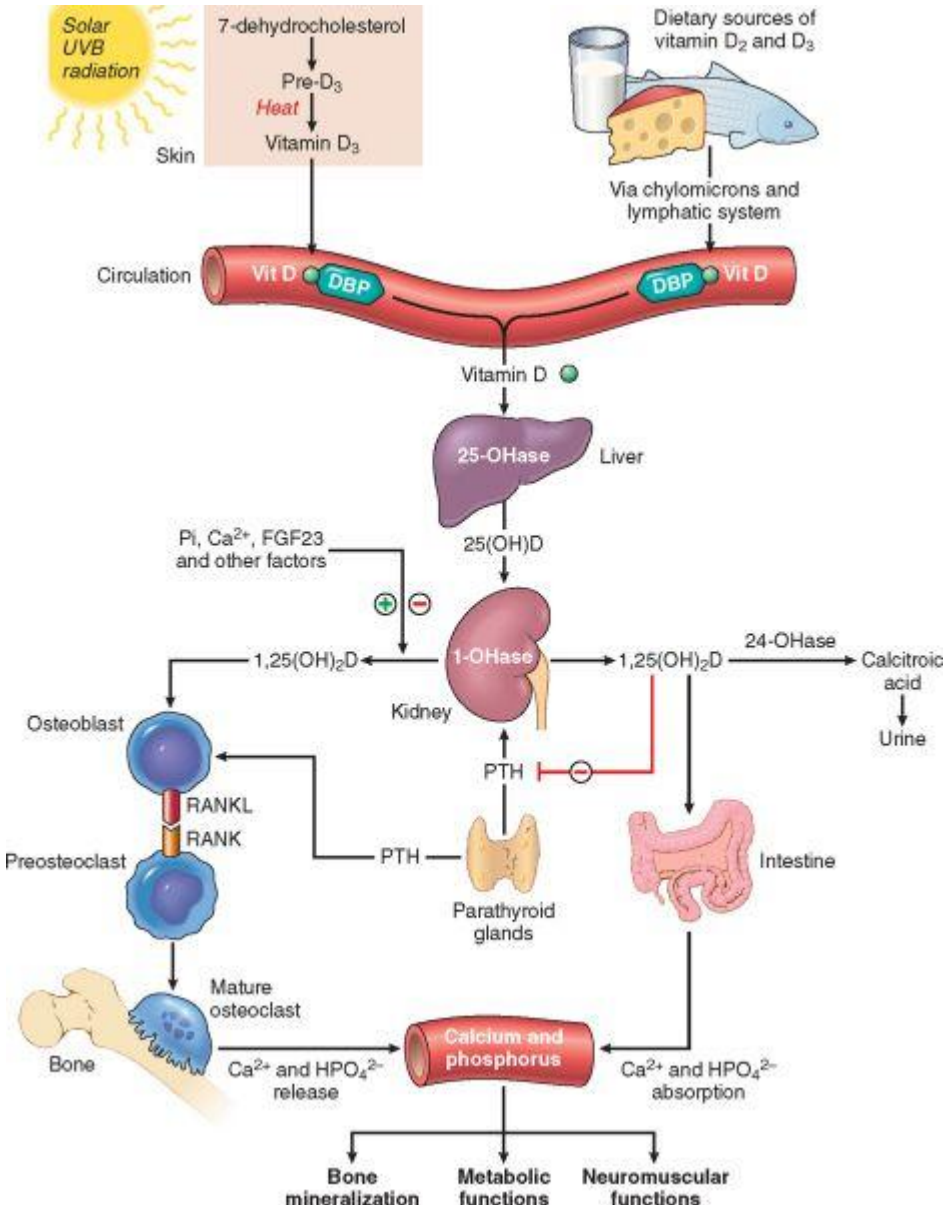

FIGURE 9-27 Vitamin D metabolism. Vitamin D is produced from 7-dehydrocholesterol in the skin or is ingested in the diet. It is converted in the liver into 25(OH)D, and in kidney into $1,25(OH)_2D$ (1,25-dihydroxyvitamin D), the active form of the vitamin. $1,25(OH)_2D$ stimulates the expression of RANKL, an important regulator of osteoclast maturation and function, on osteoblasts, and enhances the intestinal absorption of calcium and phosphorus in the intestine. See text for further details. DBP, vitamin D-binding protein (α1-globulin).

The production of 1,25-dihydroxyvitamin D in the kidney is regulated by three main mechanisms (Fig. 9-27): (a) *hypocalcemia stimulates secretion of parathyroid hormone (PTH)*, which in turn augments the conversion of 25-OH-D into 1,25-dihydroxyvitamin D by activating 1α-hydroxylase; (b) *hypophosphatemia directly activates α1-hydroxylase*, increasing the production of 1,25-dihydroxyvitamin D; (c) *through a feedback mechanism*, increased levels of 1,25dihydroxyvitamin D down-regulate its own synthesis through inhibition of 1α-hydroxylase activity.

Mechanisms of Action.

1,25-dihydroxyvitamin D, the biologically active form of vitamin D, is best regarded as a steroid hormone. It binds to *the high-affinity vitamin D receptor (VDR)*, which associates with the already mentioned RXR. This heterodimeric complex binds to vitamin D response elements located in the promoter of vitamin D target genes. The receptors for 1,25-dihydroxyvitamin D are present in most cells of the body and transduce signals that regulate plasma levels of calcium and phosphorus, through action on the small intestine, bones, and kidneys. Beyond its role on skeletal homeostasis, vitamin D also has immunomodulatory and antiproliferative effects. More recently it has been proposed that 1,25-dihydroxyvitamin D may also act through nongenomic mechanisms, which do not require the transcription of target genes. Nongenomic mechanisms may involve the binding of 1,25-dihydroxyvitamin D to a membrane vitamin D receptor, leading to the activation of protein kinase C and opening of calcium channels.[55]

Effects of Vitamin D on Calcium and Phosphorus Homeostasis.

The main functions of 1,25-dihydroxyvitamin D on calcium and phosphorus homeostasis are the following:

- *Stimulation of intestinal calcium absorption*. 1,25-dihydroxyvitamin D stimulates intestinal absorption of calcium in the duodenum through the *interaction of 1,25-dihydroxyvitamin D with nuclear vitamin D receptor and the formation of a complex with RXR*. The complex binds to vitamin D response elements and activates the transcription of TRPV6 (a member of the transient receptor potential vanilloid family), which encodes a critical calcium transport channel.
- *Stimulation of calcium reabsorption in the kidney*. 1,25-dihydroxyvitamin D increases calcium influx in distal tubules of the kidney through the increased expression of TRPV5, another member of the transient receptor potential vanilloid family. TRPV5 expression is also regulated by PTH in response to hypocalcemia.[56]
- *Interaction with parathyroid hormone (PTH) in the regulation of blood calcium*. Vitamin D maintains calcium and phosphorus at supersaturated levels in the plasma. The parathyroid glands have a key role in the regulation of extracellular calcium concentrations. These glands have a calcium receptor that senses even small changes in blood calcium concentrations.[57] In addition to their effects on calcium absorption in the intestine and kidneys already described, both 1,25-dihydroxyvitamin D and parathyroid hormone enhance the expression of RANKL (receptor activator of NF-κB ligand) on osteoblasts. RANKL binds to its receptor (RANK) located in preosteoclasts, inducing the differentiation of these cells into mature osteoclasts (Chapter 26). Through the secretion of hydrochloric acid and activation of proteases such as cathepsin K, osteoclasts dissolve bone and release calcium and phosphorus into the circulation.
- *Mineralization of bone*. Vitamin D contributes to the mineralization of osteoid matrix and epiphyseal cartilage in the formation of both flat and long bones in the skeleton. It stimulates osteoblasts to synthesize the calcium-binding protein osteocalcin, involved in the deposition of calcium during bone development. Flat bones develop by intramembranous bone formation, in which mesenchymal cells differentiate directly into osteoblasts, and synthesize the collagenous osteoid matrix on which calcium is deposited. Long bones develop by endochondral ossification, through which growing cartilage at the epiphyseal plates is provisionally mineralized and then progressively resorbed and replaced by osteoid matrix that is mineralized to create bone (Fig. 9-28A).

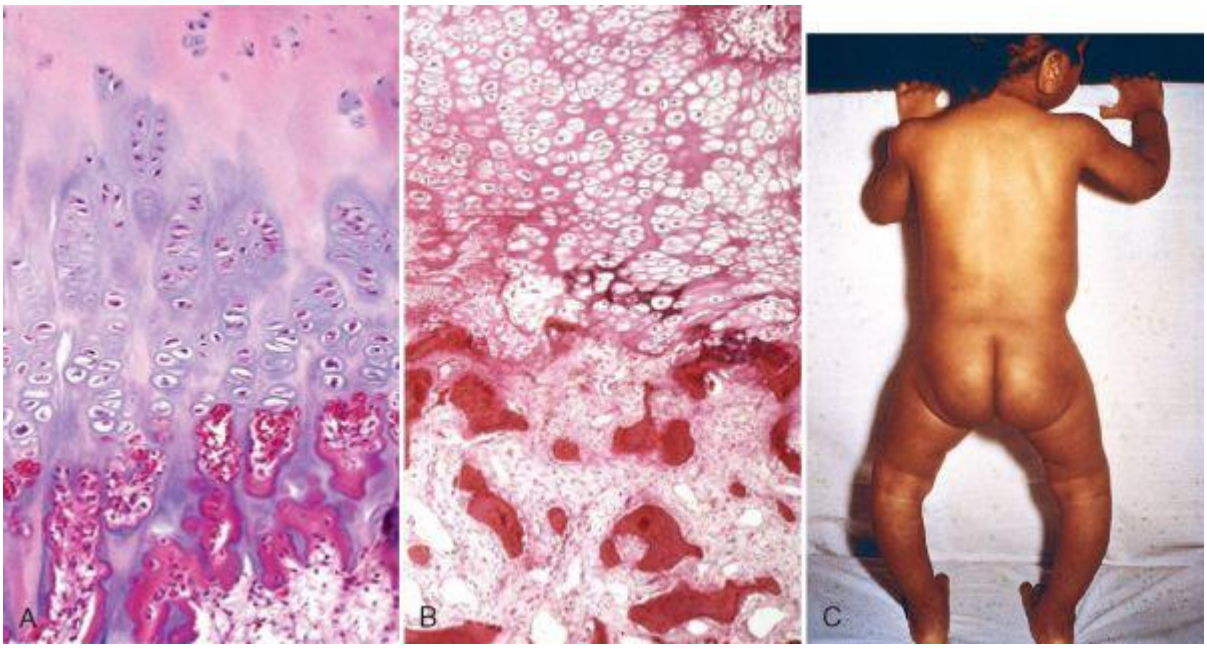

FIGURE 9-28 Rickets. **A**, Normal costochondral junction of a young child, illustrating formation of cartilage palisades and orderly transition from cartilage to new bone. **B**, Detail of a rachitic costochondral junction in which the palisades of cartilage is lost. Darker trabeculae are well-formed bone; paler trabeculae consist of uncalcified osteoid. **C**, Rickets, note bowing of legs due to formation of poorly mineralized bones. ***(B**, Courtesy of Dr. Andrew E. Rosenberg, Massachusetts General Hospital, Boston, MA.)*

When *hypocalcemia* occurs in vitamin D deficiency (Fig. 9-29), PTH production is elevated, causing (1) activation of renal 1α-hydroxylase, increasing the amount of active vitamin D and calcium absorption; (2) increased resorption of calcium from bone by osteoclasts; (3) decreased renal calcium excretion; and (4) increased renal excretion of phosphate. Fibroblast growth factor 23, which is produced by bone, is one of a group of agents known as *phosphatonins*, which block the absorption of phosphate in the intestine, and phosphate reabsorption in the kidney, causing increased urinary excretion of phosphate. Although a normal serum level of calcium may be restored, hypophosphatemia persists, impairing the mineralization of bone. Increased production of fibroblast growth factor 23 may be responsible for tumor-induced osteomalacia and some forms of hypophosphatemic rickets.[58]

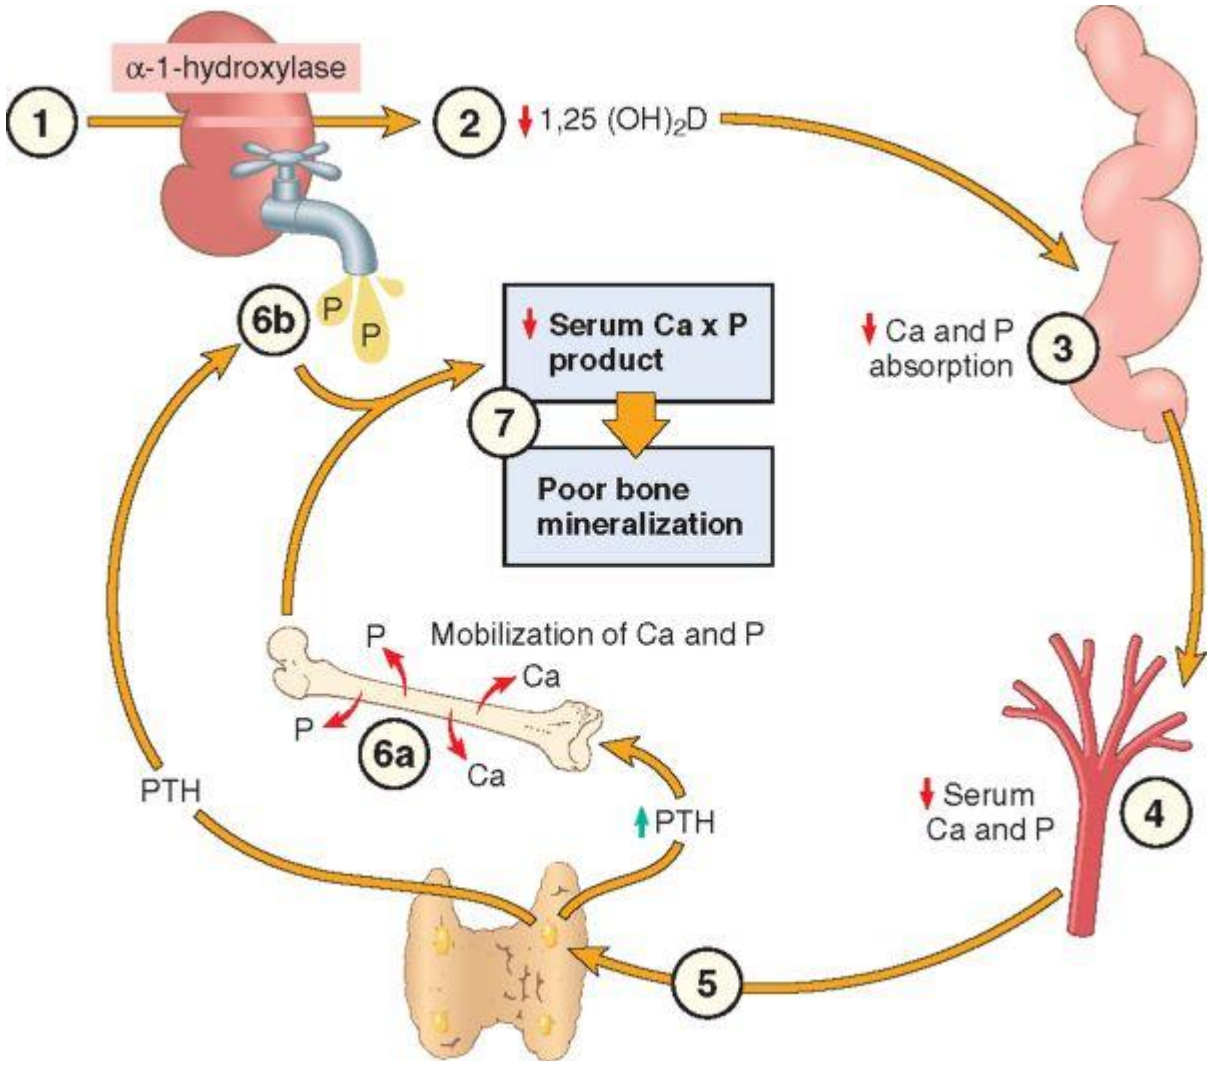

FIGURE 9-29 Vitamin D deficiency. There is inadequate substrate for the renal 1α-hydroxylase (1), yielding a deficiency of 1,25$(OH)_2$D (2), and deficient absorption of calcium and phosphorus from the gut (3), with consequently depressed serum levels of both (4). The hypocalcemia activates the parathyroid glands (5), causing mobilization of calcium and phosphorus from bone (6a). Simultaneously, the parathyroid hormone (PTH) induces wasting of phosphate in the urine (6b) and calcium retention. As a result, the serum levels of calcium are normal or nearly normal, but phosphate levels are low; hence, mineralization is impaired (7).

Deficiency States.

The normal reference range for circulating 25-(OH)-D is 20 to 100 ng/mL; concentrations of less than 20 ng/mL constitute vitamin D deficiency.

Rickets in growing children (see Fig. 9-28C) and osteomalacia in adults are skeletal diseases with worldwide distribution. They may result from diets deficient in calcium and vitamin D, but an equally important cause of vitamin D deficiency is limited exposure to sunlight. This most often affects inhabitants of northern latitudes, but can even be a problem in tropical countries, in heavily veiled women, and in children born to mothers who have frequent pregnancies followed by lactation. In all of these situations, vitamin D deficiency can be prevented by a diet high in fish oils. Other, less common causes of rickets and osteomalacia include renal disorders causing decreased synthesis of 1,25-dihydroxyvitamin D, phosphate depletion, malabsorption disorders, and some rare inherited disorders.[53] Although rickets and osteomalacia rarely occur outside high-risk groups, milder forms of vitamin D

deficiency (also called vitamin D insufficiency), leading to an increase risk of bone loss and hip fractures, are quite common in the elderly in the United States and Europe.[59] Some genetically determined variants of the vitamin D receptors are associated with an accelerated loss of bone minerals with aging and in certain familial forms of osteoporosis (Chapter 26).

Morphology. The basic derangement in both rickets and osteomalacia is an excess of unmineralized matrix. The following sequence ensues in rickets:

- Overgrowth of epiphyseal cartilage due to inadequate provisional calcification and failure of the cartilage cells to mature and disintegrate
- Persistence of distorted, irregular masses of cartilage, which project into the marrow cavity
- Deposition of osteoid matrix on inadequately mineralized cartilaginous remnants
- Disruption of the orderly replacement of cartilage by osteoid matrix, with enlargement and lateral expansion of the osteochondral junction (see Fig. 9-28B)
- Abnormal overgrowth of capillaries and fibroblasts in the disorganized zone resulting from microfractures and stresses on the inadequately mineralized, weak, poorly formed bone
- Deformation of the skeleton due to the loss of structural rigidity of the developing bones

Rickets is most common during the first year of life. The gross skeletal changes depend on the severity and duration of the process and, in particular, the stresses to which individual bones are subjected. During the nonambulatory stage of infancy, the head and chest sustain the greatest stresses. The softened occipital bones may become flattened, and the parietal bones can be buckled inward by pressure; with the release of the pressure, elastic recoil snaps the bones back into their original positions **(craniotabes)**. An excess of osteoid produces **frontal bossing** and a **squared appearance to the head**. Deformation of the chest results from overgrowth of cartilage or osteoid tissue at the costochondral junction, producing the **"rachitic rosary."** The weakened metaphyseal areas of the ribs are subject to the pull of the respiratory muscles and thus bend inward, creating anterior protrusion of the sternum **(pigeon breast deformity)**. When an ambulating child develops rickets, deformities are likely to affect the spine, pelvis, and tibia, causing **lumbar lordosis** and **bowing of the legs** (see Fig. 9-28C).

In adults, the lack of vitamin D deranges the normal bone remodeling that occurs throughout life. The newly formed osteoid matrix laid down by osteoblasts is inadequately mineralized, thus producing the excess of persistent osteoid that is characteristic of **osteomalacia**. Although the contours of the bone are not affected, the bone is weak and vulnerable to gross fractures or microfractures, which are most likely to affect vertebral bodies and femoral necks.

Histologically, the unmineralized osteoid can be visualized as a thickened layer of matrix (which stains pink in hematoxylin and eosin preparations) arranged about the more basophilic, normally mineralized trabeculae.

Non-Skeletal Effects of Vitamin D.

It was mentioned earlier that the vitamin D receptor is present in various cells and tissues that do not participate in calcium and phophorus homeostasis. Macrophages, keratinocytes, and tissues such as breast, prostate, and colon can produce 1,25-dihydroxyvitamin D.[60] Within macrophages, synthesis of 1,25-dihydroxyvitamin D occurs through the activity of CYP27B located in the mitochondria. It has been proposed that pathogen-induced activation of Toll-like receptors in macrophages causes a transcription-induced increase in vitamin D receptor and CYP27B (Fig. 9-30). The resultant

production of 1,25-dihydroxyvitamin D then stimulates the synthesis of *cathelicidin*, an antimicrobial peptide from the *defensin* family, which is effective against infection by *Mycobacterium tuberculosis*. Other effects of vitamin D in the innate and adaptive immune system have been reported,[61] but the data are often contradictory. Vitamin D regulates the expression of more than 200 genes, including genes that participate in cell proliferation, differentiation, apoptosis, and angiogenesis. It has been reported that levels of 1,25-dihydroxyvitamin D below 20 ng/mL are associated with a 30% to 50% increase in the incidence of colon, prostate, and breast cancers.

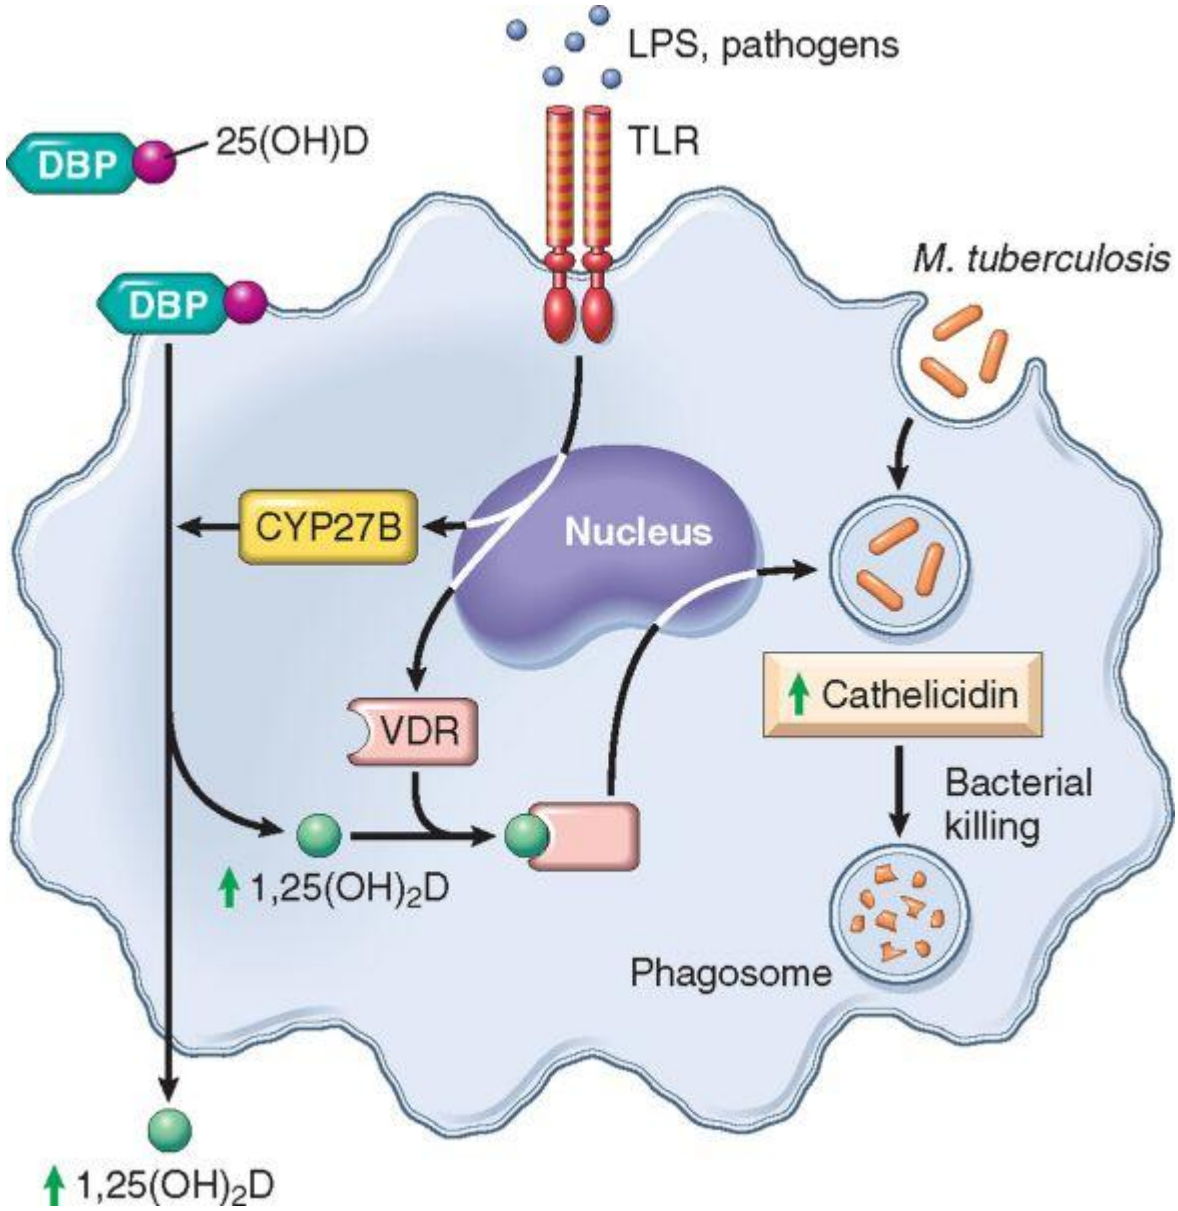

FIGURE 9-30 Anti-microbial effect of vitamin D. Pathogens and lipopolysaccharides (LPS) stimulate Toll-like receptors (TLRs) in macrophages, causing the transcription of vitamin D receptor (VDR) and an increase in CYP27B activity in mitochondria. This causes the production of $1,25(OH)_2D$ (1,25-dihydroxyvitamin D), which stimulates the synthesis of cathelicidin, an antimicrobial peptide that is particularly active against *Mycobacterium tuberculosis*.

Vitamin D Toxicity.

Prolonged exposure to normal sunlight does not produce an excess of vitamin D, but megadoses of orally administered vitamin can lead to hypervitaminosis. In children, hypervitaminosis D may take the form of metastatic calcifications of soft tissues such as the kidney; in adults it causes bone pain and hypercalcemia. In passing, we might point out that the toxic potential of this vitamin is so great that in sufficiently large doses it is a potent rodenticide!

Vitamin C (Ascorbic Acid)

A deficiency of water-soluble vitamin C leads to the development of *scurvy*, characterized principally by bone disease in growing children and by hemorrhages and healing defects in both children and adults. Sailors of the British Royal Navy were nicknamed "limeys," because at the end of the eighteenth century the Navy began to provide lime and lemon juice (rich sources of vitamin C) to sailors to prevent scurvy during their long sojourn at sea. It was not until 1932 that ascorbic acid was identified and synthesized. Ascorbic acid is not synthesized endogenously in humans; therefore, we are entirely dependent on the diet for this nutrient. Vitamin C is present in milk and some animal products (liver, fish) and is abundant in a variety of fruits and vegetables. All but the most restricted diets provide adequate amounts of vitamin C.

Function.

Ascorbic acid functions in a variety of biosynthetic pathways by accelerating hydroxylation and amidation reactions. *The best-established function of vitamin C is the activation of prolyl and lysyl hydroxylases from inactive precursors, providing for hydroxylation of procollagen*. Inadequately hydroxylated procollagen cannot acquire a stable helical configuration or be adequately cross-linked, so it is poorly secreted from the fibroblast. Those molecules that are secreted lack tensile strength and are more soluble and vulnerable to enzymatic degradation. Collagen, which normally has the highest content, of hydroxyproline, of any polypeptide is most affected, particularly in blood vessels, accounting for the predisposition to hemorrhages in scurvy. In addition, a deficiency of vitamin C suppresses the rate of synthesis of procollagen, independent of an effect on proline hydroxylation.

While the role of vitamin C in collagen synthesis has been known for many decades, it is only in relatively recent years that its *antioxidant properties* have been recognized. Vitamin C can scavenge free radicals directly and can act indirectly by regenerating the antioxidant form of vitamin E.

Deficiency States.

Consequences of vitamin C deficiency (scurvy) are illustrated in Figure 9-31 . Fortunately, because of the abundance of ascorbic acid in many foods, scurvy has ceased to be a global problem. It is sometimes encountered even in affluent populations as a secondary deficiency, particularly among elderly individuals, persons who live alone, and chronic alcoholics, groups that often have erratic and inadequate eating patterns. Occasionally, scurvy appears in patients undergoing peritoneal dialysis and hemodialysis and among food faddists. Tragically, the condition sometimes appears in infants who are maintained on formulas of evaporated milk without supplementation of vitamin C.

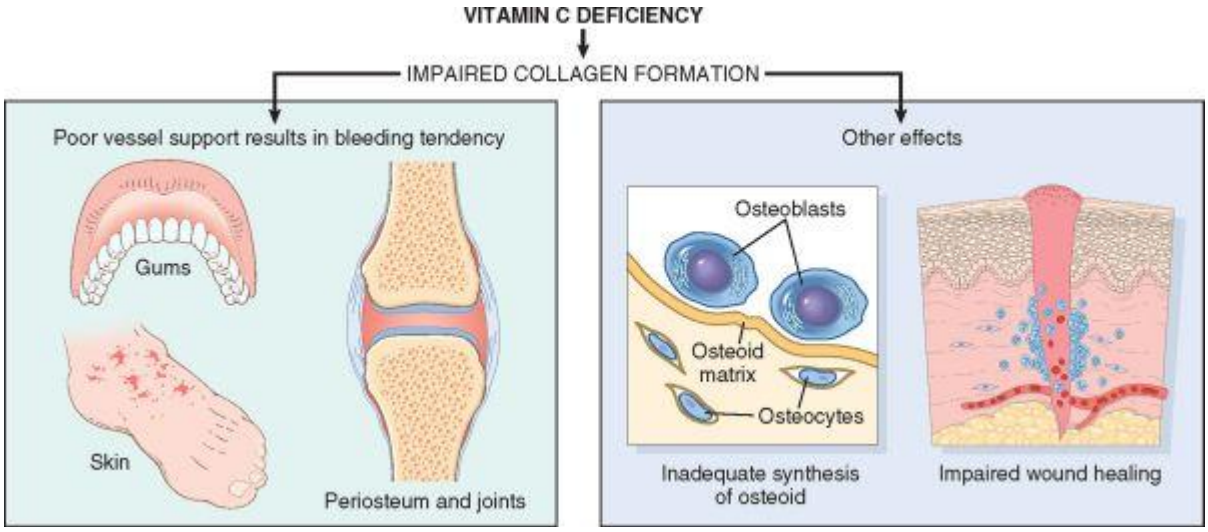

FIGURE 9-31 Major consequences of vitamin C deficiency caused by impaired formation of collagen.

Vitamin C Toxicity.

The popular notion that megadoses of vitamin C protect against the common cold, or at least allay the symptoms, has not been borne out by controlled clinical studies. Such slight relief as may be experienced is probably due to the mild antihistamine action of ascorbic acid. Similarly there is little support that large doses of vitamin C protect against cancer development. The physiologic availability of vitamin C is limited. It is unstable, poorly absorbed in the intestine, and promptly excreted in the urine.

Other vitamins and some essential minerals are listed and briefly described in Tables 9-9 and 9-10 . Some vitamins are discussed in other chapters, as indicated in the tables.

TABLE 9-10 -- Selected Trace Elements and Deficiency Syndromes

Element	Function	Basis of Deficiency	Clinical Features
Zinc	Component of enzymes, principally oxidases	Inadequate supplementation in artificial diets Interference with absorption by other dietary constituents Inborn error of metabolism	Rash around eyes, mouth, nose, and anus called acrodermatitis enteropathica Anorexia and diarrhea Growth retardation in children Depressed mental function Depressed wound healing and immune response Impaired night vision Infertility
Iron	Essential component of hemoglobin as well as several iron-containing metalloenzymes	Inadequate diet Chronic blood loss	Hypochromic microcytic anemia (Chapter 14)

Element	Function	Basis of Deficiency	Clinical Features
Iodine	Component of thyroid hormone	Inadequate supply in food and water	Goiter and hypothyroidism (Chapter 24)
Copper	Component of cytochrome *c* oxidase, dopamine β-hydroxylase, tyrosinase, lysyl oxidase, and unknown enzymes involved in cross-linking collagen	Inadequate supplementation in artificial diet Interference with absorption	Muscle weakness Neurologic defects Abnormal collagen cross-linking
Fluoride	Mechanism unknown	Inadequate supply in soil and water Inadequate supplementation	Dental caries (Chapter 16)
Selenium	Component of glutathione peroxidase Antioxidant with vitamin E	Inadequate amounts in soil and water	Myopathy Cardiomyopathy (Keshan disease)

OBESITY

Excess adiposity (known as *obesity*) and *excess body weight* are associated with the increased incidence of several of the most important diseases of humans, including type 2 diabetes, dyslipidemias, cardiovascular disease, hypertension, and cancer. Obesity is defined as an accumulation of adipose tissue that is of sufficient magnitude to impair health. As with weight loss, excess weight is best assessed by *the body mass index or BMI*. For practical reasons, *body weight*, which generally correlates well with BMI, is often used as a surrogate for BMI measurements. *The normal BMI range is 18.5 to 25 kg/m^2, although the range may differ for different countries. Individuals with BMI above 30 kg/m^2 are classified as obese; those with BMI between 25 kg/m^2 and 30 kg/m^2 are considered to be overweight*. For the sake of simplicity, unless otherwise noted, the term obesity will be applied to both the truly obese and the overweight.

Accumulation of body fat may also be measured by triceps skinfold thickness, mid-arm circumference, and the ratio between waist and hip circumferences. Not only the total body weight but also the distribution of the stored fat is of importance in obesity. *Central, or visceral, obesity*, in which fat accumulates in the trunk and in the abdominal cavity (in the mesentery and around viscera), is associated with a much higher risk for several diseases than is excess accumulation of fat diffusely in subcutaneous tissue.

Obesity is a major public health problem, which, until about a dozen years ago, was confined to developed countries. Since then, it has also become an important health problem in developing nations, and in certain countries obesity coexists with malnutrition in individual families. In the United States obesity has reached epidemic proportions. The prevalence of obesity increased from 13% to 32% between 1960 and 2004; currently 66% of adults in the United States are overweight or obese, and 16% of children are overweight. If current trends continue, it is projected that by the year 2015, 41% of adults will be obese.[62] The increase in obesity in the United States has been associated with the higher caloric content of the diet, mostly caused by increased consumption of refined sugars, sweetened beverages, and vegetable oils.

At its simplest level, obesity is a disease of caloric imbalance that results from an excess intake of calories above their consumption by the body. However, the pathogenesis of obesity is exceedingly

complex and not yet completely understood. Ongoing research has identified complex humoral and neural mechanisms that control appetite and satiety. These neurohumoral mechanisms respond to genetic, nutritional, environmental, and psychologic signals, and trigger a metabolic response through the stimulation of centers located in the hypothalamus. There is little doubt that genetic influences play an important role in weight control, but obesity is a disease that depends on the interaction between multiple factors. After all, regardless of genetic makeup, obesity would not occur without intake of food!

In a simplified way the neurohumoral mechanisms that regulate energy balance can be subdivided into three components (illustrated in Figs. 9-29 and 9-30):

- *The peripheral or afferent system* generates signals from various sites. Its main components are *leptin and adiponectin* produced by fat cells, *ghrelin* from the stomach, *peptide YY* (*PYY)* from the ileum and colon, and *insulin* from the pancreas.
- *The arcuate nucleus in the hypothalamus* processes and integrates neurohumoral peripheral signals and generates efferent signals. It contains two subsets of first-order neurons: (1) *POMC* (pro-opiomelanocortin) and *CART* (cocaine and amphetamine-regulated transcripts) neurons, and (2) neurons containing *NPY* (neuropeptide Y) and *AgRP* (agouti-related peptide). These first order neurons communicate with second order neurons.
- *The efferent system* that carries the signals generated in the second order neurons of the hypothalamus to control food intake and energy expenditure. The hypothalamic system also communicates with forebrain and midbrain centers that control the autonomic nervous system.[63]

POMC/CART neurons enhance energy expenditure and weight loss through the production of the anorexigenic α-melanocyte-stimulating hormone (MSH), and the activation of the melanocortin receptors 3 and 4 (MC3/4R) in second-order neurons. NPY/AgRP neurons promote food intake (orexigenic effect) and weight gain, through the activation of Y1/5 receptors in secondary neurons.

We will now discuss three important components of the afferent system that regulates appetite and satiety: leptin, adiponectin, and gut hormones.

Leptin.

The name leptin is derived from the Greek term *leptos*, meaning “thin.” Leptin, a *16-kD hormone synthesized by fat cells*, is the product of the *ob* gene. The leptin receptor (OB-R) is the product of the diabetes (*db*) gene and belongs to the type I cytokine receptor superfamily that includes the gp130, granulocyte-colony-stimulating factor, IL-2, and IL-6 receptors. Mice genetically deficient in leptin (*ob/ob mice*) or leptin receptors (*db/db mice*) fail to sense the adequacy of fat stores, overeat, and gain weight, behaving as if they are undernourished. Thus, the obesity of these animals is a consequence of the lack of the signal for energy sufficiency that is normally provided by leptin.[63]

Although in a general sense leptin levels are regulated by the adequacy of fat stores, the precise mechanisms that regulate the output of leptin from adipose tissue have not been completely defined, but it has been established that leptin secretion is stimulated when fat stores are abundant. It is believed that insulin-stimulated glucose metabolism is an important factor in the regulation of leptin levels. *Leptin levels are regulated by multiple post-transcriptional mechanisms* that affect its synthesis, secretion, and turnover. *In the hypothalamus, leptin stimulates POMC/CART neurons that produce anorexigenic neuropeptides (primarily melanocyte-stimulating hormone) and inhibits NPY/AgRP neurons that produce feeding-inducing (orexigenic) neuropeptides* (see Figs. 9-32 and 9-33). In individuals with stable weight, the activities of the opposing POMC/CART and NPY/AgRP pathways are properly balanced. However, when there are inadequate stores of body fat, leptin secretion is diminished and food intake is increased.

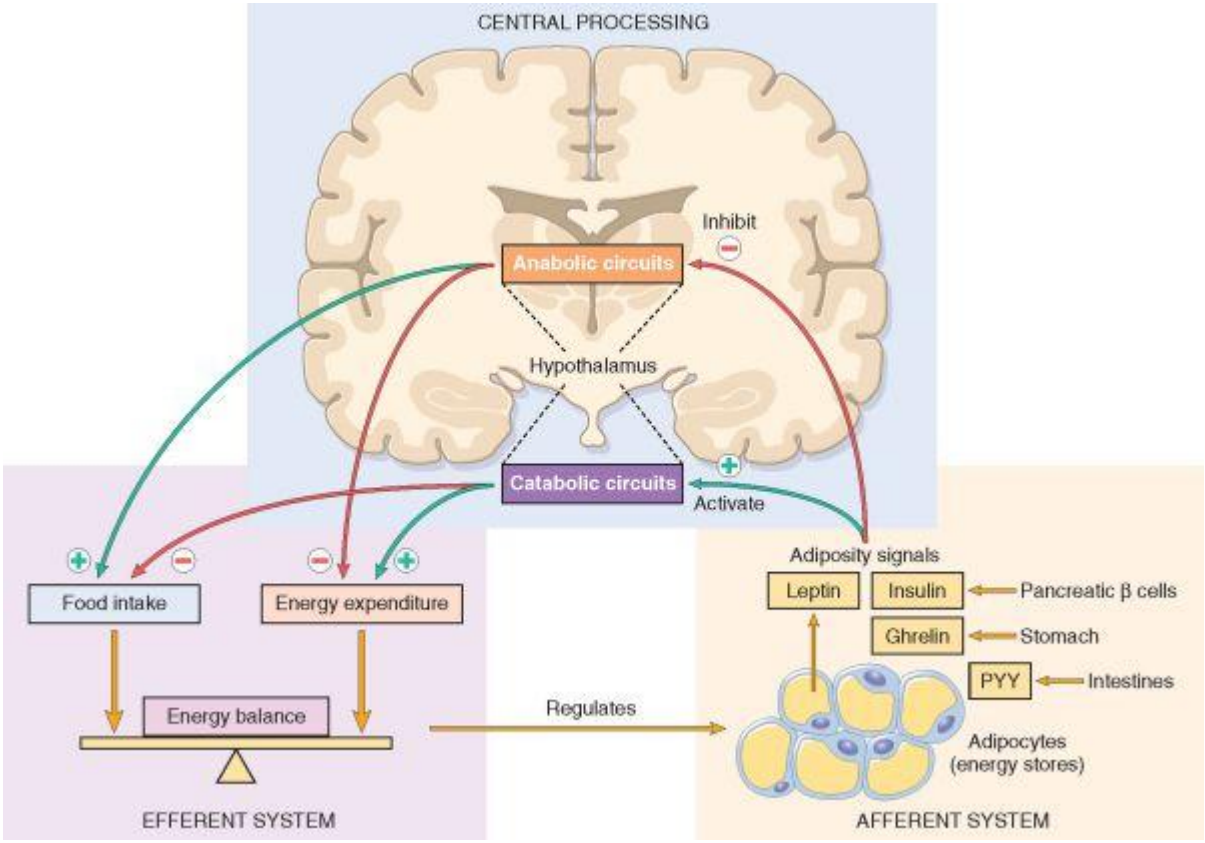

FIGURE 9-32 Regulation of energy balance. Adipose tissues generate afferent signals that influence the activity of the hypothalamus, which is the central regulator of appetite and satiety. These signals decrease food intake by inhibiting anabolic circuits, and enhance energy expenditure through the activation of catabolic circuits. PYY, peptide YY. See text for details.

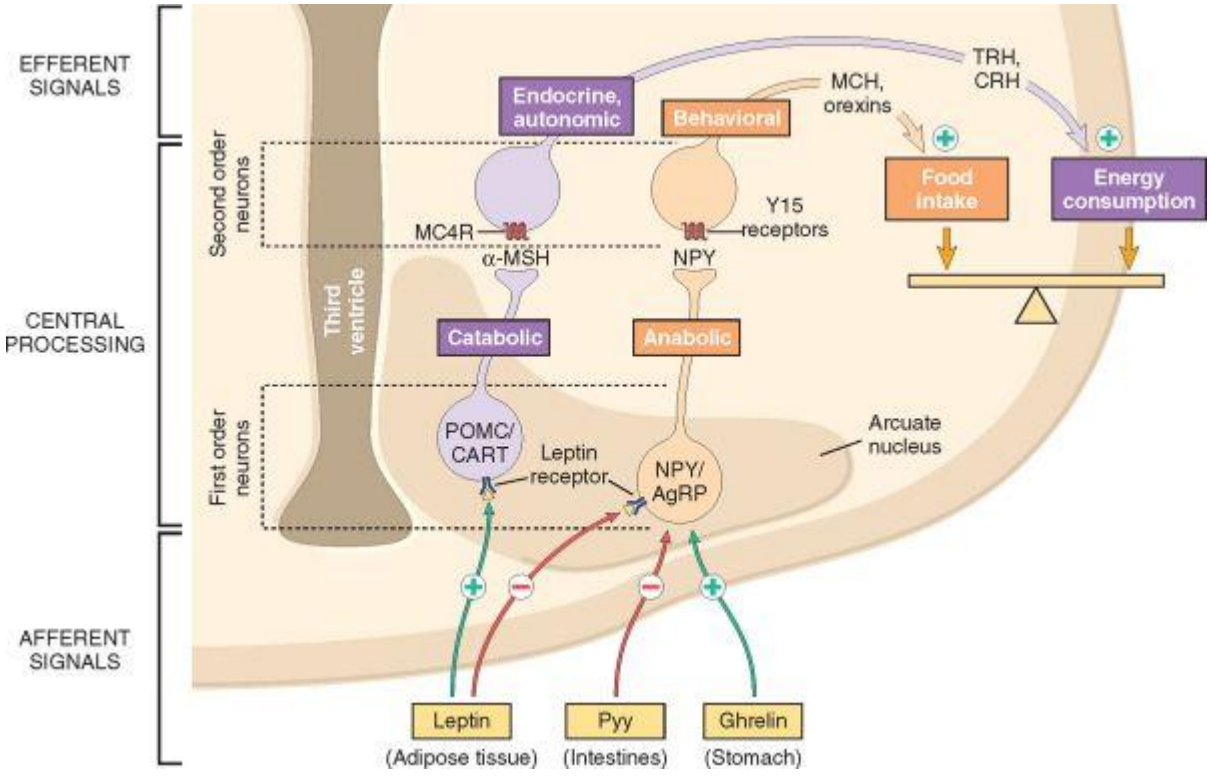

FIGURE 9-33 Neurohumoral circuits in the hypothalamus that regulate energy balance. Shown are POMC/CART anorexigenic neurons and NPY/AgRP orexigenic neurons in the arcuate nucleus of the hypothalamus, and their pathways. See text for details.

Humans with loss-of-function mutations in the leptin system develop early-onset severe obesity, but this is a rare condition. Mutations of melanocortin receptor 4 (MC4R) and its downstream pathways are more frequent, being responsible for about 5% of massive obesity. In these individuals, sensing of satiety (anorexigenic signal) is not generated, and hence they behave as if they are undernourished. It has recently been reported[64] that haplo-insufficiency of brain-derived neurotrophic factor (BDNF), an important component of MC4R downstream signaling in the hypothalamus, is associated with obesity in patients with the WAGR syndrome (this is a very rare condition that includes Wilms tumor, aniria, genito-urinary defects, and mental retardation in addition to obesity Chapter 10). Although the defects in leptin and MC4R detected so far are uncommon, they underscore the importance of these systems in the control of energy balance and body weight. Perhaps other defects in these pathways may have pathogenic effects in more common forms of obesity. For instance, it has been proposed that leptin resistance rather than leptin deficiency may be prevalent in humans.

Leptin regulates not only food intake but also energy expenditure, through a distinct set of pathways. Thus, an abundance of leptin stimulates physical activity, heat production, and energy expenditure. The neurohumoral mediators of leptin-induced energy expenditure are less well defined. *Thermogenesis*, an important catabolic effect mediated by leptin, is controlled in part by hypothalamic signals that increase the release of norepinephrine from sympathetic nerve endings in adipose tissue. In addition to these effects, leptin can function as a pro-inflammatory cytokine and participates in the regulation of hematopoiesis and lymphopoiesis.[65] The OB-R receptor is highly similar structurally to the IL-6 receptor and activates the JAK/STAT pathway.

Adiponectin.

Injections of adiponectin in mice stimulate fatty acid oxidation in muscle, causing a decrease in fat mass. This hormone is produced mainly by adipocytes. Its levels in the blood are very high, about 1000 times higher than those of other polypeptide hormones, and are lower in obese than in lean individuals.[66] Adiponectin, which has been called a “fat-burning molecule” and the “guardian angel against obesity,” directs fatty acids to muscle for their oxidation. It decreases the influx of fatty acids to the liver and the total hepatic triglyceride content, and also decreases the glucose production in the liver, causing an increase in insulin sensitivity and a protection against the metabolic syndrome (described later).[67] Adiponectin circulates as a complex of three, six, or even more aggregates of the monomeric form, and binds to two receptors, AdipoR1 and AdipoR2. These receptors are found in many tissues, including the brain, but AdipoR1 and AdipoR2 are most highly expressed in skeletal muscle and liver, respectively. Binding of adiponectin to its receptors triggers signals that activate cyclic adenosine monophosphate–activated protein kinase, which in turn phosphorylates and inactivates acetyl coenzyme A carboxylase, a key enzyme required for fatty acid synthesis.

Adipose Tissue.

In addition to leptin and adiponectin, adipose tissue produces cytokines such as TNF, IL-6, IL-1, and IL-18, chemokines, and steroid hormones. The increased production of cytokines and chemokines by adipose tissue in obese patients creates a chronic sub-clinical (asymptomatic) inflammatory state that includes high levels of circulating C-reactive protein. Through its multiple activities, adipose tissue participates in the control of energy balance and energy metabolism, functioning as a link between lipid

metabolism, nutrition, and inflammatory responses. Thus, the adipocyte that was relegated to an obscure and passive role as the “Cinderella of cells of metabolism,” is now “the Belle of the Ball” at the forefront of metabolic research.[68]

The total number of adipocytes is established during childhood and adolescence, and it is higher in obese than in lean individuals.[69] In adults the number of adipocytes remains constant, even after losses or weight gains, but there is a continuous turnover of the cell population. It is estimated that approximately 10% of adipocytes are renewed annually, regardless of the level of the individual's body mass. Thus, although the fat mass in an adult person can increase through the enlargement of existing adipocytes, their number is tightly controlled, and is predetermined in childhood and adolescence. In individuals who lose weight after dietary regimens, the well-known difficulties in maintaining weight losses are, in part, a consequence of the lack of a decrease in the number of adipocytes, and the enhanced appetite caused by leptin deficiency.

Gut Hormones.

Gut peptides act as short-term meal initiators and terminators. They include ghrelin, PYY, pancreatic polypeptide, insulin, and amylin among others.[70] *Ghrelin* is produced in the stomach and in the arcuate nucleus of the hypothalamus. *It is the only known gut hormone that increases food intake (orexigenic effect)*. Its injection in rodents elicits voracious feeding, even after repeated administration. Long-term injections cause weight gain, by increasing caloric intake and reducing energy utilization. Ghrelin acts by binding the growth hormone secretagogue receptor, which is abundant in the hypothalamus and the pituitary. Although the precise mechanisms of ghrelin action have not been identified, it most likely stimulates NPY/AgRP neurons to increase food intake. Ghrelin levels rise before meals and fall between 1 and 2 hours after eating. However, in obese individuals the postprandial suppression of ghrelin is attenuated, leading to maintenance of the obesity.

PYY is secreted from endocrine cells in the ileum and colon. Plasma levels of PYY are low during fasting and increase shortly after food intake. Intravenous administration of PYY reduces energy intake, and its levels generally increase after gastric bypass surgery. By contrast, levels of PYY generally decrease in individuals with the *Prader-Willi syndrome* (caused by loss of imprinted genes on chromosome 15q11–q13),[71] and may contribute to the development of *hyperphagia and obesity* in these persons. These observations have led to ongoing work to produce PYYs for the treatment of obesity. *Amylin*, a peptide secreted with insulin from pancreatic β-cells that reduces food intake and weight gain, is also being evaluated for the treatment of obesity and diabetes. Both PYY and amylin act centrally by stimulating POMC/CART neurons in the hypothalamus, causing a decrease in food intake.

General Consequences of Obesity

Obesity, *particularly central obesity, increases the risk for a number of conditions, including type 2 diabetes and cardiovascular disease* (Fig. 9-34). Obesity is the main driver of a cluster of alterations known as the *metabolic syndrome* characterized by visceral or intra-abdominal adiposity, insulin resistance, hyperinsulinemia, glucose intolerance, hypertension, hypertriglyceridemia, and low HDL cholesterol (Chapter 11).

- Obesity is associated with *insulin resistance* and *hyperinsulinemia*, important features of type 2 diabetes, and weight loss is associated with improvement (Chapter 24). It has been speculated that excess insulin, in turn, may play a role in the retention of sodium, expansion of blood volume, production of excess norepinephrine, and smooth muscle proliferation that are the hallmarks of hypertension. Regardless of the nature of the pathogenic mechanisms, *the risk of developing hypertension among previously normotensive persons increases proportionately with weight*.
- Obese persons generally have hypertriglyceridemia and low HDL, and these may increase the risk of

coronary artery disease in the very obese. It should be emphasized that the association between obesity and heart disease is not straightforward, and such linkage as there may be relates more to the associated diabetes and hypertension than to weight.

- Obesity is associated with *non-alcoholic fatty liver disease* (Chapter 18). This condition occurs most often in diabetic patients and can progress to fibrosis and cirrhosis. *Cholelithiasis (gallstones)* is six times more common in obese than in lean subjects. An increase in total body cholesterol, increased cholesterol turnover, and augmented biliary excretion of cholesterol all act to predispose to the formation of cholesterol-rich gallstones (Chapter 18).
- *Obesity is associated with hypoventilation and hypersomnolence. Hypoventilation syndrome* is a constellation of respiratory abnormalities in very obese persons. It has been called the *pickwickian syndrome*, after the fat lad who was constantly falling asleep in Charles Dickens' *Pickwick Papers*. Hypersomnolence, both at night and during the day, is characteristic and is often associated with apneic pauses during sleep, polycythemia, and eventual right-sided heart failure.
- Marked adiposity predisposes to the development of degenerative joint disease *(osteoarthritis)*. This form of arthritis, which typically appears in older persons, is attributed in large part to the cumulative effects of increased load on weight-bearing joints.

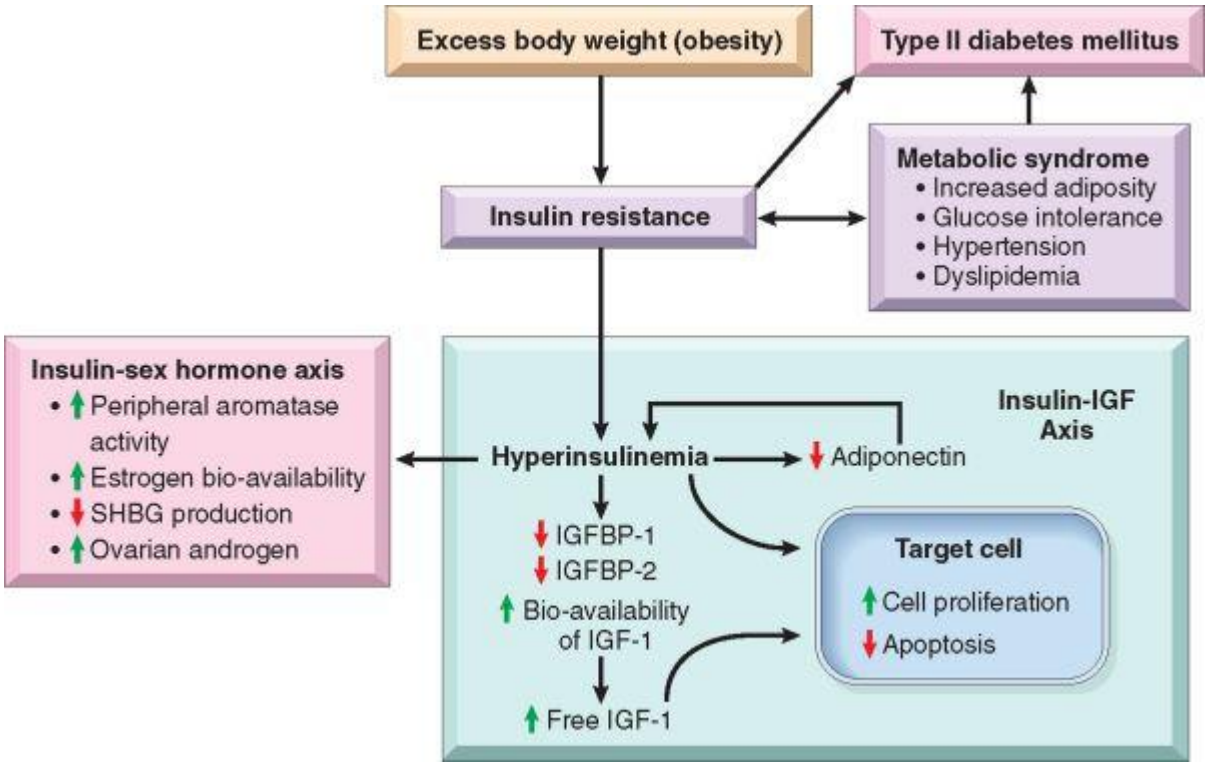

FIGURE 9-34 Obesity, metabolic syndrome, and cancer. Obesity and excessive weight are precursors of the metabolic syndrome, which is associated with insulin resistance, type 2 diabetes, and hormonal changes. Increases in insulin and IGF-1 (insulin-like growth factor-1) stimulate cell proliferation and inhibit apoptosis and may contribute to tumor development. IGF, insulin-like growth factor; IGFBP, insulin-like growth factor–binding protein; SHBG, sex hormone–binding globulin. *(Modified from Renehan AG et al.: Obesity and cancer risk: the role of the insulin-I6F axis. Trends Endocrinol Metab 17:328, 2006.)*

Obesity and Cancer

Approximately 4% of cancers in men and 7% in women are associated with obesity.[72] Data on the relationships between obesity and cancer have been obtained from the Million Women Study that examined the relationship between BMI and cancer in women aged 50 to 64 years in the United

Kingdom, and from a systematic analysis of published data sets involving more than 280,000 cases of cancer in men and women.[73,][74]

1. In men, a BMI greater than 25 kg/m^2 correlated strongly with an increased incidence of adenocarcinoma of the esophagus, and cancers of the thyroid, colon, and kidney.
2. In women, a BMI greater than 25 kg/m^2 correlated strongly with an increased incidence of adenocarcinoma of the esophagus, and of endometrial, gallbladder, and kidney cancers.

The mechanisms by which obesity is associated with these specific types of cancers are unknown, but a proposed hypothesis is that *the increased cancer risk in obese individuals is a consequence of hyperinsulinemia and insulin resistance* (Fig. 9-34). Insulin at high concentrations has multiple effects on cell growth, including the activation of phosphatidylinositol 3-kinase, extracellular-signal-regulated kinases 1 and 2, β-catenin, and Ras. All of these are important components of pathways that are dysregulated during cancer development. *Hyperinsulinemia also causes an increase in insulin-like growth factor-1 (IGF-1) concentrations, because insulin inhibits the production of the IGF-binding proteins IGFBP-1 and IGFBP-2*. IGF-1 is a mitogenic and anti-apoptotic agent that is highly expressed in many human cancers.[75] It binds with high affinity to the IGF-1R receptor, and with low affinity to the insulin receptor. IGF-1 activates many of the cell growth pathways that are also activated by insulin, and increases the production of vascular endothelial growth factor, by inducing the expression of hypoxia-inducible factor 1.

In addition to the obesity-associated effects of insulin and IGF-1 in cell growth pathways, obesity and hyperinsulimia have an effect on steroid hormones that regulate cell growth and differentiation in the breast, uterus, and other tissues: (1) obesity increases the synthesis of estrogen from androgen precursors through an effect of adipose tissue aromatases; (2) insulin increases androgen synthesis in ovaries and adrenals, and enhances estrogen availability in obese persons by inhibiting the production of sex-hormone-binding globulin (SHBG) in the liver (see Fig. 9-34).

As already discussed in this chapter, adiponectin, secreted mostly from adipose tissue, is an abundant hormone that is inversely correlated with obesity and acts as an insulinsensitizing agent. Thus, *the decreased levels of adiponectin in obese persons contribute to hyperinsulinemia and the impairment of insulin sensitivity*.

DIETS, CANCER, AND ATHEROSCLEROSIS

Diet and Cancer

The incidence of specific cancers varies widely throughout the world. The frequency of some tumors varies as much as 100-fold in different geographic areas. It is also well known that differences in incidence of various cancers is not fixed and can be modified by nongenetic factors, including changes in diet. For instance, the incidence of colon cancer in Japanese men and women 55 to 60 years of age was negligible about 50 years ago, but it is now higher than that in men of the same age in the United Kingdom.[76] Studies have also shown a progressive increase in colon cancers in Japanese populations as they moved from Japan to Hawaii and from there to the continental United States. Nevertheless, despite the very large amount of experimental and epidemiologic research, relatively few mechanisms that link diets and specific types of cancer have been established.

With respect to carcinogenesis, three aspects of the diet are of major concern: (1) the content of exogenous carcinogens, (2) the endogenous synthesis of carcinogens from dietary components, and (3) the lack of protective factors.

- Regarding *exogenous* substances, *aflatoxin* is involved in the development of hepatocellular carcinomas in

parts of Asia and Africa, generally in cooperation with hepatitis B virus. Exposure to aflatoxin causes a specific mutation in codon 249 of the *p53* gene; when found in hepatocellular carcinomas, this mutation serves as a molecular signature for aflatoxin exposure. Debate continues about the carcinogenicity of food additives, artificial sweeteners, and contaminating pesticides. Some artificial sweeteners (cyclamates and saccharin) have been implicated in bladder cancers, but convincing evidence is lacking.

- The concern about *endogenous* synthesis of carcinogens or enhancers of carcinogenicity from components of the diet relates principally to gastric carcinomas. *Nitrosamines and nitrosamides* are implicated in the generation of these tumors in humans, because they have been clearly shown to induce gastric cancer in animals. These compounds can be formed in the body from nitrites and amines or amides derived from digested proteins. Sources of nitrites include sodium nitrite added to foods as a preservative, and nitrates, present in common vegetables, which are reduced in the gut by bacterial flora. There is, then, the potential for endogenous production of carcinogenic agents from dietary components, which might well have an effect on the stomach.
- *High animal fat intake combined with low fiber intake has been implicated in the causation of colon cancer*. It has been estimated that doubling the average level of total fiber consumption to about 40 gm/day per person in most populations may decrease the risk of colon cancer by 50%.[75] The most convincing explanation of this association is that high fat intake increases the level of bile acids in the gut, which in turn modifies intestinal flora, favoring the growth of microaerophilic bacteria. Bile acid metabolites produced by these bacteria may function as carcinogens. The *protective effect of a high-fiber diet* might relate to (1) increased stool bulk and decreased transit time, which decreases the exposure of mucosa to putative offenders, and (2) the capacity of certain fibers to bind carcinogens and thereby protect the mucosa. However, attempts to document these theories in clinical and experimental studies have not generated consistent results.
- Although epidemiologic data from large populations show a strong positive correlation between total dietary fat intake and breast cancer, *it is still unclear whether increased fat consumption has a causal relationship to breast cancer development*.
- Vitamins C and E, β-carotenes, and selenium have been assumed to have anticarcinogenic effects because of their antioxidant properties. However, thus far there is no convincing evidence that these antioxidants act as chemopreventive agents. As discussed earlier in this chapter, retinoids are effective agents in the therapy of acute promyelocytic leukemia, and associations between low levels of vitamin D and cancer of the colon, prostate, and breast have been reported.

Thus, we must conclude that despite many tantalizing trends and proclamations by "diet gurus," thus far there is no definitive proof that a particular diet can cause or prevent cancer. On the other hand, given the relationships between obesity and cancer development, prevention of obesity through the consumption of a healthy diet is a commonsense measure that goes a long way in preserving good health. Concern persists that carcinogens lurk in things as pleasurable as a juicy steak, a rich ice cream, and in nuts contaminated with aflatoxin.

Diet and Atherosclerosis

A most important and controversial issue is the contribution of diet to atherogenesis. The central question is "can dietary modification—specifically, reduction in the consumption of cholesterol and saturated animal fats (e.g., eggs, butter, beef)—reduce serum cholesterol levels and prevent or retard the development of atherosclerosis (most importantly, coronary heart disease)?" The average adult in the United States consumes a large amount of fat and cholesterol daily, with a ratio of saturated fatty acids to polyunsaturated fatty acids of about 3 : 1. Lowering this ratio to 1 : 1 causes a 10% to 15% reduction in the serum cholesterol level within a few weeks. Vegetable oils (e.g., corn and safflower oils) and fish oil contain polyunsaturated fatty acids and are good sources of such cholesterol-lowering lipids. Fish oil fatty acids belonging to the omega-3 family have more double bonds than do the omega-6 fatty acids present in vegetable oils. A study of Dutch men whose usual daily diet contained 30 g of fish revealed a substantially lower frequency of death from coronary heart disease than that among comparable controls.

There is much talk about the role that caloric restriction and special diets may play in the control of body weight and prevention of cardiovascular disease. We offer just a few general observations on these topics.

- Caloric restriction has been convincingly demonstrated to decrease the incidence of some diseases, and to increase life span in experimental animals. The basis of this striking observation is not entirely clear but seems to depend on activation of sirtuins and on the lowering of insulin and IGF-1 levels (Chapter 1).[74] In calorie-restricted animals there is a more modest age-related decline in immunological functions, less oxidative damage, and greater resistance to carcinogenesis.
- Not surprisingly, there are a large number of commercial diets that are reported by its proponents to decrease the risk of heart disease. Among those are the low-carbohydrate diets (such as the Atkins Diet, the Zone, Sugar Busters, Protein Power), and others such as The Miami Diet/Hollywood 48-Hour Miracle Diet, and the South Beach Diet. The actual effect of these diets on heart disease is highly controversial.
- Most diets dictate what you cannot eat (of course, your favorite foods!). A better strategy is to simply focus on eating an enjoyable and healthy diet rich in fish, vegetables, whole grains, fruits, olive and peanut oils (to replace saturated and *trans* fats), complex carbohydrates (instead of simple carbohydrates contained in sweets and soft drinks), and low in salt (to control hypertension).
- Even lowly garlic has been touted to protect against heart disease (and also against, devils, werewolves, vampires, and, alas, kisses), although research has yet to prove this effect unequivocally. Of these, the effect on kisses is the best established!

2.10 10. Diseases of Infancy & Childhood

2.10.1 Congenital Anomalies

ANIRBAN MAITRA

Children are not merely little adults, and their diseases are not merely variants of adult diseases. Many childhood conditions are unique to, or at least take distinctive forms in, this stage of life and so are discussed separately in this chapter. Diseases originating in the perinatal period are important in that they account for significant morbidity and mortality. As would be expected, the chances for survival of live-born infants improve with each passing week. This progressrepresents, at least in part, a triumph of improved medical care. Better prenatal care, more effective methods of monitoring the condition of the fetus, and judicious resort to cesarean section before term when there is evidence of fetal distress, have all contributed toward bringing into this “mortal coil” live-born infants who in past years might have been stillborn. These infants represent an increased number of *high-risk* infants. Nonetheless, the infant mortality rate in the United States has shown a decline from a level of 20.0 deaths per 1000 live births in 1970 to about 6.8 deaths in 2004, the latest year for which these data are systematically available.[1] Although the death rate has continued to decline for all infants, African Americans continue to have an infant mortality rate more than twice (13.6 deaths per 1000 live births) that of American whites (5.6 deaths). Worldwide, infant mortality rates vary widely, from as low as 2.3 deaths per 1000 live births in Singapore, to as high as 180 deaths in the African subcontinent.

Each stage of development of the infant and child is prey to a somewhat different group of disorders. The data available permit a survey of four time spans: (1) the neonatal period (the first 4 weeks of life), (2) infancy (the first year of life), (3) age 1 to 4 years, and (4) age 5 to 14 years.

The major causes of death in infancy and childhood are listed in Table 10-1 . Congenital anomalies, disorders relating to short gestation (prematurity) and low birth weight, and sudden infant death syndrome (SIDS) represent the leading causes of death in the first 12 months of life. Once the infant survives the first year of life, the outlook brightens measurably. In the next two age groups—1 to 4 years and 5 to 14 years—injuries resulting from accidents have become the leading cause of death. Among the natural diseases, in order of importance, congenital anomalies and malignant neoplasms

assume major significance. It would appear then that, in a sense, life is an obstacle course. For the great majority, the obstacles are surmounted or, even better, bypassed.

We now take a closer look at the specific conditions en-countered during the various stages of infant and child development.

TABLE 10-1 -- Cause of Death Related with Age

Causes[*]	Rate[†]
UNDER 1 YEAR	**685.2**
Congenital malformations, deformations, and chromosomal anomalies	
Disorders related to short gestation and low birth weight	
Sudden infant death syndrome (SIDS)	
Newborn affected by maternal complications of pregnancy	
Newborn affected by complications of placenta, cord, and membranes	
Respiratory distress of newborn	
Accidents (unintentional injuries)	
Bacterial sepsis of newborn	
Intrauterine hypoxia and birth asphyxia	
Diseases of the circulatory system	
1–4 YEARS	**29.9**
Accidents and adverse effects	
Congenital malformations, deformations, and chromosomal abnormalities	
Malignant neoplasms	
Homicide and legal intervention	
Diseases of the heart[‡]	
Influenza and pneumonia	
5–14 YEARS	**16.8**
Accidents and adverse effects	
Malignant neoplasms	
Homicide and legal intervention	
Congenital malformations, deformations, and chromosomal abnormalities	
Suicide	
Diseases of the heart	
15–24 YEARS	**80.1**
Accidents and adverse effects	
Homicide	
Suicide	
Malignant neoplasms	
Diseases of the heart	

From Minino AM et al.: Deaths: final data for 2004. National Vital Statistics Rep 55:19, 2007.

* Causes are listed in decreasing order of frequency. All causes and rates are final 2004 statistics.

† Rates are expressed per 100,000 population from all causes within each age group.

‡ Excludes congenital heart disease.

Congenital Anomalies

Congenital anomalies are morphologic defects that are present at birth, but some, such as cardiac defects and renal anomalies, may not become clinically apparent until years later. The term *congenital* means "born with," but it does not imply or exclude a genetic basis for the birth defect. It is estimated that about 120,000 (1 in 33) babies are born with a birth defect each year in the United States. They are the most common cause of mortality in the first year and contribute significantly to morbidity and mortality throughout the early years of life. In a sense, anomalies found in live-born infants represent the less serious developmental failures in embryogenesis that are compatible with live birth. Perhaps 20% of fertilized ova are so anomalous that they are blighted from the outset. Others may be compatible with early fetal development, only to lead to spontaneous abortion. Less severe anomalies allow more prolonged intrauterine survival, with some disorders terminating in stillbirth and those still less significant permitting live birth despite the handicaps imposed.

DEFINITIONS

Before proceeding, we define some of the terms used for various kinds of errors in morphogenesis—*malformations*, *disruptions*, *deformations*, *sequences*, and *syndromes*.

- *Malformations* represent primary errors of morphogenesis, in which there is an *intrinsically abnormal developmental process* (Fig. 10-1). They are usually associated with multiple genetic loci (multifactorial) and not the result of a single-gene or chromosomal defect. Malformations may present in several patterns. Some, such as congenital heart defects and anencephaly (absence of brain), involve single body systems, whereas in other cases multiple malformations involving many organs may coexist.
- *Disruptions* result from secondary destruction of an organ or body region that was previously normal in development; thus, in contrast to malformations, disruptions arise from an *extrinsic disturbance in morphogenesis*. *Amniotic bands*, denoting rupture of amnion with resultant formation of "bands" that encircle, compress, or attach to parts of the developing fetus, are the classic example of a disruption (Fig. 10-2). A variety of environmental agents may cause disruptions (see below). Understandably, disruptions are not heritable and hence are not associated with risk of recurrence in subsequent pregnancies.
- *Deformations*, like disruptions, also represent an *extrinsic disturbance of development* rather than an intrinsic error of morphogenesis. Deformations are common problems, affecting approximately 2% of newborn infants to varying degrees. Fundamental to the pathogenesis of deformations is localized or generalized compression of the growing fetus by *abnormal biomechanical forces*, leading eventually to a variety of structural abnormalities. The most common underlying factor responsible for deformations is *uterine constraint*. Between the thirty-fifth and thirty-eighth weeks of gestation, rapid increase in the size of the fetus outpaces the growth of the uterus, and the relative amount of amniotic fluid (which normally acts as a cushion) also decreases. Thus, even the normal fetus is subjected to some form of uterine constraint. Several factors increase the likelihood of excessive compression of the fetus resulting in deformations. *Maternal factors* include first pregnancy, small uterus, malformed (bicornuate) uterus, and leiomyomas. *Fetal or placental factors* include oligohydramnios, multiple fetuses, and abnormal fetal presentation. An example of a deformation is clubfeet, often a component of Potter sequence, described later.
- A *sequence* is a cascade of anomalies triggered by one initiating aberration. Approximately half the time, congenital anomalies occur singly; in the remaining cases, multiple congenital anomalies are recognized. In some instances the constellation of anomalies may be explained by a single, localized aberration in organogenesis (malformation, disruption, or deformation) that sets into motion secondary effects in other organs. A good example is the *oligohydramnios* (or *Potter*) *sequence* (Fig. 10-3). Oligohydramnios (decreased amniotic fluid) may be caused by a variety of unrelated maternal, placental, or fetal

abnormalities. Causes of oligohydramnios include chronic leakage of amniotic fluid because of rupture of the amnion, uteroplacental insufficiency resulting from maternal hypertension or severe toxemia, and renal agenesis in the fetus (because fetal urine is a major constituent of amniotic fluid). The fetal compression associated with significant oligohydramnios, in turn, results in a classic phenotype in the newborn infant, including flattened facies and positional abnormalities of the hands and feet (Fig. 10-4). The hips may be dislocated. Growth of the chest wall and the contained lungs is also compromised so that the lungs are frequently hypoplastic, occasionally to the degree that they are the cause of fetal demise. Nodules in the amnion *(amnion nodosum)* are frequently present.

- A *syndrome* is a constellation of congenital anomalies, believed to be pathologically related, that, in contrast to a sequence, *cannot* be explained on the basis of a single, localized, initiating defect. Syndromes are most often caused by a single etiologic agent, such as a viral infection or specific chromosomal abnormality, which simultaneously affects several tissues.

FIGURE 10-1 Examples of malformations. *Polydactyly* (one or more extra digits) and *syndactyly* (fusion of digits), both of which are illustrated in **A**, have little functional consequence when they occur in isolation. Similarly, *cleft lip* (**B**), with or without associated *cleft palate,* is compatible with life when it occurs as an isolated anomaly; in the present case, however, this neonate had an underlying *malformation syndrome* (trisomy 13) and expired because of severe cardiac defects. **C**, The stillbirth illustrated represents a severe and essentially lethal malformation, wherein the midface structures are fused or ill-formed; in almost all cases, this degree of external dysmorphogenesis is associated with severe internal anomalies such as maldevelopment of the brain and cardiac defects. *(**A** and **C**, courtesy of Dr. Reade Quinton; and **B**, courtesy of Dr. Beverly Rogers, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)*

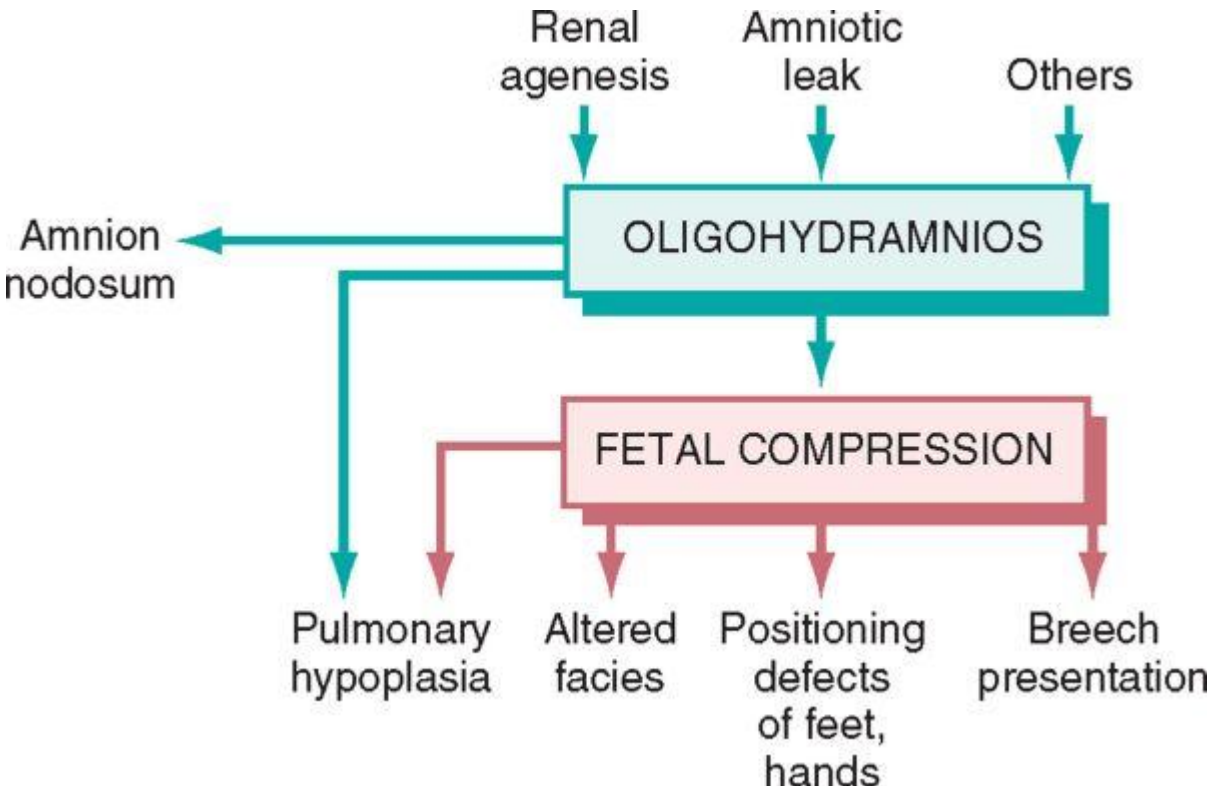

FIGURE 10-3 Schematic diagram of the pathogenesis of the oligohydramnios sequence.

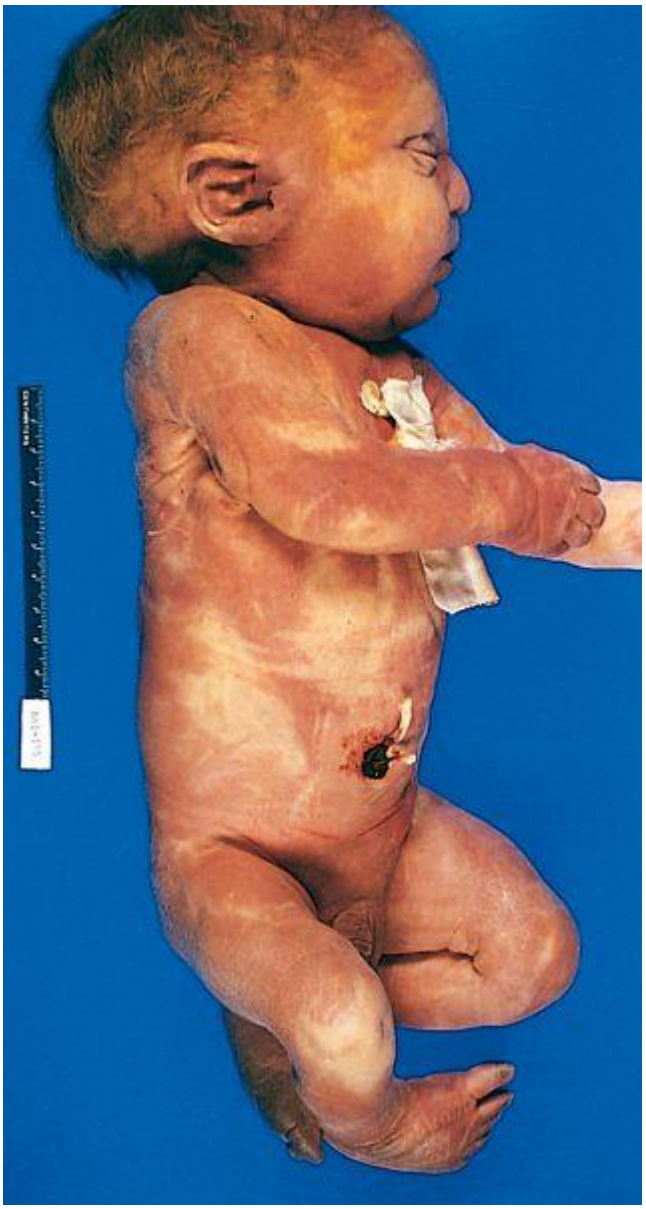

FIGURE 10-4 Infant with oligohydramnios sequence. Note the flattened facial features and deformed right foot *(talipes equinovarus).*

In addition to the aforementioned general definitions, a few organ-specific terms should be defined. *Agenesis* refers to the complete absence of an organ and its associated primordium. A closely related term, *aplasia*, refers also to the absence of an organ but one due to failure of development of the primordium. *Atresia* describes the absence of an opening, usually of a hollow visceral organ, such as the trachea and intestine. *Hypoplasia* refers to incomplete development or decreased size of an organ with decreased numbers of cells, whereas *hyperplasia* refers to the converse, that is, the enlargement of an organ due to increased numbers of cells. An abnormality in an organ or a tissue as a result of an increase or a decrease in the size (rather than the number) of individual cells defines *hypertrophy* or *hypotrophy*, respectively. Finally, *dysplasia*, in the context of malformations (versus *neoplasia*) describes an abnormal organization of cells.

CAUSES OF ANOMALIES

At one time, it was believed that the presence of a visible, external anomaly was divine punishment for wickedness, a belief that occasionally jeopardized the mother's life. Although we are learning a great deal about some of the molecular bases of congenital anomalies, *the exact cause remains unknown in at least half to three quarters of the cases*. The common *known* causes of congenital anomalies can be grouped into three major categories: genetic, environmental, and multifactorial (Table 10-2).

TABLE 10-2 -- Causes of Congenital Anomalies in Humans

Cause	Frequency (%)
GENETIC	
Chromosomal aberrations	10–15
Mendelian inheritance	2–10
ENVIRONMENTAL	
Maternal/placental infections	2–3
Rubella	
Toxoplasmosis	
Syphilis	
Cytomegalovirus	
Human immunodeficiency virus	
Maternal disease states	6–8
Diabetes	
Phenylketonuria	
Endocrinopathies	
Drugs and chemicals	1
Alcohol	
Folic acid antagonists	
Androgens	
Phenytoin	
Thalidomide	
Warfarin	
13-*cis*-retinoic acid	
Others	
Irradiations	1
MULTIFACTORIAL	**20–25**
UNKNOWN	**40–60**

Genetic Causes

Anomalies that are known to be genetic in origin can be divided into two groups:

- Those associated with chromosomal aberrations
- Those arising from single-gene mutations (“mendelian disorders”)

A third group is suspected of resulting from *multifactorial inheritance*, a term that implies the interaction of two or more genes of small effect with environmental factors, and is discussed separately.

Karyotypic abnormalities are present in approximately 10% to 15% of live-born infants with congenital anomalies, but trisomy 21 (Down syndrome) is the only one that approaches a birth frequency of greater than 10 in 10,000 total births. Next in order of frequency are trisomies 13 and 18 (Table 10-3). The remaining chromosomal syndromes associated with malformations are far rarer. *The great preponderance of these cytogenetic aberrations arises as defects in gametogenesis and so are not familial*. There are, however, several transmissible chromosomal abnormalities, for example, the form of Down syndrome associated with a robertsonian translocation in the parent, which is passed from one generation to the next, thus constituting a familial pattern of structural abnormalities (see Chapter 5). It should come as a sobering thought that *80% to 90% of fetuses with aneuploidy and other abnormalities of chromosome number die in utero, the majority in the earliest stages of gestation*.

TABLE 10-3 -- National Prevalence Estimates for the Most Common Birth Defects in the United States, 1999–2001

Birth Defect	Estimated National Prevalence (per 10,000 live births)
CHROMOSOMAL DEFECTS	
Down syndrome (Trisomy 21)	12.8
Trisomy 13	1.3
Trisomy 18	2.3
OROFACIAL DEFECTS	
Cleft palate	6.4
Cleft lip with and without cleft palate	10.5
CARDIOVASCULAR DEFECTS	
Atrioventricular septal defect (endocardial cushion defect)	4.4
Transposition of great arteries	4.7
Tetrology of Fallot	3.9
CENTRAL NERVOUS SYSTEM DEFECTS	
Spina bifida without anencephalus	3.7
Anencephalus	2.5
GASTROINTESTINAL DEFECTS	
Rectal and large intestinal atresia/stenosis	4.8
Esophageal atresia/tracheoesophageal fistula	2.4
MUSCULOSKELETAL DEFECTS	
Gastroschisis	3.7
Diaphragmatic hernia	2.9
Omphalocele	2.1

Adapted from Canfield MA et al.: National estimates and race/ethnic-specific variation of selected birth defects in the United States, 1999–2001. Birth Defects Res A 76:747–756, 2006. The data have been adjusted for maternal race and ethnicity.

Single-gene mutations of large effect may underlie major congenital anomalies, which, as expected, follow mendelian patterns of inheritance. Of these, approximately 90% are inherited in an autosomal dominant or recessive pattern, while the remainder segregates in an X-linked pattern. Not surprisingly, many of the mutations that give rise to birth defects involve loss of function of genes involved in normal organogenesis and development. For example, holoprosencephaly is the most common developmental defect of the forebrain and midface in humans (see Chapter 28); the Hedgehog signaling pathway plays a critical role in the morphogenesis of these structures, and loss-of-function mutations of individual components within this pathway are reported in families with a history of recurrent holoprosencephaly.[2] Similarly, achondroplasia, which is the most common form of short-limb dwarfism, is caused by gain-of-function mutations in *fibroblast growth factor receptor 3 (FGFR3)*.[3] The FGFR3 protein is a negative regulator of bone growth, and the activating FGFR3 mutations in achondroplasia are thought to exaggerate this physiologic inhibition, resulting in dwarfism.

Environmental Causes

Environmental influences, such as viral infections, drugs, and irradiation to which the mother was exposed during pregnancy, may cause fetal malformations (the appellation of "malformation" is loosely used in this context, since technically these anomalies represent *disruptions*).

Viruses.

Many viruses have been implicated in causing malformations, including the agents responsible for rubella, cytomegalic inclusion disease, herpes simplex, varicella-zoster infection, influenza, mumps, human immunodeficiency virus (HIV), and enterovirus infections. Among these, the rubella virus and cytomegalovirus are the most extensively investigated agents. With all viruses, the gestational age at which the infection occurs in the mother is critically important. *The at-risk period for rubella infection extends from shortly before conception to the sixteenth week of gestation*, the hazard being greater in the first 8 weeks than in the second 8 weeks. The incidence of malformations is reduced from 50% to 20% to 7% if infection occurs in the first, second, or third month of gestation. The fetal defects are varied, but the major tetrad comprises cataracts, heart defects (persistent ductus arteriosus, pulmonary artery hypoplasia or stenosis, ventricular septal defect, tetralogy of Fallot), deafness, and mental retardation, referred to as *congenital rubella syndrome*.

Intrauterine infection with cytomegalovirus, mostly asymptomatic, is the most common fetal viral infection. This viral disease is considered in detail in Chapter 8 ; *the highest at-risk period is the second trimester of pregnancy*. Because organogenesis is largely completed by the end of the first trimester, congenital malformations occur less frequently than in rubella; nevertheless, the effects of virus-induced injury on the formed organs are often severe. Involvement of the central nervous system is a major feature, and the most prominent clinical changes are mental retardation, microcephaly, deafness, and hepatosplenomegaly.

Drugs and Other Chemicals.

A variety of drugs and chemicals have been suspected to be teratogenic, but perhaps less than 1% of congenital malformations are caused by these agents. The list includes thalidomide, folate antagonists, androgenic hormones, alcohol, anticonvulsants, warfarin (oral anticoagulant), and 13-*cis*-retinoic acid used in the treatment of severe acne (see below). In many instances experimental studies in lower organisms (chick, zebrafish, etc.) have been instrumental in elucidating which developmental pathway(s) is affected by a given teratogen. For example, *thalidomide*, once used as a tranquilizer in Europe, caused an extremely high frequency (50% to 80%) of limb abnormalities in exposed fetuses. The mechanism of

thalidomide teratogenicity involves downregulation of the developmentally important wingless (WNT) signaling pathway through upregulation of endogenous WNT repressors.[4] Thalidomide and related drugs have staged a remarkable comeback as antineoplastic agents, with potent immunomodulatory and anti-angiogenic properties. Much caution must be taken when these drugs are given to cancer patients who are of reproductive age. *Alcohol* is probably the most widely used teratogen. Alcohol is responsible for several structural anomalies, as well as more subtle cognitive and behavioral defects in the fetus, collectively termed *fetal alcohol spectrum disorders* (FASDs). The most severely affected infants with FASDs have growth retardation, microcephaly, atrial septal defect, short palpebral fissures, and maxillary hypoplasia, and this classic teratogenic phenotype is labeled as *fetal alcohol syndrome*. Experiments performed in animals suggest that prenatal exposure to alcohol disrupts at least two seminal developmental signaling pathways—retinoic acid and Hedgehog—with critical roles during development.[5,][6] While cigarette smoke–derived nicotine has not been convincingly demonstrated to be a teratogen, there is a high incidence of spontaneous abortions, premature labor, and placental abnormalities in pregnant smokers; babies born to smoking mothers often have a low birth weight and may be prone to SIDS (see later). *In light of these findings, it is best to avoid nicotine exposure altogether during pregnancy*.

Radiation.

In addition to being mutagenic and carcinogenic, radiation is teratogenic. Exposure to heavy doses of radiation during the period of organogenesis leads to malformations, such as microcephaly, blindness, skull defects, spina bifida, and other deformities. Such exposure occurred in the past when radiation was used to treat cervical cancer during pregnancy.

Maternal Diabetes.

Diabetes mellitus is a common entity, and despite advances in antenatal obstetric monitoring and glucose control, the incidence of major malformations in infants of diabetic mothers stands between 6% and 10% in most series. Maternal hyperglycemia-induced fetal hyperinsulinemia results in increased body fat, muscle mass, and organomegaly *(fetal macrosomia)*; cardiac anomalies, neural tube defects, and other central nervous system malformations are some of the major anomalies seen in *diabetic embryopathy*.

Multifactorial Causes

In contrast to monogenic disorders like achondroplasia, which are caused by functional perturbation of a single gene, congenital anomalies with a multifactorial basis arise as a result of inheritance of multiple genetic polymorphisms that confer a “susceptibility phenotype.” The interaction of this underlying phenotype with the environment is then required before the disorder becomes manifest. In the case of congenital dislocation of the hip, for example, a shallow acetabular socket and laxity of the supporting ligaments are believed to be genetically determined, whereas frank breech position in utero, with hips flexed and knees extended is a key environmental factor. Such complex gene-environment interactions might explain why the monozygotic concordance rate for some common congenital anomalies like cleft lip or cleft palate is only in the range of 25% to 50%. The importance of environmental contribution to multifactorial inheritance is further underscored by a marked reduction in the incidence of neural tube defects by periconceptional intake of folic acid in the diet.[7]

The estimated frequency of some common birth defects in the United States is presented in Table 10-3 .

PATHOGENESIS OF CONGENITAL ANOMALIES

The pathogenesis of congenital anomalies is complex and still poorly understood, but two general principles of developmental pathology are relevant regardless of the etiologic agent.

1. *The timing of the prenatal teratogenic insult has an important impact on the occurrence and the type of anomaly produced* (Fig. 10-5). The intrauterine development of humans can be divided into two phases: (1) the embryonic period occupying the first 9 weeks of pregnancy and (2) the fetal period terminating at birth.
    - In the *early embryonic period* (first 3 weeks after fertilization), an injurious agent damages either enough cells to cause death and abortion or only a few cells, presumably allowing the embryo to recover without developing defects. *Between the third and the ninth weeks, the embryo is extremely susceptible to teratogenesis*, and the peak sensitivity during this period occurs between the fourth and the fifth weeks. During this period organs are being crafted out of the germ cell layers.
    - The *fetal period* that follows organogenesis is marked chiefly by the further growth and maturation of the organs, with greatly reduced susceptibility to teratogenic agents. Instead, the fetus is susceptible to growth retardation or injury to already formed organs. It is therefore possible for a given agent to produce different anomalies if exposure occurs at different times of gestation.

2. The complex interplay between environmental teratogens and intrinsic genetic defects is underscored by the fact that features of dysmorphogenesis caused by environmental insults can often be recapitulated by genetic defects in the pathways targeted by these teratogens. This is illustrated by the following representative examples.
    - *Cyclopamine* is a teratogen derived from the roots of the plant *Veratrum californicum* (California lily). Pregnant ewes who feed on this plant give birth to lambs that have severe craniofacial abnormalities including holoprosencephaly and “cyclopia” (single fused eye, hence the origin of the moniker cyclopamine). This compound is a potent inhibitor of Hedgehog signaling in the embryo, and as stated above, mutations of Hedgehog genes are present in subsets of patients with holoprosencephaly.
    - *Valproic acid* is an anti-epileptic and a recognized teratogen during pregnancy. Valproic acid disrupts expression of a family of highly conserved developmentally critical transcription factors known as *homeobox* (*HOX*) proteins.[8] The genes encoding HOX proteins have a 180-nucleotide motif, dubbed the homeobox, which binds DNA in a sequence-specific fashion. In vertebrates, HOX proteins have been implicated in the patterning of limbs, vertebrae, and craniofacial structures. Not surprisingly, mutations in HOX family genes are responsible for congenital anomalies that mimic features observed in *valproic acid embryopathy*.
    - The vitamin A (retinol) derivative *all-trans-retinoic acid* is essential for normal development and differentiation, and its *absence* during embryogenesis results in a constellation of malformations affecting multiple organ systems, including the eyes, genitourinary system, cardiovascular system, diaphragm, and lungs (see Chapter 9 for vitamin A deficiency in the postnatal period). Conversely, *excessive exposure to retinoic acid is also teratogenic*. Infants born to mothers treated with retinoic acid for severe acne have a predictable phenotype *(retinoic acid embryopathy)*, including central nervous system, cardiac, and craniofacial defects, such as *cleft lip and cleft palate*. The latter may stem from retinoic acid–mediated deregulation of components of the transforming growth factor-β (TGF-β) signaling pathway, which is involved in palatogenesis. Mice with knockout of the *Tgfb3* gene uniformly develop cleft palate,[9] once again underscoring the functional relationship between teratogenic exposure and signaling pathways in the causation of congenital anomalies.

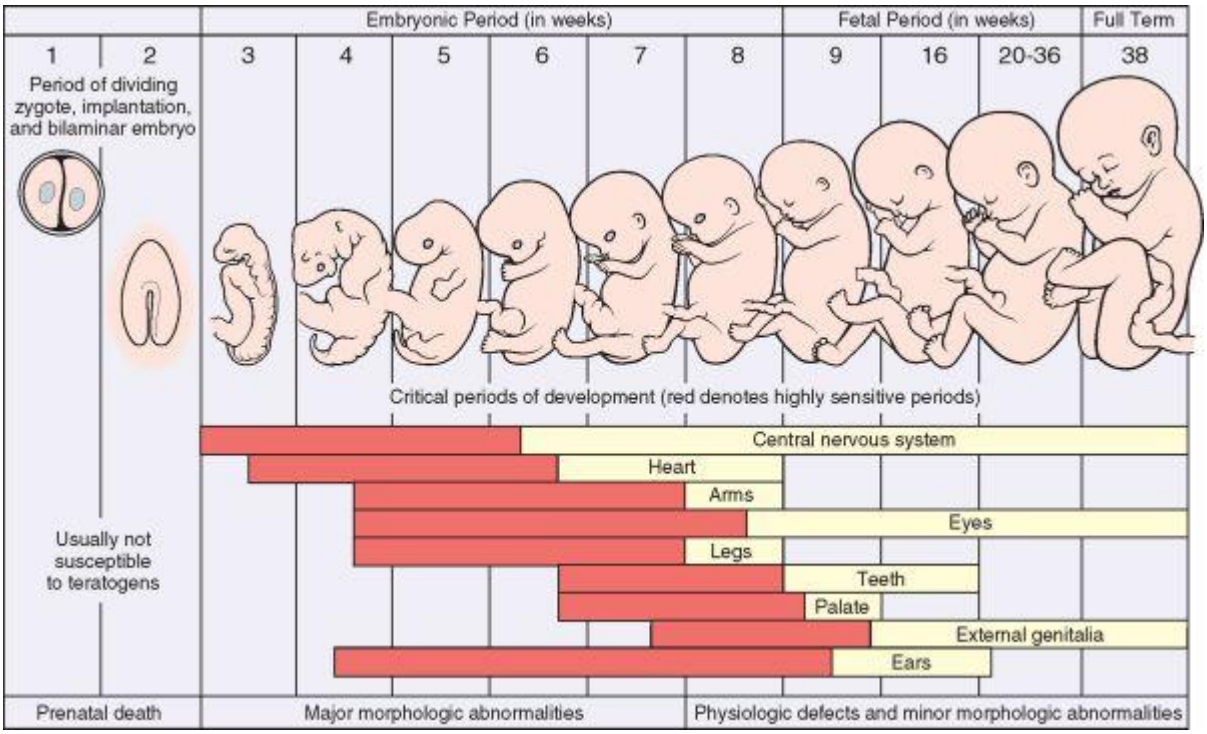

FIGURE 10-5 Critical periods of development for various organ systems and the resultant malformations. *(Modified and redrawn from Moore KL: The Developing Human, 5th ed. Philadelphia, WB Saunders, 1993, p 156.)*

2.10.2 Disorders of Prematurity

Infants born before completion of the normal gestation period or who have failed to grow normally during gestation have higher morbidity and mortality rates than full-term infants. For example, an infant weighing 2300 gm and born at 34 weeks of gestation is likely to be physiologically immature and therefore at greater riskfor suffering the consequences of organ system immaturity (e.g., respiratory distress syndrome [RDS] or transient hyperbilirubinemia) than a full-term infant also weighing 2300 gm but with corresponding functional maturity of most organ systems. Therefore, a system of classification that takes into account *both birth weight and gestational age* has been adopted. Based on birth weight, infants are classified as being

- *Appropriate for gestational age (AGA)*
- *Small for gestational age (SGA)*
- *Large for gestational age (LGA)*

Infants whose birth weight falls between the 10th and the 90th percentiles for a given gestational age are considered AGA, whereas those who fall above or below these norms are classified as LGA or SGA, respectively. With respect to gestational age, infants born before 37 weeks are considered *preterm*, whereas those delivered after the forty-second week are considered *post-term*. Such a classification is useful in risk stratification. For example, an AGA 1500-gm infant born at 32 weeks' gestation has a much lower mortality risk than an SGA, 700-gm infant born at a similar gestational age. We briefly discuss the subgroups of infants who are SGA and/or preterm, since they account for a significant proportion of perinatal mortality.

CAUSES OF PREMATURITY AND FETAL GROWTH RESTRICTION

Prematurity, defined by a gestational age less than 37 weeks, is the second most common cause of neonatal mortality, behind only congenital anomalies. The American College of Obstetrics and Gynecology (ACOG) estimates that 12% of all births in the United States are preterm deliveries, and despite extensive research into this area, this rate has increased over the last two decades.[10] The major risk factors for prematurity include:

- *Preterm premature rupture of placental membranes* (PPROM): PPROM complicates about 3% of all pregnancies and is responsible for as many as a third of all preterm deliveries. Rupture of membranes (ROM) before the onset of labor can be spontaneous or induced. PPROM refers to spontaneous ROM occurring *before* 37 weeks' gestation (hence the annotation “preterm”). In contrast, PROM refers to spontaneous ROM occurring *after* 37 weeks' gestation. This distinction is important because after 37 weeks the associated risk to the fetus is considerably decreased. Several clinical risk factors have been identified for PPROM, including a prior history of preterm delivery, preterm labor and/or vaginal bleeding during the current pregnancy, maternal smoking, low socioeconomic status, and poor maternal nutrition. Polymorphisms in genes associated with immune regulation (e.g., tumor necrosis factor [TNF]) or collagen breakdown (e.g., matrix metalloproteinases 1, 8, and 9) have been identified as possible risk factors for PPROM association.[11] These findings are not unexpected, because the pathophysiology of PPROM typically includes inflammation of placental membranes and enhanced collagen degradation by matrix metalloproteinases. The fetal and maternal outcome after PPROM depends on the gestation age of the fetus (second-trimester PPROM has a dismal prognosis), and the effective prophylaxis of infections in the exposed amniotic cavity.
- *Intrauterine infection:* This is a major cause of preterm labor with and without intact membranes. Intrauterine infection is present in approximately 25% of all preterm births, and the earlier the gestational age at delivery, the higher the frequency of intra-amniotic infection. The histologic correlates of intrauterine infection are inflammation of the placental membranes *(chorioamnionitis)* and inflammation of the fetal umbilical cord *(funisitis)*. The most common microorganisms implicated in intrauterine infections leading to preterm labor are *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Gardnerella vaginalis* (the dominant organism found in “bacterial vaginosis,” a polymicrobial infection), *Trichomonas*, *gonorrhea*, and *Chlamydia*. In developing countries, malaria and HIV are significant contributors to the burden of preterm labor and prematurity. Recent studies have begun to elucidate the molecular mechanisms of inflammation-induced preterm labor, and endogenous Toll-like receptors (TLRs), which bind bacterial components as natural ligands (see Chapter 6), have emerged as key players in this process. Specifically, experiments performed in mouse models have implicated TLR-4 activation by bacterial lipopolysaccharide as one of the initiating events in inflammation-induced preterm labor.[12] TLR-4 expression is also upregulated in preterm human placentas complicated by chorioamnionitis. It is postulated that signals produced by TLR-4 deregulate prostaglandin expression, which in turn induces uterine smooth muscle contractions.
- *Uterine, cervical, and placental structural abnormalities:* Uterine distortion (e.g., uterine fibroids), compromised structural support of the cervix (“cervical incompetence”), *placenta previa*, and *abruptio placentae* (Chapter 22) are associated with an increased risk of prematurity.
- *Multiple gestation* (twin pregnancy).

The hazards of prematurity are manifold for the newborn and include one or more of the entities listed below:

- Hyaline membrane disease (Neonatal respiratory distress syndrome)
- Necrotizing enterocolitis
- Sepsis
- Intraventricular hemorrhage
- Long-term complications, including developmental delay.

Although preterm infants have low birth weights, it is often appropriate once adjusted for their gestational age. In contrast, at least one third of infants who weigh less than 2500 gm are born at term and therefore are undergrown rather than immature. Hence, fetal growth restriction (FGR) commonly

underlies SGA. FGR has also been called intrauterine growth retardation; however, the term *FGR* probably better reflects the pathophysiology of this disorder.[13] FGR can be detected before delivery by ultrasonographic measurement of various fetal dimensions, such as biparietal diameter, head circumference, abdominal circumference, femur length (as an indicator of fetal length), head-to-abdominal circumference ratio, femur length–to–abdominal circumference ratio, and total intrauterine volume. Influences known to result in FGR can be divided into three main groups: fetal, placental, and maternal.

Fetal.

Fetal influences are those that intrinsically reduce growth potential of the fetus despite an adequate supply of nutrients from the mother. Prominent among such fetal conditions are *chromosomal disorders, congenital anomalies, and congenital infections*. Chromosomal abnormalities may be detected in up to 17% of fetuses sampled for FGR and in up to 66% of fetuses with documented ultrasonographic malformations. Among the first group, the abnormalities include triploidy (7%), trisomy 18 (6%), trisomy 21 (1%), trisomy 13 (1%), and a variety of deletions and translocations (2%). *Fetal infection* should be considered in all infants with FGR. Those most commonly responsible for FGR are the TORCH group of infections (toxoplasmosis, rubella, cytomegalovirus, herpesvirus, and other viruses and bacteria, such as syphilis). Infants who are SGA because of fetal factors are usually characterized by symmetric growth restriction (also referred to as *proportionate FGR*), meaning that all organ systems are similarly affected.

Placental.

During the third trimester of pregnancy, vigorous fetal growth places particularly heavy demands on the uteroplacental supply line. Therefore, the adequacy of placental growth in the preceding midtrimester is extremely important, and *uteroplacental insufficiency is an important cause of growth restriction*. This insufficiency may result from *umbilical-placental vascular anomalies* (such as single umbilical artery, abnormal cord insertion, placental hemangioma), *placental abruption, placenta previa, placental thrombosis and infarction, placental infection*, or *multiple gestations* (Chapter 22). In some cases the placenta may be small without any detectable underlying cause. Placental causes of FGR tend to result in *asymmetric* (or disproportionate) growth retardation of the fetus with relative sparing of the brain. Physiologically, this general type of FGR is viewed as a down-regulation of growth in the latter half of gestation because of limited availability of nutrients or oxygen.

Genetic mosaicism confined to the placenta (confined placental mosaicism) is a more recently discovered cause of FGR and has been documented in up to 15% of pregnancies with FGR.[14] Chromosomal mosaicism, in general, results from viable genetic mutations occurring after zygote formation. Depending on the developmental timing and cell of origin of the mutation, different forms of chromosomal mosaicism result. For example, genetic mutations occurring at the time of the first or second postzygotic division result in generalized constitutional mosaicism of the fetus and placenta. Conversely, if the mutation occurs later and within dividing trophoblast or extraembryonic progenitor cells of the inner cell mass (approximately 90% of the time), a genetic abnormality limited to the placenta results—confined placental mosaicism (Fig. 10-6). The phenotypic consequences of such placental mosaicism depend on both the specific cytogenetic abnormality and the percentage of cells involved. Chromosomal trisomies, in particular trisomy 7, are the abnormality most frequently documented.

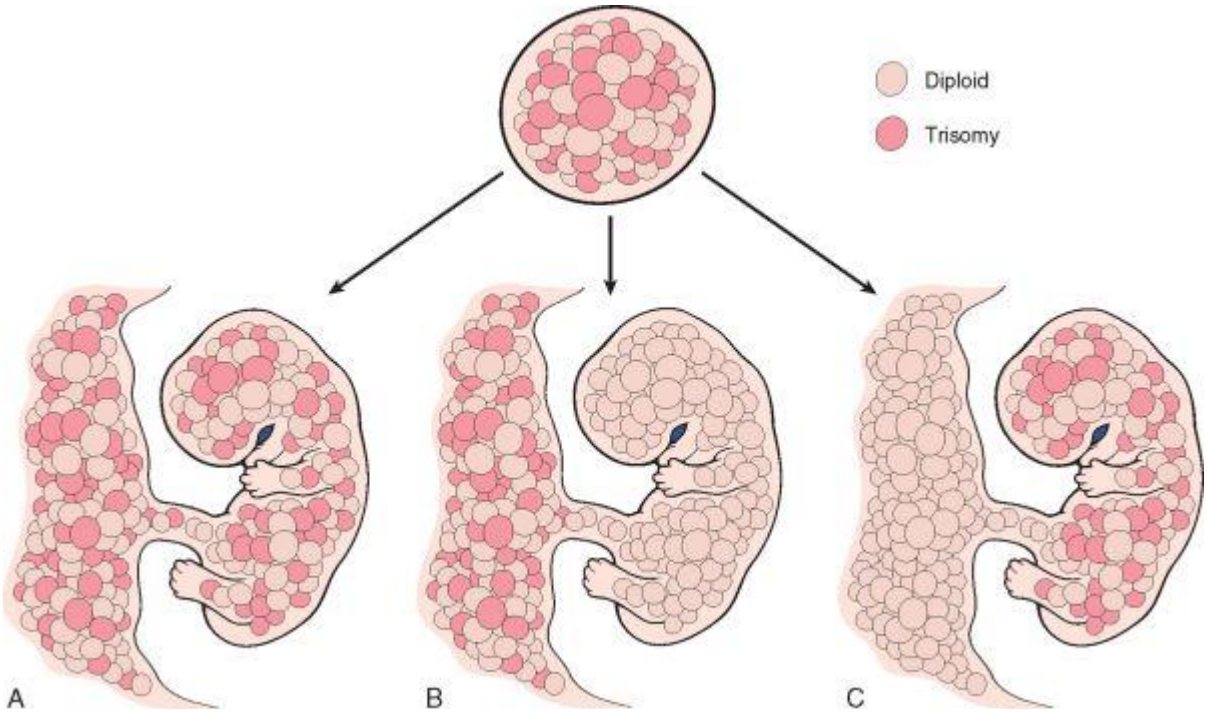

FIGURE 10-6 Diagrammatic representation of constitutional chromosomal mosaicism. **A**, Generalized. **B**, Confined to the placenta. **C**, Confined to the embryo. See text for details. See text for details. *(Modified and redrawn from Kalousek DK: Confined placental mosaicism and intrauterine development. Pediatr Pathol 10:69, 1990.)*

Maternal.

By far the most common factors associated with SGA infants are maternal conditions that result in decreased placental blood flow. Vascular diseases, such as *preeclampsia (toxemia of pregnancy)* and *chronic hypertension*, are often the underlying cause. Another class of maternal diseases increasingly being recognized in the setting of FGR is *inherited thrombophilias*, such as the factor V Leiden mutation (Chapter 4).[15] Inherited diseases of hypercoagulability are also associated with recurrent early pregnancy losses. The list of other maternal conditions associated with SGA infants is long, but some of the avoidable factors worth mentioning are maternal *narcotic abuse*, *alcohol intake*, and *heavy cigarette smoking. Drugs* causing FGR include both classic teratogens, such as antimetabolites, and some commonly administered therapeutic agents, such as phenytoin (Dilantin). *Maternal malnutrition* (in particular, prolonged hypoglycemia) may also affect fetal growth, but the association between SGA infants and the nutritional status of the mother is complex.

The SGA infant faces a difficult course, not only during the struggle for survival in the perinatal period, but also in childhood and adult life. Depending on the underlying cause of FGR and, to a lesser extent, the degree of prematurity, there is a significant risk of morbidity in the form of a major handicap, cerebral dysfunction, learning disability, or hearing and visual impairment.

Neonatal Respiratory Distress Syndrome (RDS)

There are many causes of respiratory distress in the newborn, including excessive sedation of the mother, fetal head injury during delivery, aspiration of blood or amniotic fluid, and intrauterine hypoxia brought about by coiling of the umbilical cord about the neck. The most common cause, however, is

RDS, also known as *hyaline membrane disease* because of the deposition of a layer of hyaline proteinacecous material in the peripheral airspaces of infants who succumb to this condition. An estimated 24,000 cases of RDS are reported annually in the United States, and improvements in management of this condition have sharply decreased deaths due to respiratory insufficiency from as many as 5000 per year a decade earlier to less than 900 cases.[16]

In untreated infants (not receiving surfactant), RDS generally presents in a stereotyped fashion, with characteristic clinical findings. The infant is almost always *preterm* and AGA, and there are strong, but not invariable, associations with *male gender*, *maternal diabetes*, and delivery by *cesarean section*. Resuscitation may be necessary at birth, but usually within a few minutes rhythmic breathing and normal color are re-established. Soon afterward, often within 30 minutes, breathing becomes more difficult, and within a few hours cyanosis becomes evident. Fine rales can now be heard over both lung fields. A chest x-ray film at this time usually reveals uniform minute reticulogranular densities, producing a so-called *ground-glass picture*. In the full-blown condition the respiratory distress persists, cyanosis increases, and even the administration of 80% oxygen by a variety of ventilatory methods fails to improve the situation. If therapy staves off death for the first 3 or 4 days, however, the infant has an excellent chance of recovery.

Etiology and Pathogenesis.

Immaturity of the lungs is the most important substrate on which this condition develops. It may be encountered in full-term infants but is much less frequent than in those "born before their time into this breathing world." The incidence of RDS is inversely proportional to gestational age. It occurs in about 60% of infants born at less than 28 weeks of gestation, 30% of those born between 28 to 34 weeks' gestation, and less than 5% of those born after 34 weeks' gestation.

The *fundamental defect in RDS is a deficiency of pulmonary surfactant*. As described in Chapter 15 , surfactant consists predominantly of dipalmitoyl phosphatidylcholine (lecithin), smaller amounts of phosphatidylglycerol, and two groups of surfactant-associated proteins. The first group is composed of hydrophilic glycoproteins SP-A and SP-D, which play a role in pulmonary host defense (innate immunity). The second group consists of hydrophobic surfactant proteins SP-B and SP-C, which, in concert with the surfactant lipids, are involved in the reduction of surface tension at the air-liquid barrier in the alveoli of the lung. With reduced surface tension in the alveoli, less pressure is required to keep them patent and hence aerated. The importance of surfactant proteins in normal lung function can be gauged by the occurrence of severe respiratory failure in neonates with congenital deficiency of surfactant caused by mutations in the *SFTPB* or *SFTBC* genes.[17]

Surfactant production by type II alveolar cells is accelerated after the thirty-fifth week of gestation in the fetus. At birth, the first breath of life requires high inspiratory pressures to expand the lungs. With normal levels of surfactant, the lungs retain up to 40% of the residual air volume after the first breath; thus, subsequent breaths require far lower inspiratory pressures. With a deficiency of surfactant, the lungs collapse with each successive breath, and so infants must work as hard with each successive breath as they did with the first. The problem of *stiff* atelectatic lungs is compounded by the *soft* thoracic wall that is pulled in as the diaphragm descends. Progressive atelectasis and reduced lung compliance then lead to a train of events as depicted in Figure 10-7 , resulting in a protein-rich, fibrin-rich exudation into the alveolar spaces with the formation of hyaline membranes. The fibrin-hyaline membranes constitute barriers to gas exchange, leading to carbon dioxide retention and hypoxemia. The hypoxemia itself further impairs surfactant synthesis, and a vicious cycle ensues.

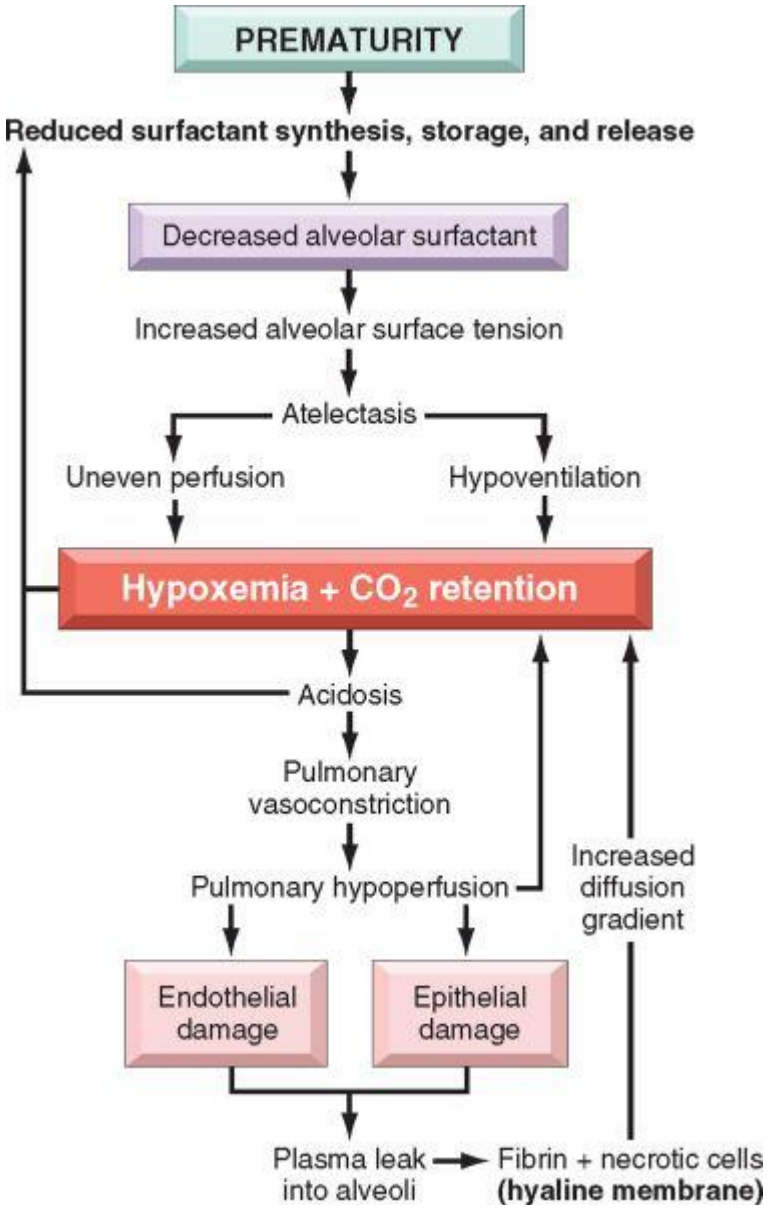

FIGURE 10-7 Schematic outline of the pathophysiology of respiratory distress syndrome (see text).

Surfactant synthesis is modulated by a variety of hormones and growth factors, including cortisol, insulin, prolactin, thyroxine, and TGF-β. *The role of glucocorticoids is particularly important*. Conditions associated with intrauterine stress and FGR that increase corticosteroid release lower the risk of developing RDS. Surfactant synthesis can be suppressed by the compensatory high blood levels of insulin in infants of diabetic mothers, which counteracts the effects of steroids. This may explain, in part, why infants of diabetic mothers have a higher risk of developing RDS. Labor is known to increase surfactant synthesis; hence, cesarean section before the onset of labor may increase the risk of RDS.

Morphology. The lungs are distinctive on gross examination. Though of normal size, they are solid, airless, and reddish purple, similar to the color of the liver, and they usually sink in water.

Microscopically, alveoli are poorly developed, and those that are present are collapsed (Fig. 10-8). When the infant dies early in the course of the disease, necrotic cellular debris can be seen in the terminal bronchioles and alveolar ducts. The necrotic material becomes incorporated within eosinophilic hyaline membranes lining the respiratory bronchioles, alveolar ducts, and random alveoli. The membranes are largely made up of fibrin admixed with cell debris derived chiefly from necrotic type II pneumocytes. The sequence of events that leads to the formation of hyaline membranes is depicted in Figure 10-7 . There is a remarkable paucity of neutrophilic inflammatory reaction associated with these membranes. The lesions of hyaline membrane disease are never seen in stillborn infants.

In infants who survive more than 48 hours, reparative changes occur in the lungs. The alveolar epithelium proliferates under the surface of the membrane, which may be desquamated into the airspace, where it may undergo partial digestion or phagocytosis by macrophages.

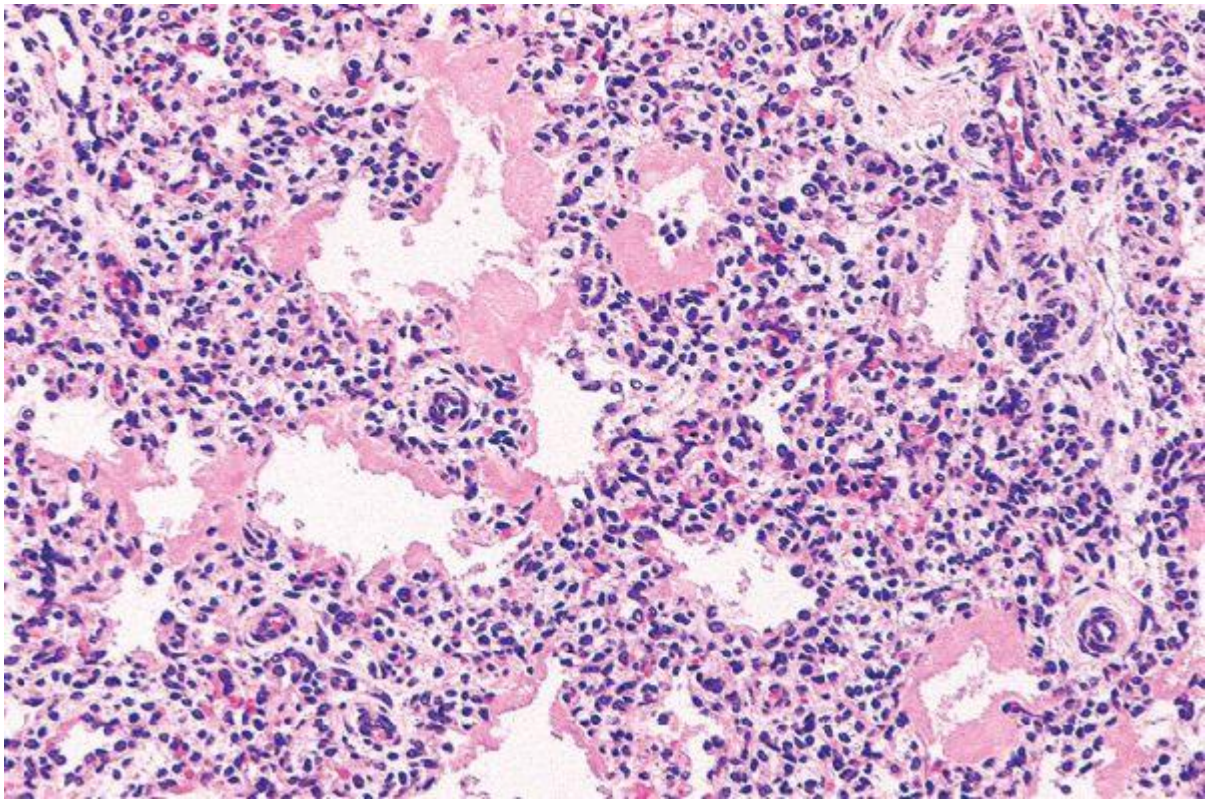

FIGURE 10-8 Hyaline membrane disease. There is alternating atelectasis and dilation of the alveoli. Note the eosinophilic thick hyaline membranes lining the dilated alveoli.

Clinical Course.

Although a classic clinical presentation before the era of treatment with exogenous surfactant was described earlier, the actual clinical course and prognosis for neonatal RDS vary, dependent on the maturity and birth weight of the infant and the promptness of institution of therapy. A major thrust in the control of RDS focuses on prevention, either by delaying labor until the fetal lung reaches maturity or by inducing maturation of the lung in the fetus at risk. Critical to these objectives is the ability to assess fetal lung maturity accurately. Because pulmonary secretions are discharged into the amniotic fluid, analysis of amniotic fluid phospholipids provides a good estimate of the level of surfactant in the

alveolar lining. Prophylactic administration of exogenous surfactant at birth to extremely premature infants (gestational age ~26 to 28 weeks) and administration of surfactant to older premature infants who are symptomatic have been shown to be extremely beneficial, such that it is now uncommon for infants to die of acute RDS. In addition, antenatal corticosteroids decrease neonatal morbidity and mortality when administered to mothers with threatened premature delivery at 24 to 34 weeks' gestation. Once the infant is born, the cornerstone of treatment is the delivery of surfactant replacement therapy and oxygen, usually accomplished by a variety of ventilatory assistance methods, including high-frequency ventilation.

In uncomplicated cases, recovery begins to occur within 3 or 4 days. Therapy, however, carries with it the now well-recognized hazard of *oxygen toxicity*, caused by oxygen-derived free radicals. High concentrations of oxygen administered for prolonged periods cause two well-known complications: *retrolental fibroplasia* (also called *retinopathy of prematurity*) *in the eyes* (Chapter 29) and *bronchopulmonary dysplasia*. The retinopathy has been ascribed to changes in expression of vascular endothelial growth factor (VEGF), which is strongly induced by hypoxia, and also serves as a survival factor for endothelial cells and promotes angiogenesis (Chapter 3).[18] During the initial *hyperoxic* phase of RDS therapy (phase I), VEGF is markedly decreased, causing endothelial cell apoptosis; VEGF increases after return to relatively hypoxic room air ventilation, inducing the retinal vessel proliferation *(neovascularization)* characteristic of the lesions in the retina (phase II).

Bronchopulmonary dysplasia (BPD), originally described in 1967, is now infrequent in infants of more than 1200 gm birth weight or with gestations exceeding 30 weeks. Gentler ventilation techniques, antenatal glucocorticoid therapy, and surfactant treatments have minimized severe lung injury in larger and more mature infants. The definition of BPD has evolved in recent years to reflect these trends, and at least 28 days of oxygen therapy in an infant who is beyond 36 weeks' post-menstrual age is required to render a diagnosis of BPD.[19] The original histopathologic descriptions of BPD reported airway epithelial hyperplasia and squamous metaplasia, alveolar wall thickening, and peribronchial as well as interstitial fibrosis. The major abnormalities in “new” BPD are a striking decrease in alveolar septation (manifested as large, simplified alveolar structures) and a dysmorphic capillary configuration. Thus, the current view is that BPD is caused by a potentially reversible impairment in the development of alveolar septation at the saccular stage.

Multiple factors—hyperoxemia, hyperventilation, prematurity, inflammatory cytokines, and vascular maldevelopment—contribute to BPD and probably act additively or synergistically to promote injury.[20] Oxygen alone can arrest septation of lungs that are in the saccular stage of development, with infants receiving higher levels of supplemental oxygen having more persistent lung disease. Mechanical ventilation of preterm animals without simultaneous exposure to high levels of supplemental oxygen also results in the pathologic lesion of BPD. The levels of a variety of pro-inflammatory cytokines (TNF, interleukin-1β [IL-1β], IL-6, and IL-8) are increased in the alveoli of infants who develop BPD, and their deregulation in animal models can impair alveolar septation, suggesting a role for these cytokines in arresting pulmonary development.[21] Recent studies in experimental models of lung development have also elucidated the requirement of appropriate vascularization within the pulmonary mesenchyme for allowing branching morphogenesis of the epithelium. In corroboration, infants who succumb to BPD often demonstrate dysmorphic capillaries and reduced levels of the angiogenic growth factor, VEGF.[22]

If oxygen toxicity is avoided, as is usually the case, and the infant can be kept alive for about 3 or 4 days, recovery of infants of 31 weeks' gestation or more can be anticipated without permanent sequelae. Infants who recover from RDS are at increased risk for developing a variety of other complications associated with preterm birth; most important among these are *patent ductus arteriosus, intraventricular hemorrhage*, and *necrotizing enterocolitis*. Thus, although current high technology saves many infants with RDS, it also brings to the surface the exquisite fragility of the immature neonate.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is most common in premature infants, with the incidence of the disease being inversely proportional to the gestational age. It occurs in approximately 1 out of 10 very low birth weight infants (<1500 gm). Approximately 2500 cases occur annually in the United States.

The pathogenesis of NEC is uncertain, but is in all likelihood multifactorial. In addition to *prematurity*, most cases are associated with *enteral feeding*, suggesting that some postnatal insult (such as introduction of bacteria) sets in motion the cascade culminating in tissue destruction. While *infectious agents* likely play a role in NEC pathogenesis, no single bacterial pathogen has been linked to the disease. A large number of *inflammatory mediators* have been associated with NEC, and their discussion is beyond the scope of this book. One particular mediator, platelet activating factor (PAF), has been implicated in increasing mucosal permeability by promoting enterocyte apoptosis and compromising intercellular tight junctions, thus adding "fuel to the fire."[23] Stool and serum samples of infants with NEC demonstrate higher PAF levels than age-matched controls. Ultimately, breakdown of mucosal barrier functions permits transluminal migration of gut bacteria, leading to a vicious cycle of inflammation, mucosal necrosis, and further bacterial entry, eventually culminating in sepsis and shock (Chapter 4).

The clinical course is fairly typical, with the onset of bloody stools, abdominal distention, and development of circulatory collapse. Abdominal radiographs often demonstrate gas within the intestinal wall *(pneumatosis intestinalis)*. NEC typically involves the terminal ileum, cecum, and right colon, although any part of the small or large intestines may be involved. The involved segment is distended, friable, and congested, or it can be frankly gangrenous; intestinal perforation with accompanying peritonitis may be seen. Microscopically, mucosal or transmural coagulative necrosis, ulceration, bacterial colonization, and submucosal gas bubbles may be seen (Fig. 10-9). Reparative changes, such as the formation of granulation tissue and fibrosis, may begin shortly after the acute episode. When detected early on, NEC can be often managed conservatively, but many cases (20% to 60%) require resection of the necrotic segments of bowel. NEC is associated with high perinatal mortality; those who survive often develop *post-NEC strictures* from fibrosis caused by the healing process.

FIGURE 10-9 Necrotizing enterocolitis (NEC). **A**, Postmortem examination in a severe case of NEC shows the entire small bowel is markedly distended with a perilously thin wall (usually this implies impending perforation). **B**, The congested portion of the ileum corresponds

to areas of hemorrhagic infarction and transmural necrosis microscopically. Submucosal gas bubbles *(pneumatosis intestinalis)* can be seen in several areas *(arrows)*.

2.10.3 Perinatal Infections

Infections of the embryo, fetus, and neonate are manifested in a variety of ways and are mentioned as etiologic factors in numerous other sections within this chapter. In general, fetal and perinatal infections are acquired through one of two primary routes—*transcervically* (also referred to as *ascending*) or *transplacentally (hematologic)*. Occasionally, infections occur by a combination of the two routes in that an ascending microorganism infects the endometrium and then the fetal bloodstream via the chorionic villi.

TRANSCERVICAL (ASCENDING) INFECTIONS

Most bacterial and a few viral (e.g., herpes simplex II) infections are acquired by the cervicovaginal route. Such infections may be acquired in utero or around the time of birth. In general the fetus acquires the infection either by inhaling infected amniotic fluid into the lungs shortly before birth or by passing through an infected birth canal during delivery. As stated before, preterm birth is often an unfortunate consequence and may be related either to damage and rupture of the amniotic sac as a direct consequence of the inflammation or to the induction of labor associated with a release of prostaglandins by the infiltrating neutrophils. Inflammation of the placental membranes and cord are usually demonstrable, although the presence or absence and severity of chorioamnionitis do not necessarily correlate with the severity of the fetal infection. In the fetus infected by inhalation of amniotic fluid, pneumonia, sepsis, and meningitis are the most common sequelae.

TRANSPLACENTAL (HEMATOLOGIC) INFECTIONS

Most parasitic (e.g., toxoplasma, malaria) and viral infections and a few bacterial infections (i.e., *Listeria*, *Treponema*) gain access to the fetal bloodstream transplacentally via the chorionic villi. This hematogenous transmission may occur at any time during gestation or occasionally, as may be the case with hepatitis B and HIV, at the time of delivery via maternal-to-fetal transfusion. The clinical manifestations of these infections are highly variable, depending largely on the gestational timing and microorganism involved.

Parvovirus B19, which causes *erythema infectiosum* or “fifth disease of childhood” in immunocompetent older children, can infect 1% to 5% of pregnant women, and the vast majorityhave a normal pregnancy outcome. Adverse pregnancy outcomes in a minority of intrauterine infections include spontaneous abortion (particularly in the second trimester), stillbirth, hydrops fetalis (see below), and congenital anemia. Parvovirus B19 has a particular tropism for erythroid cells, and diagnostic viral inclusions can be seen in early erythroid progenitor cells in infected infants (Fig. 10-10).

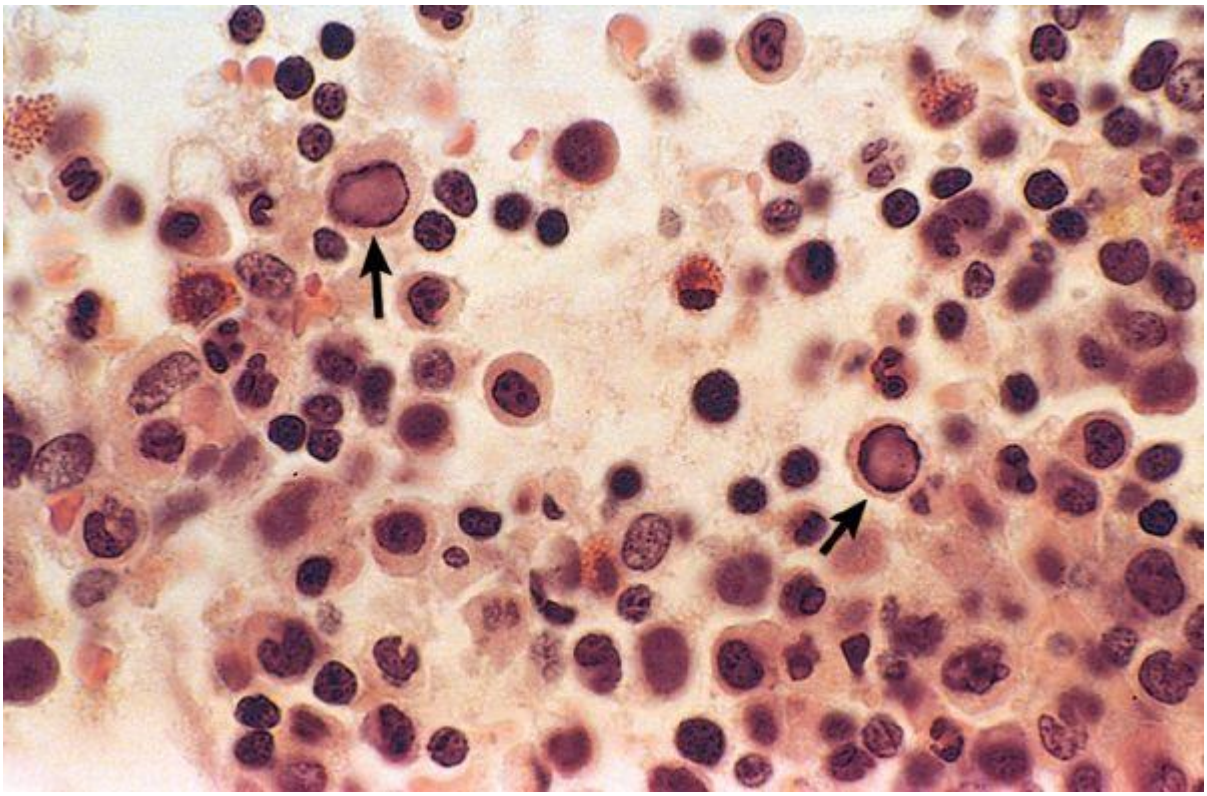

FIGURE 10-10 Bone marrow from an infant infected with parvovirus B19. The *arrows* indicate two erythroid precursors with large homogeneous intranuclear inclusions and a surrounding peripheral rim of residual chromatin.

The *TORCH group of infections* (see above) are grouped together because they may evoke similar clinical and pathologic manifestations, including *fever, encephalitis, chorioretinitis, hepatosplenomegaly, pneumonitis, myocarditis, hemolytic anemia, and vesicular or hemorrhagic skin lesions*. Such infections occurring early in gestation may also cause chronic sequelae in the child, including growth and mental retardation, cataracts, congenital cardiac anomalies, and bone defects.

SEPSIS

Perinatal sepsis can also be grouped clinically based on *early onset* (within the first 7 days of life) versus *late onset* (from 7 days to 3 months). Most cases of early-onset sepsis are acquired at or shortly before birth and tend to result in clinical signs and symptoms of pneumonia, sepsis, and occasionally meningitis within 4 or 5 days of life. Group B streptococcus is the most common organism isolated in early-onset sepsis and is also the most common cause of bacterial meningitis. Infections with *Listeria* and *Candida* follow a latent period between the time of microorganism inoculation and the appearance of clinical symptoms and present as late-onset sepsis.

2.10.4 Fetal Hydrops

Fetal hydrops refers to the accumulation of edema fluid in the fetus during intrauterine growth. Until recently, hemolytic anemia caused by Rh blood group incompatibility between mother and fetus *(immune hydrops)* was the most common cause, but with the successful prophylaxis of this disorder during pregnancy, causes of *nonimmune hydrops* have emerged as the principal culprits (Table 10-4). The intrauterine fluid accumulation can be quite variable, from progressive, generalized edema of the

fetus *(hydrops fetalis)*, a usually lethal condition, to more localized degrees of edema, such as isolated pleural and peritoneal effusions, or postnuchal fluid accumulation (*cystic hygroma*, see later) that are compatible with life.

TABLE 10-4 -- Selected Causes of Non-Immune Fetal Hydrops

CARDIOVASCULAR
Malformations
Tachyarrhythmia
High-output failure

Twin-to-twin transfusion
INFECTION (EXCLUDING PARVOVIRUS)
Cytomegalovirus
Syphilis
Toxoplasmosis
GENITOURINARY TRACT MALFORMATIONS
TUMORS
GENETIC/METABOLIC DISORDERS

IMMUNE HYDROPS

Immune hydrops is a hemolytic disease caused by blood group incompatibility between mother and fetus. When the fetus inherits red cell antigenic determinants from the father that are foreign to the mother, a maternal immune reaction may occur, leading to hemolytic disease (*in utero*). The major antigens known to induce clinically significant immunological disease are certain of the Rh antigens the ABO and blood groups. The incidence of immune hydrops in urban populations has declined remarkably, mostly as a result of the current methods of preventing Rh immunization in at-risk women. Successful prophylaxis of this disorder has resulted from an understanding of its pathogenesis.

Etiology and Pathogenesis.

The underlying basis of immune hydrops is the immunization of the mother by blood group antigens on fetal red cells and the free passage of antibodies from the mother through the placenta to the fetus (Fig. 10-11). Fetal red cells may reach the maternal circulation during the last trimester of pregnancy, when the cytotrophoblast is no longer present as a barrier, or during childbirth itself. The mother thus becomes sensitized to the foreign antigen.

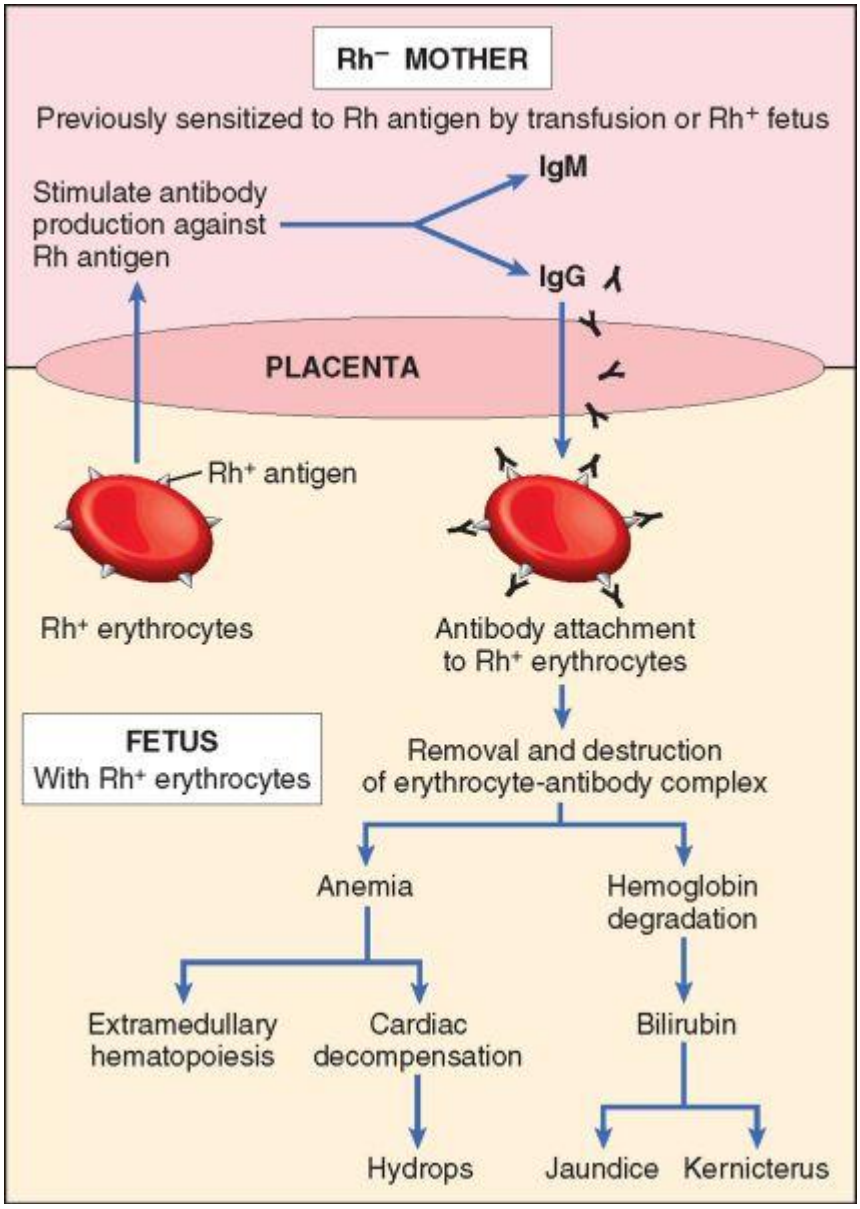

FIGURE 10-11 Pathogenesis of immune hydrops fetalis (see text).

Of the numerous antigens included in the Rh system, only the D antigen is a major cause of Rh incompatibility. Several factors influence the immune response to Rh-positive fetal red cells that reach the maternal circulation.

- Concurrent ABO incompatibility protects the mother against Rh immunization, because the fetal red cells are promptly coated and removed from the maternal circulation by anti-A or anti-B IgM antibodies that do not

cross the placenta.

- The antibody response depends on the dose of immunizing antigen; hence, hemolytic disease develops only when the mother has experienced a significant transplacental bleed (more than 1 mL of Rh-positive fetal red cells).
- The initial exposure to Rh antigen evokes the formation of IgM antibodies, so Rh disease is uncommon with the first pregnancy. Exposure during a subsequent pregnancy generally leads to a brisk IgG antibody response and the risk of immune hydrops.

The incidence of maternal Rh isoimmunization has decreased significantly since the use of Rhesus immune globulin (RhIg) containing anti-D antibodies. Administration of RhIg at 28 weeks and within 72 hours of delivery to Rhnegative mothers significantly decreases the risk for hemolytic disease in Rh-positive neonates and in subsequent pregnancies; RhIg is also administered following abortions, as thesetoo can lead to immunization. Antenatal identification and management of the at-risk fetus have been greatly facilitated by amniocentesis and the advent of chorionic villus and fetal blood sampling. In addition, cloning of the *RHD* gene has resulted in efforts to determine fetal Rh status using maternal blood. When identified, cases of severe intrauterine hemolysis may be treated by fetal intravascular transfusions via the umbilical cord and early delivery.

The pathogenesis of fetal hemolysis caused by maternal-fetal ABO incompatibility is slightly different from that caused by differences in the Rh antigens. ABO incompatibility occurs in approximately 20% to 25% of pregnancies, but laboratory evidence of hemolytic disease occurs in only 1 in 10 of such infants, and the hemolytic disease is severe enough to require treatment in only 1 in 200 cases. Several factors account for this. First, as mentioned, most anti-A and anti-B antibodies are of the IgM type and hence do not cross the placenta. Second, neonatal red cells express blood group antigens A and B poorly. Third, many cells other than red cells express A and B antigens and thus absorb some of the transferred antibody. ABO hemolytic disease occurs almost exclusively in infants of group A or B who are born of group O mothers. For reasons unknown, certain group O women possess IgG antibodies directed against group A or B antigens (or both) even without prior sensitization. Therefore, the firstborn may be affected. Fortunately, even with transplacentally acquired antibodies, lysis of the infant's red cells is minimal. There is no effective protection against ABO reactions.

There are two consequences of excessive destruction of red cells in the neonate (see Fig. 10-11). The severity of these changes varies considerably, depending on the degree of hemolysis and the maturity of the infant.

- *Anemia* is a direct result of red cell loss. If hemolysis is mild, extramedullary hematopoeisis in the spleen and liver may suffice to maintain normal levels of red cells. However, with more severe hemolysis, progressive anemia develops, and may result in hypoxic injury to the heart and liver. Because of liver injury, plasma protein synthesis decreases, and levels of these proteins may drop to as low as 2 to 2.5 mg/dL. Cardiac hypoxia may lead to cardiac decompensation and failure. *The combination of reduced plasma oncotic pressure and increased hydrostatic pressure in the circulation (secondary to cardiac failure) results in generalized edema and anasarca, culminating in hydrops fetalis*.
- *Jaundice* develops because hemolysis produces unconjugated bilirubin (Chapter 18). Bilirubin also passes through the infant's poorly developed blood-brain barrier. Being water insoluble, it blinds to lipids in the brain, resulting in demage to the central nervous system, termed *kernicterus* (Fig. 10-14).

FIGURE 10-14 Kernicterus. Note the yellow discoloration of the brain parenchyma due to bilirubin accumulation, which is most prominent in the basal ganglia deep to the ventricles.

NONIMMUNE HYDROPS

The three major causes of nonimmune hydrops include *cardiovascular defects, chromosomal anomalies*, and *fetal anemia* (Table 10-4).[24] Both structural and functional cardiovascular defects, such as congenital cardiac defects and arrhythmias, may result in intrauterine cardiac failure and hydrops. Among the chromosomal anomalies, 45,X karyotype (Turner syndrome) and the trisomies 21 and 18 are associated with fetal hydrops. Most often, underlying structural cardiac anomalies associated with the chromosomal aberrations form the basis of fetal hydrops. In the Turner phenotype, however, abnormalities of lymphatic drainage from the neck may lead to postnuchal fluid accumulation *(cystic hygromas)*. Fetal anemia, not caused by Rh- or ABO-associated antibodies, also results in hydrops. In fact, in some parts of the world (e.g., Southeast Asia), severe fetal anemia due to homozygous α-thalassemia is probably the most common cause of nonimmune hydrops. Transplacental infection by parvovirus B19 is rapidly emerging as an important cause of hydrops (see above). The virus gains preferential entry into erythroid precursors (normoblasts), where it replicates, leading to apoptosis of red

cell progenitors and isolated red cell aplasia. Parvoviral intranuclear inclusions can be seen within circulating and marrow erythroid precursors (see Fig. 10-10). Approximately 10% of cases of nonimmune hydrops are related to monozygous twin pregnancies and twin-to-twin transfusion occurring through anastomoses between the two circulations.

Morphology of Hydrops Fetalis. The anatomic findings in fetuses with intrauterine fluid accumulation vary with both the severity of the disease and the underlying etiology. As previously noted, hydropsfetalis represents the most severe and generalized manifestation (Fig. 10-12), and lesser degrees of edema such as isolated pleural, peritoneal, or postnuchal fluid collections can occur. Accordingly, infants may be stillborn, die within the first few days, or recover completely. The presence of dysmorphic features suggests a chromosomal abnormality; postmortem examination may reveal an underlying cardiac anomaly.

In hydrops associated with fetal anemia, both fetus and placenta are characteristically pale; in most cases the liver and spleen are enlarged from cardiac failure and congestion. Additionally, the bone marrow demonstrates compensatory hyperplasia of erythroid precursors (parvovirus-associated red cell aplasia being a notable exception), and extramedullary hematopoiesis is present in the liver, spleen, and lymph nodes, and possibly other tissues such as the kidneys, lungs, and even the heart. The increased hematopoietic activity accounts for the presence in the peripheral circulation of large numbers of immature red cells, including reticulocytes, normoblasts, and erythroblasts **(erythroblastosis fetalis)** (Fig. 10-13).

The most serious threat in fetal hydrops is central nervous system damage known as **"kernicterus"** (Fig. 10-14). The affected brain is enlarged and edematous and, when sectioned, has a bright yellow color, particularly the basal ganglia, thalamus, cerebellum, cerebral gray matter, and spinal cord. The precise level of bilirubin that induces kernicterus is unpredictable, but neural damage usually requires a blood bilirubin level greater than 20 mg/dL in term infants; in premature infants this threshold may be considerably lower.

FIGURE 10-12 Hydrops fetalis. **A**, There is generalized accumulation of fluid in the fetus. ***B,*** Fluid accumulation is particularly prominent in the soft tissues of the neck, and this condition has been termed *cystic hygroma*. Cystic hygromas are characteristically seen, but not limited to, constitutional chromosomal anomalies such as 45,X0 karyotypes. *(Courtesy of Dr. Beverly Rogers, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)*

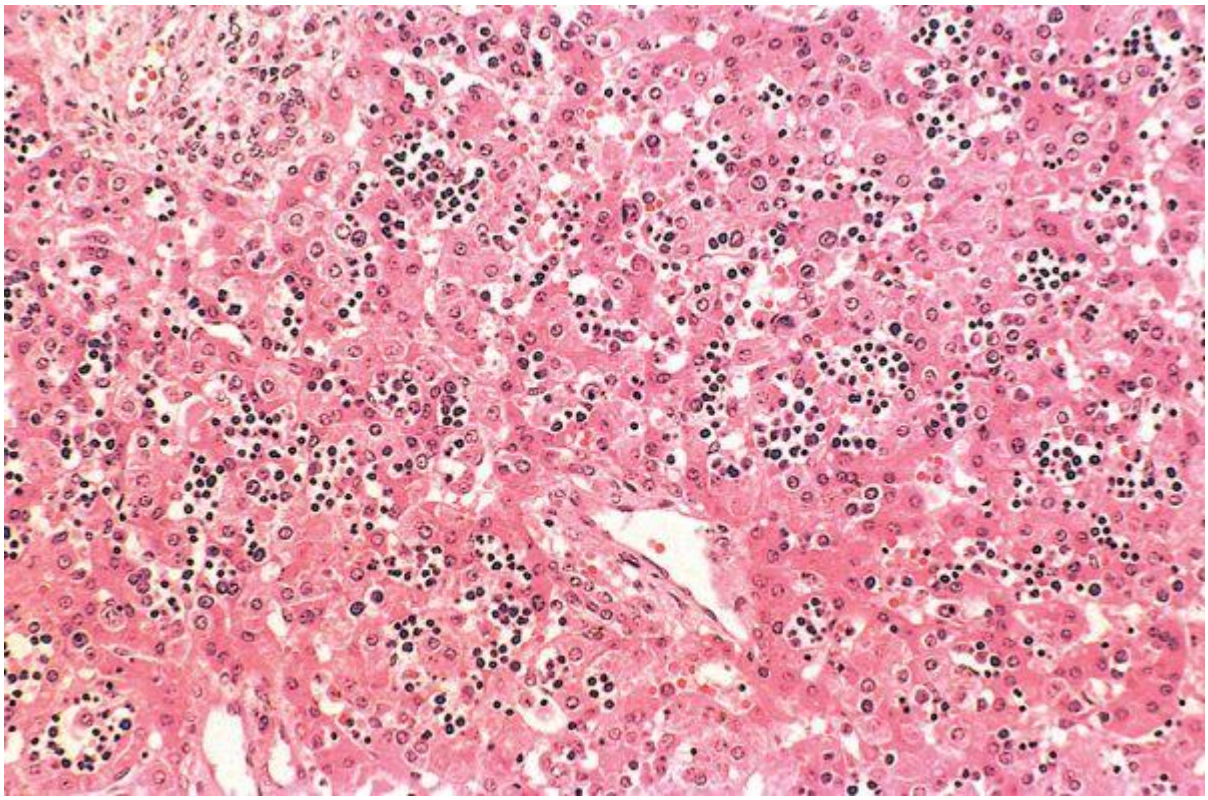

FIGURE 10-13 Numerous islands of extramedullary hematopoiesis (small blue cells) are scattered among mature hepatocytes in this infant with nonimmune hydrops fetalis.

Clinical Features.

The clinical manifestations of fetal hydrops vary with the severity of the disease and can be inferred from the preceding discussion. Minimally affected infants display pallor, possibly accompanied by hepatosplenomegaly (to which may be added jaundice with more severe hemolytic reactions), whereas the most gravely ill neonatespresent with intense jaundice, generalized edema, and signs of neurologic involvement. These infants may be supported by a variety of measures, including phototherapy (visual light oxidizes toxic unconjugated bilirubin to harmless, readily excreted, water-soluble dipyrroles) and, in severe cases, total exchange transfusion of the infant.

2.10.5 Inborn Errors of Metabolism & Other Genetic Disorders

Sir Archibald Garrod coined the term *inborn errors of metabolism* in 1908; since that time the number of well-characterized genetic disorders giving rise to congenital metabolic abnormalities has increased exponentially and is beyond the scope of this chapter. *Most inborn errors of metabolism are rare, and some were discussed in Chapter 5 . They are inherited, most commonly, as autosomal recessive or X-linked diseases*; a few are inherited as dominant traits. Mitochondrial disorders (Chapter 5) form a distinct entity by themselves. Some of the clinical features that suggest an underlying metabolic disorder in a neonate are tabulated in Table 10-5 . Three metabolic genetic defects, phenylketonuria (PKU), galactosemia, and cystic fibrosis, are selected for discussion here. PKU and galactosemia are reviewed because their early diagnosis (via neonatal screening programs) is particularly important, since appropriate dietary regimens can prevent early death or mental retardation. Cystic fibrosis is included because it is one of the most common, potentially lethal diseases occurring in individuals of Caucasian

descent. Neonatal screening for cystic fibrosis remains a controversial topic, with the benefits and risks much less clear than in the other two diseases.

TABLE 10-5 -- Abnormalities Suggesting Inborn Errors of Metabolism

GENERAL
Dysmorphic features
Deafness
Self-mutilation
Abnormal hair
Abnormal body or urine odor (“sweaty feet”; “mousy or musty”; “maple syrup”)
Hepatosplenomegaly; cardiomegaly
Hydrops
NEUROLOGIC
Hypotonia or hypertonia
Coma
Persistent lethargy
Seizures
GASTROINTESTINAL
Poor feeding
Recurrent vomiting
Jaundice
EYES
Cataract
Cherry red macula
Dislocated lens
Glaucoma
MUSCLE, JOINTS
Myopathy
Abnormal mobility

PHENYLKETONURIA (PKU)

PKU is characterized by abnormalities of phenylalanine metabolism, resulting in hyperphenylalaninemia. PKU is an autosomal recessive condition, and the vast majority of PKU is caused by bi-allelic mutations of the gene encoding the enzyme phenylalanine hydroxylase (PAH). Nevertheless, the great diversity in clinical presentation underscores the genetic complexities that underlie even classic “mendelian” diseases like PKU.[25] At the molecular level, more than 500 diseaseassociated alleles of the *PAH* gene have been identified in populations worldwide. Each mutation

induces a particular alteration in the enzyme resulting in a corresponding quantitative effect on residual enzyme activity ranging from complete absence to 50% of normal values. The degree of hyperphenylalaninemia and clinical phenotype is inversely related to the amount of residual enzyme activity. Infants with mutations resulting in a lack of PAH activity present with the classic features of PKU, while those with up to 6% residual activity present with milder disease. Moreover, some mutations result in only modest elevations of blood phenylalanine levels without associated neurologic damage. This latter condition, referred to as *benign hyperphenylalaninemia*, is important to recognize, because the individuals may well have positive screening tests but do not develop the stigmata of classic PKU. Measurement of serum phenylalanine differentiates benign hyperphenylalaninemia and classic PKU, with the concentrations being typically above 600 μM in PKU (normal phenylalanine concentrations, by contrast, are less than 120 μM).

The biochemical abnormality in PKU is an inability to convert phenylalanine into tyrosine. In normal children, less than 50% of the dietary intake of phenylalanine is necessary for protein synthesis. The rest is irreversibly converted to tyrosine by PAH in the liver as part of a complex metabolic pathway, the *hepatic PAH system* (Fig. 10-15), which, in addition to the enzyme PAH, has two other components: the cofactor *tetrahydrobiopterin (*BH_4) and the enzyme *dihydropteridine reductase*, which regenerates BH_4. Although neonatal hyperphenylalaninemia can be caused by deficiencies in any of these components, about 98% of cases are attributable to abnormalities in PAH and the remaining 2% to abnormalities in synthesis or recycling of BH_4. BH_4 is not only an essential cofactor for PAH but is also required for tyrosine and tryptophan hydroxylation. Concomitant defects in BH_4 recycling disturb the synthesis of neurotransmitters. As a result, in patients with BH_4 recycling defects neurologic damage is not arrested despite normalization of phenylalanine levels. Although they account for a small minority of patients with hyperphenylalaninemia, *it is important to recognize these PKU variants because the ongoing neurologic disturbances cannot be treated by dietary control of phenylalanine levels alone*.

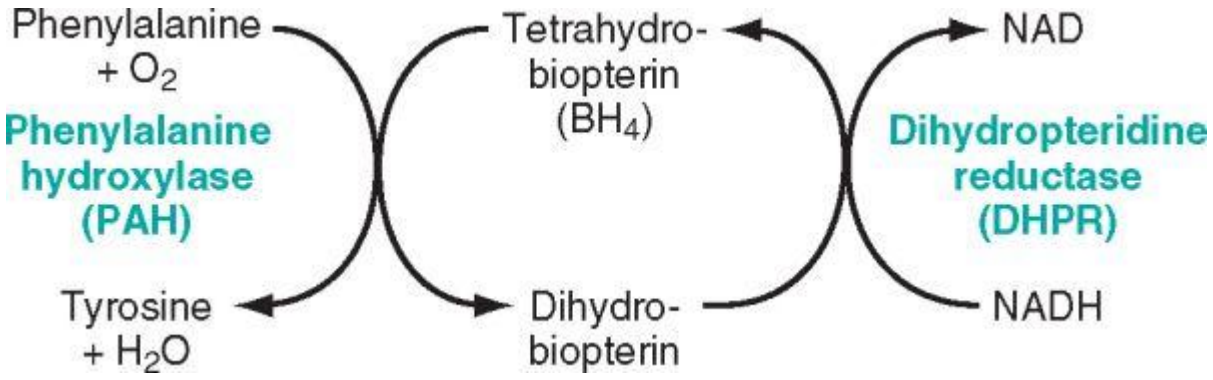

FIGURE 10-15 The phenylalanine hydroxylase system.

Individuals with "classic" PKU have a severe deficiency of PAH, leading to hyperphenylalaninemia and its pathologic consequences. With a block in phenylalanine metabolism due to lack of PAH, minor shunt pathways come into play, yielding phenylpyruvic acid, phenyllactic acid, phenylacetic acid, and *o*-hydroxyphenylacetic acid, which are excreted in large amounts in the urine in PKU. Some of these abnormal metabolites are excreted in the sweat, and phenylacetic acid in particular imparts a strong musty or mousy odor to affected infants. It is believed that excess phenylalanine or its metabolites contribute to the brain damage in PKU. Affected infants are normal at birth but within a few weeks develop a rising plasma phenylalanine level, which in some way impairs brain development. Usually by

6 months of life *severe mental retardation* becomes evident; fewer than 4% of untreated PKU children have intelligence quotient values greater than 50 or 60. About one third of these children are never able to walk, and two thirds cannot talk. Seizures, other neurologic abnormalities, decreased pigmentation of hair and skin, and eczema often accompany the mental retardation in untreated children. Hyperphenylalaninemia and the resultant mental retardation can be avoided by restriction of phenylalanine intake early in life. Hence, several screening procedures are routinely used for detection of PKU in the immediate postnatal period.

Many clinically normal female PKU patients who are treated with dietary control early in life reach childbearing age. If such individuals were to discontinue dietary treatment, the result would be marked hyperphenylalaninemia. Between 75% and 90% of children born to such women are mentally retarded and microcephalic, and 15% have congenital heart disease, even though the infants themselves are heterozygotes. This syndrome, termed *maternal PKU*, results from the teratogenic effects of phenylalanine or its metabolites that cross the placenta and affect specific fetal organs during development. The presence and severity of the fetal anomalies directly correlate with the maternal phenylalanine level, so *it is imperative that maternal dietary restriction of phenylalanine be initiated before conception and continue throughout pregnancy*.

Although dietary restriction of phenylalanine is usually successful in reducing or preventing the mental retardation associated with PKU, there are problems with long-term compliance (resulting in a decline in mental or behavioral status) and nutritional imbalances involving trace minerals, fatty acids, and lipids. A subset of patients with *PAH* missense mutations are responsive to pharmacologic dosages of BH_4; some recent analyses have predicted that as many as half of prevalent PAH mutations in some populations may be "BH_4 responsive."[26] Since there are no primary abnormalities of BH_4 in these patients, it is believed that this cofactor acts as a "molecular chaperone," preventing the degradation of misfolded PAH protein. Permanent restitution of PAH activity through gene therapy remains the ultimate goal; recent studies in animal models of PKU have produced encouraging results.[27]

GALACTOSEMIA

Galactosemia is an autosomal recessive disorder of galactose metabolism. Normally, lactose, the major carbohydrate of mammalian milk, is split into glucose and galactose in the intestinal microvilli by lactase. Galactose is then converted to glucose in three steps (Fig. 10-16). *Two variants of galactosemia have been identified. In the more common variant there is a total lack of galactose-1-phosphate uridyl transferase* (also known as *GALT*) *involved in reaction 2. The rare variant arises from a deficiency of galactokinase, involved in reaction 1*. Because galactokinase deficiency leads to a milder form of the disease not associated with mental retardation, it is not considered in this discussion. As a result of the transferase lack, *galactose-1-phosphate* accumulates in many locations, including the liver, spleen, lens of the eye, kidneys, heart muscle, cerebral cortex, and erythrocytes. Alternative metabolic pathways are activated, leading to the production of *galactitol* (a polyol metabolite of galactose) and *galactonate*, an oxidized by-product of excess galactose, both of which also accumulate in the tissues. Long-term toxicity in galactosemics has been variously imputed to these metabolic intermediates.[28] Heterozygotes may have a mild deficiency but are spared the clinical and pathologic consequences of the homozygous state.

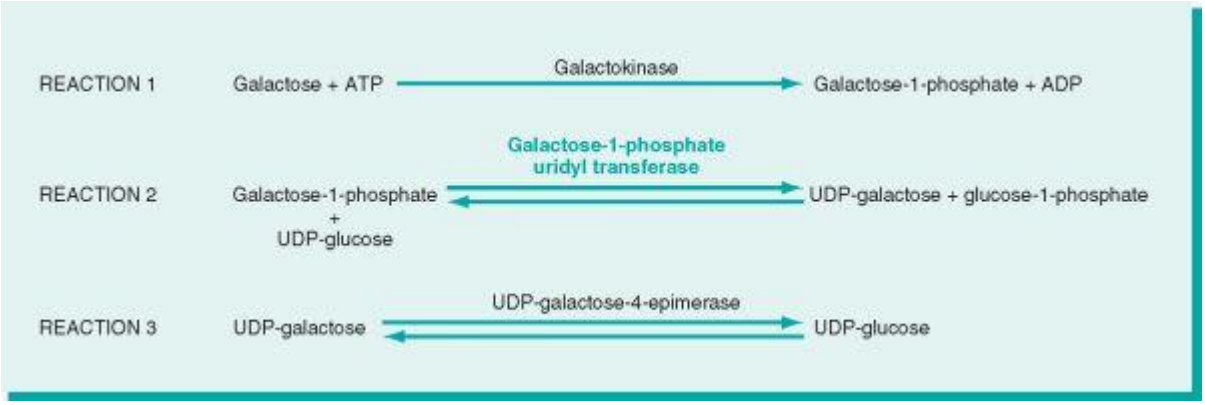

FIGURE 10-16 Pathways of galactose metabolism. ADP, adenosine diphosphate; ATP, adenosine triphosphate; UDP, uridine diphosphate.

The clinical picture is variable, probably reflecting the heterogeneity of mutations in the galactose-1-phosphate uridyl transferase gene leading to galactosemia. The liver, eyes, and brain bear the brunt of the damage. The early-to-develop *hepatomegaly* is due largely to fatty change, but in time widespread scarring that closely resembles the cirrhosis of alcohol abuse may supervene (Fig. 10-17). *Opacification of the lens (cataract)* develops, probably because the lens absorbs water and swells as galactitol, produced by alternative metabolic pathways, accumulates and increases its tonicity. *Nonspecific alterations appear in the central nervous system*, including loss of nerve cells, gliosis, and edema, particularly in the dentate nuclei of the cerebellum and the olivary nuclei of the medulla. Similar changes may occur in the cerebral cortex and white matter.

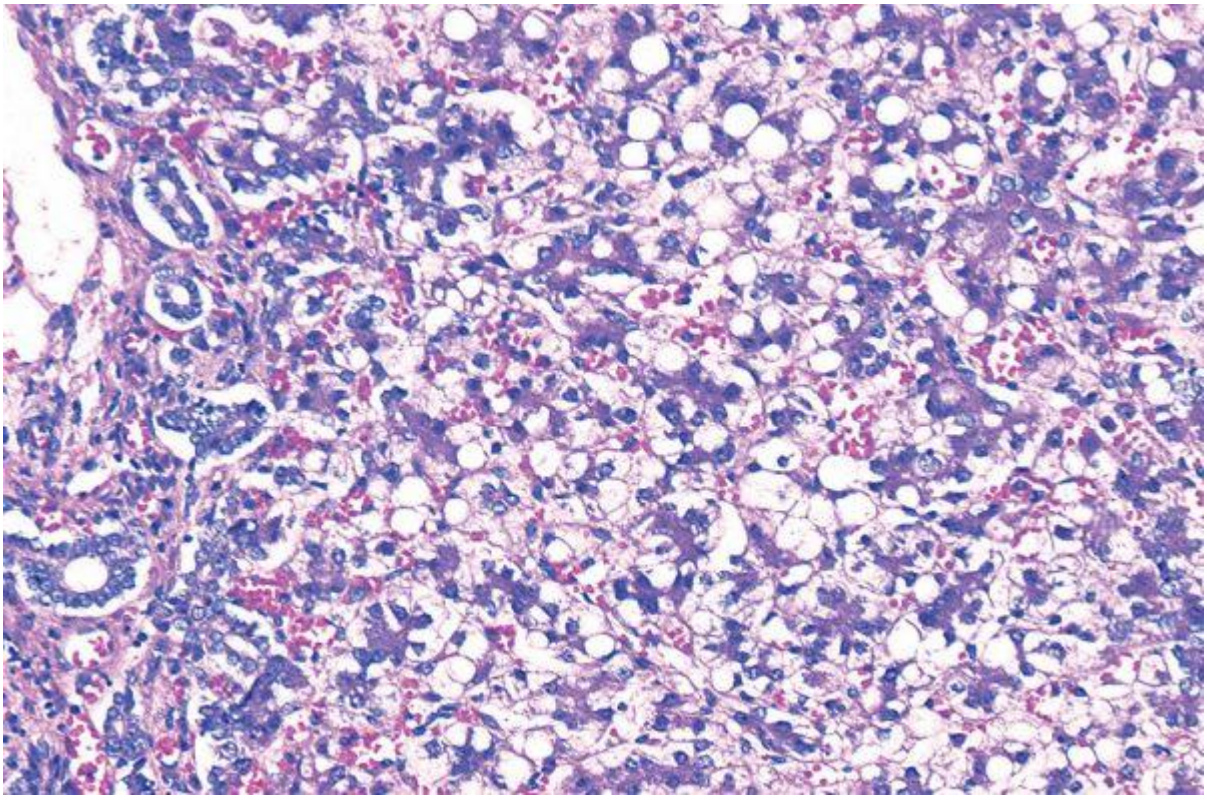

FIGURE 10-17 Galactosemia. The liver shows extensive fatty change and a delicate fibrosis. *(Courtesy of Dr. Wesley Tyson, The Children's Hospital, Denver, CO.)*

These infants *fail to thrive* almost from birth. *Vomiting* and *diarrhea* appear within a few days of milk ingestion. *Jaundice* and *hepatomegaly* usually become evident during the first week of life and may seem to be a continuation of the physiologic jaundice of the newborn. The *cataracts* develop within a few weeks, and within the first 6 to 12 months of life *mental retardation* may be detected. Even in untreated infants, however, the mental deficit is usually not as severe as that seen in PKU. Accumulation of galactose and galactose-1-phosphate in the kidney impairs amino acid transport, resulting in *aminoaciduria*. There is an increased frequency of fulminant *Escherichia coli septicemia*, possibly arising from depressed neutrophil bactericidal activity. *Hemolysis* and *coagulopathy* in the newborn period can occur as well.

The diagnosis of galactosemia can be suspected by the demonstration in the urine of a reducing sugar other than glucose, but tests that directly identify the deficiency of the transferase in leukocytes and erythrocytes are more reliable. Antenatal diagnosis is possible by the assay of GALT activity in cultured amniotic fluid cells or determination of galactitol level in amniotic fluid supernatant. More than 140 mutations have been documented in *GALT*; among these, a glutamine-to-arginine substitution at codon 188 *(Gln188Arg)* is the most prevalent mutation in non-Hispanic whites, while a serine-to-leucine substitution at codon 135 *(Ser135Leu)* is the most common mutation in African Americans.

Many of the clinical and morphologic changes of galactosemia can be prevented or ameliorated by early removal of galactose from the diet for at least the first 2 years of life. Control instituted soon after birth prevents the cataracts and liver damage and permits almost normal development. Even with dietary restrictions, however, it is now established that older patients are frequently affected by a speech disorder and gonadal failure (especially premature ovarian failure) and, less commonly, by an ataxic condition.

CYSTIC FIBROSIS (MUCOVISCIDOSIS)

Cystic fibrosis is a *disorder of ion transport in epithelial cells that affects fluid secretion in exocrine glands and the epithelial lining of the respiratory, gastrointestinal, and reproductive tracts*. In many infants this disorder leads to abnormally viscous secretions, which obstruct organ passages, resulting in most of the clinical features of this disorder, such as *chronic lung disease secondary to recurrent infections, pancreatic insufficiency, steatorrhea, malnutrition, hepatic cirrhosis, intestinal obstruction, and male infertility*. These manifestations may appear at any point in life from before birth to much later in childhood or even in adolescence.

With an incidence of 1 in 2500 live births, *cystic fibrosis is the most common lethal genetic disease that affects Caucasian populations*. The carrier frequency in the United States is 1 in 20 among Caucasians but significantly lower in African Americans, Asians, and Hispanics. Although cystic fibrosis follows an *autosomal recessive* transmission, recent data suggest that *even heterozygote carriers have a higher incidence of respiratory and pancreatic diseases* as compared with the general population.[29,][30] In addition, despite the classification of cystic fibrosis as a “mendelian” disorder, there is a wide degree of phenotypic variation that results from diverse mutations in the gene associated with cystic fibrosis, the tissue-specific effects of this gene, and the influence of newly recognized disease modifiers.[31]

The Cystic Fibrosis–Associated Gene: Normal Structure and Function.

In normal duct epithelia, chloride is transported by plasma membrane channels *(chloride channels). The primary defect in cystic fibrosis results from abnormal function of an epithelial chloride channel protein encoded by the cystic fibrosis transmembrane conductance regulator (CFTR) gene on chromosome 7q31.2*. The 1480–amino acid polypeptide encoded by *CFTR* has two transmembrane domains (each containing six α-helices), two cytoplasmic nucleotide-binding domains (NBDs), and a regulatory domain (R domain) that contains protein kinase A and C phosphorylation sites (Fig. 10-18). The two transmembrane domains form a channel through which chloride passes. Activation of the CFTR channel is mediated by agonist-induced increases in cyclic adenosine monophosphate (cAMP), followed by activation of a protein kinase A that phosphorylates the R domain. Adenosine triphosphate (ATP) binding and hydrolysis occurs at the NBD and is essential for the opening and closing of the channel pore in response to cAMP-mediated signaling. Several important facets of CFTR function have emerged in recent years:

- *CFTR regulates multiple additional ion channels and cellular processes*. Although initially characterized as a chloride-conductance channel, it is now recognized that CFTR can regulate multiple ion channels and cellular processes, primarily through interactions involving its NBD. These include so-called outwardly rectified chloride channels, inwardly rectified potassium channels (Kir6.1), the epithelial sodium channel (ENaC), gap junction channels, and cellular processes involved in ATP transport and mucus secretion. Of these, the interaction of CFTR with the ENaC has possibly the most pathophysiologic relevance in cystic fibrosis. The ENaC is situated on the apical surface of exocrine epithelial cells and is responsible for sodium uptake from the luminal fluid, rendering it (the luminal fluid) hypotonic. The ENaC is *inhibited* by normally functioning CFTR; hence, *in cystic fibrosis, ENaC activity increases, markedly augmenting sodium uptake across the apical membrane*. The importance of this phenomenon is discussed below in the context of pulmonary and gastrointestinal pathology in cystic fibrosis. The one exception to this rule happens to be the human sweat ducts, where ENaC activity *decreases* as a result of *CFTR* mutations; therefore, a hypertonic luminal fluid containing both high sweat chloride (the sine qua non of classic cystic fibrosis) and high sodium content is formed. This is the basis for the “salty” sweat that mothers can often detect in their affected infants.
- *The functions of* CFTR *are tissue-specific; therefore, the impact of a mutation in* CFTR *is also tissue-specific*. The major function of CFTR in the *sweat gland ducts* is to reabsorb luminal chloride ions and augment sodium reabsorption via the ENaC (see above). Therefore, in the sweat ducts, loss of CFTR function leads to decreased reabsorption of sodium chloride and production of hypertonic sweat (Fig. 10-19). However, in the *respiratory and intestinal epithelium*, the CFTR is one of the most important avenues for *active luminal secretion of chloride*. At these sites, *CFTR* mutations result in loss or reduction of chloride secretion into the lumen (see Fig. 10-18). Active luminal sodium absorption is also increased (due to loss of inhibition of ENaC activity), and both of these ion changes increase passive water reabsorption from the lumen, *lowering the water content of the surface fluid layer coating mucosal cells*. Thus, unlike the sweat ducts, there is no difference in the salt concentration of the surface fluid layer coating the respiratory and intestinal mucosal cells in normal individuals versus those with cystic fibrosis. Instead, *the pathogenesis of respiratory and intestinal complications in cystic fibrosis seems to stem from an isotonic but low-volume surface fluid layer*. In the lungs, this dehydration leads to defective mucociliary action and the accumulation of hyperconcentrated, viscid secretions that obstruct the air passages and predispose to recurrent pulmonary infections.[32]
- CFTR *mediates transport of bicarbonate ions*. The bicarbonate transport function of CFTR is mediated by reciprocal interactions with a family of anion exchangers called SLC26, which are co-expressed on the apical surface with CFTR.[33] It has been demonstrated in some *CFTR* mutant variants that chloride transport is completely or substantially preserved, while *bicarbonate transport is markedly abnormal*. Alkaline fluids are secreted by normal tissues, while acidic fluids (due to absence of bicarbonate ions) are secreted by epithelia harboring these mutant *CFTR* alleles. The decreased luminal pH can lead to a variety of adverse effects such as increased mucin precipitation and plugging of ducts, and increased binding of bacteria to plugged mucins. Pancreatic insufficiency, a feature of classic cystic fibrosis, is virtually always present when there are *CFTR* mutations with abnormal bicarbonate conductance.

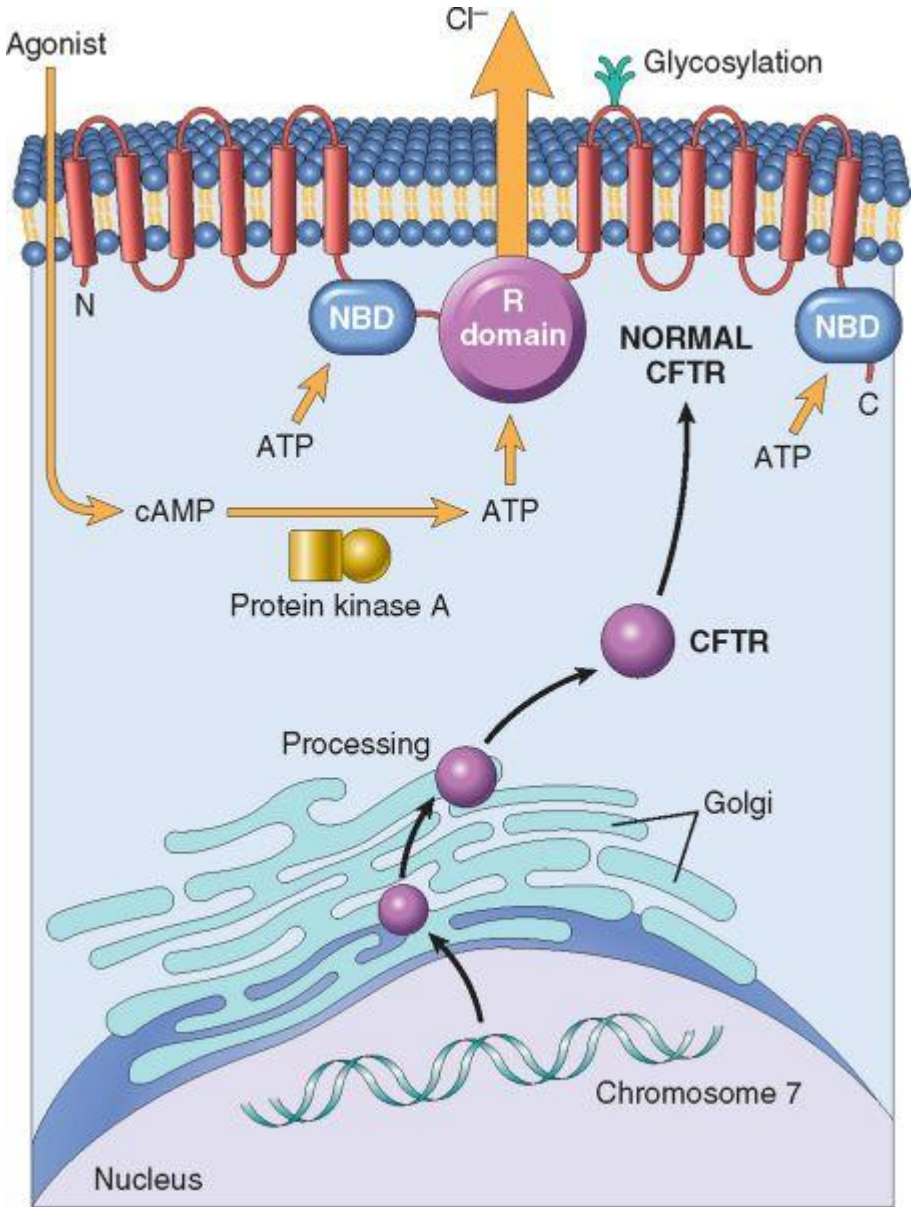

FIGURE 10-18 *Top*, Normal cystic fibrosis transmembrane conductance regulator (CFTR) structure and activation. CFTR consists of two transmembrane domains, two nucleotide-binding domains (NBDs), and a regulatory R domain. Agonists (e.g., acetylcholine) bind to epithelial cells and increase cyclic adenosine monophosphate (cAMP), which activates protein kinase A, the latter phosphorylating the CFTR at the R domain, resulting in opening of the chloride channel. *Bottom*, CFTR from gene to protein. The most common mutation in the *CFTR* gene results in defective protein folding in the Golgi/endoplasmic reticulum and degradation of CFTR before it reaches the cell surface. Other mutations affect synthesis of CFTR, NBDs and R domains, as well as membrane-spanning domains. (See text for details.)

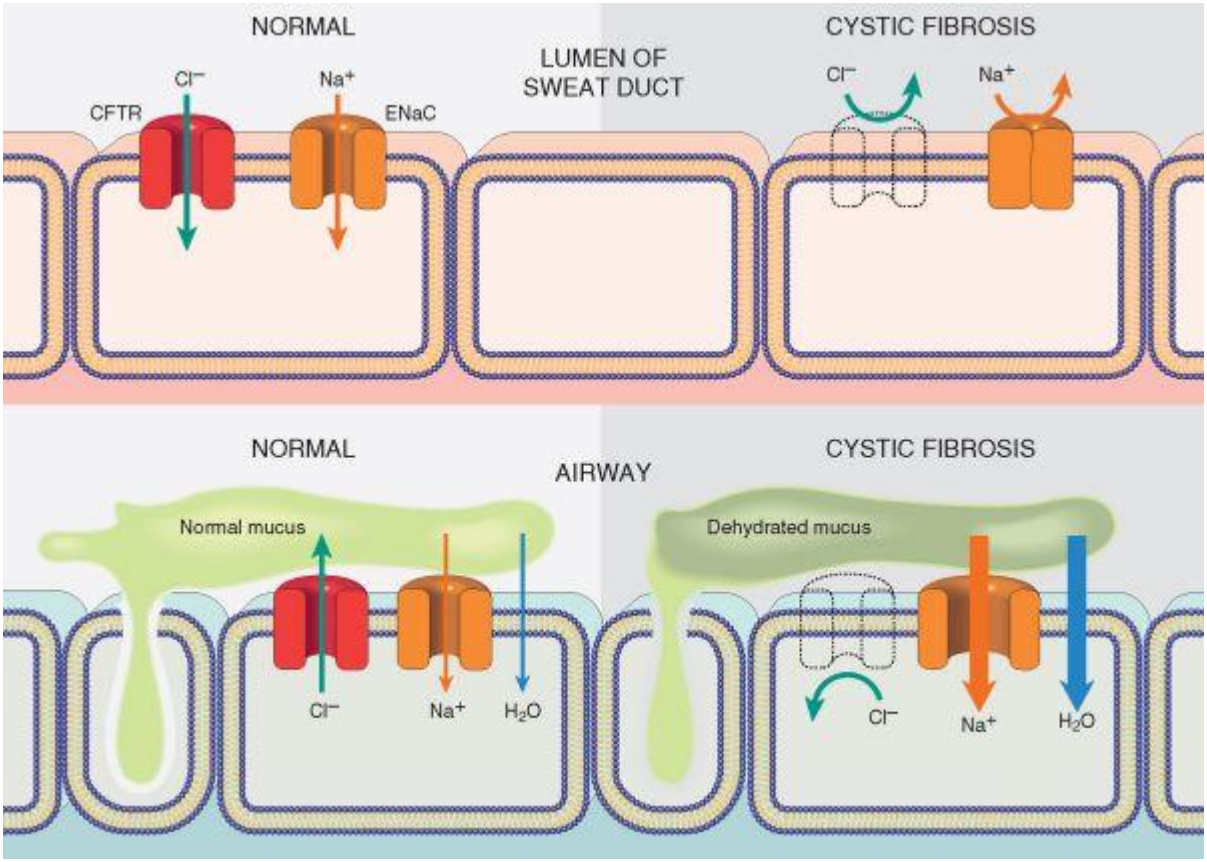

FIGURE 10-19 Chloride channel defect in the sweat duct *(top)* causes increased chloride and sodium concentration in sweat. In the airway *(bottom)*, cystic fibrosis patients have decreased chloride secretion and increased sodium and water reabsorption leading to dehydration of the mucus layer coating epithelial cells, defective mucociliary action, and mucus plugging of airways. CFTR, Cystic fibrosis transmembrane conductance regulator; ENaC, epithelial sodium channel.

The Cystic Fibrosis Gene: Mutational Spectra and Genotype-Phenotype Correlation.

Since the *CFTR* gene was cloned in 1989, more than 1300 disease-associated mutations have been identified. Various mutations can be grouped into six "classes" based on their effect on the CFTR protein:

- Class I: *Defective protein synthesis*. These mutations are associated with complete lack of CFTR protein at the apical surface of epithelial cells.
- Class II: *Abnormal protein folding, processing, and trafficking*. These mutations result in defective processing of the protein from the endoplasmic reticulum to the Golgi apparatus; the protein does not become fully folded and glycosylated and is instead degraded before it reaches the cell surface. The most common class II mutation is a deletion of three nucleotides coding for phenylalanine at amino acid position 508 (ΔF508). Worldwide, this mutation can be found in approximately 70% of cystic fibrosis patients. Class II mutations are also associated with complete lack of CFTR protein at the apical surface of epithelial cells.
- Class III: *Defective regulation*. Mutations in this class prevent activation of CFTR by preventing ATP binding and hydrolysis, an essential prerequisite for ion transport (see above). Thus, there is a normal amount of CFTR on the apical surface, but it is nonfunctional.
- Class IV: *Decreased conductance*. These mutations typically occur in the transmembrane domain of *CFTR*, which forms the ionic pore for chloride transport. There is a normal amount of CFTR at the apical membrane, but with reduced function. This class is usually associated with a milder phenotype.

- Class V: *Reduced abundance*. These mutations typically affect intronic splice sites or the *CFTR* promoter, such that there is a reduced amount of normal protein. As discussed subsequently, class V mutations are also associated with a milder phenotype.
- Class VI: *Altered regulation of separate ion channels*. As previously described, CFTR is involved in the regulation of multiple distinct cellular ion channels. Mutations in this class affect the regulatory role of CFTR. In some cases, a given mutation affects the conductance by CFTR as well as regulation of other ion channels. For example, the ΔF508 mutation is both a class II and class VI mutation.

Since cystic fibrosis is an autosomal recessive disease, affected individuals harbor mutations on both alleles. However, the combination of mutations on the two alleles can have a remarkable effect on the overall phenotype, as well as on organ-specific manifestations (Fig. 10-20). Thus, two "severe" (class I, II, and III) mutations that produce virtual absence of membrane CFTR are associated with the *classic* cystic fibrosis phenotype (pancreatic insufficiency, sinopulmonary infections, and gastrointestinal symptoms), while the presence of a "mild" (class IV or V) mutation on one or both alleles results in a less severe phenotype. This general dictum of genotype-phenotype correlation is most consistent for pancreatic disease, wherein the presence of a "mild" mutation in one allele can revert to the pancreatic insufficiency phenotype conferred by homozygosity for "severe" mutations. By contrast, genotype-phenotype correlations are far less consistent in pulmonary disease, reflecting an effect of secondary modifiers (see below). As genetic testing for *CFTR* mutations has expanded, *it has become increasingly evident that patients who present with a variety of apparently unrelated clinical phenotypes may also harbor* CFTR *mutations*. These include individuals with *idiopathic chronic pancreatitis, late-onset chronic pulmonary disease, idiopathic bronchiectasis*, and *obstructive azoospermia* caused by bilateral absence of the vas deferens (see detailed discussion of individual phenotypes later). Most of these patients do not demonstrate other features of cystic fibrosis, despite the presence of bi-allelic *CFTR* mutations, and are classified as *nonclassic or atypical cystic fibrosis*.[34] Identifying these individuals is important not only for subsequent management, but also for the purposes of genetic counseling.

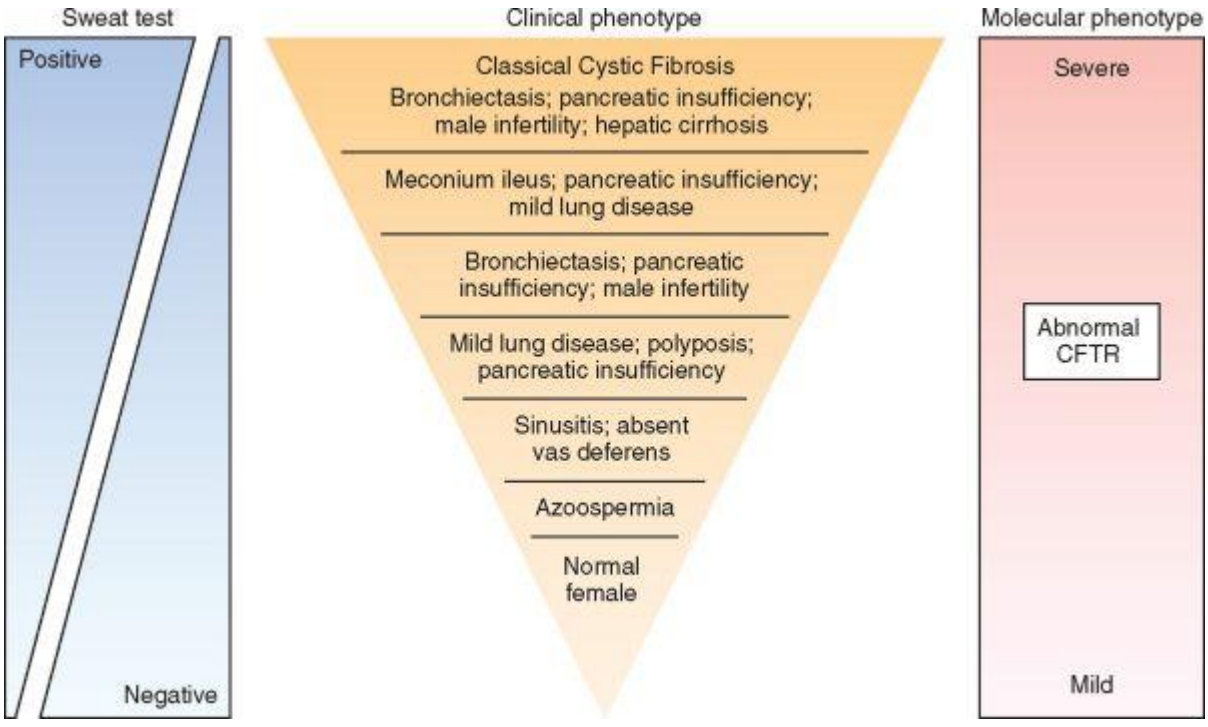

FIGURE 10-20 The many clinical manifestations of mutations in the cystic fibrosis gene, from most severe to asymptomatic. *(Redrawn from Wallis C: Diagnosing cystic fibrosis: blood, sweat, and tears. Arch Dis Child 76:85, 1997.)*

Genetic and Environmental Modifiers.

Although cystic fibrosis remains one of the best-known examples of the "one gene, one disease" axiom, there is increasing evidence that genes other than *CFTR* modify the frequency and severity of organ-specific manifestations.[35] The severity of pulmonary manifestations in cystic fibrosis is associated with polymorphic variants at several genes, the best known examples of which are *mannose-binding lectin* 2 (*MBL2*) and *transforming growth factor* β*1* (*TGFB1*). MBL is a key effector of innate immunity involved in opsonization and phagocytosis of microorganisms, and polymorphisms in the *MBL2* gene that are associated with lower circulating levels of the protein confer a threefold higher risk of end-stage lung disease. TGFβ is a direct inhibitor of CFTR function.[36,][37] A large multicenter study of patients homozygous for the ΔF508 *CFTR* mutation found two specific polymorphisms in the 5′ end of the *TGFB1* gene to be associated with severe pulmonary phenotypes.[38] Similarly, several putative genetic modifiers have been identified that influence the incidence of meconium ileus in cystic fibrosis, although the precise genes associated with the linked chromosomal regions have not yet been identified.[39]

Environmental modifiers may also cause significant phenotypic differences between individuals who share the same *CFTR* genotype. This is best exemplified in pulmonary disease, where *CFTR* genotype and phenotype correlations can be perplexing. As stated above, defective mucociliary action because of deficient hydration of the mucus results in an inability to clear bacteria from the airways. *Pseudomonas aeruginosa* species, in particular, colonize the lower respiratory tract, first intermittently and then chronically. Concurrent viral infections predispose to such colonization. The static mucus creates a hypoxic microenvironment in the airway surface fluid, which in turn favors the production of *alginate*, a mucoid polysaccharide capsule. Alginate production permits the formation of a biofilm that protects the bacteria from antibodies and antibiotics, allowing them to evade host defenses, and produce a chronic destructive lung disease. Antibody- and cell-mediated immune reactions induced by the organisms result in further pulmonary destruction, but are ineffective against the organism. It is evident, therefore, that in addition to genetic factors (e.g., class of mutation), a plethora of environmental modifiers (e.g., virulence of organisms, efficacy of therapy, intercurrent and concurrent infections by other organisms, exposure to smoking and allergens) can influence the severity and progression of lung disease in cystic fibrosis.

Morphology. The anatomic changes are highly variable in distribution and severity. In individuals with nonclassic cystic fibrosis, the disease is quite mild and does not seriously disturb their growth and development. In others, the pancreatic involvement is severe and impairs intestinal absorption because of the pancreatic achylia, and so malabsorption stunts development and post-natal growth. In others, the mucus secretion defect leads to defective mucociliary action, obstruction of bronchi and bronchioles, and crippling fatal pulmonary infections (Fig. 10-21). In all variants, the sweat glands are morphologically unaffected.

Pancreatic abnormalities are present in approximately 85% to 90% of patients with cystic fibrosis. In the milder cases, there may be only accumulations of mucus in the small ducts with some dilation of the exocrine glands. In more severe cases, usually seen in older children or adolescents, the ducts are completely plugged, causing atrophy of the exocrine glands and progressive fibrosis (Fig. 10-21). Atrophy of the exocrine portion of the pancreas may occur, leaving only the islets within a fibrofatty stroma. The loss of pancreatic exocrine secretion impairs fat absorption, and the associated avitaminosis A may contribute to squamous metaplasia of the lining epithelium of the ducts in the

pancreas, which are already injured by the inspissated mucus secretions. Thick viscid plugs of mucus may also be found in the small intestine of infants. Sometimes these cause small-bowel obstruction, known as **meconium ileus**.

The **liver involvement** follows the same basic pattern. Bile canaliculi are plugged by mucinous material, accompanied by ductular proliferation and portal inflammation. Hepatic **steatosis** is not an uncommon finding in liver biopsies. Over time, **focal biliary cirrhosis** develops in approximately a third of patients (Chapter 18), which can eventually involve the entire liver, resulting in diffuse hepatic nodularity. Such severe hepatic involvement is encountered in less than 10% of patients.

The **salivary glands** frequently show histologic changes similar to those described in the pancreas: progressive dilation of ducts, squamous metaplasia of the lining epithelium, and glandular atrophy followed by fibrosis.

The **pulmonary changes** are the most serious complications of this disease (Fig. 10-22). These stem from the viscous mucus secretions of the submucosal glands of the respiratory tree leading to secondary obstruction and infection of the air passages. The bronchioles are often distended with thick mucus associated with marked hyperplasia and hypertrophy of the mucus-secreting cells. Superimposed infections give rise to severe chronic bronchitis and bronchiectasis (Chapter 15). In many instances, lung abscesses develop. *Staphylococcus aureus*, *Hemophilus influenzae*, and *Pseudomonas aeruginosa* are the three most common organisms responsible for lung infections. As mentioned above, a mucoid form of *P. aeruginosa* (alginate-producing) is particularly frequent and causes chronic inflammation. Even more sinister is the increasing frequency of infection with another group of pseudomonads, the *Burkholderia cepacia* complex, which includes at least nine different species; of these, infections with *B. cenocepacia* are the most common in cystic fibrosis patients. This opportunistic bacterium is particularly hardy, and infection with this organism has been associated with fulminant illness (“cepacia syndrome”), longer hospital stays, and increased mortality.[40] Other opportunistic bacterial pathogens include *Stenotrophomonas maltophila* and *nontuberculous mycobacteria*; *allergic bronchopulmonary aspergillosis* also occurs with increased frequency in cystic fibrosis.

Azoospermia and infertilityare found in 95% of the males who survive to adulthood; **congenital bilateral absence of the vas deferens** is a frequent finding in these patients. In some males, bilateral absence of the vas deferens may be the only feature suggesting an underlying *CFTR* mutation.

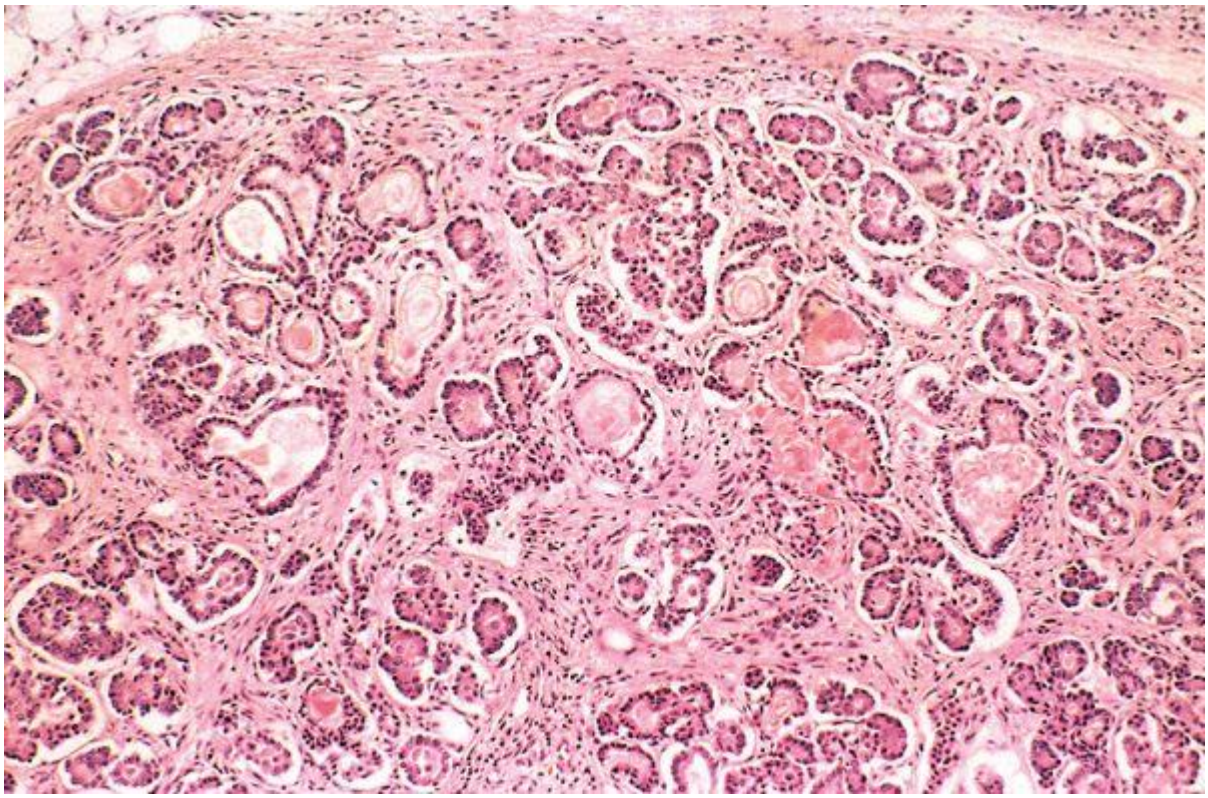

FIGURE 10-21 Mild to moderate cystic fibrosis changes in the pancreas. The ducts are dilated and plugged with eosinophilic mucin, and the parenchymal glands are atrophic and replaced by fibrous tissue.

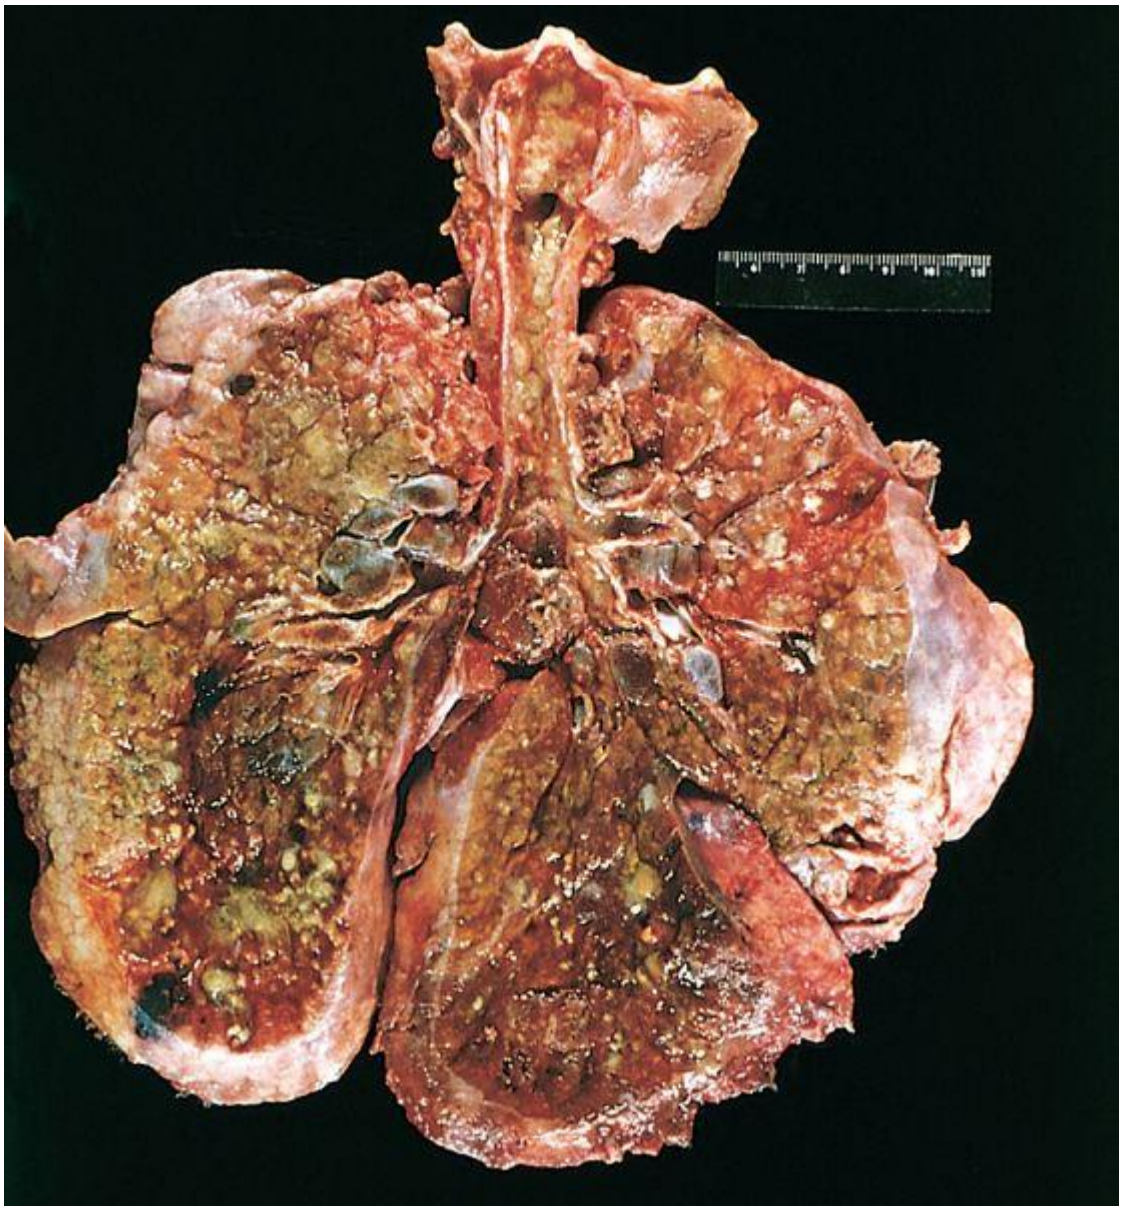

FIGURE 10-22 Lungs of a patient dying of cystic fibrosis. There is extensive mucus plugging and dilation of the tracheobronchial tree. The pulmonary parenchyma is consolidated by a combination of both secretions and pneumonia—the green color associated with *Pseudomonas* infections. *(Courtesy of Dr. Eduardo Yunis, Children's Hospital of Pittsburgh, Pittsburgh, PA.)*

Clinical Features.

Few childhood diseases are as protean as cystic fibrosis in clinical manifestations (Table 10-6). The symptoms are extremely varied and may appear at birth to years later, and involve one organ system or many. Approximately 5% to 10% of the cases come to clinical attention at birth or soon after because of *meconium ileus*. Distal intestinal obstruction can also occur in older individuals, manifesting as recurrent episodes of right lower quadrant pain sometimes associated with a palpable mass in the right iliac fossa.

TABLE 10-6 -- Clinical Features and Diagnostic Criteria for Cystic Fibrosis

CLINICAL FEATURES OF CYSTIC FIBROSIS

1. *Chronic sinopulmonary disease manifested by*
   - **a.** Persistent colonization/infection with typical cystic fibrosis pathogens, including *Staphylococcus aureus*, nontypeable *Haemopilus influenzae*, mucoid and nonmucoid *Pseudomonas aeruginosa, Burkholderia cepacia*
   - **b.** Chronic cough and sputum production
   - **c.** Persistent chest radiograph abnormalities (e.g., brochiectasis, atelectasis, infiltrates, hyperinflation)
   - **d.** Airway obstruction manifested by wheezing and air trapping
   - **e.** Nasal polyps; radiographic or computed tomographic abnormalities of paranasal sinuses
   - **f.** Digital clubbing
2. *Gastrointestinal and nutritional abnormalities, including*
   - **a.** Intestinal: meconium ileus, distal intestinal obstruction syndrome, rectal prolapse
   - **b.** Pancreatic: pancreatic insufficiency, recurrent acute pancreatitis, chronic pancreatitis
   - **c.** Hepatic: chronic hepatic disease manifested by clinical or histologic evidence of focal biliary cirrhosis, or multilobular cirrhosis, prolonged neonatal jaundice
   - **d.** Nutritional: failure to thrive (protein–calorie malnutrition), hypoproteinemia, edema, complications secondary to fat-soluble vitamin deficiency
3. *Salt-loss syndromes: acute salt depletion, chronic metabolic alkalosis*
4. *Male urogenital abnormalities resulting in obstructive azoospermia (congenital bilateral absence of vas deferens)*

CRITERIA FOR DIAGNOSIS OF CYSTIC FIBROSIS

One or more characteristic phenotypic features, OR a history of cystic fibrosis in a sibling, OR a positive newborn screening test result

AND

An increased sweat chloride concentration on two or more occasions

OR identification of two cystic fibrosis mutations, OR demonstration of abnormal epithelial nasal ion transport

Adapted with permission from Rosenstein BJ, Cutting GR: The diagnosis of cystic fibrosis: a consensus statement. J Pediatr 132:589, 1998.

Exocrine pancreatic insufficiency occurs in the majority (85% to 90%) of patients with cystic fibrosis and is associated with "severe" *CFTR* mutations on *both* alleles (e.g., Δ*F508/*Δ*F508*), whereas 10% to 15% of patients with one "severe" and one "mild" *CFTR* mutation *(*Δ*F508/R117H)* or two "mild" *CFTR* mutations retain enough pancreatic exocrine function so as not to require enzyme supplementation (*pancreassufficient* phenotype). Pancreatic insufficiency is associated with protein and fat malabsorption and increased fecal loss. Manifestations of malabsorption (e.g., large, foul-smelling stools, abdominal distention, and poor weight gain) appear during the first year of life. The faulty fat absorption may induce deficiency of the fat-soluble vitamins, resulting in manifestations of avitaminosis A, D, or K. Hypoproteinemia may be severe enough to cause generalized edema. Persistent diarrhea may result in rectal prolapse in up to 10% of children with cystic fibrosis. The *pancreas-sufficient* phenotype is usually not associated with other gastrointestinal complications, and in general, these

individuals demonstrate excellent growth and development. *"Idiopathic" chronic pancreatitis* occurs in a subset of patients with pancreas-sufficient cystic fibrosis and is associated with recurrent abdominal pain with life-threatening complications. These patients have other features of cystic fibrosis, such as pulmonary disease. By contrast, "idiopathic" chronic pancreatitis can also occur as an isolated late-onset finding in the absence of other stigmata of cystic fibrosis (Chapter 19); bi-allelic *CFTR* mutations (usually one "mild," one "severe") are demonstrable in the majority of these individuals who have *nonclassic or atypical cystic fibrosis. Endocrine pancreatic insufficiency* (i.e., diabetes) is uncommon in cystic fibrosis and is usually accompanied by substantial destruction of pancreatic parenchyma.

Cardiorespiratory complications, such as persistent lung infections, obstructive pulmonary disease, and *cor pulmonale*, are the most common cause of death (~80%) in patients in the United States. By age 18, 80% of patients with classic cystic fibrosis harbor *P. aeruginosa*. With the indiscriminate use of antibiotic prophylaxis against *Staphylococcus*, there has been an unfortunate resurgence of resistant strains of *Pseudomonas* in many patients. Individuals who carry one "severe" and one "mild" *CFTR* mutation may develop late-onset mild pulmonary disease, another example of nonclassic or atypical cystic fibrosis. Patients with mild pulmonary disease usually have little or no pancreatic disease. Adult-onset "*idiopathic*" *bronchiectasis*, has been linked to *CFTR* mutations in a subset of cases. *Recurrent sinonasal polyps* can occur in up to 25% of individuals with cystic fibrosis; hence, children who present with this finding should be tested for cystic fibrosis.

Significant *liver disease* occurs late in the natural history of cystic fibrosis and is gaining in clinical importance as life expectancies increase. In fact, after cardiopulmonary and transplantation-related complications, liver disease is the most common cause of death in cystic fibrosis. Most studies suggest that symptomatic or biochemical liver disease has its onset at or around puberty, with a prevalence of approximately 13% to 17%. However, *asymptomatic hepatomegaly* may be present in up to a third of individuals. Obstruction of the common bile duct may occur due to stones or sludge; it presents with abdominal pain and the acute onset of jaundice. As previously noted, *diffuse biliary cirrhosis* develops in less than 10% of individuals with cystic fibrosis.

Approximately 95% of males with cystic fibrosis are *infertile*, as a result of obstructive azoospermia. As mentioned earlier, this is most commonly due to congenital bilateral absence of the vas deferens, which is caused in 80% of cases by bi-allelic *CFTR* mutations.

In most cases, the diagnosis of cystic fibrosis is based on persistently elevated sweat electrolyte concentrations (often the mother makes the diagnosis by recognizing her infant's abnormally salty sweat), characteristic clinical findings (sinopulmonary disease and gastrointestinal manifestations), an abnormal newborn screening test, or a family history. A minority of patients with cystic fibrosis, especially those with at least one "mild" *CFTR* mutation, may have a normal or near-normal sweat test (<60 mM/L). Measurement of nasal transepithelial potential difference in vivo can be a useful adjunct test under these circumstances; individuals with cystic fibrosis demonstrate a significantly more negative baseline nasal potential difference than controls. Sequencing the *CFTR* gene is, of course, the "gold standard" for diagnosis of cystic fibrosis. Therefore, in patients with suggestive clinical findings or family history (or both), genetic analysis may be warranted.

There have been major improvements in the management of acute and chronic complications for cystic fibrosis, including more potent antimicrobial therapies, pancreatic enzyme replacement, and bilateral lung transplantation. Newer modalities for restituting endogenous CFTR function have also emerged in recent years. In principle, cystic fibrosis, like other single-gene disorders, should be amenable to gene therapy, and several adenoviral gene therapy vectors are currently undergoing early-phase clinical trials. Improvement in management of cystic fibrosis has resulted in enhancement of median life expectancy

to above 36 years as of 2006,[41] and increasingly, a lethal disease of childhood is changing into a chronic disease of adults.

2.10.6 Sudden Infant Death Syndrome (SIDS)

The National Institute of Child Health and Human Development defines SIDS as "the sudden death of an infant under 1 year of age which remains unexplained after a thorough case investigation, *including performance of a complete autopsy, examination of the death scene, and review of the clinical history*."[42] Thus, SIDS is a disease of unknown cause. It is important to emphasize that many cases of sudden death in infancy may have an unexpected anatomic or biochemical basis discernible at autopsy (Table 10-7), and these should *not* be labeled as SIDS. Furthermore, instances of sudden death during infancy wherein evidence for excluding alternative diagnoses is equivocal, or a postmortem diagnosis cannot be performed, are best labeled as *unclassified sudden infant death*, in line with the current rigorous definition of SIDS.[43] An aspect of SIDS that is not stressed in the definition is that the infant usually dies while asleep, mostly in the prone or side position, hence the pseudonyms of *crib death* or *cot death*.

TABLE 10-7 -- Risk Factors and Postmortem Findings Associated with Sudden Infant Death Syndrome

PARENTAL
Young maternal age (age <20 years)
Maternal smoking during pregnancy
Drug abuse in *either* parent, specifically paternal marijuana and maternal opiate, cocaine use
Short intergestational intervals
Late or no prenatal care
Low socioeconomic group
African-American and American Indian ethnicity (? socioeconomic factors)
INFANT
Brain stem abnormalities, associated with delayed development of arousal and cardiorespiratory control
Prematurity and/or low birth weight
Male sex
Product of a multiple birth
SIDS in a prior sibling
Antecedent respiratory infections
Germline polymorphisms in autonomic nervous system genes
ENVIRONMENT
Prone or side sleep position
Sleeping on a soft surface
Hyperthermia
Co-sleeping in first 3 months of life
POSTMORTEM ABNORMALITIES DETECTED IN CASES OF SUDDEN UNEXPECTED INFANT DEATH[*]
Infections • Viral myocarditis

• Bronchopneumonia
Unsuspected congenital anomaly • Congenital aortic stenosis • Anomalous origin of the left coronary artery from the pulmonary artery
Traumatic child abuse • Intentional suffocation (filicide)
Genetic and metabolic defects • Long QT syndrome (*SCN5A* and *KCNQ1* mutations) • Fatty acid oxidation disorders (*MCAD*, *LCHAD*, *SCHAD* mutations) • Histiocytoid cardiomyopathy (*MTCYB* mutations) • Abnormal inflammatory responsiveness (partial deletions in *C4a* and *C4b*)

* SIDS is not the only cause of sudden unexpected death in infancy but rather is a *diagnosis of exclusion*. Therefore, performance of an autopsy may often reveal findings that would explain the cause of sudden unexpected death. These cases should *not*, strictly speaking, be labeled as "SIDS." SCN5A, sodium channel, voltage-gated, type V, alpha polypeptide; KCNQ1, potassium voltage-gated channel, KQT-like subfamily, member 1; MCAD, medium-chain acyl coenzyme A dehydrogenase; LCHAD, long-chain 3-hydroxyacyl coenzyme A dehydrogenase; SCHAD, short-chain 3-hydroxyacyl coenzyme A dehydrogenase; MTCYB, mitochondrial cytochrome *b*; C4, complement component 4.

Epidemiology.

As infantile deaths due to nutritional problems and infections have come under control in developed countries, SIDS has assumed greater importance in these countries, including the United States. SIDS is the leading cause of death between age 1 month and 1 year in this country and the third leading cause of death overall in infancy, after congenital anomalies and diseases of prematurity and low birth weight. Mostly because of nationwide SIDS awareness campaigns by organizations such as the American Academy of Pediatrics, there has been a significant drop in SIDS-related mortality in the past decade, from an estimated 120 deaths per 100,000 live births in 1992 to 57 per 100,000 in 2002. Worldwide, in countries where unexpected infant deaths are diagnosed as SIDS only after postmortem examination, the death rates from SIDS range from 10 per 100,000 live births in the Netherlands to 80 per 100,000 in New Zealand.[44]

Approximately 90% of all SIDS deaths occur during the first 6 months of life, most between ages 2 and 4 months. Thisnarrow window of peak susceptibility is a unique characteristic that is independent of other risk factors (to be described) and the geographic locale. Most infants who die of SIDS die at home, usually during the night after a period of sleep. For many years, prolonged apnea was considered to be a risk factor for SIDS. Infants who developed a so-called "*apparent life-threatening event*" (ALTE), characterized by some combination of apnea, marked change in color or muscle tone, choking or gagging, were considered at risk for subsequent SIDS. However, epidemiologic studies have demonstrated that these "life-threatening events" and SIDS have different risk factors and ages of onset, and are probably unrelated entities. Children experiencing ALTEs are often premature or have a mechanical basis for respiratory compromise. This distinction might explain why home apnea monitors, which have proliferated among American families for "SIDS prevention," have had minimal impact on reducing the risk of SIDS.[45]

Morphology. In infants who have died of suspected SIDS, a variety of findings have been reported at postmortem examination. They are usually subtle and of uncertain significance and are not present in all cases. **Multiple petechiae** are the most common finding (~80% of cases); these are usually

present on the thymus, visceral and parietal pleura, and epicardium. Grossly, the lungs are usually congested, and **vascular engorgement** with or without **pulmonary edema** is demonstrable microscopically in the majority of cases. These changes possibly represent agonal events, since they are found with comparable frequencies in *explained* sudden deaths in infancy. Within the upper respiratory system (larynx and trachea), there may be some histologic evidence of recent infection (correlating with the clinical symptoms), although the changes are not sufficiently severe to account for death and should not detract from the diagnosis of SIDS. The central nervous system demonstrates **astrogliosis** of the brain stem and cerebellum. Sophisticated morphometric studies have revealed quantitative brain-stem abnormalities such as **hypoplasia of the arcuate nucleus** or a decrease in brain-stem neuronal populations in several cases; these observations are not uniform, however. Nonspecific findings include frequent persistence of hepatic **extramedullary hematopoiesis** and **periadrenal brown fat**; it is tempting to speculate that these latter findings relate to chronic hypoxemia, retardation of normal development, and chronic stress. Thus, autopsy usually fails to provide a clear cause of death, and this may well be related to the etiologic heterogeneity of SIDS. The importance of a postmortem examination rests in identifying other causes of sudden unexpected death in infancy, such as unsuspected infection, congenital anomaly, or a genetic disorder (see Table 10-7), the presence of any of which would *exclude* a diagnosis of SIDS; and in ruling out the unfortunate possibility of traumatic child abuse.

Pathogenesis.

The circumstances surrounding SIDS have been explored in great detail, and it is generally accepted that it is a *multifactorial condition*, with a variable mixture of contributing factors. A "triple-risk" model of SIDS has been proposed, which postulates the intersection of three overlapping factors: (1) *a vulnerable infant*, (2) *a critical developmental period in homeostatic control*, and (3) *an exogenous stressor(s)*.[46] According to this model, several factors make the infant vulnerable to sudden death during the critical developmental period (i.e., the first 6 months of life). These vulnerability factors may be attributable to the parents or the infant, while the exogenous stressor(s) is attributable to the environment (see Table 10-7).

While numerous factors have been proposed to account for a vulnerable infant, *the most compelling hypothesis is that SIDS reflects a delayed development of "arousal" and cardiorespiratory control*. The brain stem, and in particular the medulla oblongata, plays a critical role in the body's "arousal" response to noxious stimuli such as episodic hypercarbia, hypoxia, and thermal stress encountered during sleep. The serotonergic (5-HT) system of the medulla is implicated in these "arousal" responses, as well as regulation of other critical homeostatic functions such as respiratory drive, blood pressure, and upper airway reflexes. Abnormalities in serotonin-dependent signaling in the brainstem may be the underlying basis for SIDS in some infants.[47] A recently developed mouse model of disrupted somatostatin signaling in the medulla recapitulates many of the features likely to contribute to sudden death in SIDS infants, including lack of an appropriate "arousal" response to environmental stressors.[48]

Epidemiologic and genetic studies have identified additional vulnerability factors for SIDS in the "triple-risk" model. Infants who are born before term or who are low birth weight are at increased risk, and risk increases with decreasing gestational age or birth weight. As stated, male sex is associated with a slightly greater incidence of SIDS. SIDS in a prior sibling is associated with a fivefold relative risk of recurrence, underscoring the importance of a genetic predisposition (see below); *traumatic child abuse must be carefully excluded under these circumstances*. Most SIDS babies have an immediate prior history of a mild respiratory tract infection, but no single causative organism has been isolated. These infections may predispose an already vulnerable infant to even greater impairment of cardiorespiratory control and delayed arousal. In this context, *laryngeal chemoreceptors* have emerged as a putative "missing link" between upper respiratory tract infections, the prone position (see below), and SIDS.

When stimulated, these laryngeal chemoreceptors typically elicit an inhibitory cardiorespiratory reflex. Stimulation of the chemoreceptors is augmented by respiratory tract infections, which increase the volume of secretions, and by the prone position, which impairs swallowing and clearing of the airways even in healthy infants. In a previously vulnerable infant with impaired arousal, the resulting inhibitory cardiorespiratory reflex may prove fatal. Genetic vulnerability factors in the infant include polymorphic variants in genes that may confer an increased risk of SIDS. These genes include those related to serotonergic signaling and autonomic innervation, underscoring the importance of these processes in the pathophysiology of SIDS.[49]

In addition to infant vulnerability factors, several maternal risk factors have also been identified. Maternal smoking during pregnancy has consistently emerged as a risk factor in epidemiologic studies of SIDS, with children exposed to in utero nicotine having more than double the risk of SIDS as compared with children born to nonsmokers.[50] Young maternal age, frequent childbirths, and inadequate prenatal care are all risk factors associated with increased incidence of SIDS in the offspring.

Among the potential "environmental stressors," prone or side sleeping positions, sleeping with parents in the first 3 months, sleeping on soft surfaces, and thermal stress arepossibly the most important modifiable risk factors for SIDS.[42,][44] The prone or side positions predispose an infant to one or more recognized noxious stimuli (hypoxia, hypercarbia, and thermal stress) during sleep. The side position was considered a reliable alternative to the prone sleeping position, but a number of studies have established a substantial risk for both positions vis-à-vis SIDS. *The American Academy of Pediatrics now recognizes the supine sleeping position as the only safe position that reduces the risk of SIDS*. This "Back to Sleep" campaign has resulted in substantial reductions in SIDS-related deaths since its inception in 1994.

As has been stated, SIDS is not the only cause of sudden unexpected deaths in infancy. In fact, SIDS is a diagnosis of exclusion, requiring careful examination of the death scene and a complete postmortem examination. The latter can reveal an unsuspected cause of sudden death in as many as 20% or more of "SIDS" babies. Infections (e.g., viral myocarditis or bronchopneumonia) are the most common causes of sudden "unexpected" death, followed by unsuspected congenital anomalies. In part as a result of advancements in molecular diagnostics and knowledge of the human genome, several genetic causes of sudden "unexpected" infant death have emerged. For example, fatty acid oxidation disorders, characterized by defects in mitochondrial fatty acid oxidative enzymes, may be responsible for as many as 5% of sudden deaths in infancy. Other newly emerging genetic causes of *explained* sudden death are listed in Table 10-7 .

2.10.7 Tumors & Tumor-like Lesions of Infancy & Childhood

Only 2% of all malignant tumors occur in infancy and childhood; nonetheless, cancer (including leukemia) accounts for about 9% of deaths in the United States in children over age 4 and up to age 14, and only accidents cause significantly more deaths. Benign tumors are even more common than cancers. Most benign tumors are of little concern, but on occasion they cause serious complications by virtue of their location or rapid increase in size.

It is sometimes difficult to separate, on morphologic grounds, true tumors or neoplasms from tumor-like lesions in the infant and child. In this context, two special categories of tumor-like lesions should be distinguished from true tumors.

The term *heterotopia* (or *choristoma*) is applied to microscopically normal cells or tissues that are present in abnormal locations. Examples of heterotopias include a rest of pancreatic tissue found in the wall of the stomach or small intestine, or a small mass of adrenal cells found in the kidney, lungs, ovaries, or elsewhere. These heterotopic rests are usually of little significance, but they can be confused

clinically with neoplasms. Rarely, they are sites of origin of true neoplasms, producing paradoxes such as an adrenal carcinoma arising in the ovary.

The term *hamartoma* refers to an excessive, focal overgrowth of cells and tissues native to the organ in which it occurs. Although the cellular elements are mature and identical to those found in the remainder of the organ, they do not reproduce the normal architecture of the surrounding tissue. The line of demarcation between a hamartoma and a benign neoplasm is often unclear, as both lesions can be clonal. Hemangiomas, lymphangiomas, rhabdomyomas of the heart, adenomas of the liver, and developmental cysts within the kidneys, lungs, or pancreas are interpreted by some as hamartomas and by others as true neoplasms. The frequency of these lesions in infancy and childhood and their clinical behavior give credence to the belief that many are developmental aberrations. Their unequivocally benign histology, however, does not preclude bothersome and rarely life-threatening clinical problems in some cases.

BENIGN TUMORS AND TUMOR-LIKE LESIONS

Virtually any tumor may be encountered in children, but within this wide array hemangiomas, lymphangiomas, fibrous lesions, and teratomas deserve special mention. You will notice that the most common neoplasms of childhood are so-called soft-tissue tumors of mesenchymal derivation. This contrasts with adults, in whom the most common tumors, benign or malignant, have an epithelial origin. Benign tumors of various tissues are described in greater detail in appropriate chapters; here a few comments are made about their special features in childhood.

Hemangioma.

Hemangiomas (Chapter 11) are the most common tumors of infancy. Architecturally, they do not differ from those occurring in adults. Both cavernous and capillary hemangiomas may be encountered, although the latter are often more cellular than in adults, a feature that is deceptively worrisome. In children, most are located in the skin, particularly on the face and scalp, where they produce flat to elevated, irregular, red-blue masses; some of the flat, larger lesions (considered by some to represent vascular ectasias) are referred to as *port-wine stains*. Hemangiomas may enlarge along with the growth of the child, but in many instances they spontaneously regress (Fig. 10-23). In addition to their cosmetic significance, they can represent one facet of the hereditary disorder von Hippel-Lindau disease (Chapter 20). A subset of central nervous system cavernous hemangiomas can occur in the familial setting; these families harbor mutations in one of three cerebral cavernous malformation (CCM) genes.

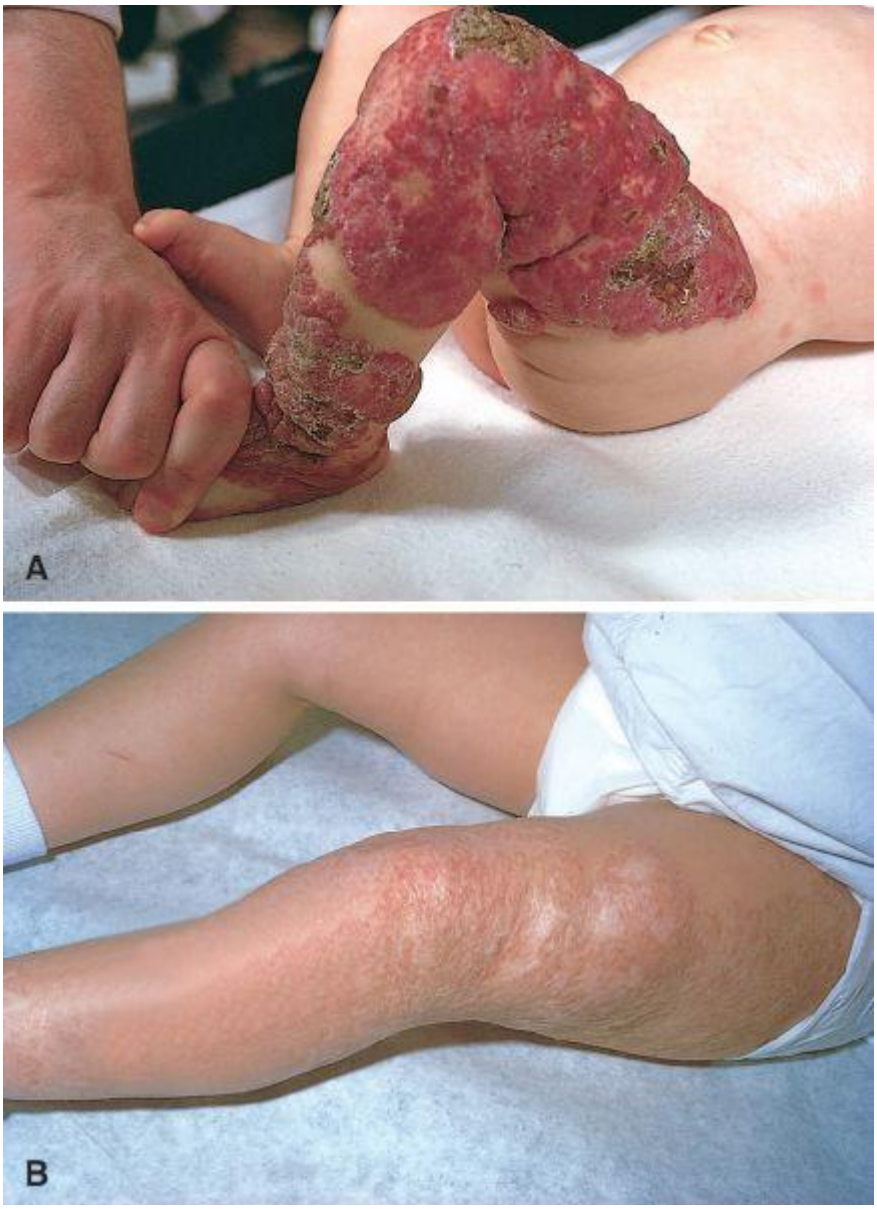

FIGURE 10-23 Congenital capillary hemangioma at birth (**A**) and at age 2 years (**B**) after spontaneous regression. *(Courtesy of Dr. Eduardo Yunis, Children's Hospital of Pittsburgh, Pittsburgh, PA.)*

Lymphatic Tumors.

A wide variety of lesions are of lymphatic origin. Some of them—*lymphangiomas*—are hamartomatous or neoplastic, whereas others seem to represent abnormal dilations of preexisting lymph channels known as *lymphangiectasis*. The *lymphangiomas* are usually characterized by cystic and cavernous spaces. Lesions of this nature may occur in the skin but are more often encountered in the deeper regions of the neck, axilla, mediastinum, retroperitoneal tissue, and elsewhere. Although histologically benign, they tend to increase in size after birth, owing to the accumulation of fluid and the budding of preexisting spaces. In this manner they may encroach on vital structures, such as those in the mediastinum or nerve trunks in the axilla, and give rise to clinical problems. *Lymphangiectasis*, in contrast, usually presents as a diffuse swelling of part or all of an extremity; considerable distortion and

deformation may occur as a consequence of the spongy, dilated subcutaneous and deeper lymphatics. The lesion is not progressive, however, and does not extend beyond its original location. Nonetheless, it creates cosmetic problems that are often difficult to correct surgically.

Fibrous Tumors.

Fibrous tumors occurring in infants and children range from sparsely cellular proliferations of spindle-shaped cells (designated as *fibromatosis*) to richly cellular lesions indistinguishable from fibrosarcomas occurring in adults (designated as *congenital-infantile fibrosarcomas*). Biologic behavior cannot be predicted based on histology alone, however, in that despite their histologic similarities with adult fibrosarcomas, the congenital-infantile variants have an excellent prognosis. Recently, a characteristic chromosomal translocation, t(12;15)(p13;q25), has been described in congenital-infantile fibrosarcomas, which results in generation of an *ETV6-NTRK3* fusion transcript.[51] The normal *ETV6* gene product is a transcription factor, while the *NTRK3* gene product (also known as TRKC, see below) is a tyrosine kinase. Like other tyrosine kinase fusion proteins found in human neoplasms, ETV6-TRKC is constitutively active and stimulates signaling through the oncogenic RAS and PI-3K/AKT pathways (Chapter 4). Among soft-tissue tumors, the ETV6-NTRK3 fusion transcript is unique to infantile fibrosarcomas, making it a useful diagnostic marker.

Teratomas.

Teratomas illustrate the relationship of histologic maturity to biologic behavior. They may occur as benign, well-differentiated cystic lesions (mature teratomas), as lesions of indeterminate potential (immature teratomas), or as unequivocally malignant teratomas (usually admixed with another germ cell tumor component such as endodermal sinus tumor) (Chapter 21). They exhibit two peaks in incidence: the first at approximately 2 years of age and the second in late adolescence or early adulthood. The first peak are congenital neoplasms; the later occurring lesions may also be of prenatal origin but are more slowly growing. *Sacrococcygeal teratomas* are the most common teratomas of childhood, accounting for 40% or more of cases (Fig. 10-24). They occur with a frequency of 1 in 20,000 to 40,000 live births, and are four times more common in girls than boys. In view of the overlap in the mechanisms underlying teratogenesis and oncogenesis, it is interesting that approximately 10% of sacrococcygeal teratomas are associated with congenital anomalies, primarily defects of the hindgut and cloacal region and other midline defects (e.g., meningocele, spina bifida) not believed to result from local effects of the tumor. Approximately 75% of these tumors are mature teratomas, and about 12% are unequivocally malignant and lethal. The remainder is immature teratomas; their malignant potential correlates with the amount of immature tissue, usually immature neuroepithelial elements, present. Most of the benign teratomas are encountered in younger infants (<4 months), whereas children with malignant lesions tend to be somewhat older. Other sites for teratomas in childhood include the testis (Chapter 21), ovaries (Chapter 22), and various midline locations, such as the mediastinum, retroperitoneum, and head and neck.

FIGURE 10-24 Sacrococcygeal teratoma. Note the size of the lesion compared with that of the stillbirth.

MALIGNANT TUMORS

Cancers of infancy and childhood differ biologically and histologically from their counterparts occurring later in life. The main differences, some of which have already been alluded to, include the following:

- Incidence and type of tumor
- Relatively frequent demonstration of a close relationship between abnormal development (teratogenesis) and tumor induction (oncogenesis)
- Prevalence of underlying familial or genetic aberrations
- Tendency of fetal and neonatal malignancies to regress spontaneously or cytodifferentiate

- Improved survival or cure of many childhood tumors, so that more attention is now being devoted to minimizing the adverse delayed effects of chemotherapy and radiation therapy in survivors, including the development of second malignancies

Incidence and Types

The most frequent childhood cancers arise in the hematopoietic system, nervous tissue (including the central and sympathetic nervous system, adrenal medulla, and retina), soft tissues, bone, and kidney. This is in sharp contrast to adults, in whom the skin, lung, breast, prostate, and colon are the most common sites of tumors.

Neoplasms that exhibit sharp peaks in incidence in children younger than age 10 years include (1) leukemia (principally acute lymphoblastic leukemia), (2) neuroblastoma, (3) Wilms tumor, (4) hepatoblastoma, (5) retinoblastoma, (6) rhabdomyosarcoma, (7) teratoma, (8) Ewing sarcoma, and finally, posterior fossa neoplasms—principally (9) juvenile astrocytoma, (10) medulloblastoma, and (11) ependymoma. Other forms of cancer are also common in childhood but do not have the same striking early peak. The approximate age distribution of these cancers is indicated in Table 10-8 . Within this large array, leukemia alone accounts for more deaths in children younger than age 15 years than all of the other tumors combined.

TABLE 10-8 -- Common Malignant Neoplasms of Infancy and Childhood

0 to 4 Years	5 to 9 Years	10 to 14 Years
Leukemia	Leukemia	
Retinoblastoma	Retinoblastoma	
Neuroblastoma	Neuroblastoma	
Wilms tumor		
Hepatoblastoma	Hepatocellular carcinoma	Hepatocellular carcinoma
Soft-tissue sarcoma (especially rhabdomyosarcoma)	Soft-tissue sarcoma	Soft-tissue sarcoma
Teratomas		
Central nervous system tumors	Central nervous system tumors	Osteogenic sarcoma
	Ewing sarcoma	Thyroid carcinoma
	Lymphoma	Hodgkin disease

Histologically, many of the malignant non-hematopoietic pediatric neoplasms are unique. In general, they tend to have a more primitive *(embryonal)* rather than pleomorphic-anaplastic microscopic appearance, are often characterized by sheets of cells with small, round nuclei, and frequently show features of organogenesis specific to the site of tumor origin. Because of this latter characteristic, these tumors are frequently designated by the suffix *-blastoma*, for example, nephroblastoma (Wilms tumor), hepatoblastoma, and neuroblastoma. Because of their primitive histologic appearance, many childhood tumors have been collectively referred to as *small round blue cell tumors*. The differential diagnosis of such tumors includes neuroblastoma, Wilms tumor, lymphoma (Chapter 14), rhabdomyosarcoma (Chapter 26), Ewing sarcoma/primitive neuroectodermal tumor (Chapter 26), medulloblastoma (Chapter 28), and retinoblastoma (Chapter 29). If the anatomic site of origin is known, diagnosis is usually possible on histologic grounds alone. Occasionally, a combination of chromosome analysis, immunoperoxidase stains, or electron microscopy is required. Two of these tumors are particularly illustrative and are discussed here: the neuroblastic tumors, specifically neuroblastoma, and Wilms tumor. The remaining tumors are discussed in their respective organspecific chapters.

The term *neuroblastic tumor* includes tumors of the sympathetic ganglia and adrenal medulla that are derived from primordial neural crest cells populating these sites. As a family, neuroblastic tumors demonstrate certain characteristic features including *spontaneous or therapy-induced differentiation of primitive neuroblasts into mature elements, spontaneous tumor regression*, and a *wide range of clinical behavior and prognosis*, which often mirror the extent of histologic differentiation. Neuroblastoma is the most important member of this family. It is the most common extracranial solid tumor of childhood, and the most frequently diagnosed tumor of infancy. The prevalence is about one case in 7000 live births, and there are approximately 700 cases diagnosed each year in the United States. The median age at diagnosis is 18 months; approximately 40% of cases are diagnosed in infancy. Most neuroblastomas occur sporadically, but 1% to 2% are familial, and in such cases the neoplasms may involve both of the adrenals or multiple primary autonomic sites. Germline mutations in the *anaplastic lymphoma kinase (ALK)* gene (Chapter 14) have recently been identified as a major cause of familial predisposition to neuroblastoma.[52] Somatic gain-of-function *ALK* mutations are also observed in a subset of sporadic neuroblastomas. It is envisioned that tumors harboring *ALK* mutations in either the germline or somatic setting will be amenable to treatment using drugs that target the activity of this kinase.

Despite the remarkable progress made in the therapy of this disease, long-term prognosis for the high-risk subsets remains modest, with a 5-year survival in the range of 40%. As will be evident later, age and stage have a remarkable effect on prognosis, and, in general, children younger than 18 months of age tend to have a significantly better prognosis than older individuals at comparable disease burdens.

Morphology In childhood about 40% of neuroblastomas arise in the adrenal medulla. The remainder occur anywhere along the sympathetic chain, with the most common locations being the paravertebral region of the abdomen (25%) and posterior mediastinum (15%). Tumors may arise in numerous other sites, including the pelvis, the neck, and within the brain (cerebral neuroblastomas).

Neuroblastomas range in size from minute nodules (so-called **in situ lesions**) to large masses more than 1 kg in weight (Fig. 10-25). In situ neuroblastomas are reported to occur 40 times more frequently than clinically overt tumors. The great majority of these silent lesions spontaneously regress, leaving only a focus of fibrosis or calcification in the adult; this has led some to question the neoplastic connotation for the in situ lesions, arguing instead in favor of labeling them as developmental anomalies (“rests”). Some neuroblastomas are often sharply demarcated by a fibrous pseudo-capsule, but others are far more infiltrative and invade surrounding structures, including the kidneys, renal vein, and vena cava, and envelop the aorta. On transection, they are composed of soft, gray-tan, tissue. Larger tumors have areas of necrosis, cystic softening, and hemorrhage. Occasionally, foci of punctate intra-tumoral calcification can be palpated.

Histologically, classic neuroblastomas are composed of small, primitive-appearing cells with dark nuclei, scant cytoplasm, and poorly defined cell borders growing in solid sheets. Such tumors may be difficult to differentiate morphologically from other small round blue cell tumors. Mitotic activity, nuclear breakdown (“karyorrhexis”), and pleomorphism may be prominent. The background often demonstrates a faintly eosinophilic fibrillary material (**neuropil**) that corresponds to neuritic processes of the primitive neuroblasts. Typically, rosettes (**Homer-Wright pseudorosettes**) can be found in which the tumor cells are concentrically arranged about a central space filled with neuropil (Fig. 10-26). Other helpful features include positive immunochemical reactions for neuron-specific enolase and ultrastructural demonstration of small, membrane-bound, cytoplasmic catecholamine-containing secretory granules; the latter contain characteristic central dense cores surrounded by a peripheral halo (dense core granules). Some neoplasms show signs of maturation that can be

spontaneous or therapy-induced. Larger cells having more abundant cytoplasm, large vesicular nuclei, and a prominent nucleolus, representing *ganglion cells* in various stages of maturation, may be found in tumors admixed with primitive neuroblasts (**ganglioneuroblastoma**). Even better differentiated lesions contain many more large cells resembling mature ganglion cells with few if any residual neuroblasts; such neoplasms merit the designation **ganglioneuroma** (Fig. 10-27). Maturation of neuroblasts into ganglion cells is usually accompanied by the appearance of **Schwann cells**. In fact, the presence of a so-called schwannian stroma composed of organized fascicles of neuritic processes, mature Schwann cells, and fibroblasts is a histologic prerequisite for the designation of ganglioneuroblastoma and ganglioneuroma; ganglion cells in and of themselves do not fulfill the criteria for maturation. The origin of Schwann cells in neuroblastoma remains an issue of contention; some investigators believe they represent a reactive population recruited by the tumor cells. However, studies using microdissection techniques have demonstrated that the Schwann cells harbor at least a subset of the same genetic alterations found in neuroblasts, and therefore are a component of the malignant clone.[53] Irrespective of histogenesis, documenting the presence of schwannian stroma is essential, since its presence is associated with a **favorable outcome** (Table 10-9).

Metastases, when they develop, appear early and widely. In addition to local infiltration and lymph node spread, there is a pronounced tendency to spread through the bloodstream to involve the liver, lungs, bone marrow, and bones.

Staging. The International Neuroblastoma Staging System, which is the most widely used staging scheme worldwide, is detailed below:

- **Stage 1:** Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral nonadherent lymph nodes negative for tumor (nodes adherent to the primary tumor may be positive for tumor).
- **Stage 2A:** Localized tumor with incomplete gross resection; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
- **Stage 2B:** Localized tumor with or without complete gross excision; ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes, which are negative for tumor microscopically.
- **Stage 3:** Unresectable unilateral tumor infiltrating across the midline with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement.
- **Stage 4:** Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs *(except as defined forstage 4S)*.
- **Stage 4S** ("S" = special): Localized primary tumor (as defined for stages 1, 2A, or 2B) with dissemination limited to skin, liver, and/or bone marrow; *stage 4S is limited to infants younger than 1 year*.

Unfortunately, most (60% to 80%) children present with stage 3 or 4 tumors, and only 20% to 40% present with stage 1, 2A, 2B, or 4S neuroblastomas. The staging system is of paramount importance in determining prognosis.

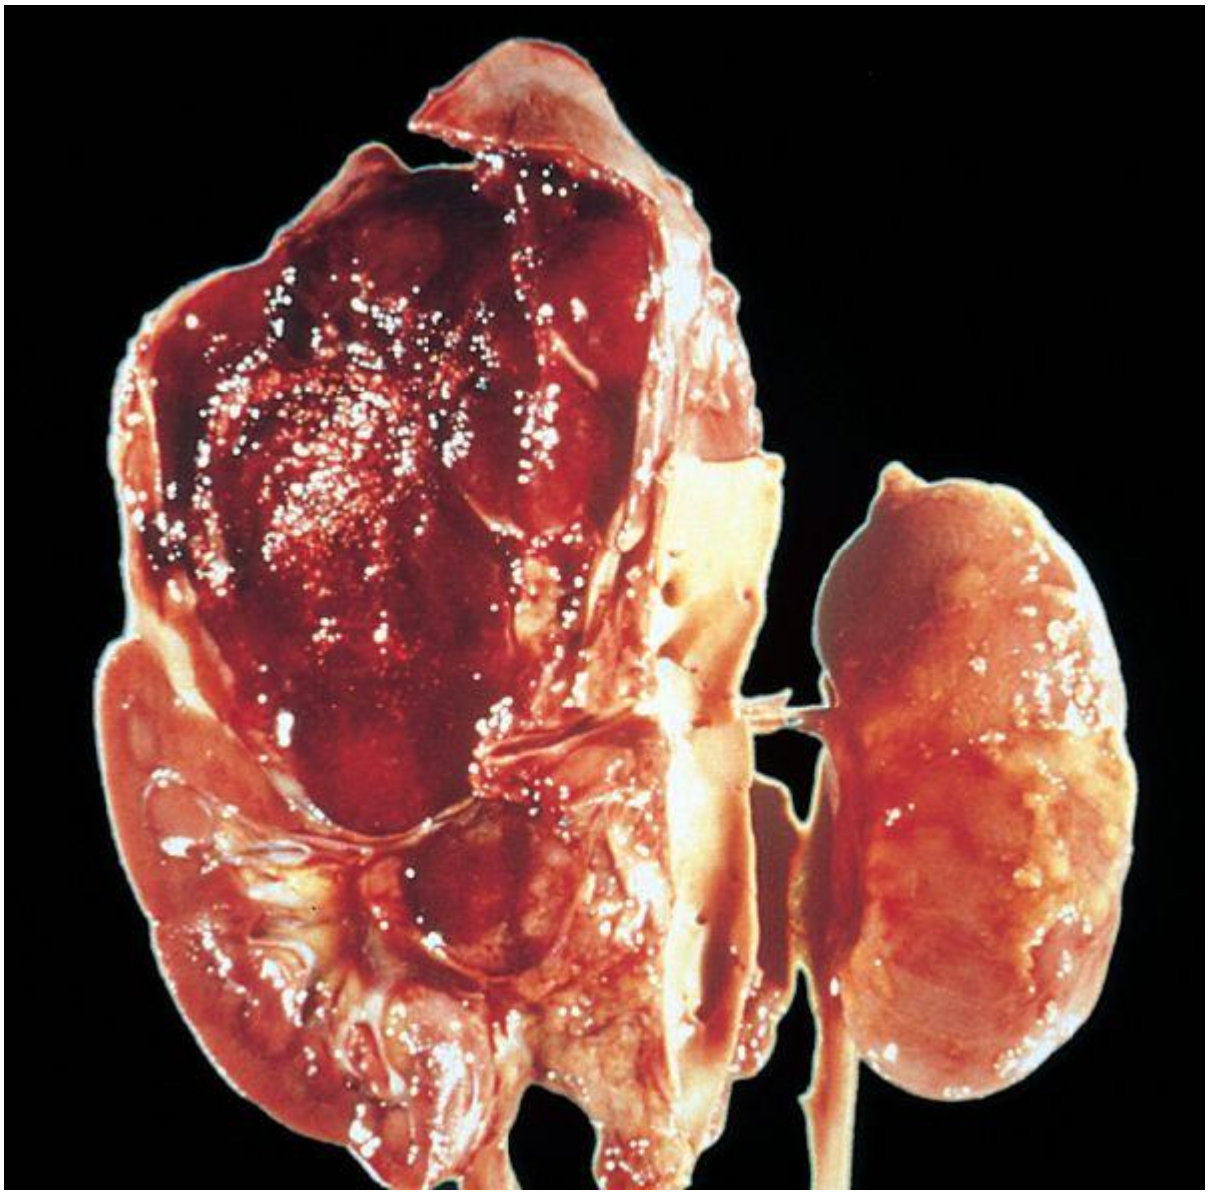

FIGURE 10-25 Adrenal neuroblastoma in a 6-month-old child. The hemorrhagic, partially encapsulated tumor has displaced the opened left kidney and is impinging on the aorta and left renal artery. *(Courtesy of Dr. Arthur Weinberg, University of Texas Southwestern Medical School, Dallas, TX.)*

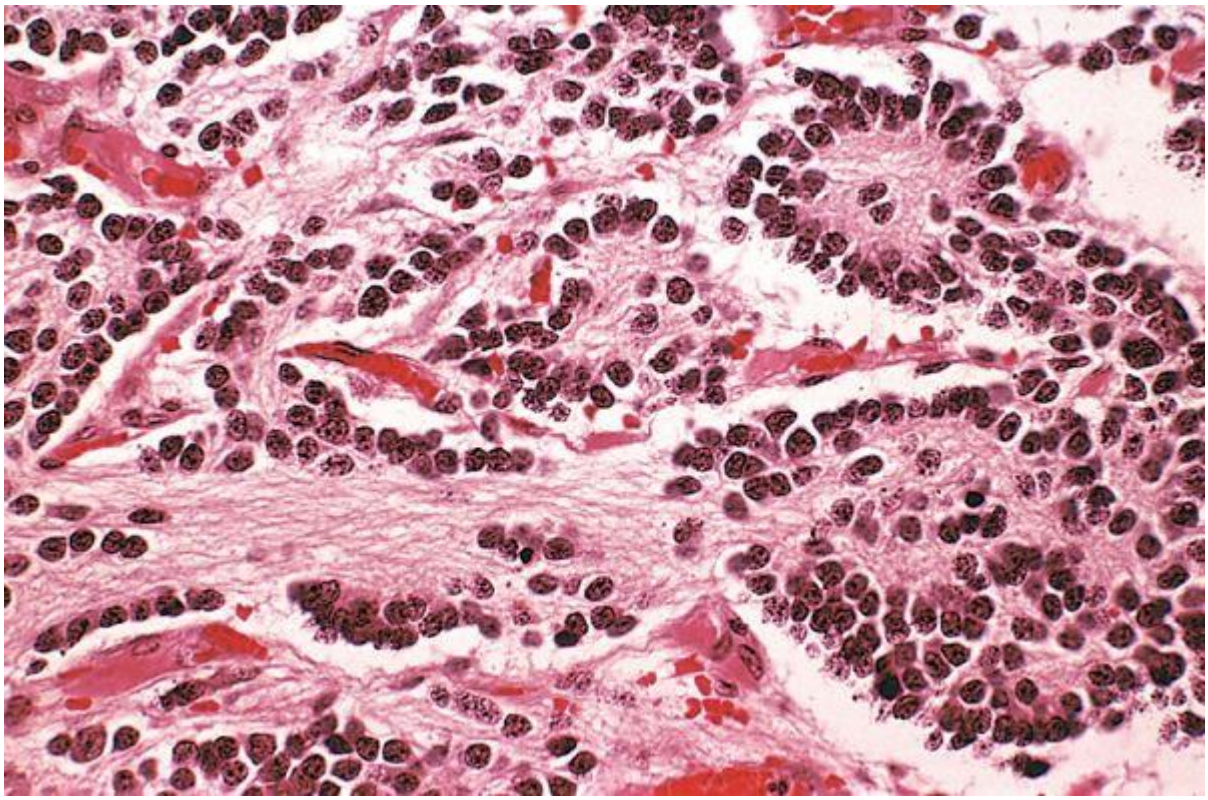

FIGURE 10-26 Adrenal neuroblastoma. This tumor is composed of small cells embedded in a finely fibrillar matrix.

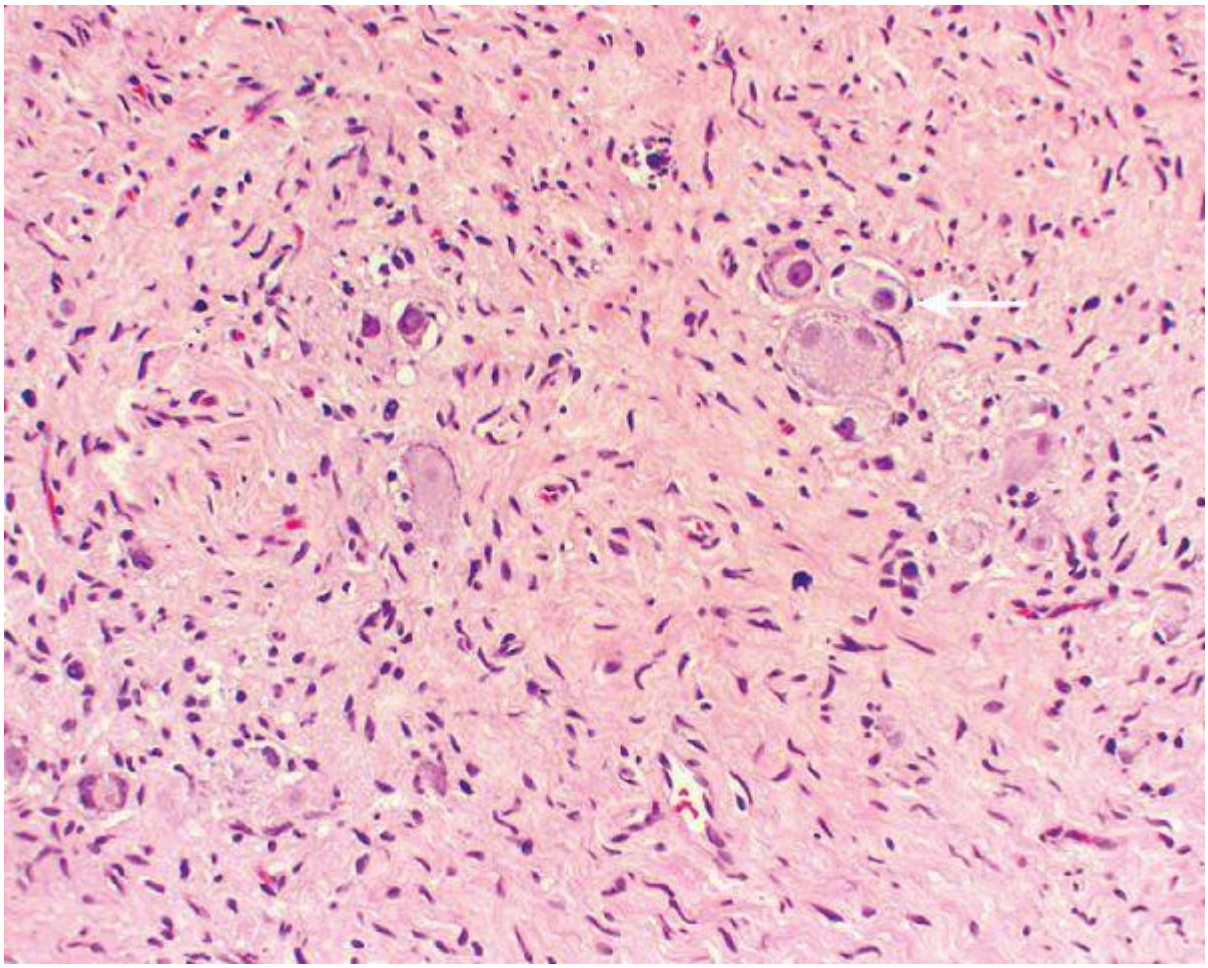

FIGURE 10-27 Ganglioneuromas, arising from spontaneous or therapy-induced maturation of neuroblastomas, are characterized by clusters of large cells with vesicular nuclei and abundant eosinophilic cytoplasm, representing neoplastic ganglion cells *(arrow)*. Spindle-shaped Schwann cells are present in the background stroma.

TABLE 10-9 -- Prognostic Factors in Neuroblastomas

Variable	Favorable	Unfavorable
Stage[*]	Stage 1, 2A, 2B, 4S	Stage 3, 4
Age[*]	<18 months	>18 months
Histology[*]		
Evidence of schwannian stroma and gangliocytic differentiation[†]	Present	Absent
Mitosis-karyorrhexis index[‡]	<200/5000 cells	>200/5000 cells
DNA ploidy[*]	Hyperdiploid or near-triploid	Near-diploid
N-MYC[*]	Not amplified	Amplified
Chromosome 17q gain	Absent	Present
Chromosome 1p loss	Absent	Present
Chromosome 11q loss	Absent	Present
TRKA expression	Present	Absent

TRKB expression	Absent	Present
Telomerase expression	Low or absent	Highly expressed

* Corresponds to the most commonly used parameters in clinical practice for assessment of prognosis and risk stratification.

† It is not only the presence but also the amount of schwannian stroma that confers the designation of a favorable histology. At least *50% or more schwannian stroma* is required before a neoplasm can be classified as ganglioneuroblastoma or ganglioneuroma.

‡ Mitotic karyorrhexis index (MKI) is defined as the number of mitotic or karyorrhectic cells per 5000 tumor cells in random foci.

Clinical Course and Prognostic Features.

In young children, under age 2 years, neuroblastomas generally present with large abdominal masses, fever, and possibly weight loss. In older children, they may not come to attention until metastases produce manifestations, such as bone pain, respiratory symptoms, or gastrointestinal complaints. Neuroblastomas may metastasize widely through the hematogenous and lymphatic systems, particularly to liver, lungs, bones, and bone marrow. Proptosis and ecchymosis may also be present, because the periorbital region is a common metastatic site. Bladder and bowel dysfunction may be caused by paraspinal neuroblastomas that impinge on nerves. In neonates, disseminated neuroblastomas may present with multiple cutaneous metastases that cause deep blue discoloration of the skin (earning the unfortunate designation of "*blueberry muffin baby*"). *About 90% of neuroblastomas, regardless of location, produce catecholamines* (similar to the catecholamines associated with pheochromocytomas), which are an important diagnostic feature (i.e., elevated blood levels of catecholamines and elevated urine levels of the metabolites vanillylmandelic acid [VMA] and homovanillic acid [HVA]). Despite the elaboration of catecholamines, hypertension is much less frequent with these neoplasms than with pheochromocytomas (Chapter 24). Ganglioneuromas, unlike their malignant counterparts, tend to produce either asymptomatic mass lesions or symptoms related to compression.

The course of neuroblastomas is extremely variable. Several clinical, histopathologic, molecular, and biochemical factors have been identified that have a bearing on prognosis (see Table 10-9)[54]; based on the collection of prognostic factors present in a given patient, they are classified as either "low," "intermediate," or "high" risk. With improvements in therapy, the first two categories result in long-term survival of 80% to 90% of patients, while less than 40% of patients in the high-risk category are long-term survivors. The most pertinent prognostic factors in neuroblastomas include the following:

- *Age and stage are the most important determinants of outcome*. Neuroblastomas at stages 1, 2A, or 2B tend to have an excellent prognosis, irrespective of age ("low" or "intermediate" risk); the one notable exception to this rule are tumors exhibiting amplification of the *N-MYC* oncogene (see below). Infants with localized primary tumors and widespread metastases to the liver, bone marrow, and skin (stage 4S) represent a special subtype, wherein it is not uncommon for the disease to regress spontaneously. The biologic basis of this welcome behavior is not clear. *The age of 18 months has emerged as a critical point of dichotomy in terms of prognosis*.[55] Children younger than 18 months of age, and especially those in the first year of life, have an excellent prognosis regardless of the stage of the neoplasm. Children older than 18 months fall into at least the "intermediate" risk category, while those with higher stage tumors or with confounding unfavorable prognostic variables like *N-MYC* amplification in the neoplastic cells are considered "high" risk.
- *Morphology* is an independent prognostic variable in neuroblastic tumors. An age-linked morphologic classification of neuroblastic tumors has recently been proposed that divides them into *favorable* and *unfavorable* histologic subtypes. The specific morphologic features that bear on prognosis are listed in Table 10-9 .
- *Amplification of the N-MYC oncogene in neuroblastomas is a molecular event that has possibly the most profound impact on prognosis*, particularly when it occurs in tumors that would otherwise portend a good outcome.[56] The presence of *N-MYC* amplification "bumps" the tumor into a "high"-risk category, irrespective of age, stage, or histology. *N-MYC* is located on the distal short arm of chromosome 2 (2p23–p24). Amplification of *N-MYC* does not karyotypically manifest at the resident 2p23–p24 site, but rather as extrachromosomal double minute chromatin bodies or homogeneously staining regions on other

chromosomes (Fig. 10-28). *N-MYC* amplification is present in about 20% to 30% of primary tumors, most presenting as advanced-stage disease and the degree of amplification correlates with worse prognosis. *N-MYC* amplification is currently the most important genetic abnormality used in risk stratification of neuroblastic tumors (see below).

- *Ploidy* of the tumor cells correlates with outcome in children less than 2 years of age but loses its independent prognostic significance in older children. Broadly, neuroblastomas can be divided into two categories: *near-diploid* and *hyper-diploid* (often near-triploid), with the latter being associated with a better prognosis. It is postulated that neuroblastomas with hyper-diploidy have an underlying defect in the mitotic machinery, leading to chromosomal nondisjunction and near-triploidy, but otherwise relatively banal karyotypes. On the contrary, the more aggressive near-diploid tumors harbor generalized genomic instability, with multiple unbalanced translocations and chromosomal rearrangements, which retains overall ploidy but results in a complex karyotype with adverse prognostic implications.

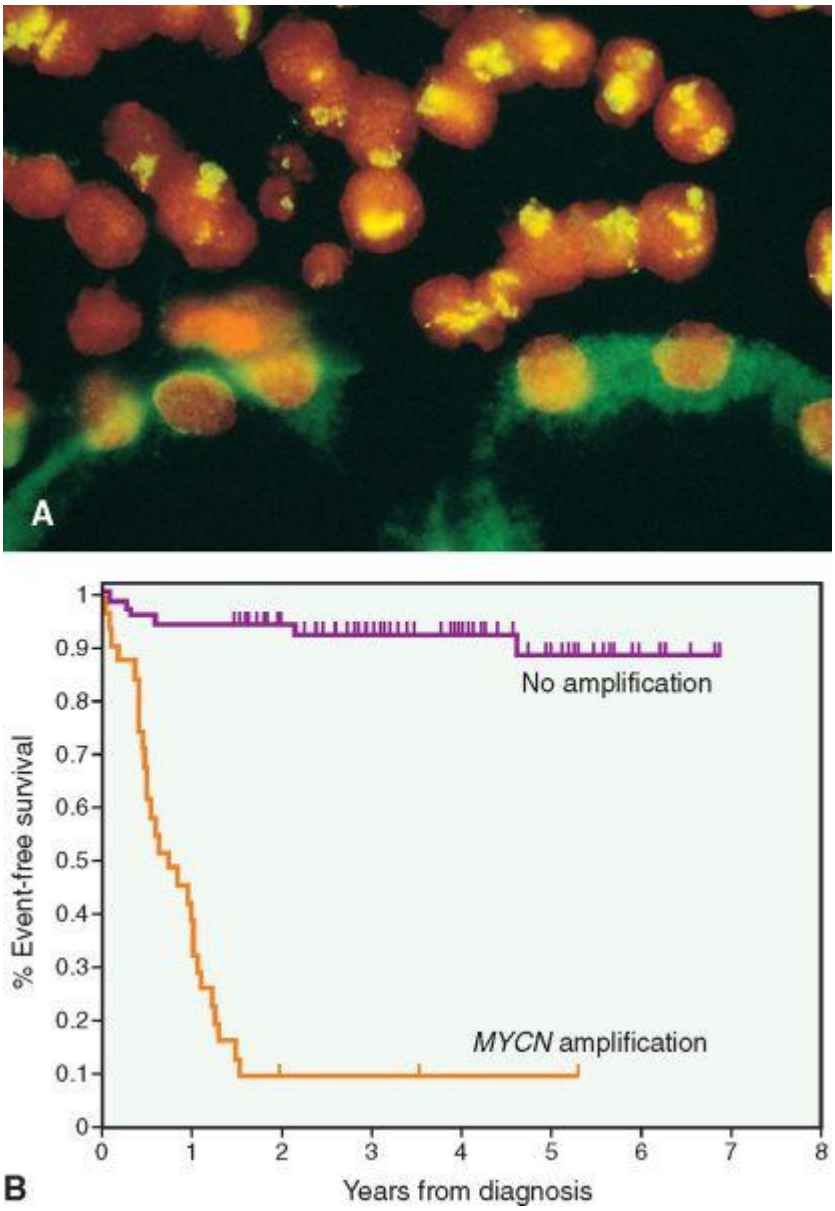

FIGURE 10-28 A, Fluorescence in situ hybridization using a fluorescein-labeled cosmid probe for *N-myc* on a tissue section. Note the neuroblastoma cells on the upper half of the photo with large areas of staining (*yellow-green*); this corresponds to amplified *N-MYC* in the form of homogeneously staining regions. Renal tubular epithelial cells in the lower half of the photograph show no nuclear staining and background (*green*) cytoplasmic staining. *(Courtesy of Dr. Timothy Triche, Children's Hospital, Los Angeles, CA.)* ***B****, A Kaplan–Meier survival curve of infants younger than 1 year of age with metastatic neuroblastoma. The 3-year event-free survival (EFS) of infants whose tumors lacked MYCN amplification was 93%, whereas those with tumors that had MYCN amplification had only a 10% EFS. (Reproduced with permission from*

While *age, stage, N-MYC status, histology,* and *DNA ploidy* are currently the "core" criteria used for the purposes of formal risk stratification and therapeutic decision, several additional molecular variables have been described with prognostic implications. The most pertinent ones include the following:

- *Hemizygous deletion of the distal short arm of chromosome 1* in the region of band p36 has been demonstrated in 25% to 35% of primary tumors. Loss of 1p36 in neuroblastomas has a strong correlation with *N-MYC* amplification, as well as advanced disease stage, and is associated with an increased risk of disease relapse in localized tumors.[57] *Hemizygous loss of chromosome 11q* genetic material is another adverse prognostic factor, and some recent high-resolution microarray studies suggest this abnormality may be the most common deletion event in neuroblastomas.[58]
- *Partial gain of the distal long arm of chromosome 17 is present in up to 50% of tumors*, and associated with an adverse outcome, particularly with the risk of relapse in localized tumors without *N-MYC* amplification.[59]
- *The expression of specific neurotrophin receptors* is also a prognostic marker for neuroblastoma. The neurotrophin receptors are a family of tyrosine kinase receptors, notably TrkA, TrkB, and TrkC (also known as NTRK3, see above), which regulate the growth, survival, and differentiation of neural cells. High TrkA expression is a favorable prognostic factor in neuroblastomas, generally associated with low-stage tumors lacking *N-MYC* amplification that occur in younger patients. In contrast, elevated TrkB expression is associated with unfavorable biological characteristics, including *N-MYC* amplification and a higher disease stage.

Although discussion of the treatment modalities for neuroblastoma is beyond the scope of this book, we will mention in passing two promising experimental approaches that are being evaluated. The first involves the use of retinoids as an adjunct therapy for inducing the differentiation of neuroblastoma. Recall that the retinoic acid pathway plays a critical role in cellular differentiation during embryogenesis. Another emerging "targeted" therapy involves disrupting oncogenic TRKB signaling in neuroblastomas, by using small-molecule inhibitors of its tyrosine kinase activity. Finally, we should mention the current status of screening programs for neuroblastoma. Since the vast majority of neuroblastomas release catecholamines into the circulation, detection of catecholamine metabolites (VMA and HVA) in urine could, in principle, form the basis for screening for asymptomatic tumors in children. However, two large studies in Europe and North America have failed to demonstrate improved mortality rates with such population screening, because most tumors detected had favorable biologic characteristics, and the costs of screening failed to outweigh the benefits.[60,][61] Therefore, community-based screening programs for neuroblastomas are not currently advocated.

Wilms Tumor

Wilms tumor afflicts approximately 1 in every 10,000 children in the United States, and it is the most common primary renal tumor of childhood and the fourth most common pediatric malignancy in the United States. The peak incidence for Wilms tumor is between 2 and 5 years of age, and 95% of tumors occur before the age of 10 years. Approximately 5% to 10% of Wilms tumors involve both kidneys, either simultaneously *(synchronous)* or one after the other *(metachronous)*. Bilateral Wilms tumors have a median age of onset approximately 10 months earlier than tumors restricted to one kidney, and these patients are presumed to harbor a germline mutation in one of the Wilms tumor–predisposing genes (see below). The biology of this tumor illustrates several important aspects of childhood neoplasms, such as the relationship between *malformations* and *neoplasia*, the histologic similarities between *organogenesis* and *oncogenesis*, the *two-hit theory* of recessive tumor suppressor genes (Chapter 7), the role of *premalignant lesions*, and perhaps most importantly, the potential for *judicious treatment*

modalities to dramatically affect prognosis and outcome.[62] Improvements in the cure rates for Wilms tumor (from as low as 30% a few decades ago, to 85% currently) represent one of the greatest successes of pediatric oncology.

Pathogenesis and Genetics.

The risk of Wilms tumor is increased in association with at least four recognizable groups of congenital malformations associated with distinct chromosomal loci. Although Wilms tumors arising in this setting account for no more than 10% of cases, these *syndromic tumors* have provided important insight into the biology of this neoplasm.

The first group of patients has the *WAGR syndrome*, characterized by aniridia, genital anomalies, and mental retardation and a 33% chance of developing Wilms tumor. Individuals with WAGR syndrome carry constitutional (germline) deletions of 11p13. Studies on these patients led to the identification of the first Wilms tumor–associated gene, *WT1*, and a contiguously deleted autosomal dominant gene for aniridia, *PAX6*, both located on chromosome 11p13. Patients with deletions restricted to *PAX6*, with normal *WT1* function, develop sporadic aniridia, but they are *not* at increased risk for Wilms tumors. The presence of germline *WT1* deletions in WAGR syndrome represents the "first hit"; the development of Wilms tumor in these patients frequently correlates with the occurrence of a nonsense or frameshift mutation in the second *WT1* allele ("second hit").

A second group of patients at a much higher risk for Wilms tumor (~90%) have the *Denys-Drash syndrome*, which is characterized by *gonadal dysgenesis* (male pseudohermaphroditism) and *early-onset nephropathy* leading to renal failure. The characteristic glomerular lesion in these patients is a *diffuse mesangial sclerosis* (Chapter 20). As in patients with WAGR, these patients also demonstrate germline abnormalities in *WT1*. In patients with the Denys-Drash syndrome, however, the genetic abnormality is a *dominant-negative missense mutation* in the zinc-finger region of the *WT1* gene that affects its DNA-binding properties. This mutation interferes with the function of the remaining wild-type allele, yet strangely, it is sufficient only in causing genitourinary abnormalities, but not tumorigenesis; Wilms tumors arising in Denys-Drash syndrome demonstrate bi-allelic inactivation of *WT1*. In addition to Wilms tumors, these individuals are also at increased risk for developing germ cell tumors called *gonadoblastomas* (Chapter 21), almost certainly a consequence of disruption in normal gonadal development.

WT1 encodes a DNA-binding transcription factor that is expressed within several tissues, including the kidney and gonads, during embryogenesis. The WT1 protein is critical for normal renal and gonadal development. WT1 has multiple binding partners, and the choice of this partner can affect whether WT1 functions as a transcriptional activator or repressor in a given cellular context.[63] Numerous transcriptional targets of WT1 have been identified, including glomerular podocyte-specific proteins, and genes associated with inducing differentiation. Despite the importance of *WT1* in nephrogenesis and its unequivocal role as a tumor suppressor gene, only about 10% of patients with *sporadic* (nonsyndromic) Wilms tumors demonstrate *WT1* mutations, suggesting that the majority of these tumors arise by genetically distinct pathways.

Clinically distinct from these previous two groups of patients but also having an increased risk of developing Wilms tumor are children with *Beckwith-Wiedemann syndrome* (BWS), characterized by enlargement of body organs (organomegaly), macroglossia, hemihypertrophy, omphalocele, and abnormal large cells in the adrenal cortex (adrenal cytomegaly). BWS has served as a model for a nonclassical mechanism of tumorigenesis in humans—*genomic imprinting* (Chapter 5).[64] The chromosomal region implicated in BWS has been localized to band 11p15.5 ("WT2"), distal to the *WT1* locus. This region contains multiple genes that are normally expressed from only *one* of the two parental alleles, with transcriptional silencing (i.e., imprinting) of the other parental homologue by

methylation of the promoter region. Unlike WAGR or Denys-Drash syndromes, the genetic basis for BWS is considerably more heterogeneous in that no single 11p15.5 gene is involved in all cases. Moreover, the phenotype of BWS, including the predisposition to tumorigenesis, is influenced by the specific "WT2" imprinting abnormalities present. One of the genes in this region—insulin-like growth factor-2 (*IGF2*)—is normally expressed solely from the *paternal allele*, while the maternal allele is silenced by imprinting. In some Wilms tumors, *loss of imprinting* (i.e., re-expression of the maternal *IGF2* allele) can be demonstrated, leading to overexpression of the IGF-2 protein. In other instances there is a selective deletion of the imprinted maternal allele, combined with duplication of the transcriptionally active paternal allele in the tumor *(uniparental paternal disomy)*, which has an identical functional effect in terms of overexpression of IGF-2. Since the IGF-2 protein is an embryonal growth factor, it could conceivably explain the features of overgrowth associated with BWS, as well as the increased risk for Wilms tumors in these patients. Of all the "WT2" genes, imprinting abnormalties of *IGF2* have the strongest relationship to tumor predisposition in BWS.[65] A subset of patients with BWS harbor mutations of the cell cycle regulator *CDKN1C* (also known as *p57* or *KIP2*); however, these patients have a significantly lower risk for developing Wilms tumors. In addition to Wilms tumors, patients with BWS are also at increased risk for developing hepatoblastoma, pancreatoblastoma, adrenocortical tumors, and rhabdomyosarcomas.

Recent genetic studies have also elucidated the role of β-catenin in Wilms tumor. It will be recalled (Chapter 7) that β-catenin belongs to the developmentally important *WNT (wingless)* signaling pathway. Gain-of-function mutations of the gene encoding β-catenin have been demonstrated in approximately 10% of sporadic Wilms tumors; there is a significant overlap between the presence of *WT1* and β-catenin mutations, suggesting a synergistic role for these events in the genesis of Wilms tumors.[66]

Nephrogenic Rests

Nephrogenic rests are putative precursor lesions of Wilms tumors and are seen in the renal parenchyma adjacent to approximately 25% to 40% of unilateral tumors; this frequency rises to nearly 100% in cases of bilateral Wilms tumors. In many instances the nephrogenic rests share genetic alterations with the adjacent Wilms tumor, underscoring their preneoplastic status. The appearance of nephrogenic rests varies from expansile masses that resemble Wilms tumors (hyperplastic rests) to sclerotic rests consisting predominantly of fibrous tissue and occasional admixed immature tubules or glomeruli. It is important to document the presence of nephrogenic rests in the resected specimen, since these patients are at an increased risk of developing Wilms tumors in the *contralateral* kidney and require frequent and regular surveillance for many years.

Morphology. Grossly, Wilms tumor tends to present as a large, solitary, well-circumscribed mass, although 10% are either bilateral or multicentric at the time of diagnosis. On cut section, the tumor is soft, homogeneous, and tan to gray with occasional foci of hemorrhage, cyst formation, and necrosis (Fig. 10-29).

Microscopically, Wilms tumors are characterized by recognizable attempts to recapitulate different stages of nephrogenesis. The classic triphasic combination of blastemal, stromal, and epithelial cell types is observed in the vast majority of lesions, although the percentage of each component is variable (Fig. 10-30). Sheets of small blue cells with few distinctive features characterize the blastemal component. Epithelial differentiation is usually in the form of abortive tubules or glomeruli. Stromal cells are usually fibrocytic or myxoid in nature, although skeletal muscle differentiation is not uncommon. Rarely, other heterologous elements are identified, including squamous or mucinous epithelium, smooth muscle, adipose tissue, cartilage, and osteoid and neurogenic tissue.

Approximately 5% of tumors reveal **anaplasia**, defined as the presence of cells with large, hyperchromatic, pleomorphic nuclei and abnormal mitoses. The presence of anaplasia correlates with the presence of *p53* mutations and the emergence of resistance to chemotherapy.[67] Recall that p53 elicits pro-apoptotic signals in response to DNA damage (Chapter 1). The loss of p53 function might explain the relative unresponsiveness of anaplastic cells to cytotoxic chemotherapy.

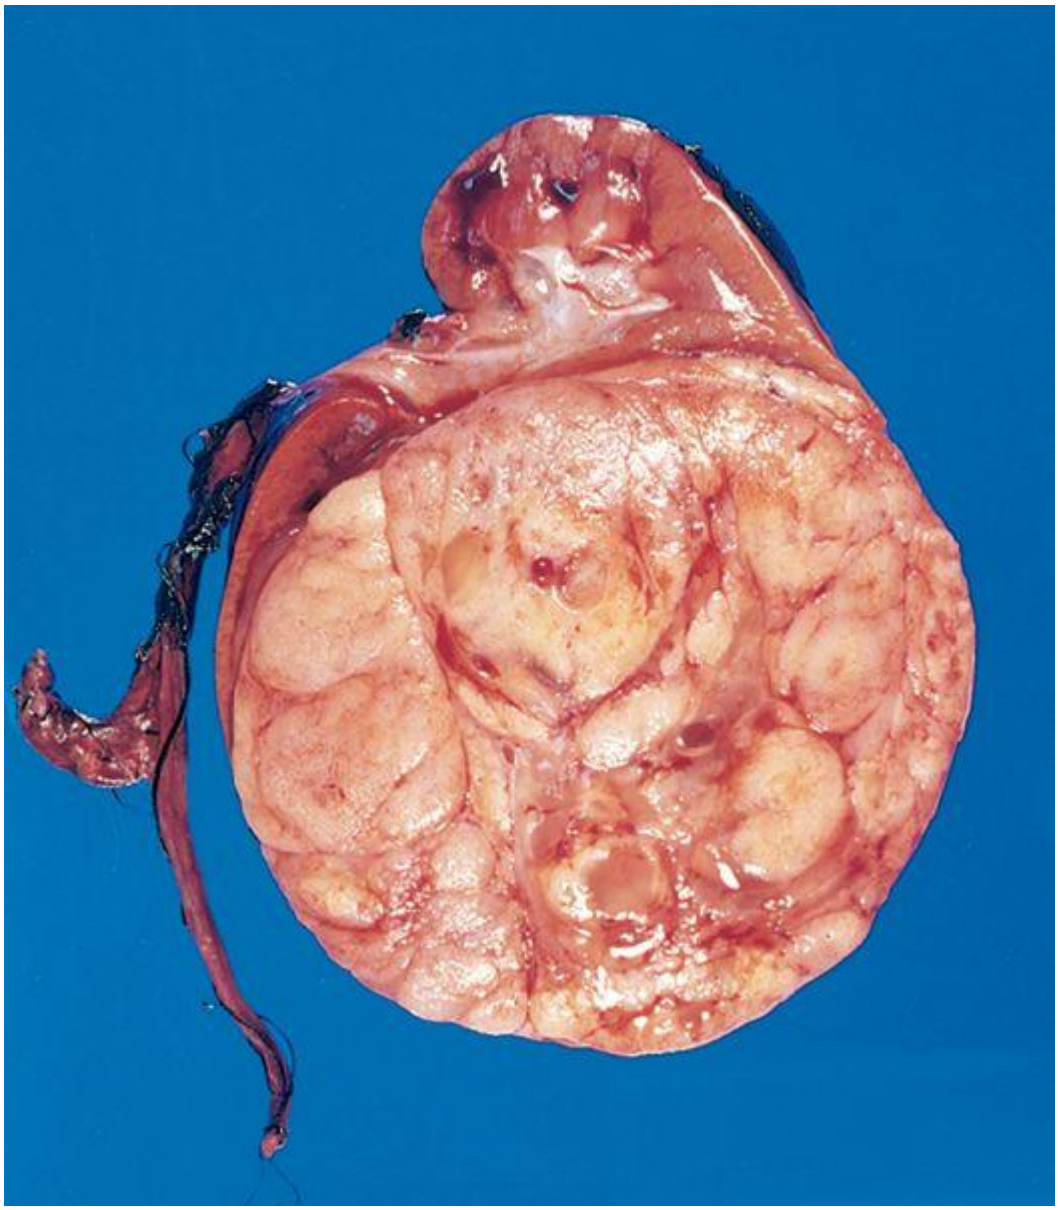

FIGURE 10-29 Wilms' tumor in the lower pole of the kidney with the characteristic tan-to-gray color and well-circumscribed margins.

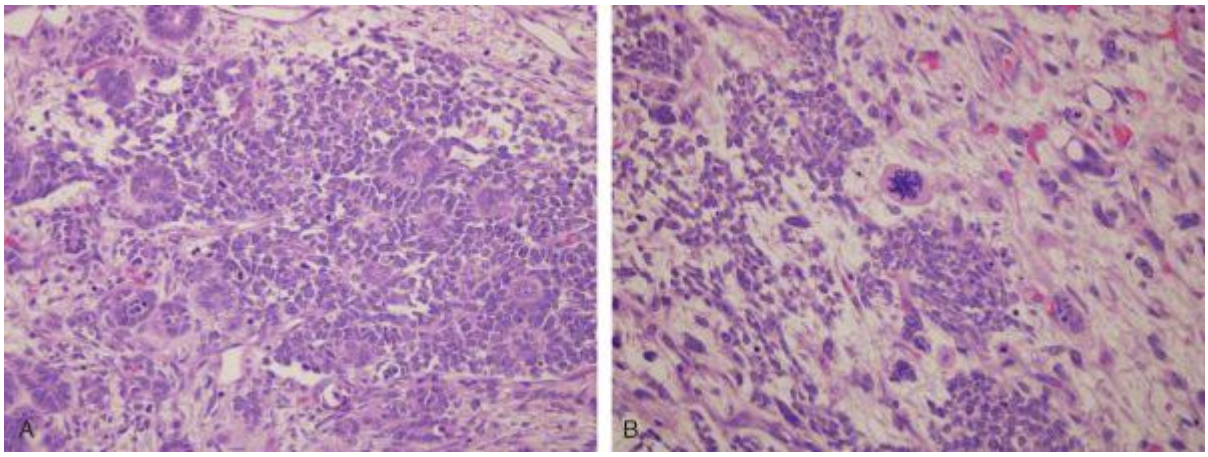

FIGURE 10-30 **A**, Wilms tumor with tightly packed blue cells consistent with the blastemal component and interspersed primitive tubules, representing the epithelial component. Although multiple mitotic figures are seen, none are atypical in this field. **B**, Focal anaplasia was present in this Wilms' tumor in other areas, characterized by cells with hyperchromatic, pleomorphic nuclei and abnormal mitoses.

Clinical Features.

Most children with Wilms tumors present with a large abdominal mass that may be unilateral or, when very large, may extend across the midline and down into the pelvis. Hematuria, pain in the abdomen after some traumatic incident, intestinal obstruction, and appearance of hypertension are other patterns of presentation. In a considerable number of these patients, pulmonary metastases are present at the time of primary diagnosis.

As stated, most patients with Wilms tumor can expect to be cured of their malignancy. Anaplastic histology remains a critical determinant of adverse prognosis. Even anaplasia restricted to the kidney (i.e., without extra-renal spread) confers an increased risk of recurrence and death, underscoring the need for correctly identifying this histologic feature. Molecular parameters that correlate with adverse prognosis include loss of genetic material on chromosomes 11q and 16q, and gain of chromosome 1q in the tumor cells. Along with the increased survival of individuals with Wilms tumor have come reports of an increased relative risk of developing second primary tumors, including bone and soft-tissue sarcomas, leukemia and lymphomas, and breast cancers. While some of these neoplasms represent the presence of a germline mutation in a cancer predisposition gene, others are a consequence of therapy, most commonly radiation administered to the cancer field.[68] This tragic, albeit uncommon, outcome has mandated that radiation therapy be used judiciously in the treatment of this and other childhood cancers.

3. II. Systemic Pathology: Diseases of Organ Systems

3.1 11. Blood Vessels

3.1.1 The Structure & Function of Blood Vessels

RICHARD N. MITCHELL,
FREDERICK J. SCHOEN

Vascular disorders—and their downstream sequelae—are responsible for more morbidity and mortality than any other category of human disease. Although the most clinically significant lesions typically involve arteries, venous diseases also occur. Vascular pathology results in disease via two principal mechanisms: (1) *Narrowing (stenosis)* or *complete obstruction* of vessel lumens, either progressively (e.g., by atherosclerosis) or precipitously (e.g., by thrombosis or embolism); and (2) *weakening* of vessel walls, leading to dilation or rupture.

We will first describe the important structural and functional characteristics of blood vessels to better appreciate how pathologic changes can result in disease states.

The Structure and Function of Blood Vessels

The general architecture and cellular composition of blood vessels are the same throughout the cardiovascular system. However, certain features of the vasculature vary with and reflect distinct functional requirements at different locations (Fig. 11-1). To withstand the pulsatile flow and higher blood pressures in arteries, arterial walls are generally thicker than the walls of veins. Arterial wall thickness gradually diminishes as the vessels become smaller, but the ratio of wall thickness to lumen diameter becomes greater.

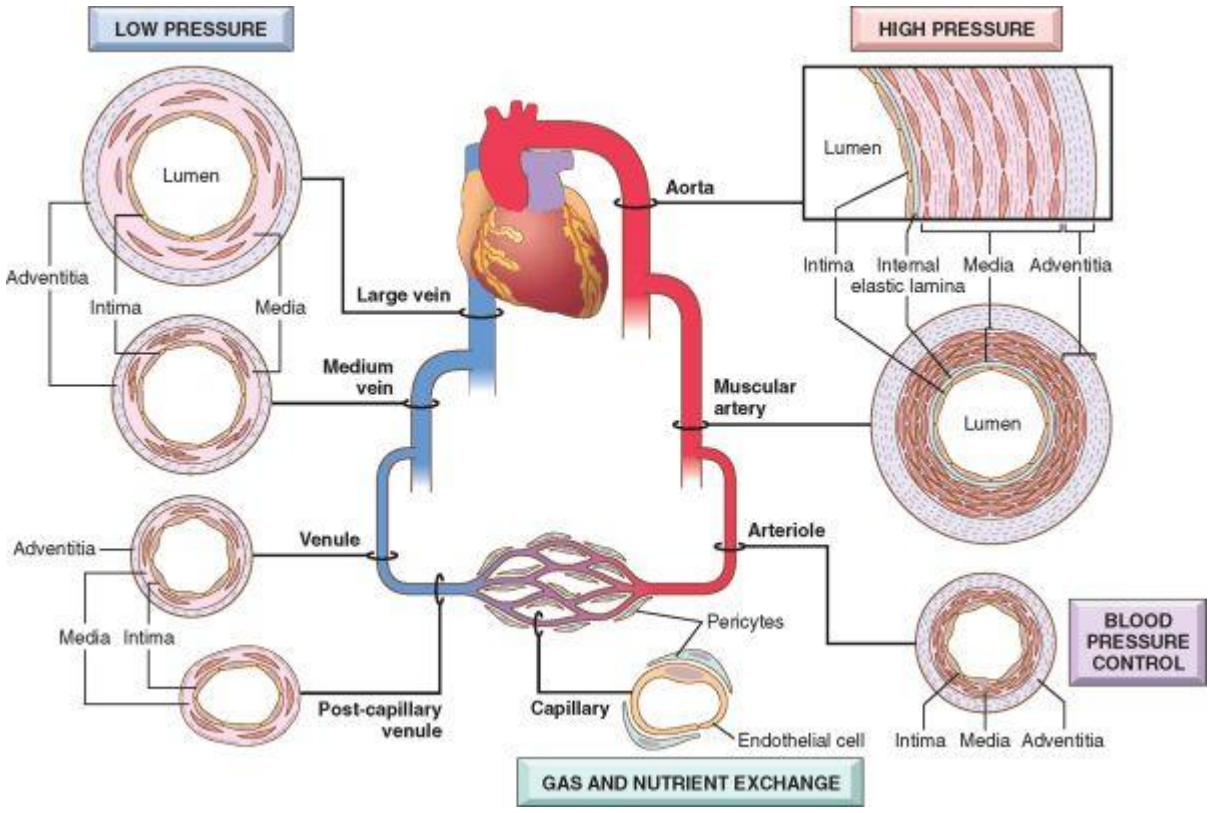

FIGURE 11-1 Regional specializations of the vasculature. Although the basic organization of the vasculature is constant, the thickness and

composition of the various layers differ according to hemodynamic forces and tissue requirements.

The basic constituents of the walls of blood vessels are endothelial cells and smooth muscle cells, and extracellular matrix (ECM), including elastin, collagen, and glycosoaminoglycans. The three concentric layers—*intima*, *media*, and *adventitia*—are most clearly defined in the larger vessels, particularly arteries. In normal arteries, the intima consists of a single layer of endothelial cells with minimal underlying subendothelial connective tissue. It is separated from the media by a dense elastic membrane called the *internal elastic lamina*. The smooth muscle cell layers of the media near the vessel lumen receive oxygen and nutrients by direct diffusion from the vessel lumen, facilitated by holes in the internal elastic membrane. However, diffusion from the lumen is inadequate for the outer portions of the media in large and medium-sized vessels, therefore these areas are nourished by small arterioles arising from outside the vessel (called *vasa vasorum*, literally "vessels of the vessels") coursing into the outer one half to two thirds of the media. The outer limit of the media of most arteries is a well-defined *external elastic lamina*. External to the media is the adventitia, consisting of connective tissue with nerve fibers and the vasa vasorum.

Based on their size and structural features, *arteries* are divided into three types: (1) large or *elastic arteries*, including the aorta, its large branches (particularly the innominate, subclavian, common carotid, and iliac), and pulmonary arteries; (2) medium-sized or *muscular arteries*, comprising other branches of the aorta (e.g., coronary and renal arteries); and (3) small arteries (less than approximately 2 mm in diameter) and *arterioles* (20 to 100 μm in diameter), within the substance of tissues and organs.

The relative amount and configuration of the basic constituents differ along the arterial system owing to local adaptations to mechanical or metabolic needs. These structural variations, from location to location, are principally in the media and in the ECM. In the elastic arteries the media is rich in elastic fibers. This allows vessels such as the aorta to expand during systole and recoil during diastole, thus propelling blood through the peripheral vascular system. With aging, the aorta loses elasticity, and large vessels expand less readily, particularly when blood pressure is increased. Thus, the arteries of older individuals often become progressively tortuous and dilated *(ectatic)*. In *muscular arteries* the media is composed predominantly of circularly or spirally arranged smooth muscle cells. In the muscular arteries and arterioles (see below), regional blood flow and blood pressure are regulated by changes in lumen size through smooth muscle cell contraction *(vasoconstriction)* or relaxation *(vasodilation)*, controlled in part by the autonomic nervous system and in part by local metabolic factors and cellular interactions. Since the resistance of a tube to fluid flow is inversely proportional to the fourth power of the diameter (i.e., halving the diameter increases resistance 16-fold), small changes in the lumen size of small arteries caused by structural change or vasoconstriction can have a profound effect. Thus, *arterioles are the principal points of physiologic resistance to blood flow*.

Capillaries, approximately the diameter of a red blood cell (7 to 8 μm), have an endothelial cell lining but no media. Collectively, capillaries have a very large total cross-sectional area; within the capillaries, the flow rate slows dramatically. With thin walls only and slow flow, capillaries are ideally suited to the rapid exchange of diffusible substances between blood and tissues. As normal tissue function depends on an adequate supply of oxygen through blood vessels, and since diffusion of oxygen in solid tissues is inefficient over distances of greater than approximately 100 μm,[1] the capillary network of most tissues is very rich. Metabolically highly active tissues, such as the myocardium, have the highest density of capillaries.

Blood from capillary beds flows initially into the *postcapillary venules* and then sequentially through collecting venules and small, medium, and large veins. *In many types of inflammation, vascular leakage and leukocyte exudation occur preferentially in postcapillary venules* (Chapter 2).

Relative to arteries, veins have larger diameters, larger lumens, and thinner and less well organized walls (see Fig. 11-1). Thus, because of their poor support, *veins are predisposed to irregular dilation, compression, and easy penetration by tumors and inflammatory processes*. The venous system collectively has a large capacity; approximately two thirds of all the blood is in veins. Reverse flow is prevented by venous valves in the extremities, where blood flows against gravity.

Lymphatics are thin-walled, endothelium-lined channels that serve as a drainage system for returning interstitial tissue fluid and inflammatory cells to the blood. *Lymphatics constitute an important pathway for disease dissemination through transport of bacteria and tumor cells to distant sites*.

As will be discussed in detail in this chapter, pathologic lesions involve vessels of a characteristic size, range, and/or type. Atherosclerosis, for example, affects elastic and muscular arteries, hypertension affects small muscular arteries and arterioles, and specific types of vasculitis involve different vascular segments.

3.1.2 Vessel Development, Growth & Remodeling

Three major processes characterize blood vessel formation and remodeling (covered in detail in Chapter 3): *vasculogenesis*, *angiogenesis*, and *arteriogenesis*.[1]

- *Vasculogenesis* is the de novo formation of blood vessels during embryogenesis. Hemangioblast angiogenic precursors develop and migrate to the sites of vascularization. These differentiate into endothelial cells that associate to form a primitive vascular plexus; with time and the influence of local genetic, metabolic, and hemodynamic factors, this network of cells remodels (through pruning and/or vessel enlargement) into the definitive vascular system.[2,][3] The various isoforms of vascular endothelial growth factor (VEGF) are the primary growth factors involved in this process. Subsequent stabilization of the endothelial tubes during development (and induction of endothelial cell quiescence) also critically requires the recruitment of pericytes and smooth muscle cells, a process that involves *angiopoietin 1* binding to endothelial cell *Tie2 receptors*.
- *Angiogenesis* (or *neovascularization*) constitutes the process of new vessel formation in the mature organism.
- *Arteriogenesis* refers to the remodeling of existing arteries in response to chronic changes in pressure or flow, and results from an interplay of endothelial cell–and smooth muscle cell–derived factors.[4]

3.1.3 Congenital Anomalies

Though rarely symptomatic, variants of the usual anatomic pattern of vascular supply can become important during surgery when a vessel in an unexpected location is injured. Variations in the normal coronary artery anatomy are also extremely important to the cardiac surgeon or interventional cardiologist.[5,][6] Among the other congenital vascular anomalies, three are particularly significant, though not necessarily common:

- *Developmental* or *berry aneurysms* occur in cerebral vessels; when ruptured these can be causes of fatal intracerebral hemorrhage. They are discussed in Chapter 28 .
- *Arteriovenous fistulas* are abnormal, typically small, direct connections between arteries and veins that bypass the intervening capillaries. They occur most commonly as developmental defects but can also result from rupture of an arterial aneurysm into an adjacent vein, from penetrating injuries that pierce arteries and veins, or from inflammatory necrosis of adjacent vessels; intentionally created arteriovenous fistulas are used to provide vascular access for chronic hemodialysis. Like berry aneurysms, ruptured arteriovenous fistulas can be an important cause of intracerebral hemorrhage.[7] Large or extensive arteriovenous fistulas become clinically significant by shunting blood from the arterial to the venous circulations and forcing the heart to

pump additional volume; high-output cardiac failure can ensue.

- *Fibromuscular dysplasia* is a focal irregular thickening of the walls of medium and large muscular arteries, including renal, carotid, splanchnic, and vertebral vessels. The cause is unknown but is probably developmental; first-degree relatives of affected individuals have an increased incidence. Segments of the vessel wall are focally thickened by a combination of irregular medial and intimal hyperplasia and fibrosis; this results in luminal stenosis, and in the renal arteries may be a cause of renovascular hypertension (Chapter 20). Vascular outpouchings *(aneurysms)* may develop in the vessel segments with attenuated media and in some cases can rupture. Fibromuscular dysplasia can manifest at any age, although it is seen most frequently in young women; there is no association with use of oral contraceptives or abnormalities of sex hormone expression.[8]

3.1.4 Vascular Wall Cells & Their Response to Injury

As the main cellular components of the blood vessels, endothelial cells and smooth muscle cells play central roles in vascular biology and pathology. Therefore, we will describe their functions and dysfunctions briefly before we discuss specific vascular disorders.

Endothelial Cells.

Endothelium is critical for maintaining vessel wall homeostasis and circulatory function. Endothelial cells contain *Weibel-Palade bodies*, intracellular membrane-bound storage organelles for von Willebrand's factor (Chapter 4). Antibodies to von Willebrand's factor and/or platelet-endothelial cell adhesion molecule-1 (PECAM-1 or CD31, a protein localized to interendothelial junctions) can be used to identify endothelial cells immunohistochemically.

Vascular endothelium is a multifunctional tissue with a wealth of synthetic and metabolic properties; at baseline it has several constitutive activities critical for normal vessel homeostasis (Table 11-1). Thus, endothelial cells maintain a nonthrombogenic blood-tissue interface (until clotting is necessitated by local injury, Chapter 4), modulate vascular resistance, metabolize hormones, regulate inflammation, and affect the growth of other cell types, particularly smooth muscle cells. In most regions the interendothelial junctions are substantially impermeable. However, tight endothelial cell junctions can loosen under the influence of hemodynamic factors (e.g., high blood pressure) and/or vasoactive agents (e.g., histamine in inflammation), resulting in the flooding of adjacent tissues by electrolytes and protein; in inflammatory states, even leukocytes can slip between adjacent endothelial cells (Chapter 2).

TABLE 11-1 -- Endothelial Cell Properties and Functions

MAINTENANCE OF PERMEABILITY BARRIER
ELABORATION OF ANTICOAGULANT, ANTITHROMBOTIC, FIBRINOLYTIC REGULATORS
Prostacyclin
Thrombomodulin
Heparin-like molecules
Plasminogen activator
ELABORATION OF PROTHROMBOTIC MOLECULES
Von Willebrand's factor
Tissue factor
Plasminogen activator inhibitor
EXTRACELLULAR MATRIX PRODUCTION (COLLAGEN, PROTEOGLYCANS)

MODULATION OF BLOOD FLOW AND VASCULAR REACTIVITY
Vasconstrictors: endothelin, ACE
Vasodilators: NO, prostacyclin
REGULATION OF INFLAMMATION AND IMMUNITY
IL-1, IL-6, chemokines
Adhesion molecules: VCAM-1, ICAM, E-selectin, P-selectin
Histocompatibility antigens
REGULATION OF CELL GROWTH
Growth stimulators: PDGF, CSF, FGF
Growth inhibitors: heparin, TGF-β
OXIDATION OF LDL

ACE, angiotensin-converting enzyme; CSF, colony-stimulating factor; FGF, fibroblast growth factor; IL, interleukin; LDL, low-density lipoprotein; NO, nitric oxide; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-β.

Although endothelial cells share many general attributes, endothelial cell populations that line different portions of the vascular tree (large vessels vs. capillaries, arterial vs. venous) have distinct transcriptional repertoires and behavior.[9] There is also substantial phenotypic variability depending on specific anatomic site. Thus, endothelial cells in liver sinusoids or in renal glomeruli are fenestrated (they have *holes*, presumably to facilitate filtration), while the endothelial cells of the central nervous system (with the associated perivascular cells) create an impermeable blood-brain barrier.

Structurally intact endothelial cells can respond to various pathophysiologic stimuli by adjusting their usual (constitutive) functions and by expressing newly acquired (inducible) properties—a process termed *endothelial activation* (Fig. 11-2).[10,][11] Inducers of endothelial activation include cytokines and bacterial products, which cause inflammation and septic shock (Chapter 2); hemodynamic stresses and lipid products, critical to the pathogenesis of atherosclerosis (see later); advanced glycosylation end products (important in diabetes, Chapter 24); as well as viruses, complement components, and hypoxia. Activated endothelial cells, in turn, express adhesion molecules (Chapter 2), and produce cytokines and chemokines, growth factors, vasoactive molecules that result either in vasoconstriction or in vasodilation, major histocompatibility complex molecules, procoagulant and anticoagulant moieties, and a variety of other biologically active products. Endothelial cells influence the vasoreactivity of the underlying smooth muscle cells through the production of both relaxing factors (e.g., nitric oxide [NO]) and contracting factors (e.g., endothelin).[12] Normal endothelial function is characterized by a balance of these responses.

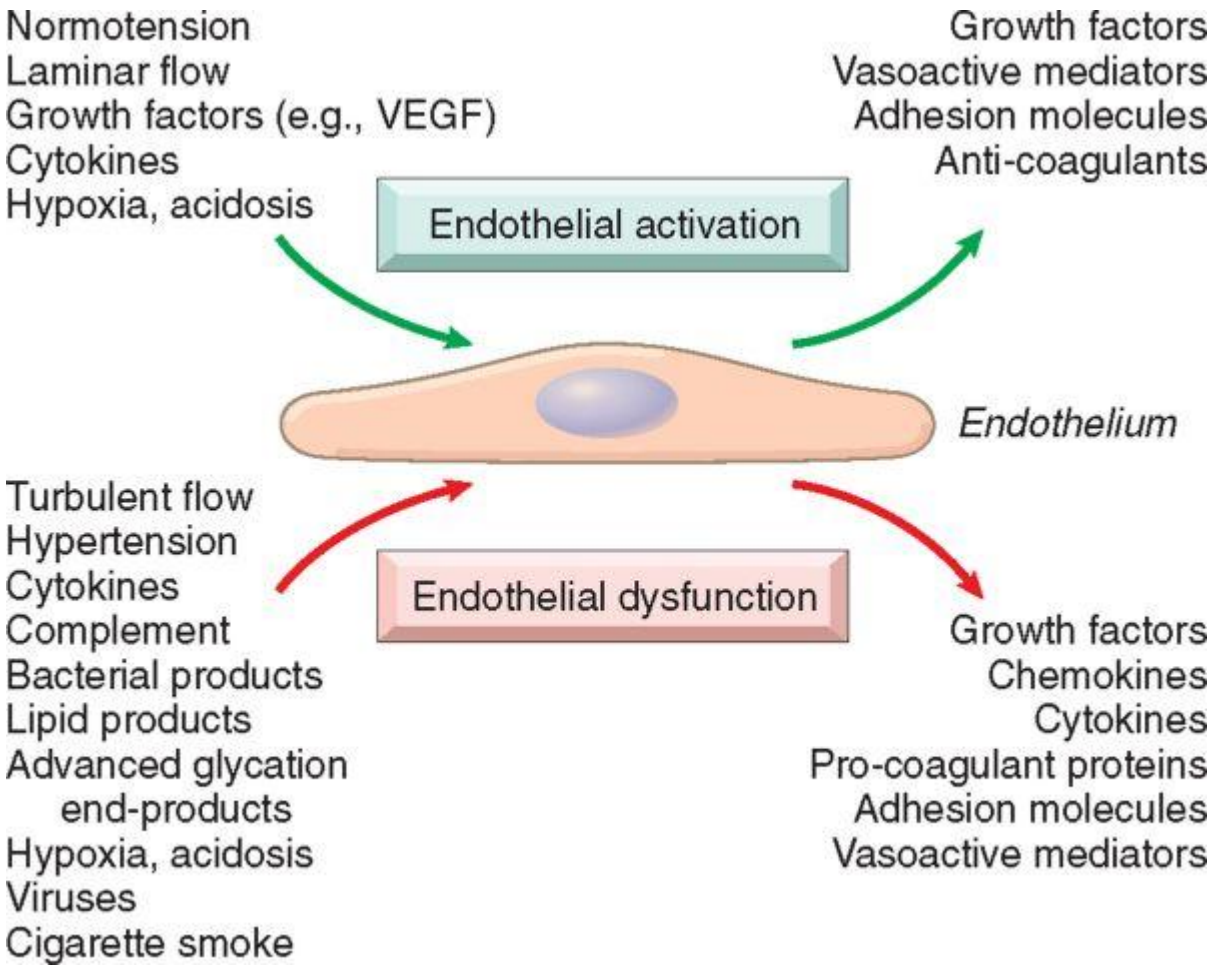

FIGURE 11-2 Endothelial cell responses to environmental stimuli. Certain cues (e.g., laminar flow and constant growth factor levels) lead to stable endothelial cell activation that maintains a nonthrombotic interface with appropriate smooth muscle cell tone. Pathologic mediators or excessive stimulation by normal physiologic pathways (e.g., increased inflammatory cytokines) can result in endothelial cell dysfunction. VEGF, vascular endothelial growth factor.

Endothelial dysfunction is defined as an altered phenotype that impairs vasoreactivity or induces a surface that is thrombogenic or abnormally adhesive to inflammatory cells. It is responsible, at least in part, for the initiation of thrombus formation, atherosclerosis, and the vascular lesions of hypertension and other disorders. Certain forms of endothelial cell dysfunction are rapid in onset (within minutes), reversible, and independent of new protein synthesis (e.g., endothelial cell contraction induced by histamine and other vasoactive mediators that cause gaps in venular endothelium, Chapter 2). Other changes involve alterations in gene expression and protein synthesis and may require hours or even days to develop.

Vascular Smooth Muscle Cells.

As the predominant cellular element of the vascular media, smooth muscle cells play important roles in normal vascular repair and pathologic processes such as atherosclerosis. Smooth muscle cells have the capacity to proliferate when appropriately stimulated; they can also synthesize ECM collagen, elastin, and proteoglycans and elaborate growth factors and cytokines. Smooth muscle cells are also responsible for the vasoconstriction or dilation that occurs in response to physiologic or pharmacologic stimuli.

The migratory and proliferative activities of smooth muscle cells are regulated by growth promoters and inhibitors. Promoters include PDGF, as well as endothelin-1, thrombin, fibroblast growth factor (FGF), interferon-γ (IFN-γ), and interleukin-1(IL-1). Inhibitors include heparan sulfates, nitric oxide, and TGF-β. Other regulators include the renin-angiotensin system (e.g., angiotensin II), catecholamines, the estrogen receptor, and osteopontin, a component of the ECM.[13]

Intimal Thickening—a Stereotypic Response To Vascular Injury.

Vascular injury—with endothelial cell loss or even just dysfunction—stimulates smooth muscle cell growth and associated matrix synthesis that thickens the intima. Healing of injured vessels is analogous to the healing process that occurs in other damaged tissues (Chapter 3); in vessels, it results in the formation of a *neointima*. During the healing process, endothelial cells that fill areas of denudation may migrate from adjacent uninjured areas or may be derived from circulating precursors.[14] Medial smooth muscle cells or smooth muscle precursor cells also migrate into the intima, proliferate, and synthesize ECM in much the same way that fibroblasts fill in a wound (Fig. 11-3). The resulting neointima is typically completely covered by endothelial cells. This neointimal response occurs with any form of vascular damage or dysfunction, regardless of cause. *Thus, intimal thickening is the stereotypical response of the vessel wall to any insult*.

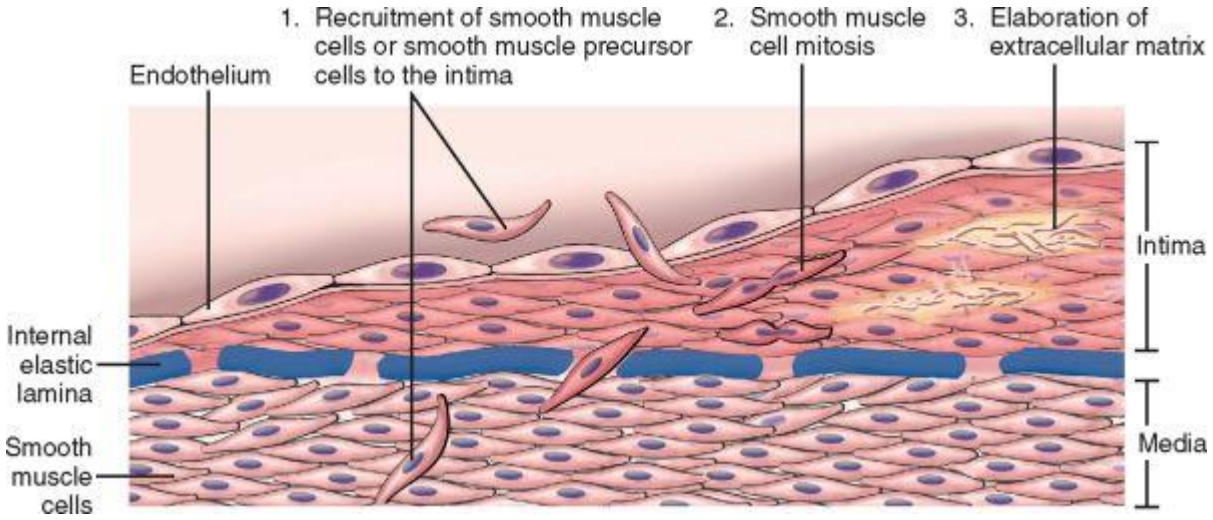

FIGURE 11-3 Schematic of intimal thickening, emphasizing smooth muscle cell migration and proliferation within the intima, with associated ECM synthesis. Intimal smooth muscle cells may derive from the underlying media or may be recruited from circulating precursors; they are shown in a different color from the medial cells to emphasize that they have a proliferative, synthetic, and noncontractile phenotype distinct from medial smooth muscle cells. *(Modified and redrawn from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989, p 254.)*

It should be emphasized that the phenotype of neointimal smooth muscle cells is distinct from that of medial smooth muscle cells; neointimal smooth muscle cells do not contract like medial smooth muscle cells but have the capacity to divide. Although these neointimal cells have long been thought to be derived from de-differentiation of smooth muscle cells migrating from the underlying media, there is increasing evidence that the intimal smooth muscle cells are at least in part derived from circulating precursor cells. [14] [15] [16] [17] The migratory, proliferative, and synthetic activities of the intimal smooth muscle cells are physiologically regulated by products derived from platelets, endothelial cells, and macrophages, as well as by activated coagulation and complement factors. PDGF, endothelin-1,

thrombin, FGF, IFN-γ, and IL-1 stimulate neointimal smooth muscle cells, while heparan sulfates, nitric oxide, and TGF-β antagonize their growth.

With time and restoration and/or normalization of the endothelial layer, the intimal smooth muscle cells can return to a nonproliferative state. However, the healing response results in permanent intimal thickening. With persistent or recurrent insults, excessive thickening can cause narrowing or stenosis of small and medium-sized blood vessels (e.g., atherosclerosis, see below), impeding downstream tissue perfusion. As a final note, it is important to remember that intimal thickening also occurs in otherwise normal arteries as a result of maturation and aging. In adult coronaries, for example, the intima and the media are frequently of approximately equal thickness. Such age-related intimal change is typically of no consequence, in part because a compensatory outward remodeling of the vessel results in little net change in the luminal diameter[18]; it also suggests that not all intimal thickening is a harbinger of disease.

3.1.5 Hypertensive Vascular Disease

Systemic and local tissue blood pressures must be maintained within a narrow range to prevent untoward consequences. Low pressures *(hypotension)* result in inadequate organ perfusion and can lead to dysfunction or tissue death. Conversely, high pressures *(hypertension)* can cause vessel and end-organ damage.

Like height and weight, blood pressure is a continuously distributed variable, and detrimental effects of blood pressure increase continuously as the pressure rises; no rigidly defined threshold level of blood pressure distinguishes risk from safety. Nevertheless, according to the National Heart, Lung, and Blood Institute of the U.S.A., a sustained diastolic pressure greater than 89 mm Hg, or a sustained systolic pressure in excess of 139 mm Hg, are associated with a measurably increased risk of atherosclerosis, and are therefore felt to represent clinically significant hypertension. Both the systolic and diastolic blood pressure are important in determining cardiovascular risk.[19] By either criterion, some 25% of individuals in the general population are hypertensive. However, it must be emphasized that these cut-offs are somewhat arbitrary, and in patients with other risk factors for vascular disease such as diabetes, lower thresholds are applicable.

Although we have an improved understanding of the molecular pathways that regulate normal blood pressure,[20,][21] the mechanisms that result in hypertension remain largely unknown in most individuals. Typically, for individuals with such “essential hypertension,” the best we can say is that the disorder is multifactorial, resulting from the combined effects of multiple genetic polymorphisms and interacting environmental factors.[22,][23]

The prevalence and vulnerability to complications of hypertension increase with age; they are also higher in African Americans. As we will see below, hypertension is one of the major risk factors for atherosclerosis and underlies numerous other diseases. It can cause—among other things—cardiac hypertrophy and heart failure (*hypertensive heart disease*, Chapter 12), multi-infarct dementia (Chapter 28), aortic dissection, and renal failure. Unfortunately, hypertension typically remains asymptomatic until late in its course and even severely elevated pressures can be clinically silent for years. Left untreated, roughly half of hypertensive patients die of ischemic heart disease (IHD) or congestive heart failure, and another third die of stroke. Prophylactic blood pressure reduction dramatically reduces the incidence and death rates from all forms of hypertension-related pathology.

Table 11-2 lists the major causes of hypertension. A small number of patients (approximately 5%) have underlying renal or adrenal disease (such as primary aldosteronism, Cushing syndrome, pheochromocytoma), narrowing of the renal artery, usually by an atheromatous plaque (renovascular hypertension) or other identifiable cause (secondary hypertension). *However, about 95% of*

hypertension is idiopathic (called essential hypertension). This form of hypertension generally does not cause short-term problems. When controlled, it is compatible with long life and is asymptomatic, unless a myocardial infarction, cerebrovascular accident, or other complication supervenes.

TABLE 11-2 -- Types and Causes of Hypertension (Systolic and Diastolic)

ESSENTIAL HYPERTENSION (90% TO 95% OF CASES)
SECONDARY HYPERTENSION
Renal
Acute glomerulonephritis
Chronic renal disease
Polycystic disease
Renal artery stenosis
Renal vasculitis
Renin-producing tumors
Endocrine
Adrenocortical hyperfunction (Cushing syndrome, primary aldosteronism, congenital adrenal hyperplasia, licorice ingestion)
Exogenous hormones (glucocorticoids, estrogen [including pregnancy-induced and oral contraceptives], sympathomimetics and tyramine-containing foods, monoamine oxidase inhibitors)
Pheochromocytoma
Acromegaly
Hypothyroidism (myxedema)
Hyperthyroidism (thyrotoxicosis)
Pregnancy-induced
Cardiovascular
Coarctation of aorta
Polyarteritis nodosa
Increased intravascular volume
Increased cardiac output
Rigidity of the aorta
Neurologic
Psychogenic
Increased intracranial pressure
Sleep apnea
Acute stress, including surgery

A small percentage, perhaps 5%, of hypertensive persons show a rapidly rising blood pressure that, if untreated, leads to death within a year or two. Called *accelerated* or *malignant hypertension*, this clinical syndrome is characterized by severe hypertension (i.e., systolic pressure over 200 mm Hg,

diastolic pressure over 120 mm Hg), renal failure, and retinal hemorrhages and exudates, with or without papilledema. It may develop in previously normotensive persons but more often is superimposed on pre-existing benign hypertension, either essential or secondary.[24,][25]

Regulation of Normal Blood Pressure.

Blood pressure is a function of cardiac output and peripheral vascular resistance (Fig. 11-4A), *two hemodynamic variables that are influenced by multiple genetic, environmental, and demographic factors*. The major factors that determine blood pressure variation within and between populations include age, gender, body mass index, and diet, particularly sodium intake.

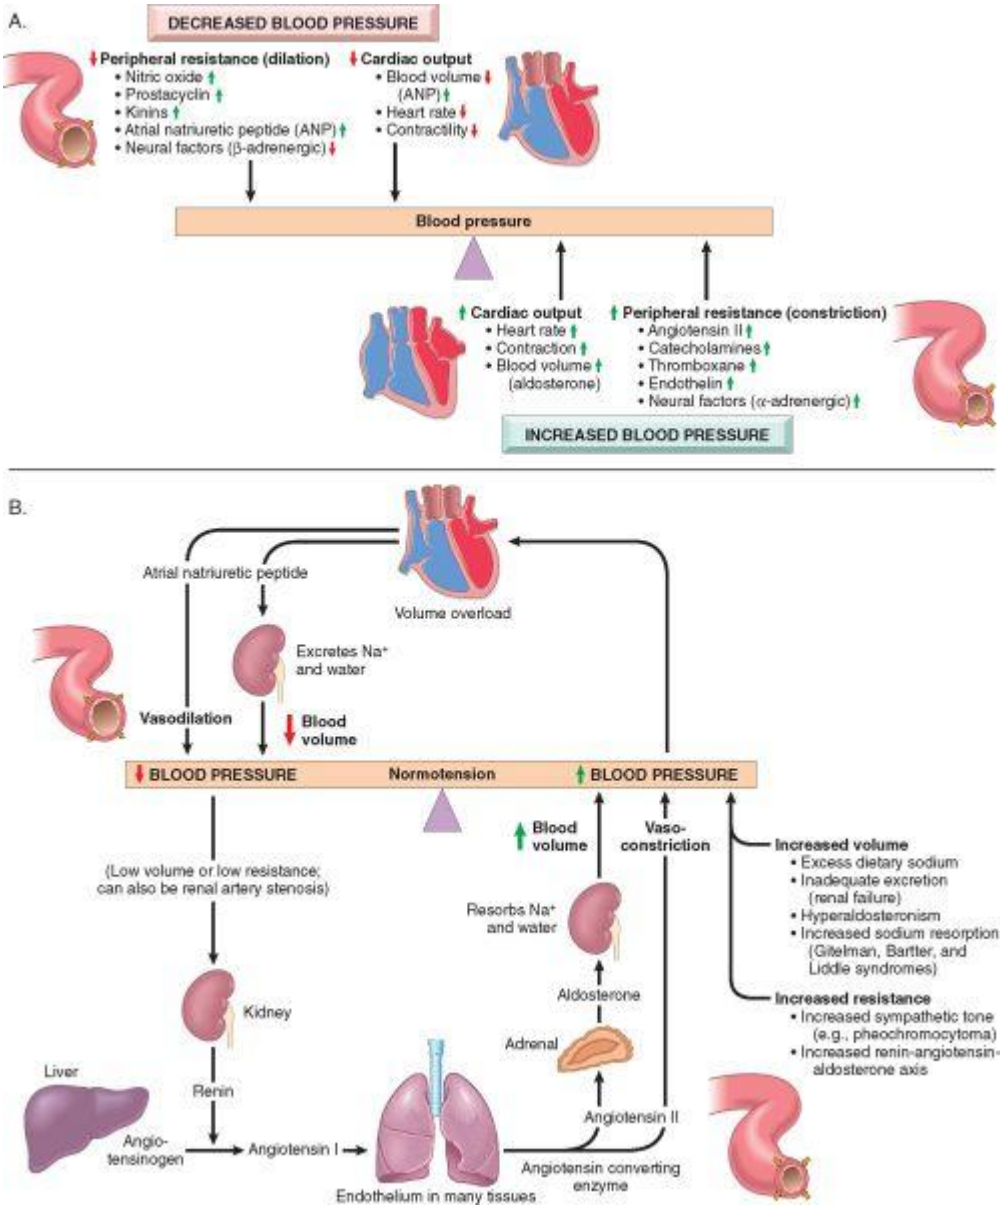

FIGURE 11-4 Blood pressure regulation. **A**, The critical roles played by cardiac output and peripheral resistance in modulating blood pressure. **B**, Interplay of renin-angiotensin-aldosterone and atrial natriuretic peptide in maintaining blood pressure homeostasis.

Cardiac output is highly dependent on blood volume, itself greatly influenced by the sodium homeostasis. Peripheral vascular resistance is determined mainly at the level of the arterioles and is affected by neural and hormonal factors. Normal vascular tone reflects the balance between humoral vasoconstricting influences (including angiotensin II, catecholamines, and endothelin) and vasodilators (including kinins, prostaglandins, and NO). Resistance vessels also exhibit *autoregulation*, whereby increased blood flow induces vasoconstriction to protect against tissue hyperperfusion. Other local factors such as pH and hypoxia, and the α- and β-adrenergic systems, which influence heart rate, cardiac contraction, and vascular tone, may also be important in regulating blood pressure. The integrated function of these systems ensures adequate perfusion of all tissues, despite regional differences in demand.

The kidneys play an important role in blood pressure regulation as follows (Fig. 11-4B):

- Through the renin-angiotensin system, the kidney influences both peripheral resistance and sodium homeostasis. Renin is secreted by the juxtaglomerular cells of the kidney in response to fall in blood pressure. It converts *plasma angiotensinogen* to *angiotensin I*, which is then converted to *angiotensin II* by angiotensinconverting enzyme. Angiotensin II raises blood pressure by increasing both peripheral resistance (direct action on vascular smooth muscle cells) and blood volume (stimulation of aldosterone secretion, and increase in distal tubular reabsorption of sodium).
- The kidney also produces a variety of vascular relaxing, or antihypertensive, substances (including prostaglandins and NO), which presumably counterbalance the vasopressor effects of angiotensin.
- When blood volume is reduced, the *glomerular filtration rate* falls, leading to increased reabsorption of sodium by proximal tubules, thereby conserving sodium and expanding blood volume.
- *Natriuretic factors*, including the natriuretic peptides secreted by atrial and ventricular myocardium in response to volume expansion, inhibit sodium reabsorption in distal tubules and thereby cause sodium excretion and diuresis. Natriuretic peptides also induce vasodilation and may be considered to represent endogenous inhibitors of the renin-angiotensin system.

Mechanisms of Essential Hypertension

Genetic factors play a definite role in determining blood pressure levels, as shown by studies comparing blood pressure in monozygotic and dizygotic twins, and other types of family studies, including comparisons of genetically related and adopted family members. Moreover, several single-gene disorders cause relatively rare forms of hypertension (and hypotension) by altering net sodium reabsorption in the kidney. The importance of sodium balance is emphasized by considering that the kidneys filter 170 liters of plasma containing 23 moles of salt daily; on a typical 100-mEq sodium diet, this means that 99.5% of the filtered salt must be reabsorbed. About 98% of the filtered sodium is reabsorbed by a number of ion channels, exchangers, and transporters that are constitutively active and not subject to regulation. Absorption of the remaining 2% of sodium occurs via the epithelial Na^+ channel (ENaC), which is tightly regulated by the renin-angiotensin system in the cortical collecting tubule; it is this resorption pathway that determines net sodium balance.[26]

Single-gene disorders cause severe but rare forms of hypertension through several mechanisms. These include:

- Gene defects affecting enzymes involved in aldosterone metabolism (e.g., aldosterone synthase, 11β-hydroxylase, 17α-hydroxylase). These lead to an increase in secretion of aldosterone, increased salt and water resorption, plasma volume expansion and, ultimately, hypertension.
- Mutations affecting proteins that influence sodium reabsorption. For example, the moderately severe form of salt-sensitive hypertension, called *Liddle syndrome*, is caused by mutations in an epithelial Na^+ channel protein that lead to increased distal tubular reabsorption of sodium induced by aldosterone.

Inherited variations in blood pressure may also depend on the cumulative effects of polymorphisms in several genes that affect blood pressure. For example, predisposition to essential hypertension has been associated with variations in the genes encoding components of the renin-angiotensin system: there is an association of hypertension with polymorphisms in both the angiotensinogen locus and the angiotensin receptor locus. Genetic variants in the renin-angiotensin system may contribute to the known racial differences in blood pressure regulation.

Reduced renal sodium excretion in the presence of normal arterial pressure may be a key initiating event in essential hypertension and, indeed, a final common pathway for the pathogenesis of hypertension. Decreased sodium excretion may lead sequentially to an increase in fluid volume, increased cardiac output, and peripheral vasoconstriction, thereby elevating blood pressure. At the higher setting of blood pressure, enough additional sodium would be excreted by the kidneys to equal intake and prevent further fluid retention. Thus, an altered but steady state of sodium excretion would be achieved ("resetting of pressure natriuresis"), but at the expense of an increase in blood pressure.

Vasoconstrictive influences, such as factors that induce vasoconstriction or stimuli that cause structural changes in the vessel wall, can lead to an increase in peripheral resistance and may also play a role in primary hypertension. Moreover, chronic or repeated vasoconstrictive influences could cause thickening and rigidity of the involved vessels.

Environmental factors can modify the impact of genetic determinants. Stress, obesity, smoking, physical inactivity, and heavy consumption of salt have all been implicated as exogenous factors in hypertension. Indeed, evidence linking the level of dietary sodium intake with the prevalence of hypertension in different population groups is particularly impressive. Moreover, in both essential and secondary hypertension, heavy sodium intake augments the condition.

To summarize, essential hypertension is a complex, multifactorial disorder. Although single gene disorders can be responsible for hypertension in rare cases, it is unlikely that such mutations are a major cause of essential hypertension. It is more likely that essential hypertension results from interactions of mutations or polymorphisms at several loci that influence blood pressure, with a variety of environmental factors (e.g., stress, salt intake). Mendelian forms of hypertension and hypotension are rare but yield insights into pathways and mechanisms of blood pressure regulation, and they may help define rational targets for therapeutic intervention. Sustained hypertension requires participation of the kidney, which normally responds to hypertension by eliminating salt and water. Susceptibility genes for essential hypertension in the larger population are currently unknown but may well include genes that govern responses to an increased renal sodium load, levels of pressor substances, reactivity of vascular smooth muscle cells to vasoconstrictive agents, or smooth muscle cell growth. In established hypertension, both increased blood volume and increased peripheral resistance contribute to the increased pressure.

Pathogenesis of Secondary Hypertension.

For many of the secondary forms of hypertension, the underlying pathways are reasonably well understood. For example, in *renovascular hypertension*, renal artery stenosis causes decreased glomerular flow and pressure in the afferent arteriole of the glomerulus. This (1) induces renin secretion, initiating angiotensin II–mediated vasoconstriction and increased peripheral resistance, and (2) increases sodium reabsorption and therefore blood volume through the aldosterone mechanism. Primary hyperaldosteronism is one of the most common causes of secondary hypertension (Chapter 24).

VASCULAR PATHOLOGY IN HYPERTENSION

Hypertension not only accelerates atherogenesis (see below) but also causes degenerative changes in the walls of large and medium arteries that can lead to aortic dissection and cerebrovascular hemorrhage.

Morphology

Hypertension is associated with two forms of small blood vessel disease: hyaline arteriolosclerosis and hyperplastic arteriolosclerosis.

Hyaline Arteriolosclerosis. Arterioles show homogeneous, pink hyaline thickening with associated luminal narrowing (Fig. 11-5A). These changes stem from plasma protein leakage across injured endothelial cells, and increased smooth muscle cell matrix synthesis in response to chronic hemodynamic stress. Although the vessels of elderly persons (either normo- or hypertensive) also frequently show hyaline arteriosclerosis, it is more generalized and severe in individuals with hypertension. The same lesions are also a common feature of diabetic microangiography; in that case the underlying etiology is hyperglycemia-induced endothelial cell dysfunction (Chapter 24). In **nephrosclerosis** due to chronic hypertension, the arteriolar narrowing of hyaline arteriosclerosis causes diffuse impairment of renal blood supply and causes glomerular scarring (Chapter 20).

Hyperplastic Arteriolosclerosis. This lesion occurs in severe (malignant) hypertension; vessels exhibit "onion-skin lesions," characterized by concentric, laminated thickening of the walls and luminal narrowing (Fig. 11-5B). The laminations consist of smooth muscle cells with thickened, reduplicated basement membranes; in malignant hypertension they are accompanied by fibrinoid deposits and vessel wall necrosis **(necrotizing arteriolitis)**, particularly in the kidney.

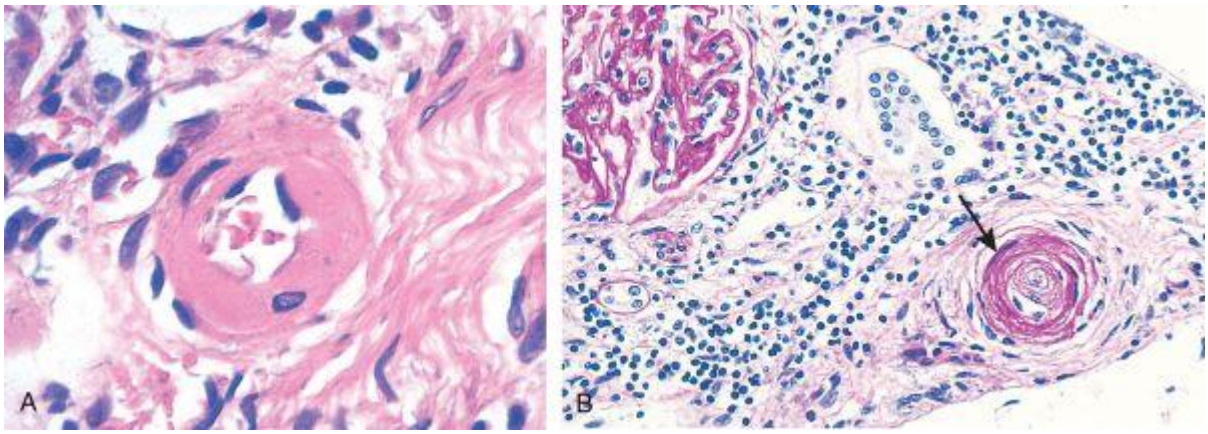

FIGURE 11-5 Vascular pathology in hypertension. **A**, Hyaline arteriolosclerosis. The arteriolar wall is thickened with increased protein deposition (hyalinized), and the lumen is markedly narrowed. **B**, Hyperplastic arteriolosclerosis (onion-skinning; *arrow*) causing lumenal obliteration (*arrow*; periodic acid–Schiff stain). *(Courtesy of Helmut Rennke, M.D., Brigham and Women's Hospital, Boston, MA.)*

3.1.6 Arteriosclerosis

Arteriosclerosis literally means "hardening of the arteries"; it is a generic term reflecting arterial wall thickening and loss of elasticity. There are three general patterns, with differing clinical and pathologic consequences:

- *Arteriolosclerosis* affects small arteries and arterioles, and may cause downstream ischemic injury. The anatomic variants, hyaline and hyperplastic, were discussed above in relation to hypertension.

- *Mönckeberg medial sclerosis* is characterized by calcific deposits in muscular arteries in persons typically older than age 50. The deposits may undergo metaplastic change into bone. Nevertheless, the lesions do not encroach on the vessel lumen and are usually not clinically significant.
- *Atherosclerosis*, from Greek root words for “gruel” and “hardening,” is the most frequent and clinically important pattern and will now be discussed in detail.

3.1.7 Atherosclerosis

Atherosclerosis is characterized by intimal lesions called *atheromas* (also called *atheromatous* or *atherosclerotic plaques*) that protrude into vessel lumens. An atheromatous plaque consists of a raised lesion with a soft, yellow, grumous core of lipid (mainly cholesterol and cholesterol esters) covered by a white fibrous cap (Fig. 11-6). Besides mechanically obstructing blood flow, atherosclerotic plaques can rupture, leading to catastrophic vessel thrombosis; plaques also weaken the underlying media and thereby lead to aneurysm formation. Atherosclerosis causes far more morbidity and mortality (roughly half of all deaths) in the Western world than any other disorder. Because coronary artery disease is an important manifestation of the disease, epidemiologic data related to atherosclerosis mortality typically reflect deaths caused by heart disease (Chapter 12); indeed, myocardial infarction is responsible for almost a quarter of all deaths in the United States. Significant morbidity and mortality are also caused by aortic and carotid atherosclerotic disease and stroke.

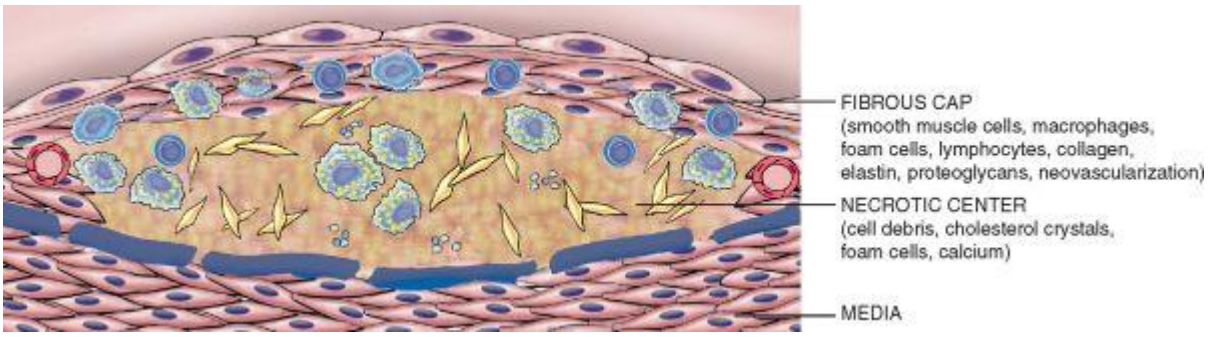

FIGURE 11-6 The major components of a well-developed intimal atheromatous plaque overlying an intact media.

EPIDEMIOLOGY

Virtually ubiquitous among most developed nations, atherosclerosis is much less prevalent in Central and South America, Africa, and parts of Asia. The mortality rate for ischemic heart disease (IHD) in the United States is among the highest in the world and is approximately five times higher than that in Japan. Nevertheless, IHD has been increasing in Japan and is now the second leading cause of death there. Moreover, Japanese immigrants who adopt American life styles and dietary customs acquire the same predisposition to atherosclerosis as the indigenous population.

The prevalence and severity of atherosclerosis and IHD among individuals and groups are related to several risk factors, some constitutional (and therefore less controllable), others acquired or related to behaviors that are potentially amenable to intervention (Table 11-3). Risk factors have been identified through several prospective studies in well-defined populations, most notably the Framingham Heart Study and Atherosclerosis Risk in Communities Study (Fig. 11-7).[27,][28] *Risk factors have a multiplicative effect*; two risk factors increase the risk approximately fourfold. When three risk factors are present (e.g., hyperlipidemia, hypertension, and smoking), the rate of myocardial infarction is increased seven times.

TABLE 11-3 -- Major Risk Factors for Atherosclerosis

NONMODIFIABLE	
Increasing age	Family history
Male gender	Genetic abnormalities
MODIFIABLE	
Hyperlipidemia	Diabetes
Hypertension	C-reactive protein
Cigarette smoking	

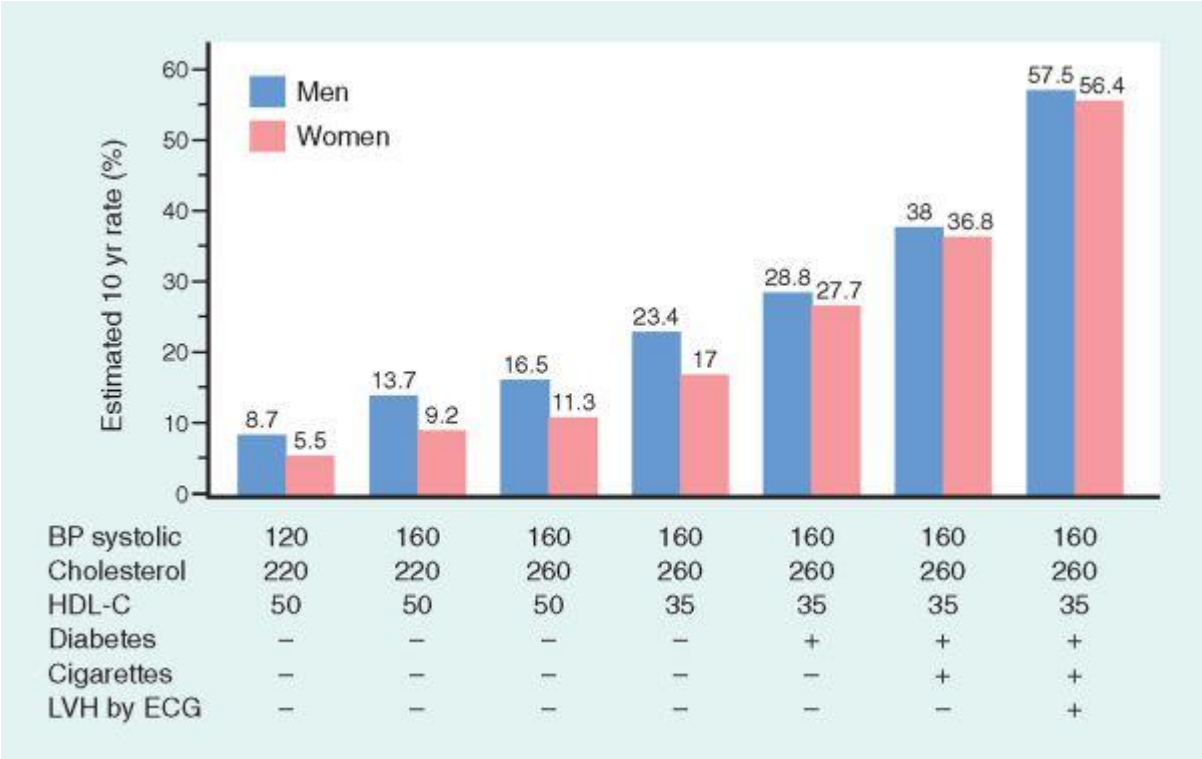

FIGURE 11-7 Estimated 10-year risk of coronary artery disease in hypothetical 55-year-old men and women as a function of traditional risk factors (hyperlipidemia, hypertension, smoking, and diabetes). BP, blood pressure; ECG, electrocardiogram; HDL-C, high-density lipoprotein cholesterol; LVH, left ventricular hypertrophy. *(From O'Donnell CJ, Kannel WB: Cardiovascular risks of hypertension: lessons from observational studies. J Hypertension 16 [Suppl. 6]:3, 1998, with permission from Lippincott Williams & Wilkins.)*

Constitutional risk factors in IHD.

These include age, gender, and genetics.

- *Age* is a dominant influence. Although atherosclerosis is typically progressive, it usually does not become clinically manifest until middle age or later (see below). Between ages 40 and 60 the incidence of myocardial infarction increases fivefold. Death rates from IHD rise with each decade even into advanced age.
- *Gender*. Other factors being equal, premenopausal women are relatively protected against atherosclerosis and its consequences compared to age-matched men. Thus, myocardial infarction and other complications

of atherosclerosis are uncommon in premenopausal women in the absence of risk factors such as diabetes, hyperlipidemia, or severe hypertension. After menopause, however, the incidence of atherosclerosis-related diseases increases and at older ages actually exceeds that of men. Although a favorable influence of estrogen has long been proposed to explain the protective effect, some clinical trials have failed to demonstrate any utility of hormonal therapy for vascular disease prevention. As discussed in greater detail in Chapter 9 , the atheroprotective effect of estrogens is related to the age at which the therapy is initiated. In younger postmenopausal women, there is a reduction in coronary atherosclerosis with estrogen therapy. The effect is unclear in older women. In addition to atherosclerosis, gender also affects a number of parameters that can influence outcomes of IHD; thus, women show differences in hemostasis, infarct healing, and myocardial remodeling.[29]

- *Genetics*. Family history is the most significant independent risk factor for atherosclerosis. Many mendelian disorders associated with atherosclerosis, such as familial hypercholesterolemia (Chapter 5), have been characterized. Nevertheless, these genetic diseases account for only a small percentage of cases. The well-established familial predisposition to atherosclerosis and IHD is usually multifactorial, relating to inheritance of various genetic polymorphisms, and familial clustering of other established risk factors, such as hypertension or diabetes.[30]

Modifiable risk factors in IHD.

These include hyperlipidemia, hypertension, cigarette smoking, and diabetes.

- *Hyperlipidemia*—and more specifically *hypercholesterolemia*—is a major risk factor for atherosclerosis; even in the absence of other factors, hypercholesterolemia is sufficient to stimulate lesion development.[28] The major component of serum cholesterol associated with increased risk is low-density lipoprotein (LDL) cholesterol (“bad cholesterol”); LDL cholesterol is the form of cholesterol that is delivered to peripheral tissues. In contrast, high-density lipoprotein (HDL, “good cholesterol”) mobilizes cholesterol from tissue and transports it to the liver for excretion in the bile. Consequently, higher levels of HDL correlate with reduced risk.
- Understandably, dietary and pharmacologic approaches that lower LDL or total serum cholesterol, and/or raise serum HDL, are of considerable interest. High dietary intake of cholesterol and saturated fats (present in egg yolks, animal fats, and butter, for example) raises plasma cholesterol levels. Conversely, diets low in cholesterol and/or with higher ratios of polyunsaturated fats lower plasma cholesterol levels. Omega-3 fatty acids (abundant in fish oils) are beneficial, whereas *trans*-unsaturated fats produced by artificial hydrogenation of polyunsaturated oils (used in baked goods and margarine) adversely affect cholesterol profiles. Exercise and moderate consumption of ethanol raise HDL levels, whereas obesity and smoking lower it.[28] *Statins* are a class of drugs that lower circulating cholesterol levels by inhibiting hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in hepatic cholesterol biosynthesis.[31]
- *Hypertension* (see above) is another major risk factor for atherosclerosis; both systolic and diastolic levels are important. On its own, hypertension increases the risk of IHD by approximately 60% (see Fig. 11-7). Hypertension is the most important cause of left ventricular hypertrophy and hence the latter is also related to IHD.
- *Cigarette smoking* is a well-established risk factor in men and probably accounts for the increasing incidence and severity of atherosclerosis in women. Prolonged (years) smoking of one pack of cigarettes or more daily doubles the death rate from IHD. Smoking cessation reduces the risk substantially.
- *Diabetes mellitus* induces hypercholesterolemia (Chapter 24) and markedly increases the risk of atherosclerosis. Other factors being equal, the incidence of myocardial infarction is twice as high in diabetics as in nondiabetics. There is also an increased risk of strokes and a 100-fold increased risk of atherosclerosis-induced gangrene of the lower extremities.

Additional risk factors.

As many as 20% of all cardiovascular events occur in the absence of hypertension, hyperlipidemia, smoking, or diabetes. Indeed, more than 75% of cardiovascular events in previously healthy women occurred with LDL cholesterol levels below 160 mg/dL (a cutoff generally considered to connote low risk).[32] Clearly, other factors contribute to risk; the assessment of some of these has entered clinical practice.

- *Inflammation*. Inflammation is present during all stages of atherogenesis and is intimately linked with atherosclerotic plaque formation and rupture (see below). With increasing recognition that inflammation plays a significant causal role in IHD, assessment of systemic inflammation has become important in overall risk stratification. While a number of circulating markers of inflammation correlate with IHD risk, *C-reactive protein (CRP)* has emerged as one of the simplest and most sensitive.[33]
  CRP is an acute-phase reactant synthesized primarily by the liver. It is downstream of a number of inflammatory triggers and plays a role in the innate immune response by opsonizing bacteria and activating complement. When CRP is secreted from cells within the atherosclerotic intima, it can activate local endothelial cells and induce a prothrombotic state and also increase the adhesiveness of endothelium for leukocytes. Most importantly, it strongly and independently predicts the risk of myocardial infarction, stroke, peripheral arterial disease, and sudden cardiac death, even among apparently healthy individuals (Fig. 11-8). Indeed, CRP levels have recently been incorporated into risk stratification algorithms.[34] Interestingly, although there is as yet no direct evidence that lowering CRP directly reduces cardiovascular risk, smoking cessation, weight loss, and exercise all reduce CRP; moreover, statins reduce CRP levels largely independent of their effects on LDL cholesterol.
- *Hyperhomocystinemia*. Clinical and epidemiologic studies show a strong relationship between total serum homocysteine levels and coronary artery disease, peripheral vascular disease, stroke, and venous thrombosis.[35] Elevated homocysteine levels can be caused by low folate and vitamin B_{12} intake, although the jury is still out on whether supplemental folate and vitamin B_{12} ingestion can reduce the incidence of cardiovascular disease. *Homocystinuria*, due to rare inborn errors of metabolism, results in elevated circulating homocysteine (>100 μmol/L) and premature vascular disease.
- *Metabolic syndrome*. The metabolic syndrome is characterized by a number of abnormalities that are associated with insulin resistance.[36] Besides glucose intolerance, patients exhibit hypertension and central obesity; indeed, abnormal adipose tissue signaling has been proposed to drive the syndrome. Dyslipidemia leads to endothelial cell dysfunction secondary to increased oxidative stress; there is also a systemic proinflammatory state that further predisposes to vascular thrombosis. Regardless of the etiology, metabolic syndrome clearly plays into many of the known risk factors for atherosclerosis.
- *Lipoprotein (a)* is an altered form of LDL that contains the apolipoprotein B-100 portion of LDL linked to apolipoprotein A. Lipoprotein (a) levels are associated with coronary and cerebrovascular disease risk, independent of total cholesterol or LDL levels.[37]
- *Factors affecting hemostasis*. Several markers of hemostatic and/or fibrinolytic function (e.g., elevated plasminogen activator inhibitor 1) are predictors of risk for major atherosclerotic events, including myocardial infarction and stroke. Thrombin, through both its procoagulant and proinflammatory effects, as well as platelet-derived factors both are increasingly recognized as major contributors to local vascular pathology.[38],39
- *Other factors*. Factors associated with a less pronounced and/or difficult-to-quantitate risk include lack of exercise; competitive, stressful life style (“type A” personality); and obesity (which is often associated with hypertension, diabetes, hypertriglyceridemia, and decreased HDL).

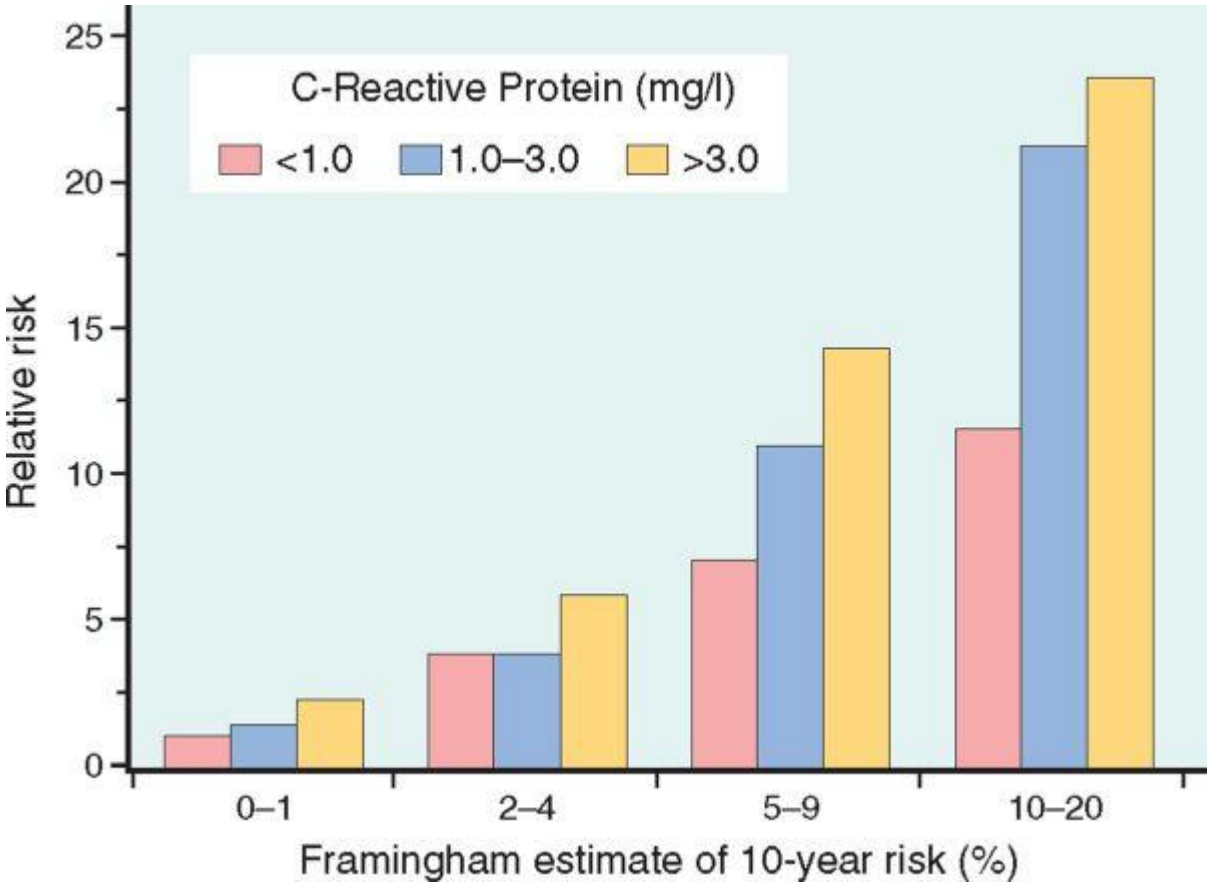

FIGURE 11-8 C-reactive protein (CRP) adds prognostic information at all levels of traditional risk identified from the Framingham Heart Study. Relative risk (*y*-axis) refers to the risk of a cardiovascular event (e.g., myocardial infarction). The *x*-axis is the 10-year risk of a cardiovascular event derived from the traditional risk factors identified in the Framingham Study. In each group of Framingham "risk", CRP values further stratify the patients. *(Adapted from Ridker PM et al: Comparison of C-reactive protein and low-density lipoprotein cholesterol levels in the prediction of first cardiovascular events. N Engl J Med 347:1557, 2002.)*

PATHOGENESIS OF ATHEROSCLEROSIS

The clinical importance of atherosclerosis has stimulated enormous interest in understanding the mechanisms that underlie this disease and its complications. Historically, there have been two dominant hypotheses: one emphasizes intimal cellular proliferation, while the other focuses on the repetitive formation and organization of thrombi. The contemporary view of atherogenesis incorporates elements of both theories and also integrates the risk factors previously discussed.[40,][41] Called the *response-to-injury hypothesis*,[42] the model views *atherosclerosis as a chronic inflammatory and healing response of the arterial wall to endothelial injury. Lesion progression occurs through the interaction of modified lipoproteins, monocyte-derived macrophages, and T lymphocytes with the normal cellular constituents of the arterial wall* (Fig. 11-9). According to this model, atherosclerosis is produced by the following pathogenic events:

- *Endothelial injury*, which causes (among other things) increased vascular permeability, leukocyte adhesion, and thrombosis
- *Accumulation of lipoproteins* (mainly LDL and its oxidized forms) in the vessel wall
- *Monocyte adhesion to the endothelium*, followed by migration into the intima and transformation into

macrophages and *foam cells*

- *Platelet adhesion*
- *Factor release* from activated platelets, macrophages, and vascular wall cells, inducing *smooth muscle cell recruitment*, either from the media or from circulating precursors
- *Smooth muscle cell proliferation and ECM production*
- *Lipid accumulation* both extracellularly and within cells (macrophages and smooth muscle cells)

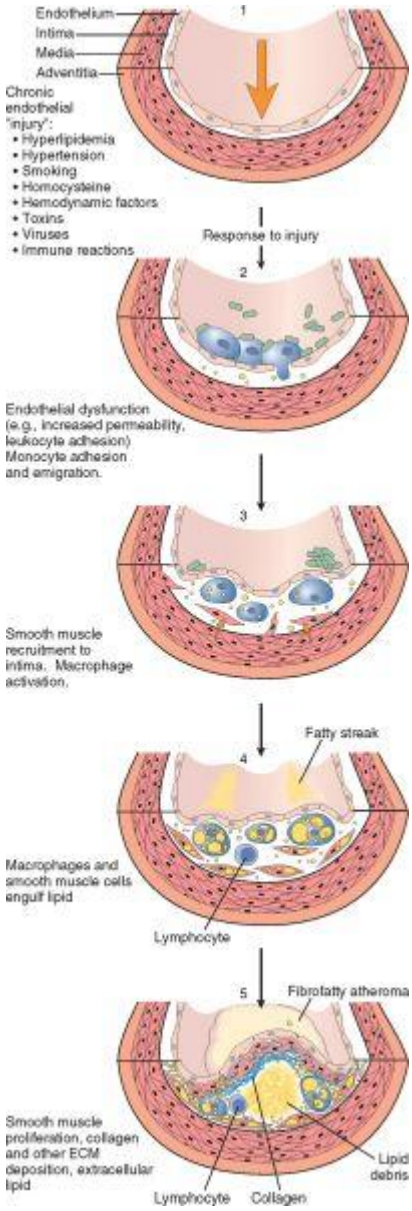

FIGURE 11-9 Evolution of arterial wall changes in the response to injury hypothesis. ***1,*** Normal. ***2,*** Endothelial injury with adhesion of monocytes and platelets (the latter to sites where endothelium has been lost). ***3,*** Migration of monocytes and smooth muscle cells into the intima. ***4,*** Smooth muscle cell proliferation in the intima with ECM production. ***5,*** Well-developed plaque.

The major mechanisms of atherogenesis will now be considered in detail.

Endothelial Injury

Endothelial cell injury is the cornerstone of the responseto-injury hypothesis. Endothelial loss due to *any* kind of injury—induced experimentally by mechanical denudation, hemodynamic forces, immune complex deposition, irradiation, or chemicals—results in intimal thickening; in the presence of high-lipid diets, typical atheromas ensue. However, early human lesions begin at sites of morphologically *intact endothelium*. Thus, *endothelial dysfunction* underlies human atherosclerosis; in this setting, dysfunctional endothelial cells show increased endothelial permeability, enhanced leukocyte adhesion, and altered gene expression.

The specific pathways and factors contributing to endothelial cell dysfunction in early atherosclerosis are not completely understood; etiologic culprits include hypertension, hyperlipidemia, toxins from cigarette smoke, homocysteine, and even infectious agents. Inflammatory cytokines (e.g., tumor necrosis factor [TNF]) can also stimulate pro-atherogenic patterns of endothelial cell gene expression. However, the two most important causes of endothelial dysfunction are hemodynamic disturbances and hypercholesterolemia.

Hemodynamic Disturbances.

The importance of hemodynamic turbulence in atherogenesis is illustrated by the observation that plaques tend to occur at ostia of exiting vessels, branch points, and along the posterior wall of the abdominal aorta, where there are disturbed flow patterns.[43] In vitro studies further demonstrate that nonturbulent laminar flow in the normal vasculature leads to the induction of endothelial genes whose products (e.g., the antioxidant superoxide dismutase) *protect* against atherosclerosis. Such "atheroprotective" genes could explain the nonrandom localization of early atherosclerotic lesions.[11]

Lipids.

Lipids are typically transported in the bloodstream bound to specific apoproteins (forming lipoprotein complexes). *Dyslipoproteinemias* can result from mutations that alter the apoproteins or the lipoprotein receptors on cells,[44] or from other disorders that affect the circulating levels of lipids (e.g., nephrotic syndrome, alcoholism, hypothyroidism, or diabetes mellitus).[45] Common lipoprotein abnormalities in the general population (indeed, present in many myocardial infarction survivors) include (1) increased LDL cholesterol levels, (2) decreased HDL cholesterol levels, and (3) increased levels of the abnormal lipoprotein (a) (see above).

The evidence implicating hypercholesterolemia in atherogenesis includes the following observations:

- The dominant lipids in atheromatous plaques are cholesterol and cholesterol esters.
- Genetic defects in lipoprotein uptake and metabolism that cause hyperlipoproteinemia are associated with accelerated atherosclerosis. Thus, homozygous familial hypercholesterolemia, caused by defective LDL receptors and inadequate hepatic LDL uptake (Chapter 5) can lead to myocardial infarction before age 20 years. Similarly, accelerated atherosclerosis occurs in animal models with engineered deficiencies in apolipoproteins or LDL receptors.
- Other genetic or acquired disorders (e.g., diabetes mellitus, hypothyroidism) that cause hypercholesterolemia lead to premature atherosclerosis.
- Epidemiologic analyses demonstrate a significant correlation between the severity of atherosclerosis and the levels of total plasma cholesterol or LDL.
- Lowering serum cholesterol by diet or drugs slows the rate of progression of atherosclerosis, causes regression of some plaques, and reduces the risk of cardiovascular events.

The mechanisms by which hyperlipidemia contributes to atherogenesis include the following:[44]

- Chronic hyperlipidemia, particularly hypercholesterolemia, can directly impair endothelial cell function by increasing local oxygen free radical production; oxygen free radicals can injure tissues and accelerate nitric oxide decay, reducing its vasodilator activity.
- With chronic hyperlipidemia, lipoproteins accumulate within the intima. These lipids are *oxidized* through the action of oxygen free radicals locally generated by macrophages or endothelial cells. Oxidized LDL is ingested by macrophages through a *scavenger receptor*, distinct from the LDL receptor, and accumulates in phagocytes, which are then called *foam cells*. In addition, oxidized LDL stimulates the release of growth factors, cytokines, and chemokines by endothelial cells and macrophages that increase monocyte recruitment into lesions. Finally, oxidized LDL is cytotoxic to endothelial cells and smooth muscle cells and can induce endothelial cell dysfunction. The importance of oxidized LDL in atherogenesis is suggested by the fact that it accumulates within macrophages in all stages of plaque formation.

Inflammation.

Inflammatory cells and pathways contribute to the initiation, progression, and complications of atherosclerotic lesions.[41,][46] Although normal vessels do not bind inflammatory cells, early in atherogenesis, dysfunctional arterial endothelial cells express adhesion molecules that encourage leukocyte adhesion; vascular cell adhesion molecule 1 (VCAM-1), in particular, binds monocytes and T cells. After these cells adhere to the endothelium, they migrate into the intima under the influence of locally produced chemokines.

- Monocytes transform into macrophages and avidly engulf lipoproteins including oxidized LDL. Monocyte recruitment and differentiation into macrophages (and ultimately into foam cells) is theoretically protective, because these cells remove potentially harmful lipid particles. However, the oxidized LDL augments macrophage activation and cytokine production (e.g., TNF). This further increases leukocyte adhesion and production of chemokines (e.g., monocyte chemotactic protein 1), creating a stimulus for recruitment of additional mononuclear inflammatory cells. Activated macrophages also produce reactive oxygen species that aggravate LDL oxidation and elaborate growth factors that drive smooth muscle cell proliferation.
- T lymphocytes recruited to the intima interact with the macrophages and can generate a chronic inflammatory state. It is not clear whether the T cells are responding to specific antigens (e.g., bacterial or viral antigens, heat-shock proteins [see below], or modified arterial wall constituents and lipoproteins) or are nonspecifically activated by the local inflammatory milieu. Nevertheless, activated T cells in the growing intimal lesions elaborate inflammatory cytokines, (e.g., IFN-γ), which can stimulate macrophages as well as endothelial cells and smooth muscle cells.
- As a consequence of the chronic inflammatory state, activated leukocytes and vascular wall cells release growth factors that promote smooth muscle cell proliferation and ECM synthesis.

Infection.

Although there is tantalizing evidence that infections may drive the local inflammatory process that underlies atherosclerosis, this hypothesis has yet to be conclusively proven. Herpesvirus, cytomegalovirus, and *Chlamydia pneumoniae* have all been detected in atherosclerotic plaques but not in normal arteries, and seroepidemiologic studies find increased antibody titers to *C. pneumoniae* in patients with more severe atherosclerosis. Of course, some of these observations are confounded by the fact that *C. pneumoniae* bronchitis is also associated with smoking, a well-established IHD risk factor. Moreover, infections with these organisms are exceedingly common (as is atherosclerosis), so that distinguishing coincidence from causality is difficult. Nevertheless, it is certainly possible that such organisms could infect sites of early atheroma formation; their foreign antigens could potentiate atherogenesis by driving local immune responses, or infectious agents could contribute to the local prothrombotic state.[47]

Smooth Muscle Proliferation

Intimal smooth muscle cell proliferation and ECM deposition convert a *fatty streak*, the earliest lesion, into a mature atheroma and contribute to the progressive growth of atherosclerotic lesions (see Fig. 11-9 , steps 4 and 5). (Recall that the intimal smooth muscle cells may be recruited from circulating

precursors and they have a proliferative and synthetic phenotype distinct from the underlying medial smooth muscle cells.) Several growth factors are implicated in smooth muscle cell proliferation and ECM synthesis, including PDGF (released by locally adherent platelets, as well as macrophages, endothelial cells, and smooth muscle cells), FGF, and TGF-α. The recruited smooth muscle cells synthesize ECM (notably collagen) that stabilizes atherosclerotic plaques. However, activated inflammatory cells in atheromas can cause intimal smooth muscle cell apoptosis, and also increase ECM catabolism resulting in unstable plaques (see below).

Overview

Figure 11-10 highlights the concept of atherosclerosis as a chronic inflammatory response—and ultimately an attempt at vascular "healing"—driven by a variety of insults, including endothelial cell injury, lipid accumulation and oxidation, and thrombosis. Atheromas are dynamic lesions consisting of dysfunctional endothelial cells, recruited and proliferating smooth muscle cells, and admixed lymphocytes and macrophages. All four cell types are capable of liberating mediators that can influence atherogenesis. Thus, at early stages, intimal plaques are little more than smooth muscle cell and macrophage foam cell aggregates. With progression, the atheroma is modified by ECM synthesized by smooth muscle cells; connective tissue is particularly prominent in the intima, where it forms a fibrous cap, although lesions also typically retain a central core of lipid-laden cells and fatty debris that can become calcified. The intimal plaque may progressively encroach on the vessel lumen, or compress and cause degeneration of the underlying media; disruption of the fibrous cap can lead to thrombosis and acute vascular occlusion.

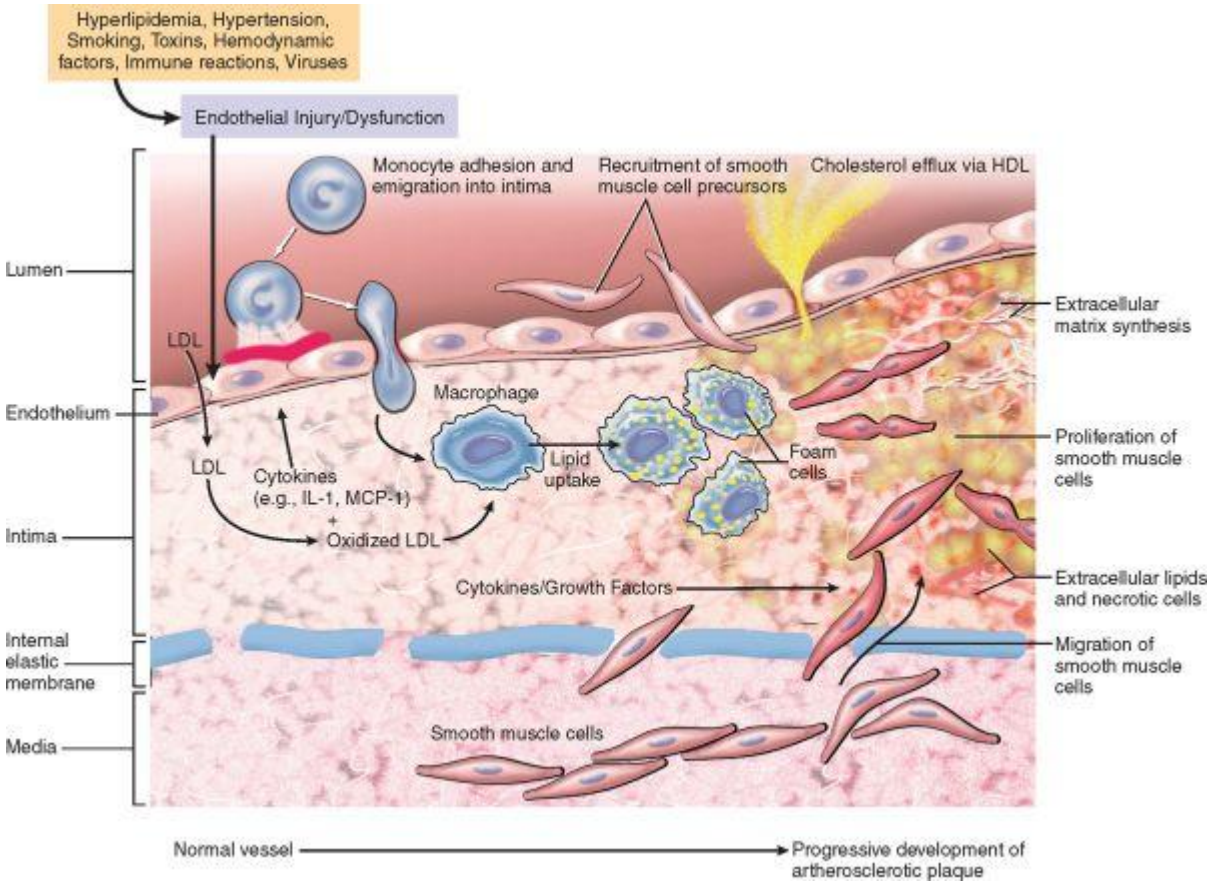

FIGURE 11-10 Hypothetical sequence of cellular interactions in atherosclerosis. Hyperlipidemia and other risk factors are thought to cause endothelial injury, resulting in adhesion of platelets and monocytes and release of growth factors, including platelet-derived growth factor (PDGF), which lead to smooth muscle cell migration and proliferation. Foam cells of atheromatous plaques are derived from both macrophages

and smooth muscle cells—from macrophages via the very-low-density lipoprotein (VLDL) receptor and low-density lipoprotein (LDL) modifications recognized by scavenger receptors (e.g., oxidized LDL), and from smooth muscle cells by less certain mechanisms. Extracellular lipid is derived from insudation from the vessel lumen, particularly in the presence of hypercholesterolemia, and also from degenerating foam cells. Cholesterol accumulation in the plaque reflects an imbalance between influx and efflux, and high-density lipoprotein (HDL) probably helps clear cholesterol from these accumulations. Smooth muscle cells migrate to the intima, proliferate, and produce ECM, including collagen and proteoglycans. IL-1, interleukin-1; MCP-1, monocyte chemoattractant protein 1.

With this overview of pathogenesis, we will now discuss the morphologic features and evolution of atherosclerosis.

Morphology

Fatty Streaks. Fatty streaks are the earliest lesions in atherosclerosis. They are composed of lipid-filled foamy macrophages. Beginning as multiple minute flat yellow spots, they eventually coalesce into elongated streaks 1 cm or more in length. These lesions are not significantly raised and do not cause any flow disturbance (Fig. 11-11). Aortas of infants less than 1 year old can exhibit fatty streaks, and such lesions are seen in virtually all children older than 10 years, regardless of geography, race, sex, or environment. The relationship of fatty streaks to atherosclerotic plaques is uncertain; although they may evolve into precursors of plaques, not all fatty streaks are destined to become advanced lesions. Nevertheless, coronary fatty streaks begin to form in adolescence, at the same anatomic sites that later tend to develop plaques.

Atherosclerotic Plaque. The key processes in atherosclerosis are intimal thickening and lipid accumulation (see Fig. 11-10). Atheromatous plaques impinge on the lumen of the artery and grossly appear white to yellow; superimposed thrombus over ulcerated plaques is red-brown. Plaques vary from 0.3 to 1.5 cm in diameter but can coalesce to form larger masses (Fig. 11-12).

Atherosclerotic lesions are patchy, usually involving only a portion of any given arterial wall, and are rarely circumferential; on cross-section, the lesions therefore appear "eccentric" (Fig. 11-13A). The focality of atherosclerotic lesions—despite the uniform exposure of vessel walls to such factors as cigarette smoke toxins, elevated LDL, hyperglycemia, etc.—is attributable to the vagaries of vascular hemodynamics. Local flow disturbances (e.g., turbulence at branch points) leads to increased susceptibility of certain portions of a vessel wall to plaque formation. Though focal and sparsely distributed at first, atherosclerotic lesions can become more numerous and more diffuse with time.

In humans, the abdominal aorta is typically involved to a much greater degree than the thoracic aorta. In descending order, the most extensively involved vessels are the lower abdominal aorta, the coronary arteries, the popliteal arteries, the internal carotid arteries, and the vessels of the circle of Willis. Vessels of the upper extremities are usually spared, as are the mesenteric and renal arteries, except at their ostia. Nevertheless, in an individual case, the severity of atherosclerosis in one artery does not predict its severity in another. Moreover, in any given vessel, lesions at various stages often coexist.

Atherosclerotic plaques have three principal components: (1) cells, including smooth muscle cells, macrophages, and T cells; (2) ECM, including collagen, elastic fibers, and proteoglycans; and (3) intracellular and extracellular lipid (Fig. 11-13). These components occur in varying proportions and configurations in different lesions. Typically, there is a superficial fibrous cap composed of smooth muscle cells and relatively dense collagen. Beneath and to the side of the cap (the "shoulder") is a more cellular area containing macrophages, T cells, and smooth muscle cells.

Deep to the fibrous cap is a necrotic core, containing lipid (primarily cholesterol and cholesterol esters), debris from dead cells, foam cells (lipid-laden macrophages and smooth muscle cells), fibrin, variably organized thrombus, and other plasma proteins; the cholesterol is frequently present as crystalline aggregates that are washed out during routine tissue processing and leave behind only empty "clefts." The periphery of the lesions show neovascularization (proliferating small blood vessels; Fig. 11-13C). Typical atheromas contain abundant lipid, but some plaques ("fibrous plaques") are composed almost exclusively of smooth muscle cells and fibrous tissue.

Plaques generally continue to change and progressively enlarge due to cell death and degeneration, synthesis and degradation (remodeling) of ECM, and organization of thrombus. Moreover, atheromas often undergo **calcification** (see Fig. 11-13C).

Atherosclerotic plaques are susceptible to the following clinically important changes (see also subsequent discussion):

- **Rupture, ulceration, or erosion** of the intimal surface of atheromatous plaques exposes the blood to highly thrombogenic substances and induces **thrombosis**. Such thrombosis can partially or completely occlude the lumen and lead to downstream ischemia (Chapter 12) (Fig. 11-14). If the patient survives the initial thrombotic occlusion, the clot may become organized and incorporated into the growing plaque.
- **Hemorrhage into a plaque**. Rupture of the overlying fibrous cap, or of the thin-walled vessels in the areas of neovascularization, can cause intra-plaque hemorrhage; a contained hematoma may expand the plaque or induce plaque rupture.
- **Atheroembolism**. Plaque rupture can discharge atherosclerotic debris into the bloodstream, producing microemboli.
- **Aneurysm formation**. Atherosclerosis-induced pressure or ischemic atrophy of the underlying media, with loss of elastic tissue, causes weakness resulting in aneurysmal dilation and potential rupture (see below).

Cybulsky, M.D., University of Toronto, Toronto, ON, Canada.)*

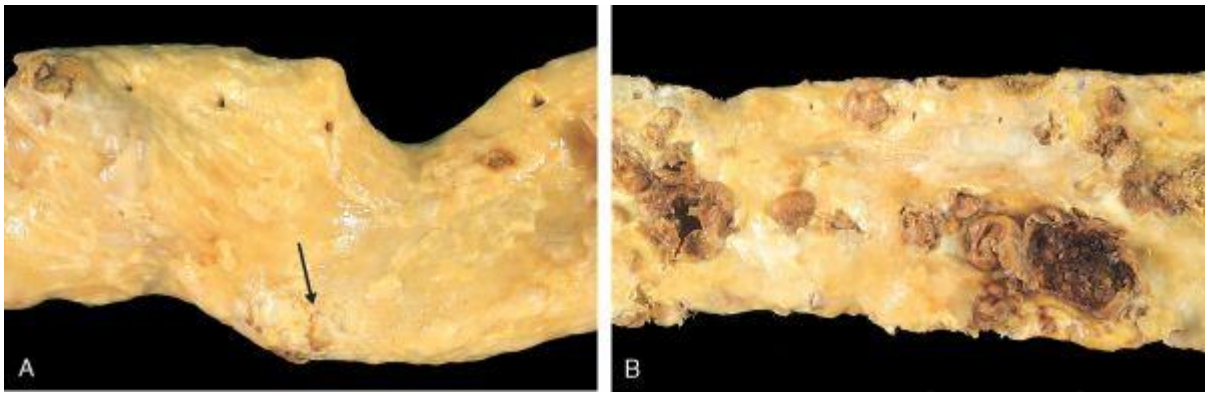

FIGURE 11-12 Gross views of atherosclerosis in the aorta. **A**, Mild atherosclerosis composed of fibrous plaques, one of which is denoted by the *arrow*. **B**, Severe disease with diffuse and complicated lesions (with plaque rupture and superimposed thrombosis), some of which have coalesced.

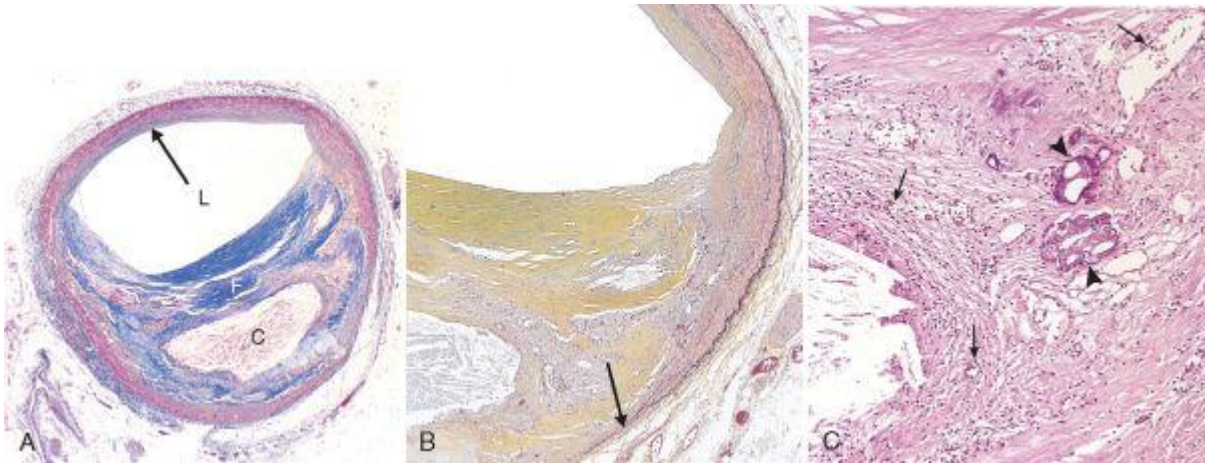

FIGURE 11-13 Histologic features of atheromatous plaque in the coronary artery. **A**, Overall architecture demonstrating fibrous cap (F) and a central necrotic (largely lipid) core (C). The lumen (L) has been moderately compromised. Note that a segment of the wall is free of plaque *(arrow)*; the lesion is therefore "eccentric". In this section, collagen has been stained blue (Masson's trichrome stain). **B**, Higher power photograph of a section of the plaque shown in **A**, stained for elastin (black), demonstrating that the internal and external elastic membranes are attenuated and the media of the artery is thinned under the most advanced plaque *(arrow)*. **C**, Higher magnification photomicrograph at the junction of the fibrous cap and core, showing scattered inflammatory cells, calcification *(arrowhead)* and neovascularization *(small arrows)*.

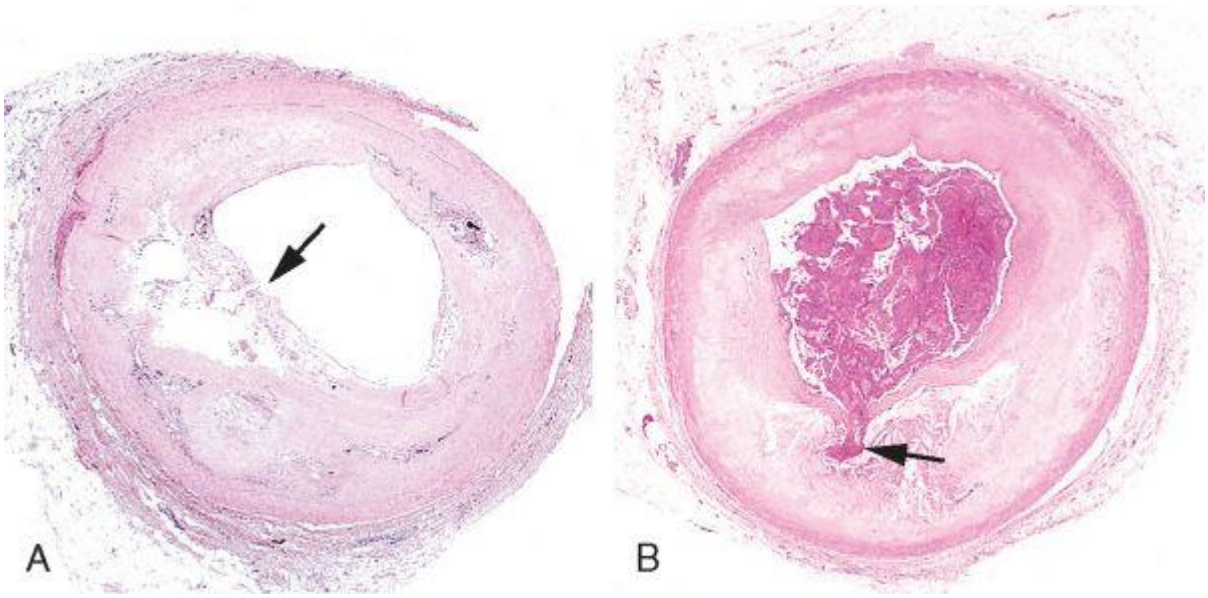

FIGURE 11-14 Atherosclerotic plaque rupture. **A**, Plaque rupture without superimposed thrombus, in a patient who died suddenly. **B**, Acute coronary thrombosis superimposed on an atherosclerotic plaque with focal disruption of the fibrous cap, triggering fatal myocardial infarction. In both **A** and **B**, an *arrow* points to the site of plaque rupture. ***(B**, Reproduced from Schoen FJ: Interventional and Surgical Cardiovascular pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989, p 61.)*

CONSEQUENCES OF ATHEROSCLEROTIC DISEASE

Large elastic arteries (e.g., the aorta, carotid, and iliac arteries) and large and medium-sized muscular arteries (e.g., coronary and popliteal arteries) are the major targets of atherosclerosis. Symptomatic atherosclerotic disease most often involves the arteries supplying the heart, brain, kidneys, and lower extremities. *Myocardial infarction (heart attack), cerebral infarction (stroke), aortic aneurysms, and peripheral vascular disease (gangrene of the legs) are the major consequences of atherosclerosis*. The natural history, principal morphologic features, and main pathogenic events are schematized in Figure 11-15 . The principal outcomes depend on the size of the involved vessels, the relative stability of the plaque itself, and the degree of degeneration of the underlying arterial wall:

- Smaller vessels can become occluded, compromising distal tissue perfusion.
- Ruptured plaque can embolize atherosclerotic debris and cause distal vessel obstruction, or can lead to acute (and frequently catastrophic) vascular thrombosis.
- Destruction of the underlying vessel wall can lead to aneurysm formation, with secondary rupture and/or thrombosis.

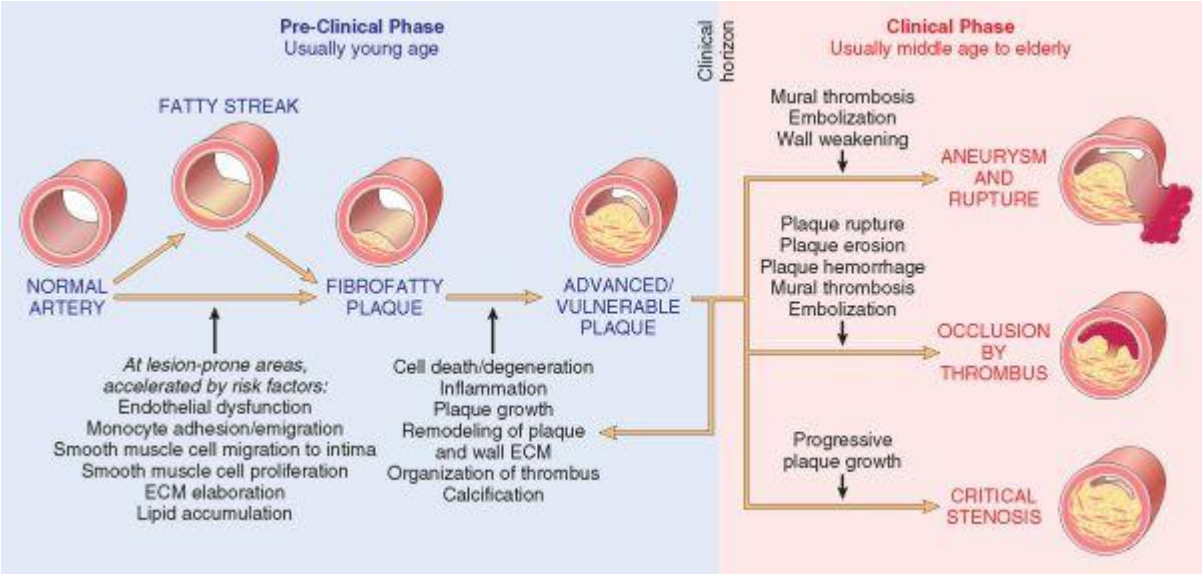

FIGURE 11-15 The natural history, morphologic features, main pathogenic events, and clinical complications of atherosclerosis.

Chronic stenosis and plaque rupture will be covered next, followed by a discussion of aneurysms.

Atherosclerotic Stenosis.

In small arteries, atherosclerotic plaques can gradually occlude vessel lumens, compromising blood flow and causing ischemic injury. At early stages of stenosis, outward remodeling of the vessel media tends to preserve luminal diameter as the total circumference expands.[18] However, there are limits on this outward remodeling, and eventually the expanding atheroma impinges on blood flow. *Critical stenosis* is the Rubicon at which chronic occlusion significantly limits flow, and demand begins exceeding supply. In the coronary (and other) circulations, this typically occurs at approximately 70% fixed occlusion (i.e., loss of area through which blood can flow); at this degree of stenosis, patients classically develop chest pain *(angina)* on exertion (so-called *stable angina*; see Chapter 12). Although acute plaque rupture (below) is the most dangerous complication, atherosclerosis also takes a toll through chronically diminished arterial perfusion: *mesenteric occlusion and bowel ischemia*, *chronic IHD*, *ischemic encephalopathy*, and *intermittent claudication* (diminished extremity perfusion) are all consequences of flowlimiting stenoses. The effects of vascular occlusion ultimately depend on arterial supply and the metabolic demand of the affected tissue.

Acute Plaque Change.

Plaque erosion or rupture is typically promptly followed by partial or complete vascular thrombosis (see Fig. 11-14), resulting in *acute tissue infarction (e.g., myocardial or cerebral infarction)*.[40,][48] Plaque changes fall into three general categories:

- *Rupture/fissuring*, exposing highly thrombogenic plaque constituents
- *Erosion/ulceration*, exposing the thrombogenic subendothelial basement membrane to blood
- *Hemorrhage into the atheroma*, expanding its volume

It is now recognized that the precipitating lesion in patients who develop myocardial infarction and other acute coronary syndromes is not necessarily a severely stenotic and hemodynamically significant lesion before its acute change. Pathologic and clinical studies show that the majority of plaques that undergo abrupt disruption and coronary occlusion previously showed only mild to moderate luminal stenosis.[49] The worrisome conclusion is that a rather large number of now asymptomatic adults may well have a real but unpredictable risk of a catastrophic coronary event. Regrettably, it is presently impossible to reliably detect individuals who will have plaque disruption or subsequent thrombosis.

The events that trigger abrupt changes in plaque configuration and superimposed thrombosis are complex and include both intrinsic factors (e.g., plaque structure and composition) and extrinsic factors (e.g., blood pressure, platelet reactivity)[40,][50]; rupture of a plaque indicates that it was unable to withstand the mechanical stresses of vascular shear forces. We next discuss the intrinsic and extrinsic factors that influence the risk of plaque rupture.

It is important to remember that the composition of plaques is dynamic and can materially contribute to risk of rupture. Thus, plaques that contain large areas of foam cells and extracellular lipid, and those in which the fibrous caps are thin or contain few smooth muscle cells or have clusters of inflammatory cells, are more likely to rupture, and are therefore called "vulnerable plaques"[48] (Fig. 11-16).

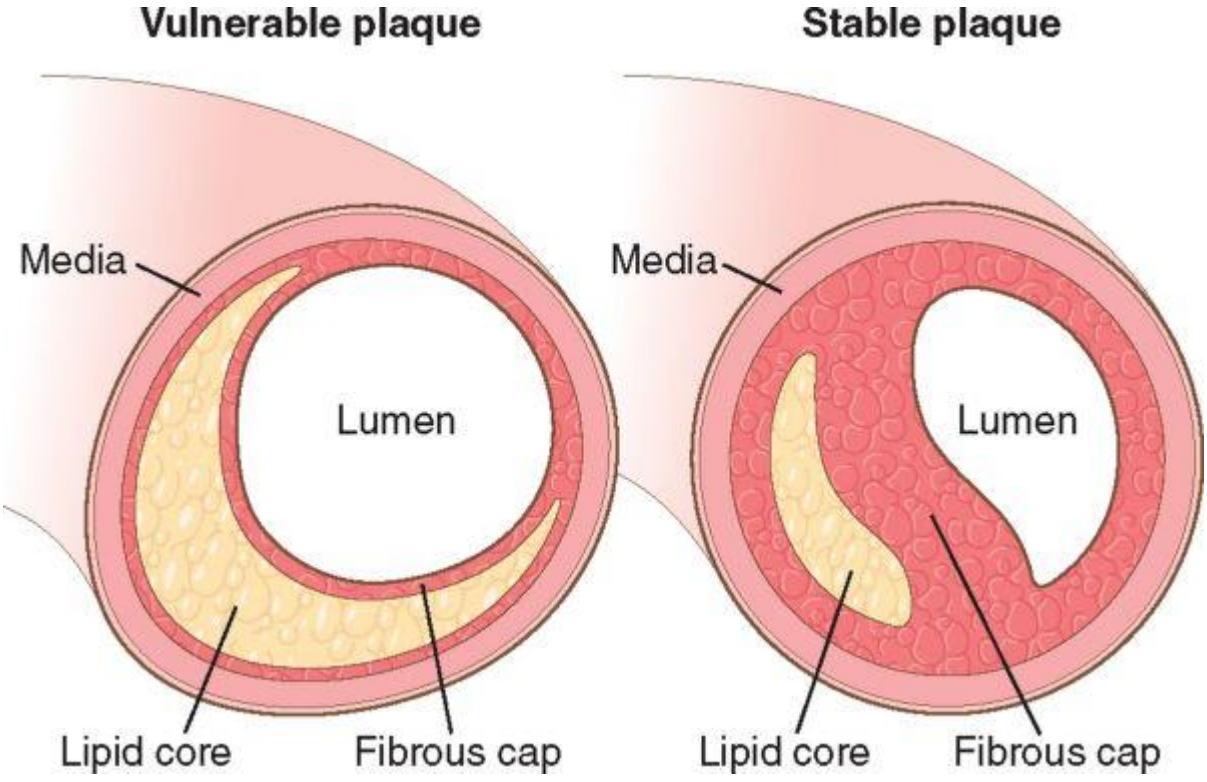

FIGURE 11-16 Schematic comparing vulnerable and stable atherosclerotic plaque. Whereas stable plaques have densely collagenous and thickened fibrous caps with minimal inflammation and negligible underlying atheromatous core, vulnerable plaques *(prone to rupture) are characterized by thin fibrous caps, large lipid cores, and increased inflammation. (Adapted from Libby P: Circulation 91:2844, 1995.)*

It is also established that the fibrous cap undergoes continuous remodeling that may make the plaque susceptible to acute alterations. Collagen represents the major structural component of the fibrous cap,

and accounts for its mechanical strength and stability. Thus, the balance of collagen synthesis versus degradation affects cap stability. Collagen in atherosclerotic plaque is produced primarily by smooth muscle cells, so that loss of these cellular elements results in a weaker cap. Moreover, collagen turnover is controlled by matrix metalloproteinases (MMPs), enzymes elaborated largely by macrophages within the atheromatous plaque; conversely, tissue inhibitors of metalloproteinases (TIMPs), produced by endothelial cells, smooth muscle cells, and macrophages, modulate MMP activity. In general, plaque inflammation results in a net increase in collagen degradation and reduces collagen synthesis, thereby destabilizing the mechanical integrity of the fibrous cap (see below). Interestingly, statins may have a beneficial therapeutic effect not only by reducing circulating cholesterol levels but also by stabilizing plaques through a reduction in plaque inflammation.[51]

Influences extrinsic to plaques are also important. Thus, adrenergic stimulation can increase systemic blood pressure or induce local vasoconstriction, thereby increasing the physical stresses on a given plaque. Indeed, the adrenergic stimulation associated with waking and rising can cause blood pressure spikes (followed by heightened platelet reactivity) that have been causally linked to the pronounced circadian periodicity for the peak time of onset of acute myocardial infarction (between 6 AM and 12 noon).[52] Intense emotional stress can also contribute to plaque disruption; this is most dramatically illustrated by the uptick in the incidence of sudden death associated with disasters such as earthquakes and the September 11, 2001 attacks.[53]

It is also important to note that not all plaque ruptures result in occlusive thromboses with catastrophic consequences. Indeed, plaque disruption and ensuing platelet aggregation and thrombosis are probably common, repetitive, and often clinically silent complications of atheroma. Healing of these subclinical plaque disruptions—with their overlying thromboses—is an important mechanism in the growth of atherosclerotic lesions.

Thrombosis.

As mentioned above, partial or total thrombosis associated with a disrupted plaque is critical to the pathogenesis of the acute coronary syndromes. In the most serious form, thrombus superimposed on a disrupted but previously only partially stenotic plaque converts it to a total occlusion. In contrast, in other coronary syndromes (Chapter 12), luminal obstruction by thrombosis is usually incomplete, and can even wax and wane with time.

Mural thrombus in a coronary artery can also embolize. Indeed, small fragments of thrombotic material in the distal intra-myocardial circulation or microinfarcts can be found at autopsy in patients after sudden death or in rapidly accelerating anginal syndromes. Finally, thrombus is a potent activator of multiple growth-related signals in smooth muscle cells, which can contribute to the growth of atherosclerotic lesions.

Vasoconstriction.

Vasoconstriction compromises lumen size, and, by increasing the local mechanical forces can potentiate plaque disruption. Vasoconstriction at sites of atheroma is stimulated by (1) circulating adrenergic agonists, (2) locally released platelet contents, (3) impaired secretion of endothelial cell relaxing factors (nitric oxide) relative to contracting factors (endothelin) as a result of endothelial cell dysfunction, and possibly (4) mediators released from perivascular inflammatory cells.

3.1.8 Aneurysms & Dissection

An *aneurysm* is a *localized abnormal dilation of a blood vessel or the heart* (Fig. 11-17); it can be congenital or acquired. When an aneurysm involves an intact attenuated arterial wall or thinned

ventricular wall of the heart, it is called a *true aneurysm*. Atherosclerotic, syphilitic, and congenital vascular aneurysms, and ventricular aneurysms that follow transmural myocardial infarctions are of this type. In contrast, a *false aneurysm* (also called *pseudo-aneurysm*) is a defect in the vascular wall leading to an extravascular hematoma that freely communicates with the intravascular space ("pulsating hematoma"). Examples include a ventricular rupture after myocardial infarction that is contained by a pericardial adhesion, or a leak at the sutured junction of a vascular graft with a natural artery. An arterial *dissection* arises when blood enters the arterial wall itself, as a hematoma dissecting between its layers. Dissections are often but not always aneurysmal (see also below). Both true and false aneurysms as well as dissections can rupture, often with catastrophic consequences.

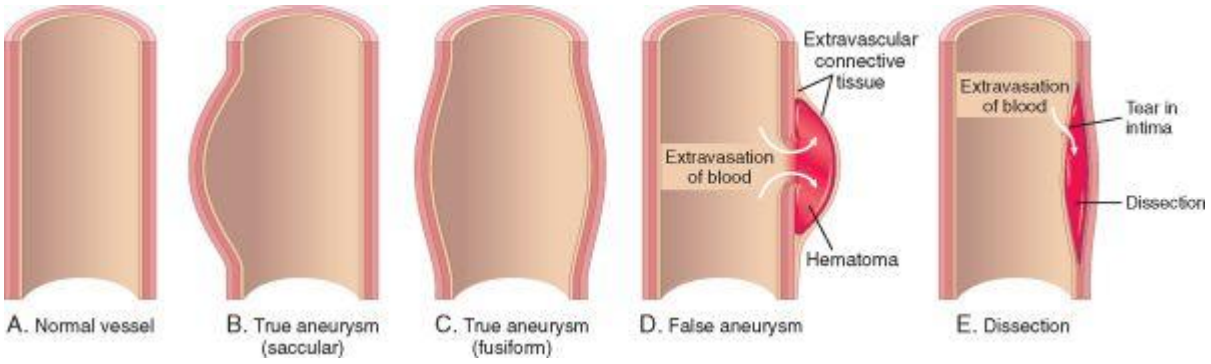

FIGURE 11-17 Aneurysms. **A**, Normal vessel. **B**, True aneurysm, saccular type. The wall focally bulges outward and may be attenuated but is otherwise intact. **C**, True aneurysm, fusiform type. There is circumferential dilation of the vessel, without rupture. **D**, False aneurysm. The wall is ruptured, and there is a collection of blood (hematoma) that is bounded externally by adherent extravascular tissues. **E**, Dissection. Blood has entered *(dissected)* the wall of the vessel and separated the layers. Although this is shown as occurring through a tear in the lumen, dissections can also occur by rupture of the vessels of the vaso vasorum within the media.

Aneurysms are generally classified by shape and size (see Fig. 11-17). *Saccular* aneurysms are spherical outpouchings (involving only a portion of the vessel wall); they vary from 5 to 20 cm in diameter and often contain thrombus. *Fusiform* aneurysms involve diffuse, circumferential dilation of a long vascular segment; they vary in diameter (up to 20 cm) and in length, and can involve extensive portions of the aortic arch, abdominal aorta, or even the iliac arteries. These types are not specific for any disease or clinical manifestations.

Pathogenesis of Aneurysms.

Arteries are dynamically remodeling tissues that maintain their integrity by constantly synthesizing, degrading, and repairing damage to their ECM constituents. Aneurysms can occur when the structure or function of the connective tissue within the vascular wall is compromised. Although we cite here examples of inherited defects in connective tissues, weakening of vessel walls is important in the common, sporadic forms of aneurysms as well.

- *The intrinsic quality of the vascular wall connective tissue is poor*. In *Marfan syndrome*, for example (Chapter 5), defective synthesis of the scaffolding protein *fibrillin* leads to aberrant TGF-β activity and progressive weakening of elastic tissue; in the aorta, the consequence is progressive dilation due to remodeling of the inelastic media.[54] *Loeys-Dietz syndrome* is another recently recognized cause of aneurysms; in this disorder, mutations in TGF-β receptors lead to abnormalities in elastin and collagen I and III. Aneurysms in such individuals can rupture fairly easily (even at small size).[55] Weak vessel walls due to defective type III collagen synthesis are also a hallmark of the vascular forms of *Ehlers-Danlos syndrome* (Chapter 5), and altered collagen cross-linking associated with vitamin C (ascorbate) deficiency is an

example of a nutritional basis for aneurysm formation.

- *The balance of collagen degradation and synthesis is altered by local inflammatory infiltrates and the destructive proteolytic enzymes they produce*. In particular, increased MMP production, especially by macrophages in atherosclerotic plaque or in vasculitis, probably contributes to aneurysm development[56]; these enzymes have the capacity to degrade virtually all components of the ECM in the arterial wall (collagens, elastin, proteoglycans, laminin, fibronectin). Concurrently, decreased tissue inhibitor of metalloproteinase (TIMP) expression can also contribute to the overall ECM degradation. Genetic predisposition to aneurysm formation in the setting of inflammatory lesions (such as atherosclerosis) may be related to polymorphisms of MMP and/or TIMP genes, or to the nature of the local inflammatory response that results in increased production of MMP.[57]
- *The vascular wall is weakened through loss of smooth muscle cells or the inappropriate synthesis of noncollagenous or nonelastic ECM*. Ischemia of the inner media occurs when there is atherosclerotic thickening of the intima, which increases the distance that oxygen and nutrients must diffuse. Systemic hypertension can also cause significant narrowing of arterioles of the vasa vasorum (e.g., in the aorta), which can cause outer medial ischemia. Ischemia is reflected in “degenerative changes” of the aorta, whereby smooth muscle cell loss—or change in synthetic phenotype—leads to scarring (and loss of elastic fibers), inadequate ECM synthesis, and production of increasing amounts of amorphous ground substance (glycosaminoglycan). Histologically these changes are collectively called *cystic medial degeneration* (Fig. 11-18). These changes are nonspecific and can be seen in a variety of settings, including Marfan disease and scurvy.

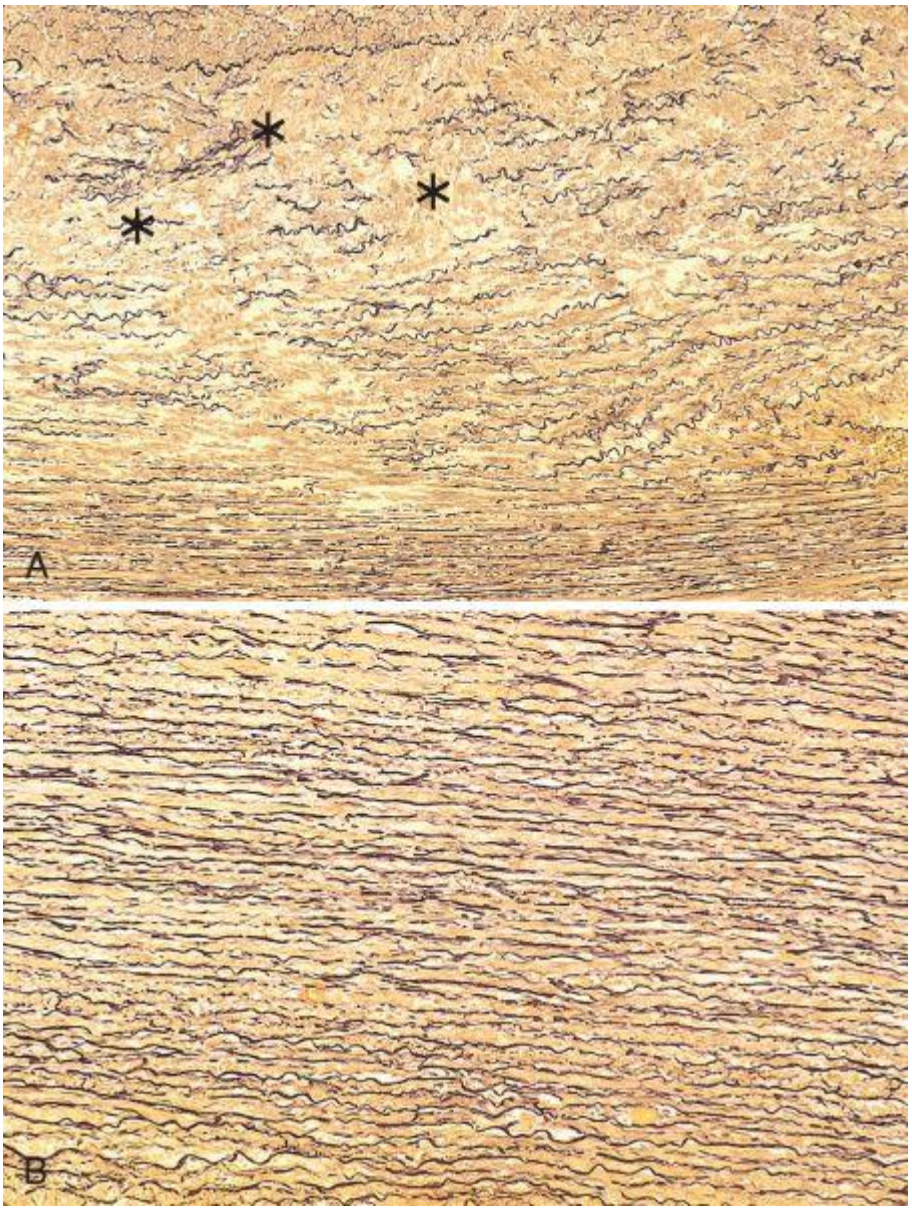

FIGURE 11-18 Cystic medial degeneration. **A**, Cross-section of aortic media from a patient with Marfan syndrome, showing marked elastin fragmentation and formation of areas devoid of elastin that resemble cystic spaces *(asterisks)*. **B**, Normal media for comparison, showing the regular layered pattern of elastic tissue. In both **A** and **B**, elastin is stained black.

The two most important disorders that predispose to aortic aneurysms are atherosclerosis and hypertension; atherosclerosis is a greater factor in abdominal aortic aneurysms, while hypertension is the most common condition associated with aneurysms of the ascending aorta.[58] Other conditions that weaken vessel walls and lead to aneurysms include trauma, vasculitis (see below), congenital defects (e.g., *berry aneurysms* typically in the circle of Willis; Chapter 28), and infections *(mycotic aneurysms)*. Mycotic aneurysms can originate (1) from embolization of a septic embolus, usually as a complication of infective endocarditis; (2) as an extension of an adjacent suppurative process; or (3) by circulating organisms directly infecting the arterial wall. Tertiary syphilis is now a rare cause of aorticaneurysms. The obliterative endarteritis characteristic of late-stage syphilis shows a predilection for small vessels, including those of the vasa vasorum of the thoracic aorta. This leads to ischemic injury of the aortic media and aneurysmal dilation, which sometimes involves the aortic valve annulus.[59]

ABDOMINAL AORTIC ANEURYSM (AAA)

Aneurysms associated with atherosclerosis occur most commonly in the abdominal aorta. Atherosclerotic plaque in the intima compresses the underlying media and compromises nutrient and waste diffusion from the vascular lumen into the arterial wall. The media therefore undergoes degeneration and necrosis that results in arterial wall weakness and consequent thinning. Nevertheless, as described above, the major influence that leads to aneurysm formation is the production of MMP by inflammatory cell infiltrates.[56]

Abdominal aortic aneurysms occur more frequently in men and in smokers, and rarely develop before age 50. Atherosclerosis is a major cause of AAAs, but other factors clearly contribute since the incidence is less than 5% in men older than 60 years of age, despite almost universal abdominal aortic atherosclerosis in that population.

Morphology. Usually positioned below the renal arteries and above the bifurcation of the aorta, AAAs can be saccular or fusiform, up to 15 cm in diameter, and up to 25 cm in length (Fig. 11-19). Typically the intimal surface of the aneurysm shows severe complicated atherosclerosis with destruction and thinning of the underlying aortic media; the aneurysm frequently contains a bland, laminated, poorly organized mural thrombus that may fill some or all of the dilated segment. Occasionally the aneurysm can affect the renal and superior or inferior mesenteric arteries, either by producing direct pressure or by narrowing or occluding vessel ostia with mural thrombi. Not infrequently, AAAs are accompanied by smaller aneurysms of the iliac arteries.

Two AAA variants merit special mention:

- **Inflammatory AAAs** are characterized by dense periaortic fibrosis containing abundant lymphoplasmacytic inflammation with many macrophages and often giant cells. Their cause is uncertain.
- **Mycotic AAAs** are lesions that have become infected by the lodging of circulating microorganisms in the wall, particularly in bacteremia from a primary *Salmonella* gastroenteritis. In such cases suppuration further destroys the media, potentiating rapid dilation and rupture.

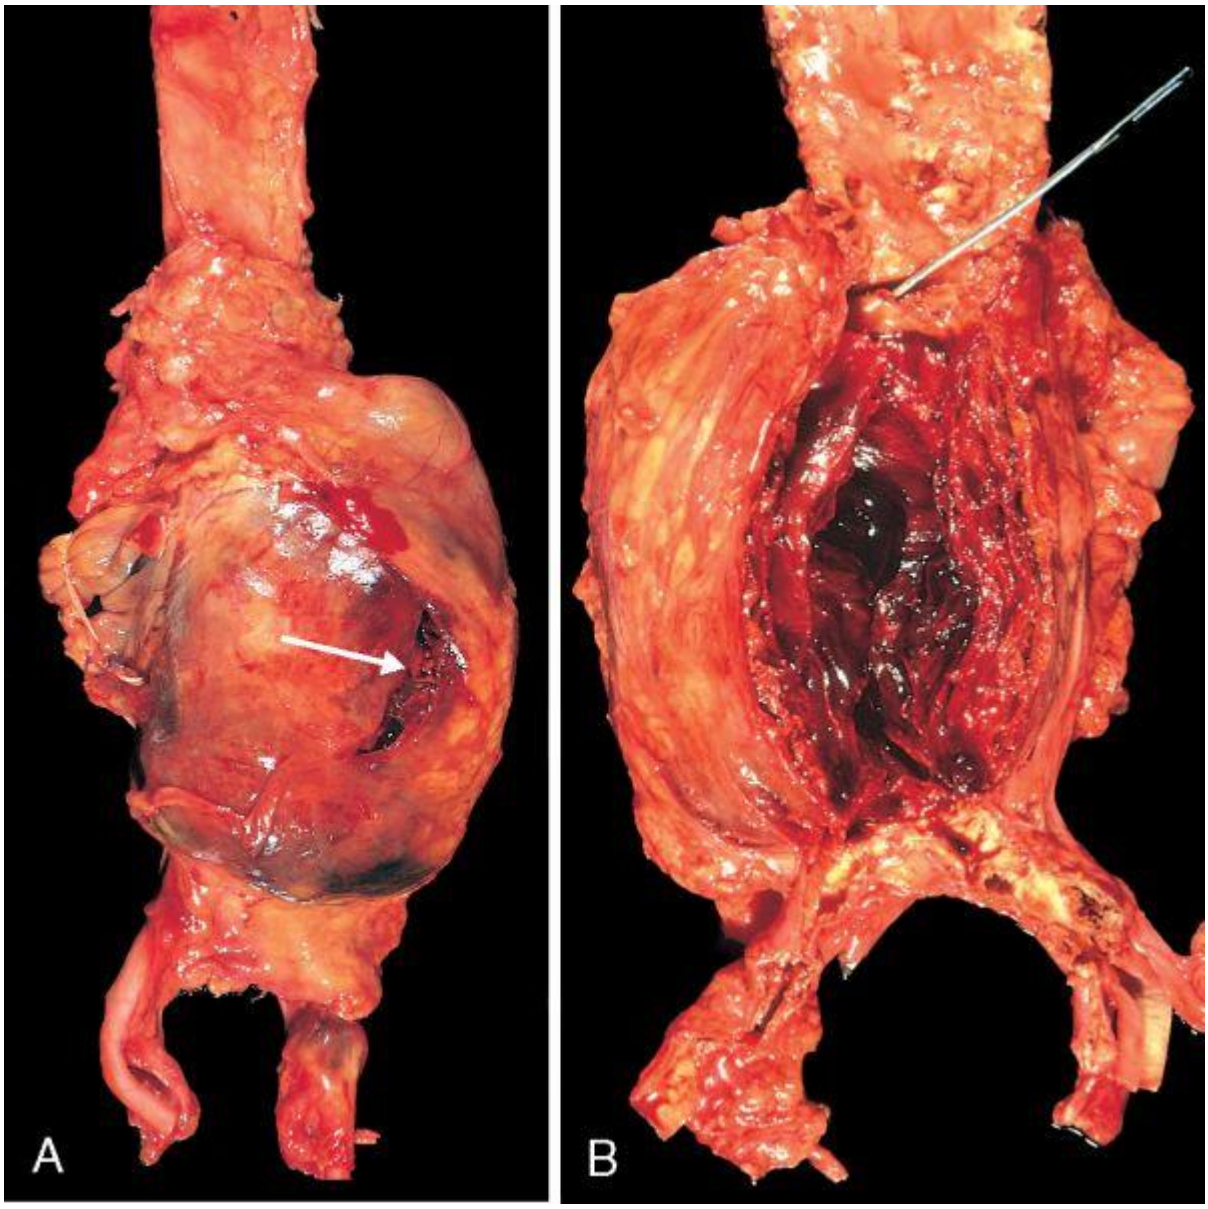

FIGURE 11-19 Abdominal aortic aneurysm. **A**, External view, gross photograph of a large aortic aneurysm that ruptured; the rupture site is indicated by the *arrow*. **B**, Opened view, with the location of the rupture tract indicated by a probe. The wall of the aneurysm is exceedingly thin, and the lumen is filled by a large quantity of layered but largely unorganized thrombus.

Clinical Features.

The clinical consequences of AAA include

- Rupture into the peritoneal cavity or retroperitoneal tissues with massive, potentially fatal hemorrhage
- Obstruction of a branch vessel resulting in ischemic injury of downstream tissues, for example, iliac (leg), renal (kidney), mesenteric (gastrointestinal tract), or vertebral (spinal cord) arteries
- Embolism from atheroma or mural thrombus
- Impingement on an adjacent structure, e.g., compression of a ureter or erosion of vertebrae

- Presentation as an abdominal mass (often palpably pulsating) that simulates a tumor

The risk of rupture is directly related to the size of the aneurysm,[60] varying from nil for AAAs of 4 cm or less in diameter, to 1% per year for AAAs between 4 and 5 cm, to 11% per year for AAAs between 5 and 6 cm, and 25% per year for aneurysms greater than 6 cm in diameter. Most aneurysms expand at a rate of 0.2 to 0.3 cm/yr, but 20% expand more rapidly. In general, aneurysms of 5 cm and larger are managed aggressively, usually by surgical bypass involving prosthetic grafts. Currently, aneurysm treatment is evolving toward endoluminal approaches using stent grafts (expandable wire frames covered by a cloth sleeve) in selected patients.[61] Timely surgery is critical; operative mortality for unruptured aneurysms is approximately 5%, whereas emergency surgery after rupture carries a mortality rate of more than 50%. It is worth reiterating that because atherosclerosis is a systemic disease, a person with AAA is also very likely to have atherosclerosis in other vascular beds and is at a significantly increased risk of IHD and stroke.

THORACIC AORTIC ANEURYSMS

Thoracic aortic aneurysms are most commonly associated with hypertension, although other causes such as Marfan and Loeys-Dietz syndromes are increasingly recognized.[58] Regardless of etiology, these give rise to signs and symptoms referable to (1) encroachment on mediastinal structures, (2) respiratory difficulties due to encroachment on the lungs and airways, (3) difficulty in swallowing due to compression of the esophagus, (4) persistent cough due to irritation of or pressure on the recurrent laryngeal nerves, (5) pain caused by erosion of bone (i.e., ribs and vertebral bodies), (6) cardiac disease as the aortic aneurysm leads to aortic valve dilation with valvular insufficiency or narrowing of the coronary ostia causing myocardial ischemia, and (7) rupture. Most patients with syphilitic aneurysms die of heart failure induced by aortic valvular incompetence.

AORTIC DISSECTION

Aortic dissection occurs when blood splays apart the laminar planes of the media to form a blood-filled channel within the aortic wall (Fig. 11-20); this can be catastrophic if the dissection then ruptures through the adventitia and hemorrhages into adjacent spaces.[62] In contrast to atherosclerotic and syphilitic aneurysms, aortic dissection may or may not be associated with aortic dilation. Consequently, the older term “dissecting aneurysm” should be avoided.

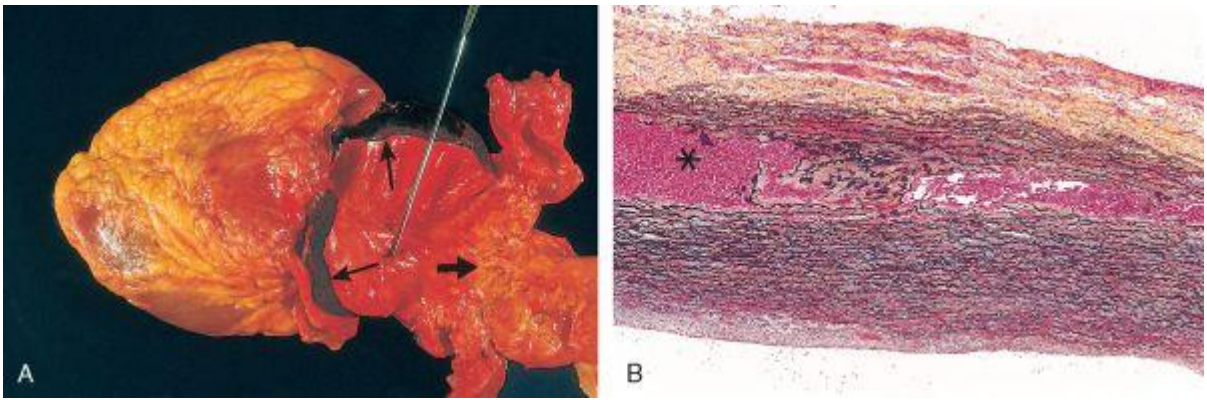

FIGURE 11-20 Aortic dissection. **A**, An opened aorta with proximal dissection originating from a small, oblique intimal tear *(identified by the probe)*, allowing blood to enter the media and creating an intramural hematoma *(narrow arrows)*. Note that the intimal tear has occurred in a region largely free of atherosclerotic plaque and that propagation of the intramural hematoma is arrested at a site more distally where atherosclerosis begins *(broad arrow)*. **B**, Histologic view of the dissection demonstrating an aortic intramural hematoma *(asterisk)*. Aortic elastic layers are black and blood is red in this section, stained with the Movat stain.

Aortic dissection occurs principally in two groups: (1) men aged 40 to 60, with antecedent hypertension (more than 90% of cases of dissection); and (2) younger patients with systemic or localized abnormalities of connective tissue affecting the aorta (e.g., Marfan syndrome). Dissections can also be iatrogenic (e.g., complicating arterial cannulations during diagnostic catheterization or cardiopulmonary bypass). Rarely, for unknown reasons, dissection of the aorta or other branches, including the coronary arteries, occurs during or after pregnancy. Dissection is unusual in the presence of substantial atherosclerosis or other cause of medial scarring such as syphilis, presumably because the medial fibrosis inhibits propagation of the dissecting hematoma.

Pathogenesis.

Hypertension is the major risk factor in aortic dissection. Aortas of hypertensive patients have medial hypertrophy of the vasa vasorum associated with degenerative changes in the aortic media and variable loss of medial smooth muscle cells, suggesting that pressure-related mechanical injury and/or ischemic injury (due to diminished flow through the vasa vasorum) is contributory. A considerably smaller number of dissections are related to inherited or acquired connective tissue disorders causing abnormal vascular ECM (e.g., Marfan syndrome, Ehlers-Danlos syndrome, vitamin C deficiency, copper metabolic defects). However, recognizable medial damage seems to be neither a prerequisite for dissection nor a guarantee that dissection is imminent. Regardless of the underlying etiology causing medial weakness, the trigger for the intimal tear and initial intramural aortic hemorrhage is not known in most cases. Nevertheless, once the tear has occurred, blood flow under systemic pressure dissects through the media, fostering progression of the medial hematoma. Accordingly, aggressive pressure-reducing therapy may be effective in limiting an evolving dissection. In some cases disruption of penetrating vessels of the vasa vasorum can give rise to an intramural hematoma *without* an intimal tear.

Morphology. In most cases, no specific underlying causal pathology is identified in the aortic wall. The most frequent preexisting histologically detectable lesion is **cystic medial degeneration** (see Fig. 11-18); inflammation is characteristically absent. However, dissections can occur in the setting of rather trivial medial degeneration, and the relationship of the structural changes to the pathogenesis of dissection is uncertain.

An aortic dissection usually initiates with an intimal tear. In the vast majority of spontaneous dissections, the tear is found in the ascending aorta, usually within 10 cm of the aortic valve (Fig. 11-20A). Such tears are typically transverse or oblique and 1 to 5 cm in length, with sharp, jagged edges. The dissection can extend along the aorta retrograde toward the heart as well as distally, sometimes into the iliac and femoral arteries. The dissecting hematoma spreads characteristically along the laminar planes of the aorta, usually between the middle and outer thirds (Fig. 11-20B). It often ruptures out through the adventitia causing massive hemorrhage (e.g., in the thoracic or abdominal cavities) or cardiac tamponade (hemorrhage into the pericardial sac).[62] In some (lucky) instances, the dissecting hematoma reenters the lumen of the aorta through a second distal intimal tear, creating a new vascular channel and forming a “double-barreled aorta” with a false channel.[62] This averts a fatal extra-aortic hemorrhage. In the course of time, false channels may be endothelialized and become chronic dissections.

Clinical Features.

The risk and nature of complications of aorta dissection depend strongly on the region(s) affected; the most serious complications occur with dissections that involve the aorta from the aortic valve to the arch.

Thus, aortic dissections are generally classified into two types (Fig. 11-21). They are named after Dr. Michael DeBakey, a pioneer in vascular surgery.

- More common (and dangerous) *proximal* lesions (called *type A dissections*), involving either both the ascending and descending aorta or just the ascending aorta (types I and II of the DeBakey classification)
- *Distal lesions not involving the ascending part* and usually beginning distal to the subclavian artery (called *type B dissections* or DeBakey type III)

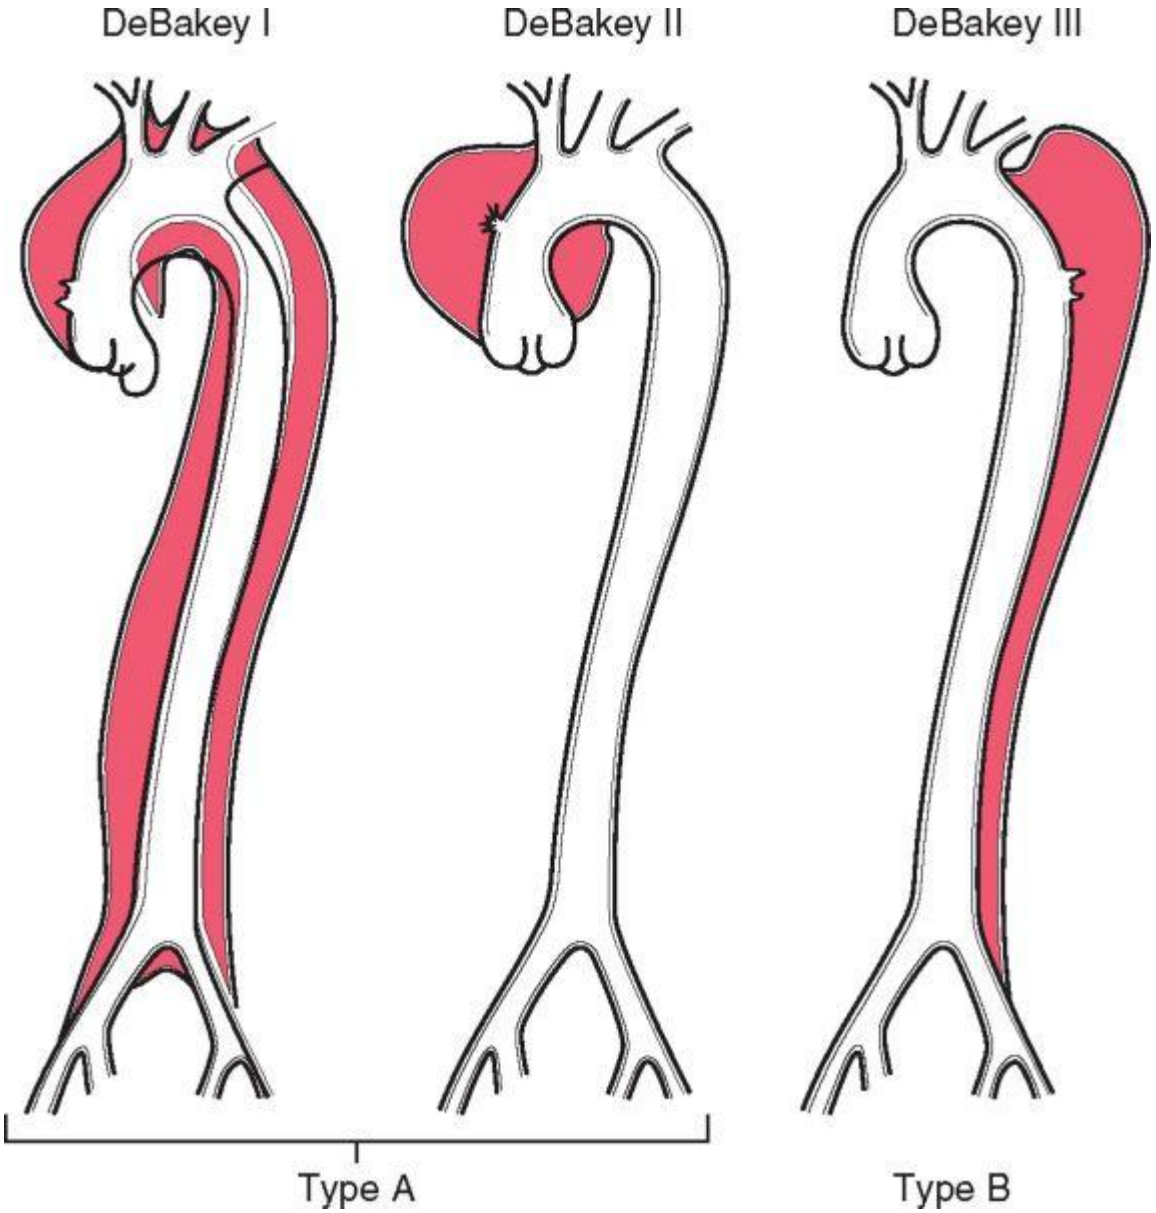

FIGURE 11-21 Classification of dissections. Type A (proximal) involves the ascending aorta, either as part of a more extensive dissection (DeBakey I) or in isolation (DeBakey II). Type B (distal or DeBakey III) dissections arise beyond the takeoff of the great vessels. The serious complications predominantly occur in type A dissections.

The classic clinical symptoms of aortic dissection are the sudden onset of excruciating pain, usually beginning in the anterior chest, radiating to the back between the scapulae, and moving downward as the dissection progresses; the pain can be confused with that of myocardial infarction.

The most common cause of death is rupture of the dissection outward into the pericardial, pleural, or peritoneal cavities. Retrograde dissection into the aortic root can cause disruption of the aortic valvular apparatus. Thus, common clinical manifestations include cardiac tamponade, aortic insufficiency, and myocardial infarction or extension of the dissection into the great arteries of the neck or into the coronary, renal, mesenteric, or iliac arteries, causing critical vascular obstruction and associated ischemic consequences; compression of spinal arteries may cause transverse myelitis.

In the past aortic dissection was typically fatal, but the prognosis has markedly improved. Rapid diagnosis and institution of intensive antihypertensive therapy, coupled with surgical procedures involving plication of the aortic wall, permit 65% to 75% of stricken individuals to be saved.

3.1.9 Vasculitis

Vasculitis is a general term for vessel wall inflammation. The clinical features of the various vasculitides are diverse and largely depend on the vascular bed affected (e.g., central nervous system vs. heart vs. small bowel). Besides the findings referable to the specific tissue(s) involved, the clinical manifestations typically include constitutional signs and symptoms such as fever, myalgias, arthralgias, and malaise.

Vessels of any type in virtually any organ can be affected; most vasculitides involve small vessels, from arterioles to capillaries to venules.[63] Several of the vasculitides tend to affect only vessels of a particular size or particular vessel beds. There are vasculitic entities that primarily affect the aorta and medium-sized arteries, while others principally affect only smaller arterioles. Some 20 primary forms of vasculitis are recognized, and classification schemes attempt (with variable success) to group them according to vessel size, role of immune complexes, presence of specific autoantibodies, granuloma formation, organ specificity, and even population demographics! Though a subject of ongoing evolution,[64] the so-called Chapel Hill nomenclature remains the most widely accepted approach to organizing this diverse group of entities[65] (Table 11-4 and Fig. 11-22). As we will see, there is considerable clinical and pathologic overlap among many of them.

TABLE 11-4 -- Classification and Characteristics of Selected Immune-Mediated Vasculitides

Vasculitis Type[*]	Examples	Description
LARGE-VESSEL VASCULITIS	Giant-cell (temporal) arteritis	Granulomatous inflammation; frequently involves the temporal artery. Usually occurs in patients older than age 50 and is associated with polymyalgia rheumatica.
Aorta and large branches to extremities, head, and neck	Takayasu arteritis	Granulomatous inflammation usually occurring in patients younger than age 50
MEDIUM-VESSEL VASCULITIS	Polyarteritis nodosa	Necrotizing inflammation typically involving renal arteries but sparing pulmonary vessels
Main visceral arteries and their branches	Kawasaki disease	Arteritis with mucocutaneous lymph node syndrome; usually occurs in children. Coronary arteries can be involved with aneurysm formation and/or thrombosis.
SMALL-VESSEL VASCULITIS	Wegener granulomatosis	Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small vessels, including glomerular vessels. Associated with PR3-ANCAs.
Arterioles, venules, capillaries, and occasionally small arteries	Churg-Strauss syndrome	Eosinophil-rich granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small vessels. Associated with asthma and blood eosinophilia. Associated with MPO-ANCAs.
	Microscopic polyangiitis	Necrotizing small-vessel vasculitis with few or no immune deposits; necrotizing arteritis of small and medium-sized arteries can occur.

Vasculitis Type[*]	Examples	Description
		Necrotizing glomerulonephritis and pulmonary capillaritis are common. Associated with MPO-ANCAs.

Modified from Jennette JC, et al. Nomenclature of systemic vasculitides: The proposal of an international consensus conference. Arthritis Rheum 37:187, 1994.

MPO-ANCAs, antineutrophil cytoplasmic antibodies, directed against myeloperoxidase (p-ANCA); PR3-ANCAs, antineutrophil cytoplasmic antibodies, directed against proteinase 3 (c-ANCA).

[*] Note that some small- and large-vessel vasculitides may involve medium-sized arteries, but large- and medium-sized vessel vasculitides do not involve vessels smaller than arteries.

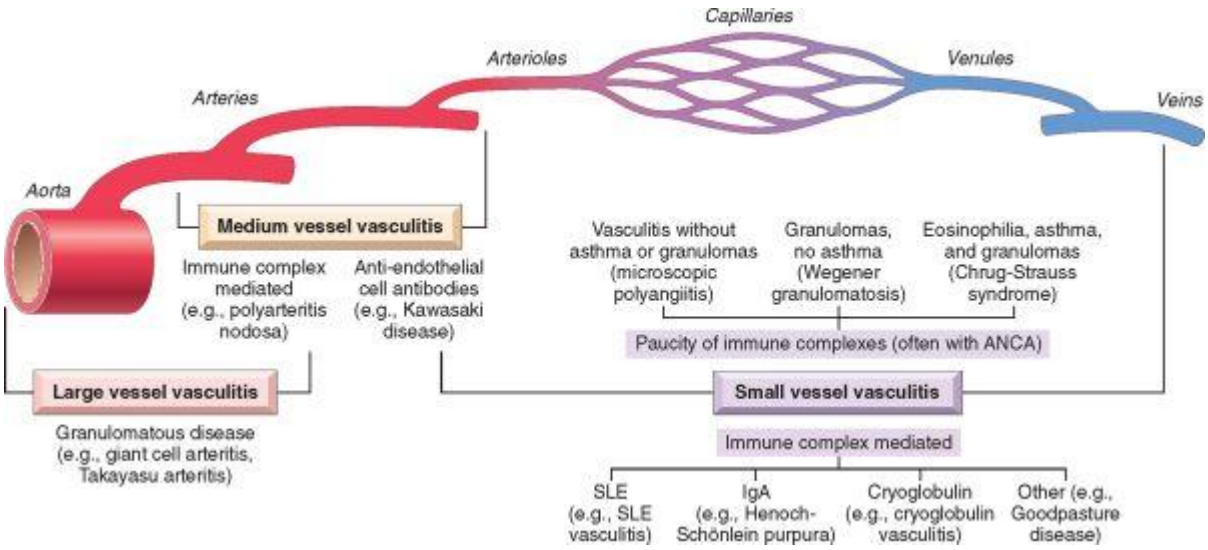

FIGURE 11-22 Diagrammatic representation of the typical vascular sites involved with the more common forms of vasculitis, as well as the presumptive etiologies. Note that there is a substantial overlap in distributions. ANCA, antineutrophil cytoplasmic antibody; SLE, systemic lupus erythematosus. *(Modified from Jennette JC, Falk RJ: Nosology of primary vasculitis. Curr Opin Rheumatol 19:10, 2007.)*

The two most common pathogenic mechanisms of vasculitis are immune-mediated inflammation and direct invasion of vascular walls by infectious pathogens. Predictably, *infections can also indirectly induce a noninfectious vasculitis*, for example, by generating immune complexes or triggering cross-reactivity. In any given patient, it is critical to distinguish between infectious and immunological mechanisms, because immunosuppressive therapy is appropriate for immunemediated vasculitis but could very well worsen infectious vasculitis. Physical and chemical injury, such as from irradiation, mechanical trauma, and toxins, can also cause vasculitis.

NONINFECTIOUS VASCULITIS

The main immunological mechanisms that initiate noninfectious vasculitis are (1) immune complex deposition, (2) antineutrophil cytoplasmic antibodies, and (3) anti–endothelial cell antibodies.

Immune Complex–Associated Vasculitis.

The lesions resemble those found in experimental immune complex–mediated conditions such as the Arthus reaction and serum sickness (Chapter 6). Many systemic immunological diseases, such as systemic lupus erythematosus (SLE) and polyarteritis nodosa, manifest as immune complex-mediated vasculitis. Antibody and complement are typically detected in vasculitic lesions, although the nature of the antigens responsible for their deposition cannot usually be determined. Circulating antigen-antibody complexes may also be seen (e.g., DNA–anti-DNA complexes in SLE–associated vasculitis [Chapter 6]), but the sensitivity and specificity of circulating immune complex assays in such diseases are low. In addition, immune complexes are implicated in the following vasculitides:

- Immune complex deposition underlies the vasculitis associated with *drug hypersensitivity*. In some cases (e.g., penicillin) the drugs bind to serum proteins; other agents, like streptokinase, are themselves foreign proteins. In either case, antibodies directed against the drug-modified proteins or foreign molecules lead to the formation of immune complexes. Manifestations vary widely but are most frequently seen in the skin (see below); they can be mild and self-limiting, or severe and even fatal. It is important to identify vasculitis due to drug hypersensitivities, since discontinuation of the offending agent will typically lead to resolution.
- In vasculitis secondary to *viral infections*, antibody to viral proteins forms immune complexes that can be found in the serum and the vascular lesions. Thus, as many as 30% of patients with polyarteritis nodosa (see below) have an underlying hepatitis B infection that produces a vasculitis attributable to complexes of hepatitis B surface antigen (HBsAg) and anti-HbsAg antibody.

In many cases of immune complex vasculitis, it is not clear whether the antigen-antibody complexes form elsewhere and then deposit in a particular vascular bed, or if they form in situ from the seeding of antigen in a vessel wall followed by antibody binding (Chapter 6). Moreover, in many cases of presumed immune complex vasculitis, antigen-antibody deposits are scarce. Either the immune complexes have been largely cleared at the time that the tissue diagnosis is made, or else other mechanisms may apply in such “pauci-immune” cases.

Antineutrophil Cytoplasmic Antibodies.

Many patients with vasculitis have circulating antibodies that react with neutrophil cytoplasmic antigens, so-called *antineutrophil cytoplasmic antibodies (ANCAs)*. ANCAs are a heterogeneous group of autoantibodies directed against constituents (mainly enzymes) of neutrophil primary granules, monocyte lysosomes, and endothelial cells. These were previously classified according to their intracellular distribution, either cytoplasmic (c-ANCA) or perinuclear (p-ANCA). More commonly now, they are discriminated based on their target antigens:

- Anti-myeloperoxidase (MPO-ANCA): MPO is a lysosomal granule constituent normally involved in generating oxygen free radicals (Chapter 2). MPO-ANCAs can be induced by a variety of therapeutic agents, in particular propylthiouracil. These have been called p-ANCA.
- Anti-proteinase-3 (PR3-ANCA): PR3 is also a neutrophil azurophilic granule constituent. That it shares homology with numerous microbial peptides may explain how PR3-ANCAs develop.[66] These have been called c-ANCA.

Although not entirely specific, PR3-ANCAs are typical of Wegener granulomatosis and MPO-ANCAs are characteristic of microscopic polyangiitis and Churg-Strauss syndrome (see below); racial and geographic variables also influence the association of particular ANCAs and disease entities.

ANCAs serve as useful diagnostic markers for the ANCA-associated vasculitides, and their titers may reflect the degree of inflammatory activity. ANCA titers also rise with recurrent disease and are therefore useful in clinical management. The close association between ANCA titers and disease activity suggests a pathogenic role. Although the precise mechanisms are unknown, ANCA can directly activate neutrophils and may thereby stimulate neutrophils to release reactive oxygen species and

proteolytic enzymes; within the vasculature, this also leads to endothelial cell-neutrophil interactions and subsequent endothelial cell damage.[67] Moreover, the antigenic targets of ANCAs are primarily intracellular and therefore might not be expected to be accessible to circulating antibodies, but there is now abundant evidence that ANCA antigens (in particular PR3) are either constitutively present at low levels on the plasma membrane or are translocated to the cell surface in activated and apoptotic neutrophils.[66,][68]

A plausible mechanism for ANCA vasculitis is the following[66,][68]:

- Drugs or cross-reactive microbial antigens induce ANCAs; alternatively, neutrophil surface expression or release of PR3 and MPO (e.g., in the setting of infections) incites ANCA formation in a susceptible host.
- Subsequent infection, endotoxin exposure, or other inflammatory stimuli elicit cytokines such as TNF that cause surface expression of PR3 and MPO on neutrophils and other cell types.
- ANCAs react with these cytokine-activated cells and either cause direct injury (e.g., to endothelial cells) or induce further activation (e.g., in neutrophils).
- ANCA-activated neutrophils degranulate and also cause injury by releasing reactive oxygen species, engendering endothelial cell toxicity and other indirect tissue injury.

Interestingly, ANCAs directed against constituents other than PR3 and MPO are also found in some patients with inflammatory disorders that do not involve vasculitis (e.g., inflammatory bowel disease, primary sclerosing cholangitis, rheumatoid arthritis).

Anti-Endothelial Cell Antibodies.

Antibodies to endothelial cells may predispose to certain vasculitides, for example, Kawasaki disease[69,][70] (see below).

We will now briefly present several of the best-characterized vasculitides, again emphasizing that there is substantial overlap among the different entities. Moreover, it should be kept in mind that some patients with vasculitis do not have a classic constellation of findings that allows them to be neatly pigeonholed into one specific diagnosis.

GIANT-CELL (TEMPORAL) ARTERITIS

Giant-cell (temporal) arteritis is the most common form of vasculitis among elderly individuals in the United States and Europe. It is a chronic, typically granulomatous inflammation of large to small-sized arteries that affects principally the arteries in the head—especially the temporal arteries—but also the vertebral and ophthalmic arteries.[71] Ophthalmic arterial involvement can lead to permanent blindness; consequently, giant-cell arteritis is a medical emergency requiring prompt recognition and treatment. Lesions also occur in other arteries, including the aorta (giant-cell aortitis).

Pathogenesis.

The cause of giant-cell arteritis remains elusive, although most evidence supports an initial T cell–mediated immune response against an unknown, possibly vessel wall, antigen. Pro-inflammatory cytokines (in particular TNF), and anti–endothelial cell humoral immune responses also probably contribute.[72] An immune etiology is supported by the characteristic granulomatous reaction, a correlation with certain HLA class II haplotypes, and a therapeutic response to steroids. The extraordinary predilection for a single vascular site (temporal artery) remains unexplained.

Morphology. Involved arterial segments develop **nodular intimal thickening** (with occasional

thromboses) **that reduces the lumenal diameter**. Classic lesions exhibit medial **granulomatous inflammation** that leads to **elastic lamina fragmentation**; there is an infiltrate of T cells (CD4+> CD8+) and macrophages. Multinucleated giant cells are found in upwards of 75% of adequately biopsied specimens (Fig. 11-23). Occasionally, granulomas and giant cells are rare or absent, and lesions show only a nonspecific panarteritis composed predominantly of lymphocytes and macrophages. Inflammatory lesions are not continuous along the vessel, and long segments of relatively normal artery may be interposed. The healed stage is marked by medial scarring and intimal thickening, typically with residual elastic tissue fragmentation.

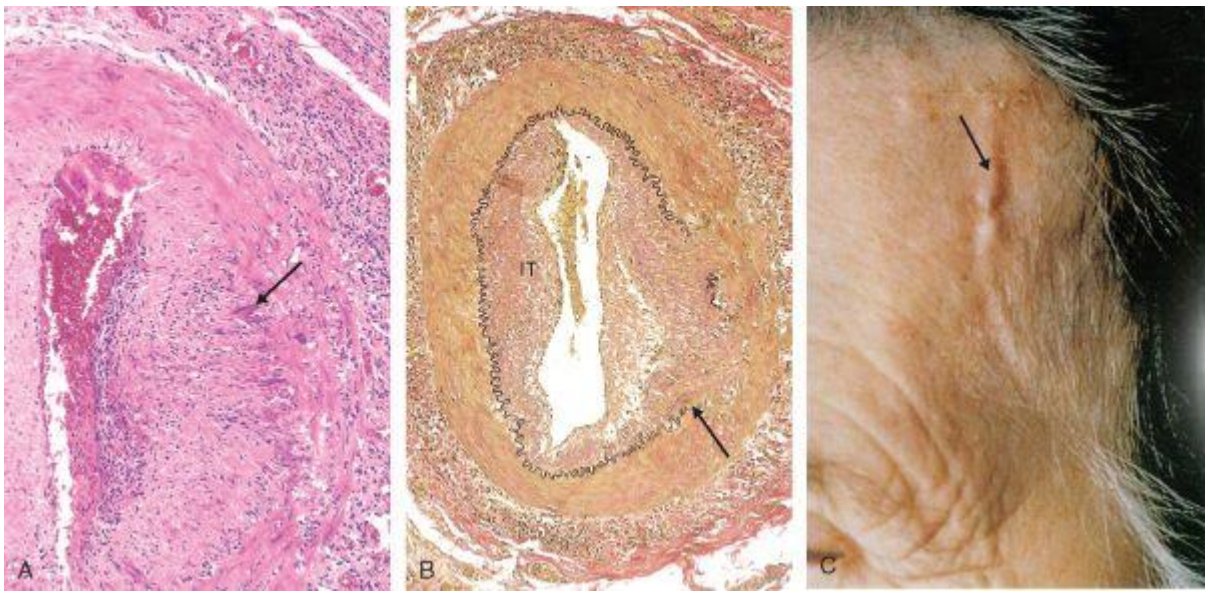

FIGURE 11-23 Giant-cell (temporal) arteritis. **A**, H&E stain of section of temporal artery showing giant cells at the degenerated internal elastic lamina in active arteritis *(arrow)*. **B**, Elastic tissue stain demonstrating focal destruction of internal elastic lamina *(arrow)* and intimal thickening (IT) characteristic of long-standing or healed arteritis. **C**, Examination of the temporal artery of a patient with giant-cell arteritis shows a thickened, nodular, and tender segment of a vessel on the surface of head *(arrow)*. *(**C** from Salvarani C et al.: Polymyalgia rheumatica and giant-cell arteritis. N Engl J Med 347:261, 2002.)*

Clinical Features.

Temporal arteritis is rare before the age of 50. Symptoms may be vague and constitutional—fever, fatigue, weight loss—or include facial pain or headache that is most intense along the course of the superficial temporal artery, which can be painful to palpation. Ocular symptoms (associated with involvement of the ophthalmic artery) appear abruptly in about 50% of patients; these range from diplopia to complete vision loss. Diagnosis depends on biopsy and histologic confirmation. However, because giant-cell arteritis is extremely segmental, adequate biopsy requires at least a 2- to 3-cm length of artery; even then, a negative biopsy result does not exclude the diagnosis. Treatment with corticosteroids is generally effective, with anti-TNF therapy showing promise in refractory cases.[71]

TAKAYASU ARTERITIS

This is a *granulomatous vasculitis* of medium and larger arteries characterized principally by ocular disturbances and marked weakening of the pulses in the upper extremities (hence, its other name, *pulseless disease*). Takayasu arteritis manifests with transmural fibrous thickening of the aorta—particularly the aortic arch and great vessels—and severe luminal narrowing of the major branch vessels

(Fig. 11-24). *Aortic lesions share many attributes with giant-cell aortitis*, including clinical features and histology; indeed, the distinction is typically made only on the basis of the age of the patient. Those over 50 years of age are designated as having giant-cell aortitis, while those under 50 have Takayasu aortitis.[64] Though traditionally associated with the Japanese population and a subset of HLA haplotypes, Takayasu aortitis has a global distribution. The cause and pathogenesis are unknown, although immune mechanisms are suspected.[71,][72]

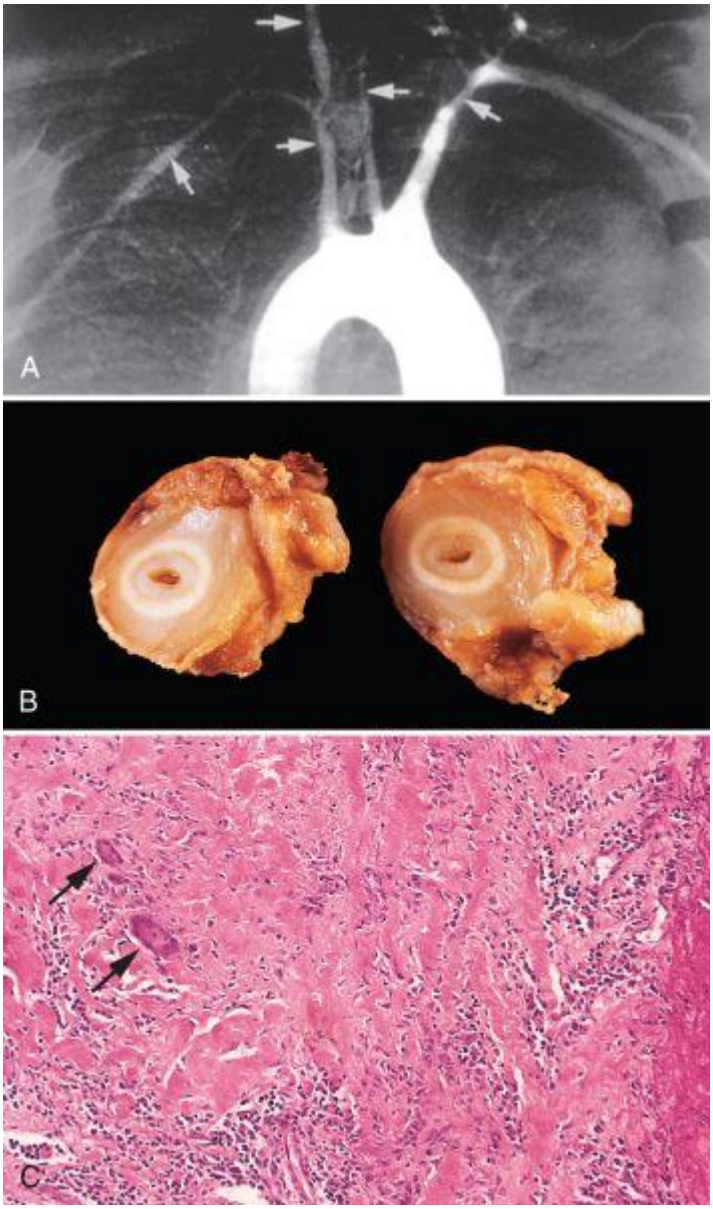

FIGURE 11-24 Takayasu arteritis. **A**, Aortic arch angiogram showing narrowing of brachiocephalic, carotid, and subclavian arteries *(arrows)*. **B**, Gross photograph of two cross-sections of the right carotid artery taken at autopsy of the patient shown in **A**, demonstrating marked intimal thickening with minimal residual lumen. **C**, Histologic view of active Takayasu aortitis, illustrating destruction of the arterial media by mononuclear inflammation with giant cells *(arrows)*.

Morphology. Takayasu arteritis classically involves the aortic arch. In a third of patients it also affects the remainder of the aorta and its branches. The pulmonary artery is involved in half of cases;

coronary and renal arteries may be similarly affected. There is irregular thickening of the vessel wall with intimal hyperplasia; when the aortic arch is involved the great vessel lumens can be markedly narrowed or even obliterated (Fig. 11-24A and B). Such narrowing explains the weakness of the peripheral pulses. Histological changes range from adventitial mononuclear infiltrates with perivascular cuffing of the vasa vasorum, to intense mononuclear inflammation in the media, to granulomatous inflammation, replete with giant cells and patchy medial necrosis. The histologic appearance (Fig. 11-24C) is indistinguishable from that of giant-cell (temporal) arteritis. As the disease progresses, collagenous scarring, with admixed chronic inflammatory infiltrates, occurs in all three layers of the vessel wall. Occasionally, aortic root involvement causes aortic insufficiency.

Clinical Features.

Initial symptoms are usually nonspecific, including fatigue, weight loss, and fever. With progression, vascular symptoms appear and dominate the clinical picture, including reduced blood pressure and weaker pulses in the upper extremities; ocular disturbances, including visual defects, retinal hemorrhages, and total blindness; and neurologic deficits. Involvement of the more distal aorta may lead to claudication of the legs; pulmonary artery involvement may cause pulmonary hypertension. Narrowing of the coronary ostia may lead to myocardial infarction, and involvement of the renal arteries leads to systemic hypertension in roughly half of patients. The course of the disease is variable. In some there is rapid progression, while others enter a quiescent stage at 1 to 2 years, permitting long-term survival, albeit sometimes with visual or neurologic deficits.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a systemic vasculitis of small or medium-sized muscular arteries (but not arterioles, capillaries, or venules), typically involving renal and visceral vessels but sparing the pulmonary circulation. There is no association with ANCAs, but about 30% of patients with PAN have chronic hepatitis B with HBsAg-HbsAb complexes in affected vessels, indicating an immune complex–mediated etiology (see Chapter 6) in that subset. Nevertheless, the cause remains unknown in the majority of cases; there may be etiologic and important clinical distinctions between classic idiopathic PAN, the cutaneous forms of PAN, and the PAN associated with chronic hepatitis.[73,][74] Clinical manifestations result from ischemia and infarction of affected tissues and organs.[73]

Morphology. Classic PAN is characterized by **segmental transmural necrotizing inflammation ofsmall to medium-sized arteries**. Vessels of the kidneys, heart, liver, and gastrointestinal tract are involved in descending order of frequency. Lesions usually affect only part of the vessel circumference and show a predilection for branch points. The inflammatory process **weakens the arterial wall** and can lead to aneurysms or even rupture. **Impaired perfusion** resulting in ulcerations, infarcts, ischemic atrophy, or hemorrhages in the distribution of affected vessels may be the first sign of disease.

During the acute phase there is **transmural inflammation** of the arterial wall with a mixed infiltrate of neutrophils, eosinophils, and mononuclear cells, frequently accompanied by **fibrinoid necrosis** (Fig. 11-25). Luminal thrombosis can occur. Later, the acute inflammatory infiltrate is replaced by **fibrous** (occasionally nodular) **thickening of the vessel wall** that can extend into the adventitia. **Characteristically, all stages of activity** (from early to late) **coexist in different vessels or even within the same vessel, suggesting ongoing and recurrent insults**.

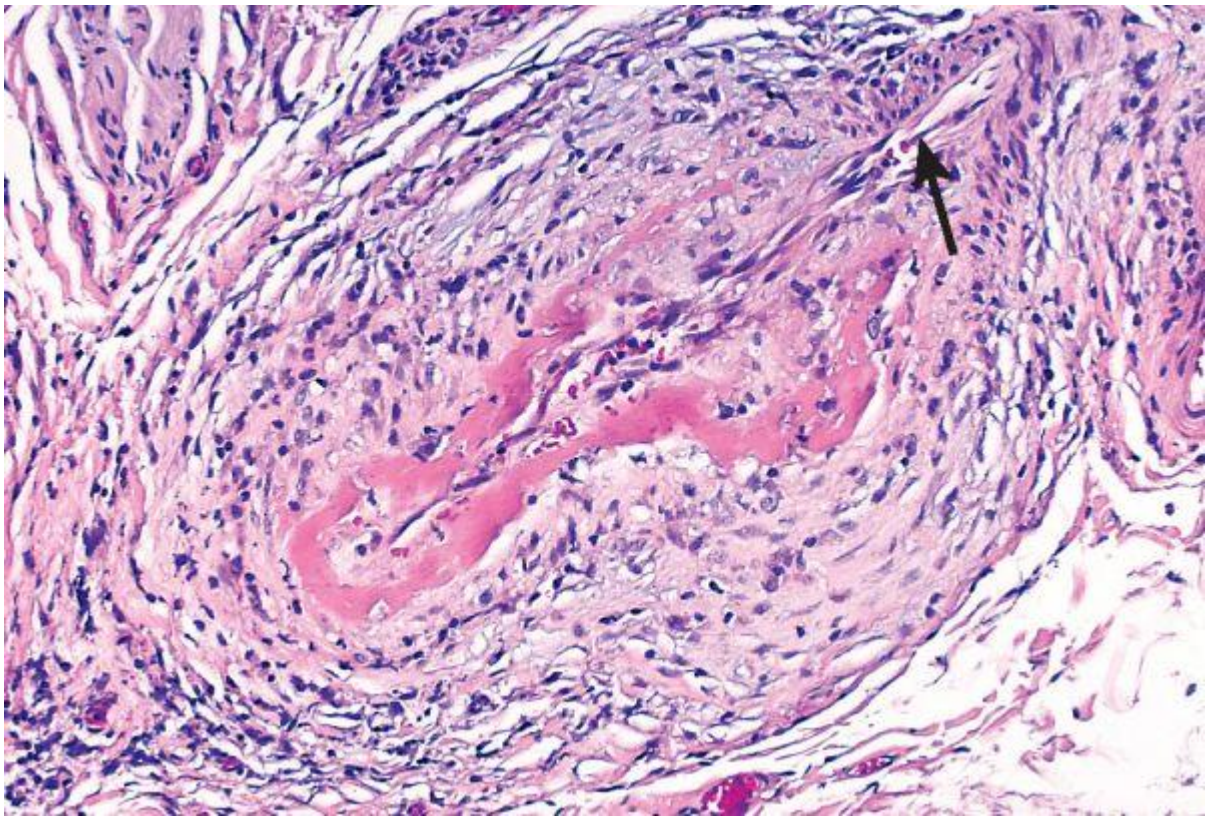

FIGURE 11-25 Polyarteritis nodosa. There is segmental fibrinoid necrosis and thrombotic occlusion of the lumen of this small artery. Note that part of the vessel wall at the upper right *(arrow)* is uninvolved. *(Courtesy of Sidney Murphree, M.D., Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Clinical Features.

Though typically a disease of young adults, PAN can also occur in pediatric and geriatric populations. The course may be acute, subacute, or chronic, and is frequently remitting and episodic, with long symptom-free intervals. Because the vascular involvement is widely scattered, the clinical signs and symptoms of PAN may be varied, puzzling, and not always referable to a vascular source. The most common manifestations are malaise, fever, and weight loss; hypertension, usually developing rapidly due to renal involvement; abdominal pain and melena (bloody stool) due to vascular lesions in the gastrointestinal tract; diffuse muscular aches and pains; and peripheral neuritis. Renal arterial involvement is often prominent and a major cause of death. Untreated, the disease is fatal in most cases, either during an acute fulminant attack or following a protracted course. However, therapy with corticosteroids and cyclophosphamide results in remissions or cures in 90% of cases.

KAWASAKI DISEASE

The leading cause of acquired heart disease in children, *Kawasaki disease*, is an acute febrile, usually self-limited illness of infancy and childhood (80% are younger than 4 years) associated with an *arteritis affecting large to medium-sized, and even small, vessels*. Its clinical significance stems primarily from a predilection for coronary artery involvement; such coronary arteritis can cause aneurysms that rupture or thrombose, resulting in acute myocardial infarctions. Originally described in Japan, the disease is now increasingly reported in the United States and other countries. The etiology is uncertain, but the

vasculitis is thought to result from a delayed-type hypersensitivity reaction of T cells to an as yet uncharacterized antigen. This leads to cytokine production and macrophage activation, and is accompanied by polyclonal B-cell activation. This results in formation of autoantibodies to endothelial cells and smooth muscle cells, which precipitate the acute vasculitis. It is currently speculated that a variety of infectious agents (most likely viral) can trigger the disease in genetically susceptible persons.[69,][70]

Morphology. As with polyarteritis nodosa, lesions exhibit pronounced inflammation affecting the entire thickness of the vessel wall; however, fibrinoid necrosis is usually less prominent. Although the acute vasculitis subsides spontaneously or in response to treatment, aneurysm formation with thrombosis can supervene. As with other causes of arteritis, healed lesions may have obstructive intimal thickening. Pathologic changes outside the cardiovascular system are rarely significant.

Clinical Features.

Kawasaki disease is also known as mucocutaneous lymph node syndrome, because it presents with conjunctival and oral erythema and erosion, edema of the hands and feet, erythema of the palms and soles, a desquamative rash, and cervical lymph node enlargement. Approximately 20% of untreated patients develop cardiovascular sequelae, ranging from asymptomatic coronary arteritis, to coronary artery ectasia and aneurysm formation, to giant coronary artery aneurysms (7–8 mm) with rupture or thrombosis, myocardial infarction, and sudden death. With intravenous immunoglobulin therapy and aspirin, the rate of coronary artery disease is reduced to about 4%.[69,][70]

MICROSCOPIC POLYANGIITIS

This is *a necrotizing vasculitis that generally affects capillaries, as well as arterioles and venules* of a size smaller than those involved in polyarteritis nodosa; rarely, larger arteries may be involved. It is also called *hypersensitivity vasculitis* or *leukocytoclastic vasculitis*. Unlike polyarteritis nodosa, *all lesions of microscopic polyangiitis tend to be of the same age in any given patient*. The skin, mucous membranes, lungs, brain, heart, gastrointestinal tract, kidneys, and muscle can all be involved; *necrotizing glomerulonephritis (90% of patients) and pulmonary capillaritis are particularly common*. Disseminated vascular lesions of hypersensitivity angiitis can also occur as a presentation of other disorders (e.g., Henoch-Schönlein purpura, essential mixed cryoglobulinemia, and vasculitis associated with connective tissue disorders).[66,][75]

Pathogenesis.

In some cases, an antibody response to antigens such as drugs (e.g., penicillin), microorganisms (e.g., streptococci), heterologous proteins, or tumor proteins has been implicated; this can either result in immune complex deposition or may trigger secondary immune responses (e.g., the development of p-ANCAs) that are ultimately pathogenic. However, most lesions are pauci-immune (devoid of immune complexes), and increasingly, MPO-ANCAs are causally im-plicated.[68] Recruitment and activation of neutrophils within a particular vascular bed may be responsible for the disease manifestations.

Morphology. Microscopic polyangiitis is characterized by segmental fibrinoid necrosis of the media with focal transmural necrotizing lesions; granulomatous inflammation is absent. These lesions morphologically resemble polyarteritis nodosa but typically spare medium-sized and larger arteries; consequently, macroscopic infarcts are uncommon. In some areas (typically post-capillary venules), only infiltrating and fragmenting neutrophils are seen, giving rise to the term **leukocytoclastic**

vasculitis (Fig. 11-26A). Although immunoglobulins and complement components can be demonstrated in early skin lesions, little or no immunoglobulin can be seen in most lesions (so-called **pauci-immune injury**).

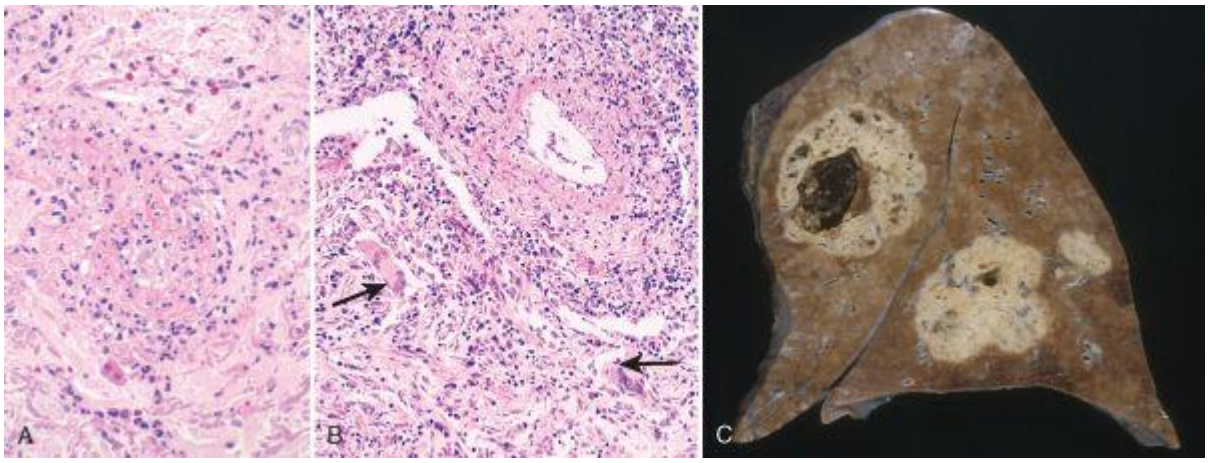

FIGURE 11-26 Representative forms of ANCA-associated small-vessel vasculitis. **A**, Leukocytoclastic vasculitis (microscopic polyangiitis) with fragmentation of neutrophils in and around blood vessel walls. **B** and **C**, Wegener granulomatosis. **B**, Vasculitis of a small artery with adjacent granulomatous inflammation including epithelioid cells and giant cells *(arrows)*. **C**, Gross photo from the lung of a patient with fatal Wegener granulomatosis, demonstrating large nodular centrally cavitating lesions. *(**A**, Courtesy of Scott Granter, M.D., Brigham and Women's Hospital, Boston, MA; **C**, courtesy of Sidney Murphree, M.D., Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Clinical Features.

Depending on the vascular bed involved, major clinical features include hemoptysis; hematuria, and proteinuria; bowel pain or bleeding; muscle pain or weakness; and palpable cutaneous purpura. With the exception of those who develop widespread renal or brain involvement, cyclophosphamide and steroid immunosuppression induces remission and markedly improves long-term survival.[76]

CHURG-STRAUSS SYNDROME

Churg-Strauss syndrome (also called *allergic granulomatosis and angiitis*) is a relatively rare (roughly one in a million people) *small-vessel necrotizing vasculitis classically associated with asthma, allergic rhinitis, lung infiltrates, peripheral hypereosinophilia, and extravascular necrotizing granulomas*. Vascular lesions can be histologically similar to polyarteritis nodosa or microscopic polyangiitis but are also characteristically accompanied by granulomas and eosinophils.[77] ANCAs (mostly MPO-ANCAs) are present in less than half the cases and raise the possibility that there are distinct subsets of patients with the syndrome. Nevertheless, when present, the ANCAs are probably responsible for the vascular manifestations of the disease. Cutaneous involvement (palpable purpura), gastrointestinal tract bleeding, and renal disease (primarily as focal and segmental glomerulosclerosis) are the major associations. Myocardial infiltrates of eosinophils and cytotoxicity caused by them are implicated in the cardiomyopathy seen in Churg-Strauss syndrome; the heart is involved in 60% of patients, and accounts for almost half of the deaths in the syndrome.[77] The etiology remains obscure, but has been suggested to result from hyper-responsiveness to an allergic stimulus; in asthmatics, leukotriene receptor antagonists are reported as a trigger.[78]

WEGENER GRANULOMATOSIS

Wegener granulomatosis is a necrotizing vasculitis characterized by a triad of

- *Acute necrotizing granulomas* of the upper respiratory tract (ear, nose, sinuses, throat) or the lower respiratory tract (lung) or both
- *Necrotizing or granulomatous vasculitis* affecting *small to medium-sized vessels* (e.g., capillaries, venules, arterioles, and arteries), most prominent in the lungs and upper airways but affecting other sites as well
- Renal disease in the form of *focal necrotizing*, *often crescentic*, *glomerulonephritis*

"Limited" forms of Wegener granulomatosis may be restricted to the respiratory tract. Conversely, a widespread form of the disease can affect eyes, skin, and other organs, notably the heart; clinically, this resembles polyarteritis nodosa except that there is also respiratory involvement.

Pathogenesis.

Wegener granulomatosis probably represents a form of T cell–mediated hypersensitivity reaction, possibly to an inhaled infectious or other environmental agent; such a pathogenesis is supported by the presence of granulomas and a dramatic response to immunosuppressive therapy. PR3-ANCAs are present in up to 95% of cases; they are a useful marker of disease activity and may participate in disease pathogenesis. After immunosuppressive treatment, a rising PR3-ANCA titer suggests a relapse; most patients in remission have a negative test or falling titers.[79]

Morphology. Upper respiratory tract lesions range from inflammatory sinusitis with mucosal granulomas to ulcerative lesions of the nose, palate, or pharynx, rimmed by **granulomas with geographic patterns of central necrosis and accompanying vasculitis** (Fig. 11-26B). The necrotizing granulomas are surrounded by a zone of fibroblastic proliferation with giant cells and leukocyte infiltrate, reminiscent of mycobacterial or fungal infections. Multiple granulomas can coalesce to produce radiographically visible nodules that can also cavitate; late-stage disease may be marked by extensive necrotizing granulomatous involvement of the parenchyma (Fig. 11-26C); alveolar hemorrhage may be prominent. Lesions may ultimately undergo progressive fibrosis and organization.

A spectrum of **renal lesions** may be seen (Chapter 20). In early stages, glomeruli exhibit only focal necrosis with thrombosis of isolated glomerular capillary loops (focal and segmental necrotizing glomerulonephritis); there is minimal parietal cell proliferation in Bowman's capsule. More advanced glomerular lesions are characterized by diffuse necrosis and parietal cell proliferation to form crescents (crescentic glomerulonephritis).

Clinical Features.

Males are affected more often than females, at an average age of about 40 years. Classic features include persistent pneumonitis with bilateral nodular and cavitary infiltrates (95%), chronic sinusitis (90%), mucosal ulcerations of the nasopharynx (75%), and evidence of renal disease (80%). Other features include rashes, muscle pains, articular involvement, mononeuritis or polyneuritis, and fever. Left untreated, the disease is usually rapidly fatal; 80% of patients die within 1 year. Treatment with steroids, cyclophosphamide, and more recently TNF-antagonists, have turned Wegener granulomatosis into a chronic remitting and relapsing disease.[80]

THROMBOANGIITIS OBLITERANS (BUERGER DISEASE)

Thromboangiitis obliterans (Buerger disease) is a distinctive disease that often leads to vascular insufficiency; it is characterized by *segmental, thrombosing, acute and chronic inflammation of medium-sized and small arteries*, principally the tibial and radial arteries, with occasional secondary extension into the veins and nerves of the extremities. Buerger disease is a condition that occurs almost exclusively in heavy cigarette smokers, usually before the age of 35.

Pathogenesis.

The strong relationship to cigarette smoking is thought to be due to direct endothelial cell toxicity by some component of tobacco, or an idiosyncratic immune response to the same agents. Most patients have hypersensitivity to intradermally injected tobacco extracts, and their vessels exhibit impaired endothelium-dependent vasodilation when challenged with acetylcholine. Genetic influences are suggested by an increased prevalence in certain ethnic groups (Israeli, Indian subcontinent, Japanese) and an association with certain HLA haplotypes.[81]

Morphology. Thromboangiitis obliterans is characterized by a **sharply segmental acute and chronic vasculitis of medium-sized and small arteries**, predominantly of the extremities. Microscopically, there is acute and chronic inflammation, accompanied by luminal thrombosis. Typically, the thrombus contains small **microabscesses** composed of neutrophils surrounded by granulomatous inflammation (Fig. 11-27); the thrombus may eventually organize and recanalize. The inflammatory process extends into contiguous veins and nerves (rare with other forms ofvasculitis), and in time all three structures become encased in fibrous tissue.

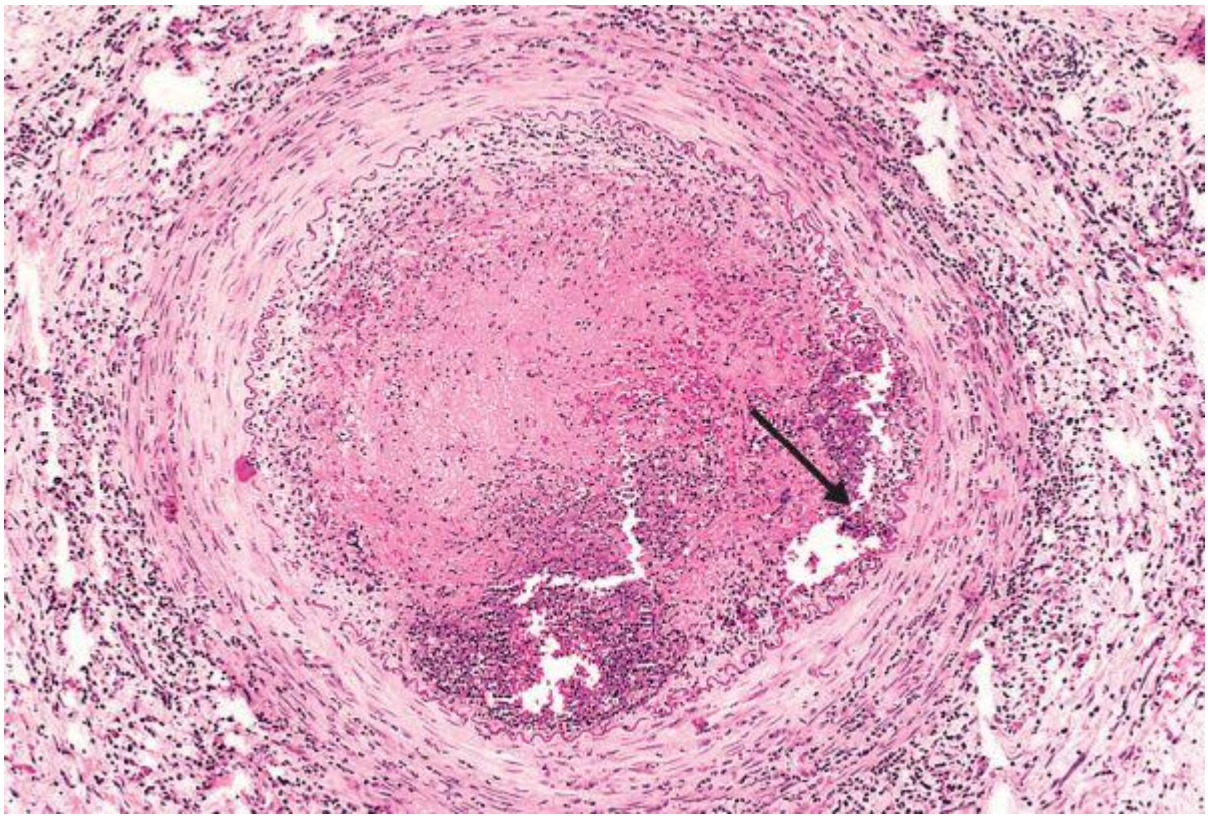

FIGURE 11-27 Thromboangiitis obliterans (Buerger disease). The lumen is occluded by a thrombus containing abscesses *(arrow)*, and the vessel wall is infiltrated with leukocytes.

Clinical Features.

The early manifestations are a superficial nodular phlebitis, cold sensitivity of the Raynaud type (see below) in the hands, and pain in the instep of the foot induced by exercise (so-called *instep claudication*). In contrast to the insufficiency caused by atherosclerosis, in Buerger disease there tends to be severe pain, even at rest, related undoubtedly to the neural involvement. Chronic ulcerations of the toes, feet, or fingers may appear, which can be followed in time by frank gangrene. Abstinence from cigarette smoking in the early stages of the disease often brings dramatic relief from further attacks.

VASCULITIS ASSOCIATED WITH OTHER DISORDERS

Vasculitis resembling hypersensitivity angiitis or classic polyarteritis nodosa may sometimes be associated with other disorders, such as rheumatoid arthritis, SLE, cancer, or systemic illnesses such as mixed cryoglobulinemia, antiphospholipid antibody syndrome, and Henoch-Schönlein purpura. *Rheumatoid vasculitis* occurs predominantly after longstanding, severe rheumatoid arthritis and usually affects small and medium-sized arteries. It can lead to visceral infarction and sometimes causes a clinically significant aortitis. Identifying the underlying pathology may be therapeutically important. For example, although classic immune complex *lupus vasculitis* and antiphospholipid antibody syndrome are morphologically similar, anti-inflammatory therapy is required in the former while anticoagulant therapy is indicated in the latter.

INFECTIOUS VASCULITIS

Localized arteritis may be caused by the direct invasion of infectious agents, usually bacteria or fungi, and in particular *Aspergillus* and *Mucor* species. Vascular invasion can be part of a localized tissue infection (e.g., bacterial pneumonia or adjacent to abscesses), or—less commonly—it can arise from hematogenous seeding of bacteria during septicemia or embolization from sepsis of infective endocarditis.

Vascular infections can weaken arterial walls and culminate in *mycotic aneurysms* (see earlier), or can induce thrombosis and infarction. Thus, inflammation-induced thrombosis of meningeal vessels in bacterial meningitis can cause infarction of the underlying brain.

3.1.10 Raynaud Phenomenon

Raynaud phenomenon results from an exaggerated vasoconstriction of digital arteries and arterioles. These vascular changes induce paroxysmal pallor or cyanosis of the digits of the hands or feet; infrequently, the nose, earlobes, or lips can also be involved. Characteristically, the involved digits show red, white, and blue color changes from most proximal to most distal, correlating with proximal vasodilation, central vasoconstriction, and more distal cyanosis (Fig. 11-28). Raynaud phenomenon may be a primary disease entity or be secondary to a variety of conditions.[82]

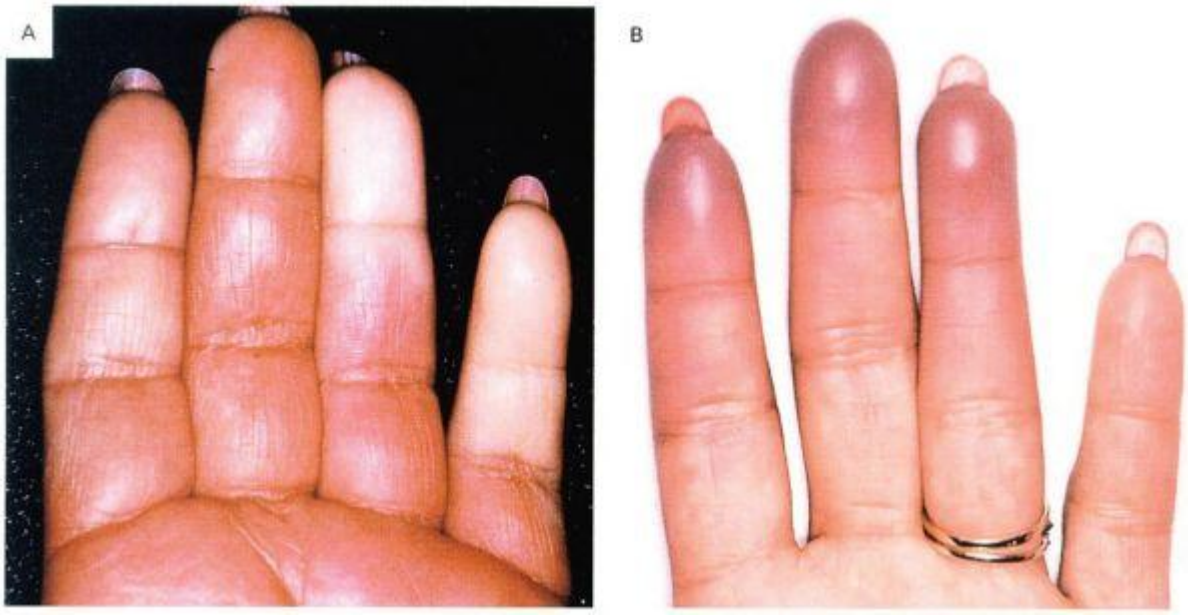

FIGURE 11-28 Raynaud's phenomenon. **A**, Sharply demarcated pallor of the distal fingers resulting from the closure of digital arteries. **B**, Cyanosis of the fingertips. *(Reproduced from Salvarani C, et al.: Polymyalgia rheumatica and giant-cell arteritis. N Engl J Med 347:261, 2002.)*

Primary Raynaud phenomenon (previously called Raynaud disease) reflects an exaggeration of central and local vasomotor responses to cold or emotional stresses. It affects 3% to 5% of the general population and shows a predilection for young women. Structural changes in the arterial walls are absent except late in the course, when intimal thickening can appear. The course of Raynaud phenomenon is usually benign, but when long-standing can result in atrophy of the skin, subcutaneous tissues, and muscles. Ulceration and ischemic gangrene are rare.[83]

In contrast, *secondary Raynaud phenomenon* refers to vascular insufficiency of the extremities secondary to arterial disease caused by other entities including SLE, scleroderma, Buerger disease, or even atherosclerosis. Since Raynaud phenomenon may be the first manifestation of such conditions, any patient with new symptoms should be evaluated. Of these individuals, some 10% will eventually manifest an underlying disease.

3.1.11 Veins & Lymphatics

Varicose veins and phlebothrombosis/thrombophlebitis together account for at least 90% of clinical venous disease.

VARICOSE VEINS

Varicose veins are abnormally dilated, tortuous veins produced by prolonged, increased intraluminal pressure and loss of vessel wall support. The *superficial veins* of the upper and lower leg are typically involved (Fig. 11-29). When legs are dependent for prolonged periods, venous pressures in these sites can be markedly elevated (up to 10 times normal) and can lead to venous stasis and pedal edema, even in essentially normal veins *(simple orthostatic edema)*. Some 10% to 20% of adult males and 25% to 33% of adult females develop lower extremity varicose veins; obesity increases risk, and the higher incidence

in women is a reflection of the elevated venous pressure in lower legs caused by pregnancy. A *familial tendency* toward premature varicosities has been noted.

FIGURE 11-29 Varicose veins of the leg *(arrow). (Courtesy of Magruder C. Donaldson, M.D., Brigham and Women's Hospital, Boston, MA.)*

Clinical Features.

Varicose dilation renders the venous valves incompetent and leads to stasis, congestion, edema, pain, and thrombosis. The most disabling sequelae include persistent edema in the extremity and ischemic skin changes, including *stasis dermatitis* and ulcerations; poor wound healing and superimposed infections can lead to chronic *varicose ulcers. Notably, embolism from these superficial veins is very rare. This is in sharp contrast to the relatively frequent thromboembolism that arises from thrombosed deep veins* (see below and Chapter 4).

Varicosities that occur in two other sites deserve special mention:

- *Esophageal varices*. Liver cirrhosis (less frequently, portal vein obstruction or hepatic vein thrombosis) causes portal vein hypertension (Chapter 18). Portal hypertension leads to the opening of porto-systemic shunts that increase the blood flow into veins at the gastro-esophageal junction (forming *esophageal varices*), the rectum (forming *hemorrhoids*), and periumbilical veins of the abdominal wall (forming a *caput medusa*). Esophageal varices are the most important, since their rupture can lead to massive (even fatal) upper gastrointestinal hemorrhage.
- *Hemorrhoids* can also result from primary varicose dilation of the venous plexus at the anorectal junction (e.g., through prolonged pelvic vascular congestion due to pregnancy or chronic constipation). Hemorrhoids are uncomfortable and may be a source of bleeding; they can also thrombose and get inflamed, and are prone to painful ulceration.

THROMBOPHLEBITIS AND PHLEBOTHROMBOSIS

Deep leg veins are the site of more than 90% of cases of thrombophlebitis and *phlebothrombosis*; the two terms are largely interchangeable designations for venous thrombosis and inflammation. The periprostatic venous plexus in males and the pelvic venous plexus in females are additional sites, as are the large veins in the skull and the dural sinuses (especially in the setting of infection or inflammation). Peritoneal infections, including peritonitis, appendicitis, salpingitis, and pelvic abscesses, as well as certain thrombophilic conditions associated with platelet hyperactivity (e.g., polycythemia vera, Chapter 13), can lead to portal vein thrombosis. For deep venous thrombosis (DVT) of the legs, *prolonged immobilization resulting in decreased blood flow through the veins is the most important predisposing condition*. This can occur with extended bed rest or from just sitting during extended travel in an airplane or automobile; the postoperative state is another independent risk factor in DVT formation. Clearly, other mechanical factors that slow venous return also promote the development of DVT; these include congestive heart failure, pregnancy, and obesity.

Systemic hypercoagulability (Chapter 4) *often predisposes to thrombophlebitis*. In patients with cancer, particularly adenocarcinomas, hypercoagulability occurs as a paraneoplastic syndrome related to elaboration of pro-coagulant factors by the tumor cells (Chapter 7). In this setting, venous thromboses classically appear in one site, disappear, and then reoccur in other veins; this is referred to as *migratory thrombophlebitis (Trousseau sign)*.

Thrombi in the legs tend to produce few, if any, reliable signs or symptoms. Indeed, local manifestations, including distal edema, cyanosis, superficial vein dilation, heat, tenderness, redness, swelling, and pain may be entirely absent, especially in bedridden patients. In some cases pain can be elicited by pressure over affected veins, squeezing the calf muscles, or forced dorsiflexion of the foot *(Homan sign)*; *absence of these findings does not exclude a diagnosis of DVT*.

Pulmonary embolism is a serious complication of DVT (Chapter 4), resulting from fragmentation or detachment of the whole venous thrombus. In many cases *the first manifestation of thrombophlebitis is a pulmonary embolus*. Depending on the size and number of emboli, the outcome can range from no symptoms to death.

SUPERIOR AND INFERIOR VENA CAVAL SYNDROMES

The *superior vena caval syndrome* is usually caused by neoplasms that compress or invade the superior vena cava, such as bronchogenic carcinoma or mediastinal lymphoma. The resulting obstruction produces a characteristic clinical complex that includes marked dilation of the veins of the head, neck, and arms and cyanosis. Pulmonary vessels can also be compressed, causing respiratory distress.

The *inferior vena caval syndrome* can be caused by neoplasms that compress or invade the inferior vena cava (IVC) or by a thrombus from the hepatic, renal, or lower extremity veins that propagates upward.

Certain neoplasms—particularly hepatocellular carcinoma and renal cell carcinoma—show a striking tendency to grow within veins, and these may ultimately occlude the IVC. IVC obstruction induces marked lower extremity edema, distention of the superficial collateral veins of the lower abdomen, and—with renal vein involvement—massive proteinuria.

LYMPHANGITIS AND LYMPHEDEMA

Primary disorders of lymphatic vessels are extremely uncommon; secondary processes are much more frequent and develop in association with inflammation or malignancies.

Lymphangitis is the acute inflammation elicited when bacterial infections spread into lymphatics; the most common agents are group A β-hemolytic streptococci, although any microbe may be associated. The affected lymphatics are dilated and filled with an exudate of neutrophils and monocytes; these infiltrates can extend through the vessel wall into the perilymphatic tissues and, in severe cases, produce cellulitis or focal abscesses. Clinically, lymphangitis is recognized by red, painful subcutaneous streaks (the inflamed lymphatics), and painful enlargement of draining lymph nodes *(acute lymphadenitis)*. If bacteria are not successfully contained within the lymph nodes, subsequent passage into the venous circulation can result in bacteremia or sepsis.

Primary lymphedema can occur due to an isolated congenital defect (simple congenital lymphedema) or as the familial *Milroy disease (heredofamilial congenital lymphedema)*, which causes lymphatic agenesis or hypoplasia. *Secondary* or *obstructive lymphedema* stems from blockage of a previously normal lymphatic; such obstruction can result from

- Malignant tumors obstructing either the lymphatic channels or the regional lymph nodes
- Surgical procedures that remove regional groups of lymph nodes (e.g., axillary lymph nodes in radical mastectomy)
- Post-irradiation fibrosis
- Filariasis
- Post-inflammatory thrombosis and scarring

Regardless of the cause, lymphedema increases the hydrostatic pressure in the lymphatics distal to the obstruction and causes increased interstitial fluid accumulation. Persistence of this edema leads to increased deposition of interstitial connective tissue, *brawny induration* or *peau d'orange* (orange peel) appearance of the overlying skin, and eventually ulcers due to inadequate tissue perfusion. Milky accumulations of lymph in various spaces are designated *chylous ascites* (abdomen), *chylothorax*, and *chylopericardium*; these are caused by rupture of dilated lymphatics, typically obstructed secondary to an infiltrating tumor mass.

3.1.12 Tumors

Tumors of blood vessels and lymphatics range from benign hemangiomas to lesions that are locally aggressive but infrequently metastasize, to relatively rare, highly malignant angiosarcomas (Table 11-5). Primary tumors of large vessels (aorta, pulmonary artery, and vena cava) are extremely rare and are mostly connective tissue sarcomas. Congenital or developmental malformations and reactive vascular proliferations (e.g., *bacillary angiomatosis*) can also present as tumor-like lesions.

TABLE 11-5 -- Classification of Vascular Tumors and Tumor-like Conditions

BENIGN NEOPLASMS, DEVELOPMENTAL AND ACQUIRED CONDITIONS

Hemangioma Capillary hemangioma Cavernous hemangioma Pyogenic granuloma Lymphangioma Simple (capillary) lymphangioma Cavernous lymphangioma (cystic hygroma) Glomus tumor Vascular ectasias Nevus flammeus Spider telangiectasia (arterial spider) Hereditary hemorrhagic telangiectasis (Osler-Weber-Rendu disease) Reactive vascular proliferations Bacillary angiomatosis
INTERMEDIATE-GRADE NEOPLASMS
Kaposi sarcoma Hemangioendothelioma
MALIGNANT NEOPLASMS
Angiosarcoma Hemangiopericytoma

Vascular neoplasms can be endothelium-derived (e.g., hemangioma, lymphangioma, angiosarcoma) or arise from cells that support and/or surround blood vessels (e.g., glomus tumor, hemangiopericytoma). Although a benign, welldifferentiated hemangioma can usually be readily discriminated from an anaplastic high-grade angiosarcoma, the distinction between benign and malignant can occasionally be difficult. Two general rules of thumb are as follows:

- Benign tumors usually produce obvious vascular channels filled with blood cells or lymph, lined by a layer of normal-appearing endothelial cells.
- Malignant tumors are more cellular, show cytologic atypia, and are proliferative, including mitotic figures; they usually do not form well-organized vessels. The endothelial derivation of neoplasms that do not form distinct vascular lumens can usually be confirmed by immunohistochemical demonstration of endothelial cell–specific markers such as CD31 or von Willebrand's factor.

Because vascular tumors result from dysregulated vascular proliferation, the possibility of controlling such growth by inhibitors of blood vessel formation (anti-angiogenic factors) is being explored.

BENIGN TUMORS AND TUMOR-LIKE CONDITIONS

Hemangioma

Hemangiomas are very common tumors characterized by increased numbers of normal or abnormal vessels filled with blood (Fig. 11-30); they may be difficult to distinguish from vascular malformations.

These lesions constitute 7% of all benign tumors of infancy and childhood; most are present from birth and expand along with the growth of the child. Nevertheless, many of the capillary lesions eventually regress spontaneously. Although some hemangiomas can involve large portions of the body (*angiomatosis*), most are localized. The majority are superficial lesions, often of the head or neck, but they can occur internally, with nearly one third being found in the liver. Malignant transformation occurs rarely, if ever. There are several histologic and clinical variants:

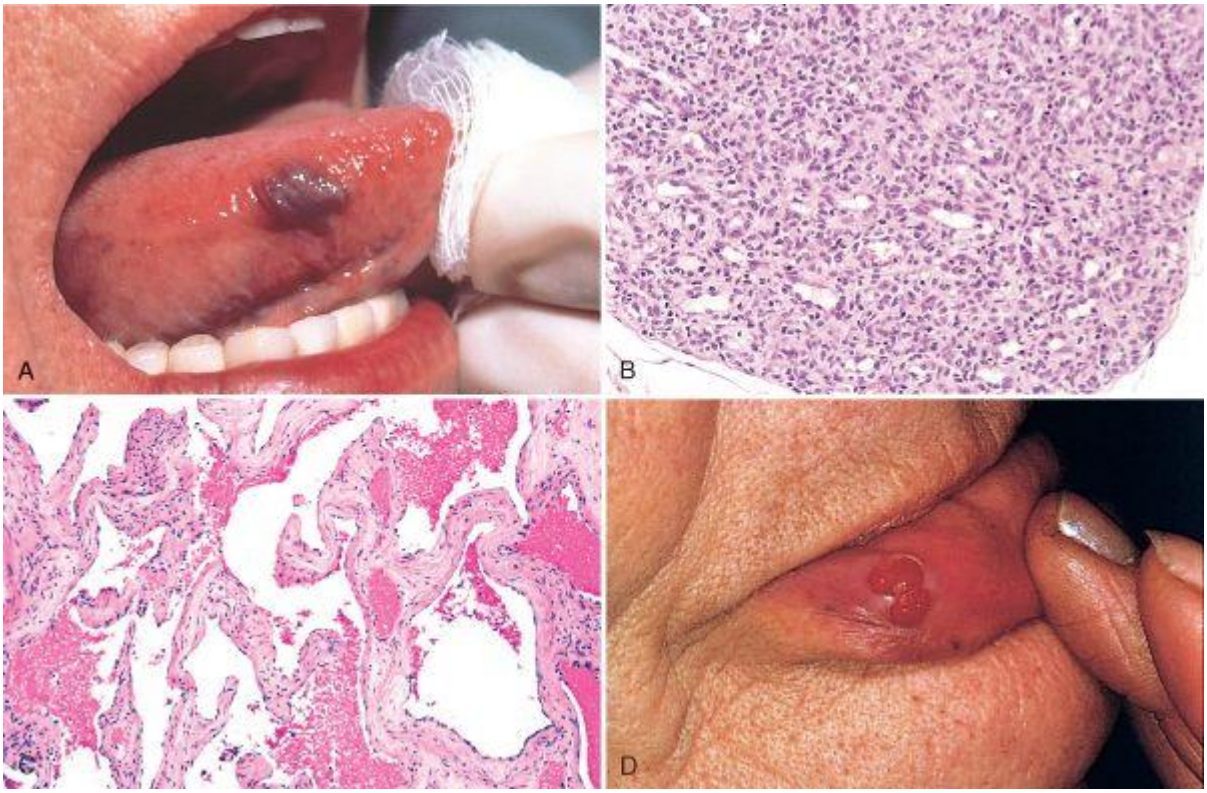

FIGURE 11-30 Hemangiomas. **A**, Hemangioma of the tongue. **B** and **C**, Histologic appearance of (**B**) juvenile capillary hemangioma and (**C**) cavernous hemangioma. **D**, Pyogenic granuloma of the lip. *(**A** and **D**, Courtesy of John Sexton, M.D., Beth Israel Hospital, Boston, MA; **B**, courtesy of Christopher D.M. Fletcher, M.D., Brigham and Women's Hospital, Boston; **C**, courtesy of Thomas Rogers, M.D., University of Texas Southwestern Medical School, Dallas, TX.)*

Capillary Hemangioma.

The most common variant, *capillary hemangiomas*, occur in the skin, subcutaneous tissues, and mucous membranes of the oral cavities and lips, as well as in the liver, spleen, and kidneys. The "strawberry type" or *juvenile hemangioma* of the skin of newborns is extremely common (1 in 200 births) and may be multiple. It grows rapidly in the first few months but then fades at 1 to 3 years of age and completely regresses by age 7 in 75% to 90% of cases.

Morphology. Capillary hemangiomas are bright red to blue and vary from a few millimeters to several centimeters in diameter; hemangiomas can be level with the surface of the skin or slightly elevated, and have an intact overlying epithelium (Fig. 11-30A). Histologically, these are unencapsulated aggregates of **closely packed, thin-walled capillaries**, usually blood-filled and lined by flattened endothelium; vessels are separated by scant connective tissue stroma (Fig. 11-30B). The

lumens may be partially or completely thrombosed and organized. Vessel rupture accounts for hemosiderin pigment in these lesions as well as focal scarring.

Cavernous Hemangioma.

These exhibit large, dilated vascular channels; compared with capillary hemangiomas, *cavernous hemangiomas* are less well circumscribed and more frequently involve deep structures. Since they may be locally destructive and show no spontaneous tendency to regress, some may require surgery. In most cases, the tumors are of little clinical significance; however, they can be a cosmetic disturbance and are vulnerable to traumatic ulceration and bleeding. Moreover, visceral hemangiomas detected by imaging studies may have to be distinguished from more ominous (e.g., malignant) lesions. Brain hemangiomas are most problematic, because they can cause pressure symptoms or rupture. Cavernous hemangiomas are a component of *von Hippel-Lindau disease* (Chapter 28), occurring within the cerebellum, brain stem, or retina, along with similar angiomatous lesions or cystic neoplasms in the pancreas and liver; von Hippel-Lindau disease is also associated with renal neoplasms.

Morphology. Cavernous hemangiomas are red-blue, soft, spongy masses 1 to 2 cm in diameter; rare giant forms can affect large subcutaneous areas of the face, extremities, or other body regions. Histologically, the mass is sharply defined but not encapsulated, and composed of **large, cavernous blood-filled vascular spaces**, separated by a modest connective tissue stroma (Fig. 11-30C). Intravascular thrombosis with associated dystrophic calcification is common.

Pyogenic Granuloma.

This form of capillary hemangioma is a rapidly growing pedunculated red nodule on the skin, or gingival or oral mucosa; it bleeds easily and is often ulcerated (Fig. 11-30D). Roughly a third of the lesions develop after trauma, reaching a size of 1 to 2 cm within a few weeks. The proliferating capillaries are often accompanied by extensive edema and an acute and chronic inflammatory infiltrate, strikingly similar to exuberant granulation tissue. *Pregnancy tumor (granuloma gravidarum)* is a pyogenic granuloma that occurs infrequently (1% of patients) in the gingiva of pregnant women. These lesions can spontaneously regress (e.g., after pregnancy) or undergo fibrosis; in some cases surgical excision is required. Recurrence is rare.

Lymphangiomas

Lymphangiomas are the benign lymphatic analogues of blood vessel hemangiomas.

Simple (Capillary) Lymphangioma.

These are composed of small lymphatic channels predominantly occurring in the head, neck, and axillary subcutaneous tissues. They are slightly elevated or sometimes pedunculated lesions up to 1 to 2 cm in diameter. Histologically, lymphangiomas exhibit networks of endothelium-lined spaces that can be *distinguished from capillary channels only by the absence of erythrocytes*.

Cavernous Lymphangioma (Cystic Hygroma).

These lesions are typically found in the neck or axilla of children, and rarely occur in the retroperitoneum; cavernous lymphangiomas of the neck are common in Turner syndrome (Chapter 10). Cavernous lymphangiomas can occasionally be enormous (up to 15 cm in diameter) and may fill the axilla or produce gross deformities about the neck. Tumors are composed of massively dilated lymphatic spaces lined by endothelial cells and separated by intervening connective tissue stroma

containing lymphoid aggregates. The tumor margins are not discrete and the lesions are not encapsulated, making definitive resection difficult.

Glomus Tumor (Glomangioma)

Glomus tumors are benign, exquisitely painful tumors *arising from modified smooth muscle cells of the glomus body*, a specialized arteriovenous structure involved in thermoregulation. Although they can resemble cavernous hemangiomas, glomus tumors constitute a distinct entity by virtue of their constituent cells. They are most commonly found in the distal portion of the digits, especially under the fingernails. Excision is curative.

Morphology. Glomus tumor lesions are round, slightly elevated, red-blue, firm nodules (usually <1 cm in diameter) that initially resemble a minute focus of hemorrhage. Histologically, these are **aggregates, nests, and masses of specialized glomus cells** intimately associated with branching vascular channels, all within a connective tissue stroma. Individual tumor cells are small, uniform, and round or cuboidal, with scant cytoplasm and ultrastructural features akin to smooth muscle cells.

Vascular Ectasias

Vascular ectasias are common lesions characterized by local dilation of preexisting vessels; *they are not true neoplasms*. *Telangiectasia* is a term used for a congenital anomaly or acquired exaggeration of preformed vessels—usually in the skin or mucous membranes—composed of capillaries, venules, and arterioles that creates a discrete red lesion.

Nevus Flammeus.

This lesion is the ordinary "birthmark" and is the most common form of ectasia; it is characteristically a flat lesion on the head or neck, ranging in color from light pink to deep purple. Histologically, there is only vascular dilation; most ultimately regress.

The so-called *port wine stain* is a special form of nevus flammeus; these lesions tend to grow with a child, thicken the skin surface, and demonstrate no tendency to fade. Such lesions in a trigeminal nerve distribution are occasionally associated with the *Sturge-Weber syndrome* (also called *encephalotrigeminal angiomatosis*). Sturge-Weber syndrome is a rare congenital disorder associated with venous angiomatous masses in the cortical leptomeninges and ipsilateral facial port wine nevi; mental retardation, seizures, hemiplegia, and skull radioopacities also occur. Thus, *a large facial vascular malformation in a child with mental deficiency may indicate the presence of more extensive vascular malformations*.[84]

Spider Telangiectasia.

This non-neoplastic vascular lesion grossly resembles a spider; there is a radial, often pulsatile array of dilated subcutaneous arteries or arterioles (resembling legs) about a central core (resembling a body) that blanches when pressure is applied to its center. It is commonly seen on the face, neck, or upper chest and is most frequently associated with hyper-estrogenic states such as pregnancy or patients with cirrhosis; how elevated estrogen levels contribute to "spider" formation is not known.

Hereditary Hemorrhagic Telangiectasia (OslerWeber-Rendu Disease).

In this autosomal dominant disorder the telangiectasias are malformations composed of dilated capillaries and veins. Present from birth, they are widely distributed over the skin and oral mucous

membranes, as well as in the respiratory, gastrointestinal, and urinary tracts. Occasionally, these lesions rupture, causing serious epistaxis (nosebleeds), GI bleeding, or hematuria.

Bacillary Angiomatosis

Bacillary angiomatosis is a vascular proliferation resulting from an opportunistic infection in immunocompromised individuals; lesions can involve skin, bone, brain, and other organs. First described in patients with acquired immunodeficiency syndrome (AIDS), bacillary angiomatosis is caused by infection with gram-negative bacilli of the *Bartonella* family. Two species are implicated: *Bartonella henselae*, the organism responsible for cat-scratch disease (the domestic cat is the principal reservoir), and *B. quintana*, the cause of "trench fever" in World War I (the organism is transmitted by human body lice).[85]

Morphology. Skin lesions are red papules and nodules, or rounded subcutaneous masses; histologically, there is capillary proliferation with prominent epithelioid endothelial cells exhibiting nuclear atypia and mitoses (Fig. 11-31). Lesions contain neutrophils, nuclear dust, and the causal bacteria.

Though difficult to cultivate in the laboratory, the bacteria can be unequivocally demonstrated using molecular methods such as polymerase chain reaction with species-specific primers. The vascular proliferation results from induction of host HIF-1α by the bacteria; HIF-1α in turn drives VEGF production.[86] The infections (and lesions) are cleared by macrolide antibiotics (including erythromycin).

INTERMEDIATE-GRADE (BORDERLINE) TUMORS

Kaposi Sarcoma

Though rare in other populations, Kaposi sarcoma (KS) is common in patients with AIDS; indeed, its presence is used as a criterion for diagnosing AIDS (Chapter 6). Four forms of the disease are recognized (based primarily on population demographics and risks), although all share the same underlying viral pathogenesis[87] (see below):

- *Chronic KS* (also called *classic* or *European KS*) was first described by Kaposi in 1872; it characteristically occurs in older men of Eastern European (especially Ashkenazi Jews) or Mediterranean descent and is uncommon in the United States. While chronic KS can be associated with an underlying second malignancy or altered immunity, it is not associated with human immunodeficiency virus (HIV). Chronic KS presents with multiple red to purple skin plaques or nodules, usually in the distal lower extremities; these slowly increase in size and number and spread more proximally. Although locally persistent, the tumors are typically asymptomatic and remain localized to the skin and subcutaneous tissue.
- *Lymphadenopathic KS* (also called *African* or *endemic KS*) has the same general geographic distribution as Burkitt lymphoma and is particularly prevalent among South African Bantu children; it is also not associated with HIV. Skin lesions are sparse, and patients present instead with lymphadenopathy due to KS involvement; the tumor occasionally involves the viscera and is extremely aggressive. In combination with AIDS-associated KS (see below), KS is now the most common tumor in central Africa (50% of all tumors in men in some countries).
- *Transplant-associated KS* occurs in the setting of solid-organ transplantation with its attendant long-term immunosuppression. It tends to be aggressive (even fatal) with nodal, mucosal, and visceral involvement; cutaneous lesions may be absent. Lesions occasionally regress when immunosuppressive therapy is attenuated, but at the risk of organ rejection.
- *AIDS-associated (epidemic) KS* was originally found in a third of AIDS patients, particularly male homosexuals (Chapter 6). However, with current regimens of antiretroviral therapy, KS incidence is now less than 1% (although it is still the most prevalent malignancy in AIDS patients in the United States). AIDS-associated KS can involve lymph nodes or viscera and disseminates widely early in the course of the disease. Most patients eventually die of opportunistic infections rather than from KS.

Pathogenesis.

In 1994, a previously unrecognized herpesvirus—*human herpesvirus-8 (HHV-8)* or *KS-associated herpesvirus (KSHV)* was identified in a cutaneous KS lesion in an AIDS patient (Chapter 6). Indeed, regardless of the clinical subtype (described above), 95% of KS lesions have subsequently been shown to be KSHV-infected.[88] Like Epstein-Barr virus, KSHV is a member of the γ-herpesvirus subfamily; it is transmitted sexually and by poorly understood nonsexual routes—perhaps including saliva.

KSHV is accepted as a necessary requirement for KS development, but tumor progression also requires a cofactor; HIV clearly can provide this, but the identity of the cofactor in non-HIV-associated KS is controversial. KSHV induces a lytic as well as a latent infection in endothelial cells, both of which are probably important in KS pathogenesis. Cytokines derived from HIV-infected T cells, or inflammatory cells recruited in response to the lytic infection, create a local proliferative milieu; a virally encoded G protein also induces local VEGF production. In latently infected cells, KSHV proteins disrupt normal cellular proliferation controls and prevent apoptosis by viral production of p53 inhibitors and a viral homologue of cyclin D. Thus, latently infected cells have a growth advantage; the local environment also favors cellular proliferation. The increasing recognition of the various viral gene products has nevertheless opened a number of new avenues for therapeutic interventions against affected intracellular kinase pathways and downstream targets. In its early stages, only a few cells are infected; with time virtually all spindle cells of late-stage lesions carry KSHV; these spindle cells express both endothelial cell and smooth muscle cell markers.

Morphology. In the indolent, classic disease of older men (and sometimes in other variants), three stages are recognized: patch, plaque, and nodule.

- **Patches** are red to purple macules typically confined to the distal lower extremities (Fig. 11-32A). Histology shows only dilated irregular endothelial cell–lined vascular spaces with interspersed lymphocytes, plasma cells, and macrophages (sometimes containing hemosiderin). The lesions can be difficult to distinguish from granulation tissue.
- With time, lesions spread proximally and become larger, violaceous, **raised plaques** (see Fig. 11-32A)

composed of dermal accumulations of dilated, jagged vascular channels lined and surrounded by plump spindle cells. Scattered between the vascular channels are extravasated red cells, hemosiderin-laden macrophages, and other mononuclear inflammatory cells.

- Eventually, lesions become **nodular** and more distinctly neoplastic. These lesions are composed of sheets of plump, proliferating spindle cells, mostly in the dermis or subcutaneous tissues (Fig. 11-32B), encompassing small vessels and slitlike spaces containing red cells. More marked hemorrhage, hemosiderin pigment, and mononuclear inflammation is present; mitotic figures are common, as are round, pink, cytoplasmic globules of uncertain nature. The nodular stage often heralds nodal and visceral involvement, particularly in the African and AIDS-associated variants.

Fletcher, M.D., Brigham and Women's Hospital, Boston, MA.)*

Clinical Features.

The course of KS varies widely and is significantly affected by the clinical setting. Most primary KSHV infections are asymptomatic. Classic KS is—at least initially—largely restricted to the surface of the body, and surgical resection is usually adequate for an excellent prognosis. Radiation can be used for multiple lesions in a restricted area, and chemotherapy yields satisfactory results for more disseminated disease. Lymphadenopathic KS can also be treated with chemotherapy or radiation therapy with good results. In immunosuppression-associated KS, withdrawal of immunosuppression (perhaps with adjunct chemotherapy or radiation therapy) is often effective. For AIDS-associated KS, antiretroviral therapy for HIV is usually helpful, with or without therapy targeted to the KS lesions. IFN-α and angiogenesis inhibitors are variably effective, while newer strategies aimed at specific intracellular kinase pathways or the downstream mammalian target of rapamycin are showing promise.[89,][90]

Hemangioendothelioma

Hemangioendothelioma denotes a wide spectrum of vascular neoplasms with clinical behaviors *intermediate between benign, well-differentiated hemangiomas and highly malignant angiosarcomas*, described below.

Epithelioid hemangioendothelioma is an example; it is a vascular tumor of adults occurring around medium-sized and large veins. The tumor cells are plump and often cuboidal (resembling epithelial cells); well-defined vascular channels are inconspicuous. Clinical behavior is variable; most are cured by excision, but up to 40% recur, 20% to 30% eventually metastasize, and perhaps 15% of patients die of the tumors.

MALIGNANT TUMORS

Angiosarcoma

Angiosarcomas are malignant endothelial neoplasms (Fig. 11-33) with histology varying from well-differentiated tumors that resemble hemangiomas *(hemangiosarcoma)* to anaplastic lesions difficult to distinguish from carcinomas or melanomas. Older adults are more commonly affected, with equal gender predilections; they occur at any site but most often involve skin, soft tissue, breast, and liver.

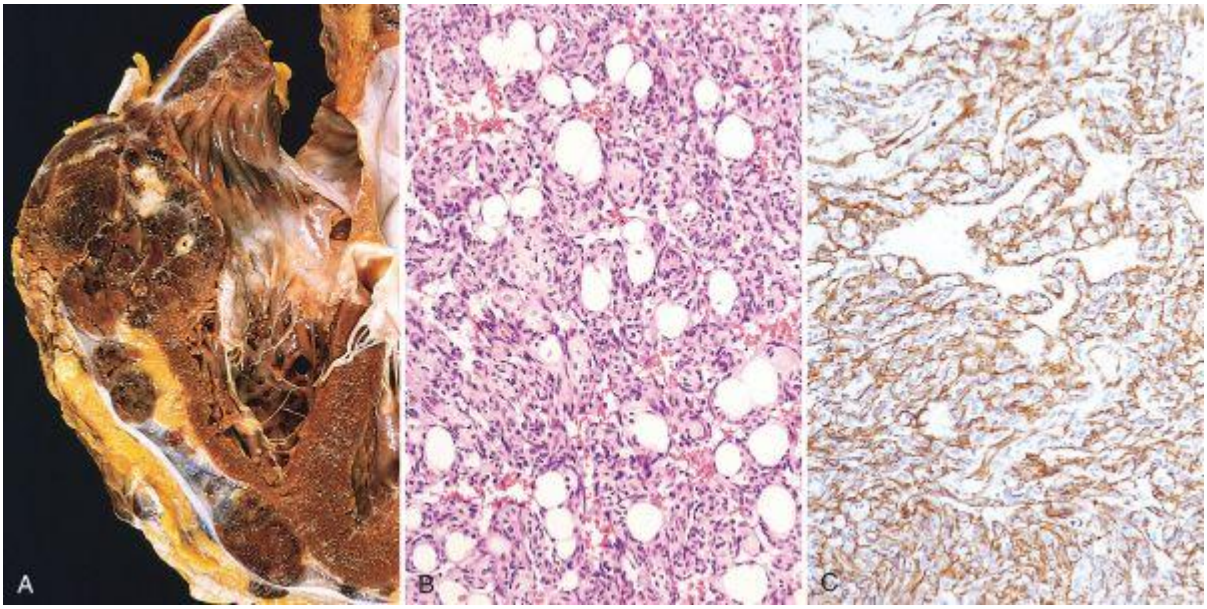

FIGURE 11-33 Angiosarcoma. **A**, Gross photograph of angiosarcoma of the heart (right ventricle). **B**, Photomicrograph of moderately well-differentiated angiosarcoma with dense clumps of irregular, moderate anaplastic cells and distinct vascular lumens. **C**, Immunohistochemical staining for the endothelial cell marker CD31, demonstrating the endothelial nature of the tumor cells.

Hepatic angiosarcomas are associated with carcinogen exposures, including arsenic (arsenical pesticides), Thorotrast (a radioactive contrast agent formerly used for radiologic imaging), and polyvinyl chloride (a widely used plastic). All of these agents have long latent periods between initial exposure and eventual tumor development. The increased frequency of angiosarcomas among polyvinyl chloride workers is one of the well-documented instances of human chemical carcinogenesis.

Angiosarcomas can also arise in the setting of lymphedema, classically in the ipsilateral upper extremity several years after radical mastectomy (i.e., with lymph node resection) for breast cancer; the tumor presumably arises from lymphatic vessels *(lymphangiosarcoma)*. Angiosarcomas have also been induced by radiation and are rarely associated with foreign material introduced into the body either iatrogenically or accidentally.

Morphology. Cutaneous angiosarcomas can begin as deceptively small, sharply demarcated, asymptomatic, often multiple red nodules; most eventually become large, fleshy masses of red-tan to gray-white tissue (Fig. 11-33A). The margins blend imperceptibly with surrounding structures. Central areas of necrosis and hemorrhage are frequent.

Microscopically, **all degrees of differentiation can be seen**, from plump, anaplastic but recognizable

endothelial cells producing vascular channels (Fig. 11-33B) to wildly undifferentiated tumors with a solid spindle cell appearance and without definite blood vessels. The endothelial cell origin of these tumors can be demonstrated by staining for CD31 or von Willebrand factor (Fig. 11-33C).

Clinically, angiosarcomas are locally invasive and can metastasize readily. Angiosarcomas are aggressive tumors with current 5-year survival rates approaching 30%.

Hemangiopericytoma

Hemangiopericytomas are rare tumors derived from pericytes—myofibroblast-like cells that are normally arranged around capillaries and venules. Hemangiopericytomas can occur as slowly enlarging, painless masses at any anatomic site, but are most common on the lower extremities (especially the thigh) and in the retroperitoneum. They consist of numerous branching capillary channels and gaping sinusoidal spaces enclosed within nests of spindle-shaped to round cells. Special stains confirm that these cells are outside the endothelial cell basement membrane and are therefore pericytes. The tumors may recur after excision, and roughly half will metastasize, usually hematogenously to lungs, bone, or liver.

3.1.13 Pathology of Vascular Interventions

The morphologic changes that occur in vessels after therapeutic intervention—balloon angioplasty, stenting, or bypass surgery—typically recapitulate many of the changes that occur in the setting of any vascular insult. Local endothelial cell trauma (e.g., due to a stent), vascular thrombosis (after angioplasty), or abnormal mechanical forces (e.g., a saphenous vein inserted into the arterial circulation as a coronary artery bypass graft), all induce similar responses characteristic of vessel wall healing. Thus, in the same way that various injuries can induce an intimal hyperplastic response that we recognize as atherosclerosis (see above), the trauma caused by vascular interventions tends to induce a concentric intimal thickening composed of recruited smooth muscle cells and their associated matrix deposition.

ANGIOPLASTY AND ENDOVASCULAR STENTS

Balloon angioplasty (dilation of a stenotic artery by inserting an intravascular catheter), with or without endovascular stenting, is used extensively to restore flow at sites of focal vascular stenosis—especially in the coronary circulation *(percutaneous transluminal coronary angioplasty)*. The morphologic outcomes of angioplasty, as well as the now more commonly used *endovascular stents*, are demonstrated in Figure 11-34 .

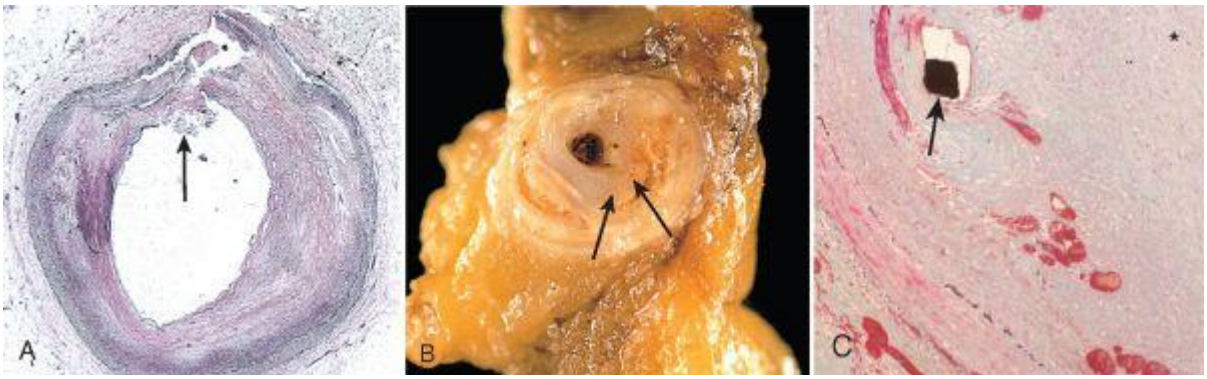

FIGURE 11-34 Balloon angioplasty and endovascular stents. **A**, Coronary artery after balloon angioplasty, showing the dissection encompassing the intima and media *(arrow)*. **B**, Gross photograph of restenosis following balloon angioplasty, demonstrating residual atherosclerotic plaque *(left arrow)* and a new, glistening proliferative lesion *(right arrow)*. **C**, Coronary arterial stent implanted long term, demonstrating thickened neointima separating the stent wires (black spot shown by *arrow*) from the lumen *(asterisk)*. *(**C**, Reproduced from Schoen FJ, Edwards WD: Pathology of cardiovascular interventions, including endovascular therapies, revascularization, vascular replacement, cardiac assist/replacement, arrhythmia control, and repaired congenital heart disease. In Silver MD et al. (eds): Cardiovascular Pathology, 3rd ed. Philadelphia, Churchill Livingstone, 2001.)*

Simple balloon dilation (without stenting) of an atherosclerotic vessel induces medial stretching and causes plaque fracture, often with accompanying localized hemorrhagic dissection of the adjacent arterial wall (Fig. 11-34A); in this manner vascular flow is restored, albeit with the attendant risks of more extensive dissection and luminal thrombosis (to prevent the latter, anticoagulation is required for a period of time after the procedure). Most patients improve symptomatically, at least in the short term. *Abrupt reclosure* may occur as a result of compression of the lumen by an extensive circumferential or longitudinal dissection or by thrombosis. The long-term success of angioplasty is primarily limited by the development of *proliferative restenosis*, due to intimal thickening; this occurs in approximately 30% to 50% of patients within the first 4 to 6 months after the procedure (Fig. 11-34B). The conditions causing restenosis are undoubtedly the same as those that occur in response to vascular damage of any type (e.g., atherosclerosis); in this case the injury is mechanical and is also compounded by the resolution of any associated thrombosis. The end result is an occlusive, progressive fibrous lesion that contains abundant smooth muscle cells and extracellular matrix.

Coronary stents are expandable tubes of metallic mesh that are inserted to preserve lumenal patency during angioplasty; they are now used in over 90% of angioplasty procedures. Stents provide a larger and more regular lumen, "tack down" the intimal flaps and dissections that occur during angioplasty, and mechanically limit vascular spasm. Nevertheless, by also causing focal plaque erosion and/or endothelial cell disruption, stents can cause acute thrombosis, and a successful procedure also requires at least transient anticoagulation with potent anti-thrombotic agents (platelet antagonists).[91] A *late complication* of bare metal stents involves proliferative intimal thickening leading to proliferative restenosis much like that seen with percutaneous transluminal coronary angioplasty alone (Fig. 11-34C). The newest generation of stents are coated with anti-proliferative drugs (e.g., paclitaxel or rapamycin) that limit smooth muscle cell hyperplasia; this results in markedly diminished intimal thickening, although there is evidence that the anti-proliferative agents also slow the process of re-endothelialization of the coated stents and prolong the required period of anticoagulation therapy.[92]

VASCULAR REPLACEMENT

Synthetic or autologous vascular grafts are increasingly used to replace damaged vessels or bypass diseased arteries. With synthetic grafts (usually expanded polytetrafluoroethylene, a spongy Teflon fabric), large-bore (12- to 18-mm) conduits function well in high-flow locations such as the aorta; unfortunately, small-diameter artificial grafts (≤8 mm in diameter) generally fail because of early thrombosis or late intimal hyperplasia, primarily at the junction of the graft with the native vasculature (Fig. 11-35).

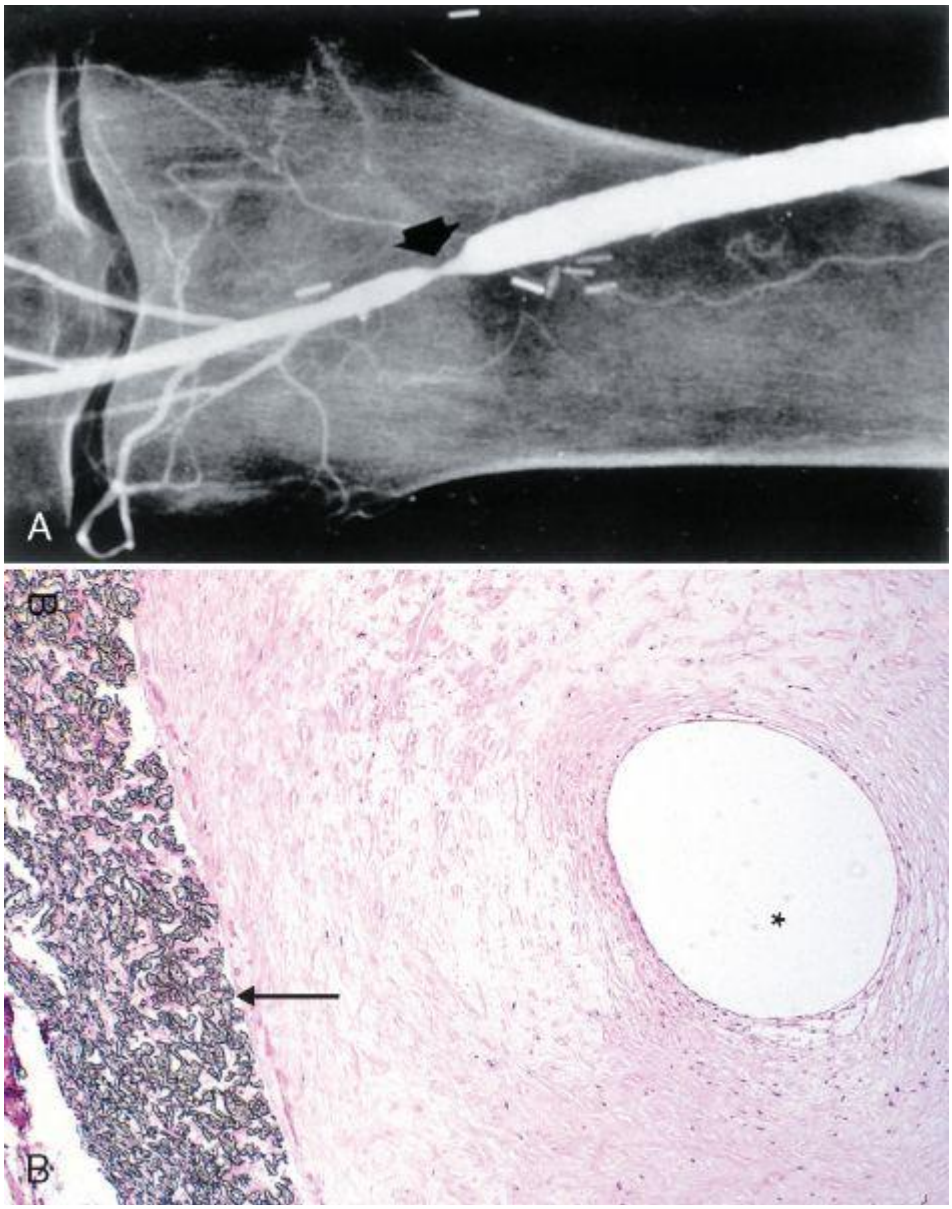

FIGURE 11-35 Anastomotic hyperplasia at the distal anastomosis of synthetic femoropopliteal graft. **A**, Angiogram demonstrating constriction *(arrow)*. **B**, Photomicrograph demonstrating Gore-Tex graft *(arrow)* with prominent intimal proliferation and very small residual lumen *(asterisk)*. *(**A**, Courtesy of Anthony D. Whittemore, M.D., Brigham and Women's Hospital, Boston, MA.)*

Consequently, where small-bore vessels are needed (e.g., for coronary artery bypass surgery performed in more than 400,000 U.S. patients per year), grafts are most commonly composed of either reversed autologous saphenous vein (taken from the patient's own leg) or left internal mammary artery (because of its proximity to the heart). The long-term patency of saphenous vein grafts is only 50% at 10 years; grafts occlude because of thrombosis (typically early), intimal thickening (months to years postoperatively), and vein graft atherosclerosis—sometimes with superimposed plaque rupture, thrombi, or aneurysms (usually >2–3 years). In contrast, greater than 90% of internal mammary artery grafts are patent at 10 years.[93]

3.2 12. The Heart

3.2.1 Cardiac Structure & Specializations

FREDERICK J. SCHOEN,
RICHARD N. MITCHELL

The human heart is a remarkably efficient, durable, and reliable pump that propels over 6000 liters of blood through the body daily and beats more than 40 million times a year, thereby providing the tissues with a steady supply of vital nutrients and facilitating the excretion of waste products. As might be anticipated, cardiac dysfunction can be associated with devastating physiologic consequences. Cardiovascular disease is the number one cause of death worldwide, with about 80% of the burden occurring in developing countries.[1,][2] In the United States, heart disease accounts for nearly 40% of all postnatal deaths, totaling about 750,000 individuals annually; this is nearly 1.5 times the number of deaths caused by all forms of cancer combined. It is estimated that one third of Americans have one or more types of cardiovascular disease. Moreover, 32% of heart disease deaths are “premature,” occurring in individuals younger than age 75.[3] If all major forms of cardiovascular disease were eliminated, life expectancy would increase by 7 years. The yearly economic burden of ischemic heart disease, the most prevalent subgroup, is estimated to be in excess of $100 billion in the United States.

The major categories of cardiac diseases considered in this chapter include congenital heart abnormalities, ischemic heart disease, heart disease caused by systemic hypertension, heart disease caused by pulmonary diseases (cor pulmonale), diseases of the cardiac valves, and primary myocardial diseases. A few comments about pericardial diseases and cardiac neoplasms as well as cardiac transplantation are also offered. Before considering details of specific conditions, we will briefly review the anatomy of the normal heart, because many diseases cause changes in the size and appearance of one or more of its components. We will also discuss the principles of cardiac hypertrophy and failure, the common end points of many different types of heart disease; these are essential for later discussion of disease processes.

Cardiac Structure and Specializations

Heart weight varies with body height and weight; it normally averages approximately 250 to 300 gm in females and 300 to 350 gm in males, or roughly 0.4% to 0.5% of body weight. The usual thickness of the free wall of the right ventricle is 0.3 to 0.5 cm, and that of the left ventricle 1.3 to 1.5 cm. Increases in cardiac size and weight accompany many forms of heart disease. Greater heart weight or ventricular

thickness indicates *hypertrophy*, and an enlarged chamber size implies *dilation*. An increase in cardiac weight or size or both (resulting from hypertrophy and/or dilation) is termed *cardiomegaly*.

The efficient pumping of blood by the heart to the entire body requires the normal function of each of its key components, the myocardium, valves, conduction system, and coronary arterial circulation.

MYOCARDIUM

The pumping function of the heart is accomplished by the cardiac muscle, the *myocardium*, composed primarily of a collection of specialized muscle cells called *cardiac myocytes*. Ventricular myocytes are arranged circumferentially in a spiral orientation and contract during systole and relax during diastole. The contractile unit is the *sarcomere*, an orderly arrangement of thick filaments composed principally of *myosin*, thin filaments containing *actin*, and regulatory proteins such as troponin and tropomyosin. Cardiac muscle cells contain strings of sarcomeres in series, which are responsible for the striated appearance of these cells. Contraction depends on a coordinated ratcheting mechanism whereby each myosin filament pulls the neighboring actin filaments toward the center of the sarcomere, leading to the shortening of the myocyte. The amount of force generated is determined by the distance each sarcomere shortens. Moderate ventricular dilation during diastole increases the extent of sarcomere shortening and the force of contraction during systole. With further dilation, however, there is a point at which effective overlap of the actin and myosin filaments is reduced and the force of contraction decreases sharply, as occurs in heart failure.

Atrial myocytes are generally smaller and arranged more haphazardly than their ventricular counterparts. Some atrial cells have distinctive electron-dense granules in the cytoplasm called *specific atrial granules;* these are the storage sites of *atrial natriuretic peptide*. Atrial natriuretic peptide can produce a variety of physiologic effects, including vasodilation, natriuresis, and diuresis, actions beneficial in pathologic states such as hypertension and congestive heart failure.[4]

Functional integration of cardiac myocytes is mediated by structures called *intercalated discs*, which link individual cells and contain specialized intercellular junctions that permit both mechanical and electrical (ionic) coupling. Within the intercalated discs, *gap junctions* facilitate synchronous myocyte contraction through electrical coupling by permitting relatively unrestricted passage of ions across the membranes of adjoining cells. Abnormalities in the spatial distribution of gap junctions and their respective proteins in ischemic and myocardial heart disease may contribute to electromechanical dysfunction (*arrhythmia*) and heart failure.[5]

VALVES

The four cardiac valves (tricuspid, pulmonary, mitral, and aortic) maintain unidirectional blood flow through the heart. Their function depends on the mobility, pliability, and structural integrity of their delicate flaps, called leaflets (in the tricuspid and mitral valves) or cusps (in the aortic and pulmonary valves, also known as the semilunar valves). All four valves have a similar, layered architecture: a dense collagenous core (fibrosa) close to the outflow surface and continuous with valvular supporting structures, a central core of loose connective tissue (spongiosa), a layer rich in elastin (ventricularis or atrialis depending on which chamber it faces) below the inflow surface, and an endothelial covering. The collagen is responsible for the mechanical integrity of a valve. The valve is populated throughout by interstitial cells, which produce and continuously repair the extracellular matrix (especially collagen), allowing the valve to respond and adapt to changing mechanical conditions.[6,][7]

The function of the semilunar valves depends on the integrity and coordinated movements of the cuspal attachments. Thus, dilation of the aortic root can hinder coaptation of the aortic valve cusps during closure, yielding regurgitation. In contrast, the competence of the atrioventricular valves depends on not

only the leaflets and their attachments, but also on tendinous connections to the papillary muscles of the ventricular wall. Left ventricular dilation, a ruptured tendon, or papillary muscle dysfunction can all interfere with mitral valve closure, leading to regurgitation.

Because they are thin enough to be nourished by diffusion from the heart's blood, normal leaflets and cusps have only scant blood vessels limited to the proximal portion. Pathologic changes of valves are largely of three types: damage to collagen that weakens the leaflets, exemplified by mitral valve prolapse; nodular calcification beginning in interstitial cells, as in calcific aortic stenosis; and fibrotic thickening, the key feature in rheumatic heart disease (see later).

CONDUCTION SYSTEM

Coordinated contraction of the cardiac muscle depends on propagation of electrical impulses, which is accomplished by specialized excitatory and conducting myocytes within the cardiac conduction system that regulate heart rate and rhythm. Key components of the conduction system include (1) the sinoatrial (SA) pacemaker of the heart, the *SA node,* located near the junction of the right atrial appendage and the superior vena cava; (2) the *AV node,* located in the right atrium along the atrial septum; (3) the *bundle of His,* which courses from the right atrium to the summit of the ventricular septum; and its major divisions (4) the *right and left bundle branches,* which further arborize in the respective ventricles through the anterior-superior and posterior-inferior divisions of the left bundle and the Purkinje network. The cells of the specialized cardiac conduction system depolarize spontaneously, enabling them to function as cardiac pacemakers. Because the normal rate of spontaneous depolarization in the SA node (60 to 100 beats/minute) is faster than the other components, it normally sets the pace. The AV node serves as a kind of “gatekeeper”; by delaying the transmission of signals from the atria to the ventricles, it ensures that atria contraction precedes ventricular contraction.

The *autonomic nervous system* (the same part of the nervous system involved in blood pressure control) controls the rate of firing of the SA node to trigger the start of the cardiac cycle. Autonomic inputs can increase the heart rate to twice normal within only 3 to 5 seconds, and are important in cardiac responses to exercise or other states associated with increased oxygen demand.

BLOOD SUPPLY

To meet their energy needs, cardiac myocytes rely almost exclusively on oxidative phosphorylation, which is manifest by the abundant mitochondria that are found in these cells.[5] Oxydative phosphorylation requires oxygen, making cardiac myocytes extremely vulnerable to ischemia. A constant supply of oxygenated blood is thus essential for cardiac function. Most of the myocardium depends on nutrients and oxygen delivered via the the coronary arteries, which arise immediately distal to the aortic valve, initially running along the external surface of the heart *(epicardial coronary arteries)* and then penetrating the myocardium *(intramural arteries).* These small penetrating arteries yield arterioles and, ultimately, provide a rich network of capillaries enveloping individual cardiac muscle cells.

The three major epicardial coronary arteries are (1) the left anterior descending (LAD) and (2) the left circumflex (LCX) arteries, both arising from branches of the left (main) coronary artery, and (3) the right coronary artery. Branches of the LAD are called “diagonal” and “septal perforators,” and those of the LCX are “obtuse marginals.” Most coronary arterial blood flow to the myocardium occurs during ventricular diastole, when the microcirculation is not compressed by cardiac contraction.

There are a number of normal variations on the anatomy of the coronary arteries, which determine the areas of myocardium that are “at risk” in coronary artery disease and are of great practical importance to the heart surgeon and the invasive cardiologist; these are discussed later.

3.2.2 Effects of Aging on the Heart

The number of individuals aged 65 years and older will approximately double from 2000 to 2050 (from 35 million to 79 million in the United States). Considering this, one can see that knowledge of changes that occur in the cardiovascular system with aging will become increasingly important. Changes associated with aging can affect the pericardium, cardiac chambers, valves, coronary arteries, conduction system, myocardium, and aorta (Table 12-1).

TABLE 12-1 -- Changes in the Aging Heart

CHAMBERS
Increased left atrial cavity size
Decreased left ventricular cavity size
Sigmoid-shaped ventricular septum
VALVES
Aortic valve calcific deposits
Mitral valve annular calcific deposits
Fibrous thickening of leaflets
Buckling of mitral leaflets toward the left atrium
Lambl excrescences
EPICARDIAL CORONARY ARTERIES
Tortuosity
Increased cross-sectional luminal area
Calcific deposits
Atherosclerotic plaque
MYOCARDIUM
Increased mass
Increased subepicardial fat
Brown atrophy
Lipofuscin deposition
Basophilic degeneration
Amyloid deposits
AORTA
Dilated ascending aorta with rightward shift
Elongated (tortuous) thoracic aorta
Sinotubular junction calcific deposits
Elastic fragmentation and collagen accumulation
Atherosclerotic plaque

With advancing age, the amount of epicardial fat increases, particularly over the anterior surface of the right ventricle and in the atrial septum. A reduction in the size of the left ventricular cavity, particularly in the base-to-apex dimension, occurs with aging and may be exacerbated by systemic hypertension and sometimes by bulging of the basal ventricular septum into the left ventricular outflow tract (termed *sigmoid septum*). These changes in the left ventricular cavity can produce a functional outflow obstruction similar to that seen in hypertrophic cardiomyopathy, discussed later in this chapter.

Valvular aging changes include calcification of the mitral annulus and aortic valve, the latter frequently leading to aortic stenosis. In addition, the valves can develop fibrous thickening, and the mitral leaflets

tend to buckle back toward the left atrium during ventricular systole, simulating a prolapsing (myxomatous) mitral valve. Moreover, many older persons develop small filiform processes *(Lambl excrescences)* on the closure lines of aortic and mitral valves, probably resulting from the organization of small thrombi.

Compared with younger myocardium, "elderly" myocardium has fewer myocytes, increased collagenized connective tissue and, in some individuals, deposition of amyloid. Lipofuscin deposits (Chapter 1) and *basophilic degeneration*, an accumulation within cardiac myocytes of a gray-blue by-product of glycogen metabolism, may also be present. Extensive lipofuscin deposition in a small, atrophied heart is called *brown atrophy;* this change often accompanies cachexia, as seen in terminal cancer.

3.2.3 Heart Disease: Overview of Pathophysiology

Although many diseases can involve the heart and blood vessels,[8,][9] cardiovascular dysfunction results from one or more of six principal mechanisms, most with detectable morphologic manifestations:

- *Failure of the pump*. In the most common circumstance, the cardiac muscle contracts weakly, and the chambers cannot empty properly. In some conditions, the muscle cannot relax sufficiently to permit ventricular filling.
- *Obstruction to flow*. Lesions can obstruct blood flow through a vessel (e.g., atherosclerotic plaque) or prevent valve opening or otherwise cause increased ventricular chamber pressure (e.g., aortic valvular stenosis, systemic hypertension, or aortic coarctation). In the case of a valvular blockage, the increased pressure overworks the chamber that pumps against the obstruction.
- *Regurgitant flow*. In this situation, at least part of the output from each contraction flows backward, adding a volume workload to each of the chambers (e.g., left ventricle in aortic regurgitation; left atrium and left ventricle in mitral regurgitation).
- *Shunted flow*. Blood can be diverted from one part of the heart to another (e.g., from the left ventricle to the right ventricle), through defects that may be congenital or acquired (such as following myocardial infarction). Shunted flow can also occur between blood vessels, as in patent ductus arteriosus.
- *Disorders of cardiac conduction*. Conduction defects or arrhythmias due to uncoordinated generation of impulses (e.g., atrial or ventricular fibrillation) lead to nonuniform and inefficient contractions of the muscular walls.
- *Rupture of the heart or a major vessel*. In such circumstances (e.g., a gunshot wound through the thoracic aorta), there is massive bleeding into body cavities or externally.

Most cardiovascular disease results from a complex interplay of genetics and environmental factors that disrupt networks of genes and signaling pathways that control morphogenesis, myocyte survival and response to injury, biomechanical stress responses, contractility, or electrical conduction.[10] For example, the pathogenesis of many congenital heart defects involves an underlying genetic abnormality whose expression is modified by environmental or maternal factors (see later). Moreover, genes that control the development of the heart may also regulate the response of the heart to aging or to various types of injuries and stresses. As we will discuss, certain types of adult-onset heart disease have a predominantly genetic basis, and it is suspected that genetic polymorphisms in the same genes (or other genes in the same pathways) are likely to modify the risk of many forms of heart disease. These genetic discoveries are providing new insights into the molecular causes of heart disease and are likely to increasingly become part of its diagnosis and classification.

3.2.4 Heart Failure

Heart failure, often called congestive heart failure (CHF), is a common, usually progressive condition with a poor prognosis. Each year in the United States, CHF affects nearly 5 million individuals (approximately 2% of the population), necessitates over 1 million hospitalizations, and is the primary or

contributing cause of death of an estimated 300,000 people. It is the leading discharge diagnosis in patients over 65 years of age in the United States and has an associated annual cost of $18 billion.

CHF occurs when the heart is unable to pump blood at a rate sufficient to meet the metabolic demands of the tissues or can do so only at an elevated filling pressure. It can appear during the end stage of many forms of chronic heart disease. In this setting, it most often develops insidiously due to the cumulative effects of chronic work overload (such as in valve disease or hypertension) or ischemic heart disease (e.g., following myocardial infarction with extensive heart damage). However, acute hemodynamic stresses, such as fluid overload, acute valvular dysfunction, or a large myocardial infarction, can cause CHF to appear suddenly.

When cardiac function is impaired or the work load increases, several physiologic mechanisms maintain arterial pressure and perfusion of vital organs. The most important of these are the following:

- *The Frank-Starling mechanism*, in which increased filling volumes dilate the heart and thereby increase functional cross-bridge formation within the sarcomeres, enhancing contractility.
- *Myocardial adaptations, including hypertrophy with or without cardiac chamber dilation*. The collective molecular, cellular, and structural changes that occur as a response to injury or changes in loading conditions are called *ventricular remodeling*.[11] Often adaptive, especially in early stages, these changes can culminate in impaired cardiac function. In many pathologic states, heart failure is preceded by cardiac hypertrophy, the compensatory response of the myocardium to increased mechanical work.
- *Activation of neurohumoral systems*, especially (1) release of norepinephrine by adrenergic cardiac nerves of the autonomic nervous system (which increases heart rate and augments myocardial contractility and vascular resistance); (2) activation of the renin-angiotensin-aldosterone system; and (3) release of atrial natriuretic peptide. The latter two factors act to adjust filling volumes and pressures.

These adaptive mechanisms may be adequate to maintain normal cardiac output in the face of heart disease, but their capacity to do so may ultimately be overwhelmed. Moreover, superimposed pathologic changes, such as myocyte apoptosis, cytoskeletal alterations, and the deposition of extracellular matrix may cause further structural and functional disturbances. Most frequently, heart failure results from progressive deterioration of myocardial contractile function *(systolic dysfunction);* this may be attributable to ischemic injury, pressure or volume overload due to valvular disease or hypertension, or dilated cardiomyopathy. Sometimes, however, failure results from an inability of the heart chamber to expand and fill sufficiently during diastole *(diastolic dysfunction)*, as can occur with massive left ventricular hypertrophy, myocardial fibrosis, deposition of amyloid, or constrictive pericarditis (see below).[12]

CARDIAC HYPERTROPHY: PATHOPHYSIOLOGY AND PROGRESSION TO FAILURE

Increased mechanical work due to pressure or volume overload (e.g., systemic hypertension or aortic stenosis), or trophic signals (e.g., those mediated through the activation of β-adrenergic receptors) causes myocytes to increase in size *(hypertrophy);* cumulatively, this causes an increase in the size and weight of the heart (Fig. 12-1). Hypertrophy is dependent upon increased protein synthesis, which enables the assembly of additional sarcomeres. Hypertrophic myocytes also contain increased numbers of mitochondria and have enlarged nuclei. The latter alteration appears to be due to increases in DNA ploidy, which result from DNA replication in the absence of cell division. The pattern of hypertrophy reflects the nature of the stimulus. In response to increases in pressure (e.g., hypertension or aortic stenosis), ventricles develop *pressure-overload hypertrophy*, which usually causes a concentric increase in wall thickness. In pressure overload, new sarcomeres are predominantly assembled in parallel to the long axes of cells, expanding the cross-sectional area of myocytes. In contrast, *volume-overload hypertrophy* is characterized by ventricular dilation. This is because the new sarcomeres assembled in response to volume overload are largely positioned in series with existing sacromeres. As a result, in

dilation due to volume overload the wall thickness may be increased, normal, or less than normal; thus, heart weight, rather than wall thickness, is the best measure of hypertophy in volume overloaded hearts.

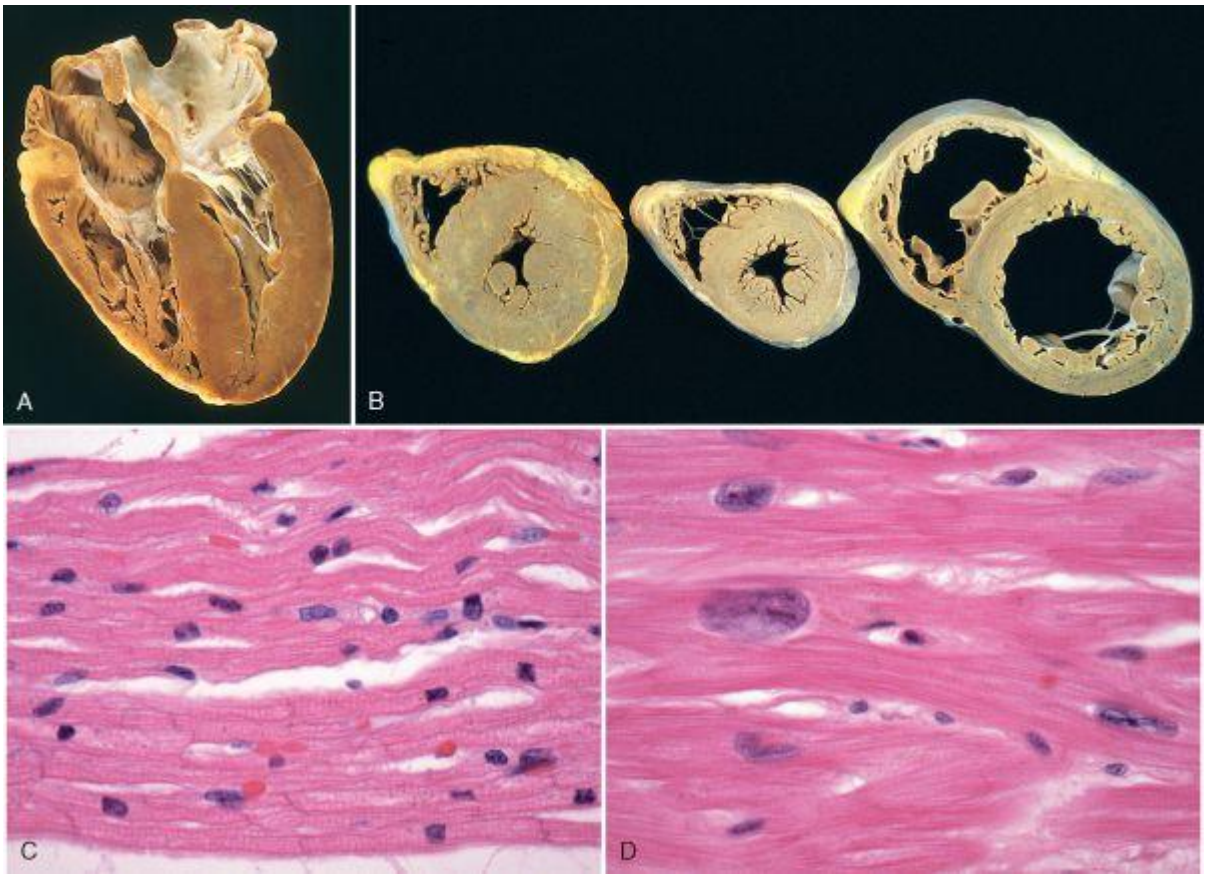

FIGURE 12-1 Left ventricular hypertrophy. **A**, Pressure hypertrophy due to left ventricular outflow obstruction. The left ventricle is on the lower right in this apical four-chamber view of the heart. **B**, Left ventricular hypertrophy with and without dilation, viewed in transverse heart sections. Compared with a normal heart *(center)*, the pressure-hypertrophied hearts (*left* and in **A**) have increased mass and a thick left ventricular wall, while the hypertrophied, dilated heart *(right)* has increased mass and a normal wall thickness. **C**, Normal myocardium. **D**, Hypertrophied myocardium. Note the increases in both cell size and nuclear size in the hypertrophied myocytes. *(A,B, Reproduced by permission from Edwards WD: Cardiac anatomy and examination of cardiac specimens. In Emmanouilides GC et al. (eds): Moss and Adams Heart Disease in Infants, Children, and Adolescents: Including the Fetus and Young Adults, 5th ed. Philadelphia, Williams & Wilkins, 1995, p 86.)*

Cardiac hypertrophy can be substantial in clinical heart disease. Heart weights of two to three times normal are common in patients with systemic hypertension, ischemic heart disease, aortic stenosis, mitral regurgitation, or dilated cardiomyopathy, and heart weights can be threefold to fourfold greater than normal in those with aortic regurgitation or hypertrophic cardiomyopathy.

Important changes at the tissue and cell level occur with cardiac hypertrophy. The increase in myocyte size is not accompanied by a proportional increase in capillary numbers. As a result, the supply of oxygen and nutrients to the hypertrophied heart, particularly one undergoing pressure overload hypertrophy, is more tenuous than in the normal heart. At the same time, oxygen consumption by the hypertrophied heart is elevated due to the increased workload that drives the process. Hypertrophy is also often accompanied by deposition of fibrous tissue. Molecular changes include the expression of immediate-early genes (e.g., *c-fos, c-myc, c-jun*, and *EGR1*) (Chapter 1).[13] With prolonged

hemodynamic overload, there may be a shift to a gene expression pattern resembling that seen during fetal cardiac development (including selective expression of embryonic/fetal forms of β-myosin heavy chain, natriuretic peptides, and collagen).

At a functional level, cardiac hypertrophy is associated with heightened metabolic demands due to increases in wall tension, heart rate, and contractility (inotropic state, or force of contraction), all of which increase cardiac oxygen consumption. *As a result of these changes, the hypertrophied heart is vulnerable to decompensation*, which can evolve to cardiac failure and eventually lead to death.[14] The proposed sequence of initially beneficial, and later harmful, events in response to increased cardiac work is summarized in Figure 12-2 . *The molecular and cellular changes in hypertrophied hearts that initially mediate enhanced function may themselves contribute to the development of heart failure*. This can occur through (1) abnormal myocardial metabolism,[15,][16] (2) alterations of intracellular handling of calcium ions, (3) apoptosis of myocytes, and (4) reprogramming of gene expression.[17,][18] The latter appears to occur in part through changes in expression of miRNAs, small noncoding RNAs that inhibit the expression of proteins at the level of mRNA stability or translation (Chapter 5). Cardiac hypertrophy is associated with down-regulation of miR-208 and upregulation of miR-195; of interest, enforced over-expression of miR-195 can produce cardiac hypertrophy and dilation in the mouse, whereas over-expression of miR-208 is protective even in the setting of pressure overload, suggesting a cause and effect relationship.

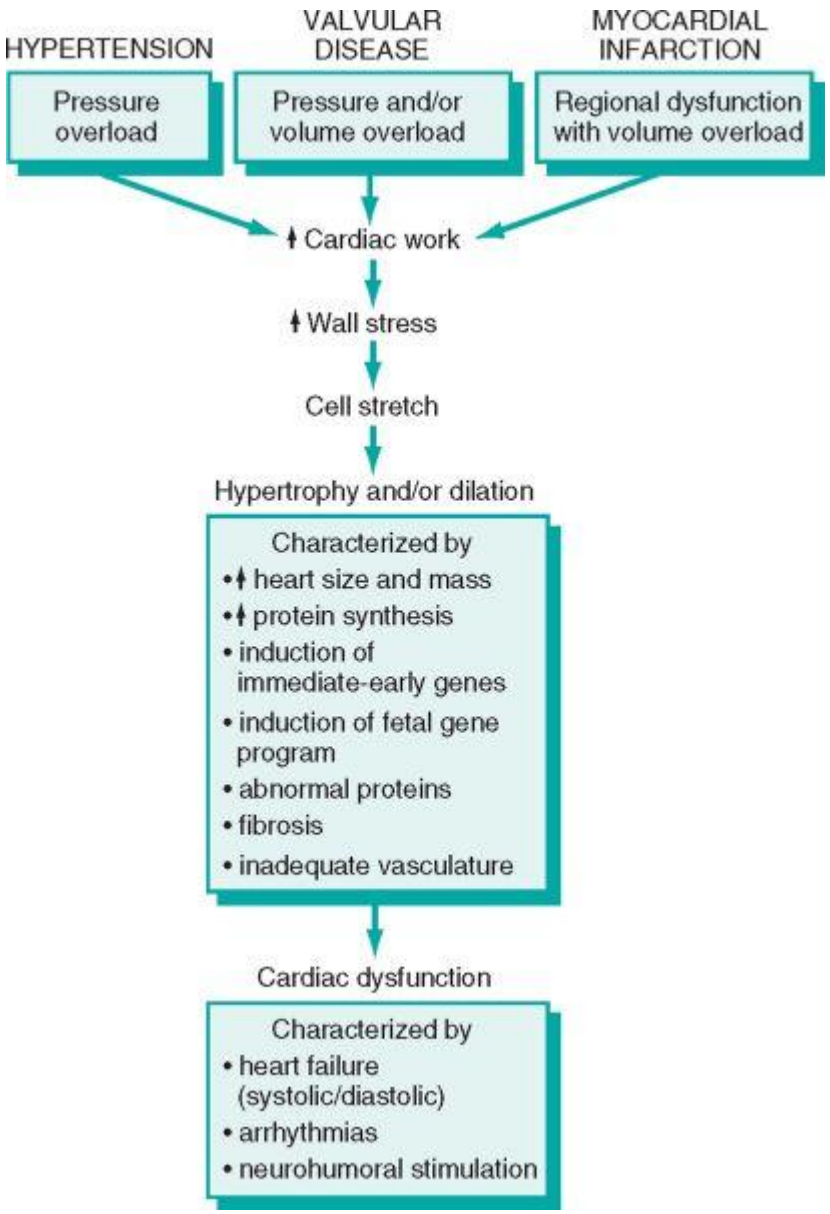

FIGURE 12-2 Schematic representation of the causes and consequences of cardiac hypertrophy.

The degree of structural abnormality of the heart in CHF does not always reflect the level of dysfunction, and the structural, biochemical, and molecular basis for myocardial contractile failure can be obscure. Indeed, it may be impossible from morphologic examination to distinguish a damaged but functional heart from one that has failed. At autopsy, the hearts of patients with CHF are generally heavy, dilated, and thin-walled and exhibit microscopic evidence of hypertrophy, but the extent of these changes is extremely variable. In myocardial infarction, loss of pumping capacity due to myocyte death leads to work-related hypertrophy of the surrounding viable myocardium. In valvular heart disease, the increased pressure or volume overloads the myocardium globally.

Increased heart mass is correlated with excess cardiac mortality and morbidity; indeed, cardiomegaly is an independent risk factor for sudden death.[19] In contrast to pathologic hypertrophy (which is often associated with contractile impairment), hypertrophy induced by regular strenuous exercise has varied

effects on the heart depending on the type of exercise. Aerobic exercise (e.g., long distance running) tends to be associated with volume-load hypertrophy that may be accompanied by increases in capillary density (unlike other forms of hypertrophy) and decreases in resting heart rate and blood pressure, effects that are all beneficial. These changes are sometimes referred to as *physiologic hypertrophy*. Static exercise (e.g., weight lifting) is associated with pressure hypertrophy and appears more likely to be associated with deleterious changes.

Whatever its basis, CHF is characterized by variable degrees of decreased cardiac output and tissue perfusion (sometimes called forward failure), as well as pooling of blood in the venous system (backward failure); the latter may cause pulmonary edema, peripheral edema, or both. Thus, many of the significant clinical features and morphologic changes noted in CHF are secondary to injuries induced by hypoxia and congestion in tissues distant from the heart.

The cardiovascular system is a closed circuit. Thus, although left-sided and right-sided failure can occur independently, failure of one side (particularly the left) often produces excessive strain on the other, terminating in global heart failure. Despite this interdependency, it is easiest to understand the pathology of heart failure by considering right- and left-sided heart failure separately.

LEFT-SIDED HEART FAILURE

Left-sided heart failure is most often caused by (1) ischemic heart disease, (2) hypertension, (3) aortic and mitral valvular diseases, and (4) myocardial diseases. The morphologic and clinical effects of left-sided CHF primarily result from congestion of the pulmonary circulation, stasis of blood in the left-sided chambers, and hypoperfusion of tissues leading to organ dysfunction.

Morphology.

Heart. The findings in the heart vary depending on the disease process; gross structural abnormalities such as myocardial infarcts or a deformed, stenotic, or regurgitant valve may be present. Except for failure caused by mitral valve stenosis or unusual restrictive cardiomyopathies (described later), the left ventricle is usually hypertrophied and often dilated, sometimes massively. The microscopic changes are non-specific, consisting mainly of myocyte hypertrophy and variable degrees of interstitial fibrosis. The impaired left ventricular function usually causes dilation of the left atrium and increases the risk of atrial fibrillation. This in turn results in stasis, particularly in the atrial appendage, which is a common site of thrombus formation.

Lungs. Pulmonary congestion and **edema** produce heavy, wet lungs, as described elsewhere (Chapters 4 and 15 . Pulmonary changes include, in sequence from mildest to most severe, the following: (1) perivascular and interstitial edema, particularly in the interlobular septa, which is responsible for the characteristic Kerley B lines noted on chest roentgenogram; (2) progressive edematous widening of alveolar septa; and (3) accumulation of edema fluid in the alveolar spaces. Some red cells extravasate into the edema fluid within the alveolar spaces, where they are phagocytosed and digested by macrophages, which store the iron recovered from hemoglobin in the form of hemosiderin. These hemosiderin-laden macrophages are telltale signs of previous episodes of pulmonary edema and are often referred to as **heart failure cells**.

Clinically, in early left-sided heart failure symptoms may be quite subtle and are often related to pulmonary congestion and edema. Cough and *dyspnea* (breathlessness), initially with exertion and later at rest, are two of the earliest complaints. As failure progresses, worsening pulmonary edema may lead to *orthopnea* (dyspnea when lying down that is relieved by standing), requiring the patient to sleep in an

upright position; or *paroxysmal nocturnal dyspnea*, a form of dyspnea usually occurring at night that is so severe that it induces a feeling of suffocation. Particularly in the setting of *atrial fibrillation*, an arrhythmia characterized by uncoordinated, chaotic contraction of the atrium, stasis greatly increases the risk of thrombosis and thomboembolic stroke.[20]

Decreased cardiac output causes a reduction in renal perfusion, which leads to the activation of the renin-angiotensin-aldosterone system. This in turn induces the retention of salt and water and the expansion of the interstitial and intravascular fluid volumes (Chapters 4 and 11 , compensatory effects that can contribute to or exacerbate pulmonary edema. If the hypoperfusion of the kidney becomes sufficiently severe, impaired excretion of nitrogenous products may cause azotemia (called *prerenal azotemia* because of its vascular origin; Chapter 20). In far-advanced CHF, cerebral hypoxia can give rise to *hypoxic encephalopathy* (Chapter 28), with irritability, loss of attention span, and restlessness. In end-stage CHF, this can even progress to stupor and coma.

Left-sided heart failure can be divided on clinical grounds into systolic and diastolic failure. Systolic failure is defined by insufficient cardiac output (pump failure), and can thus be caused by any of the many disorders that damage or derange the contractile function of the left ventricle. In diastolic failure, cardiac output is relatively preserved at rest, but the left ventricle is abnormally stiff or otherwise restricted in its ability to relax during diastole. As a result, the heart is unable to increase its output in response to increases in the metabolic demands of peripheral tissues (e.g., during exercise). Moreover, because the left ventricle cannot expand normally, any increase in filling pressure is immediately referred back to the pulmonary circulation, producing rapid onset pulmonary edema (sometimes referred to as *flash pulmonary edema*), which may be severe. Diastolic failure predominantly occurs in patients over the age of 65 and for unclear reasons is more common in women. Hypertension is the most common underlying etiology. Other risk factors include diabetes mellitus, obesity, and bilateral renal artery stenosis. The reduction in the ability of the left ventricle to relax and fill may stem from myocardial fibrosis (such as occurs in cardiomyopathies and ischemic heart disease), infiltrative disorders associated with restrictive cardiomyopathies (e.g., cardiac amyloidosis), and restrictive pericarditis. Diastolic failure may also appear in elderly patients without any known predisposing factors, possibly as an exaggeration of the normal stiffening of the heart with age, as discussed previously.

RIGHT-SIDED HEART FAILURE

Most commonly, right-sided heart failure is caused by left-sided heart failure, as any increase in pressure in the pulmonary circulation incidental to left-sided failure inevitably burdens the right side of the heart. The causes of right-sided heart failure must then include all of those that induce left-sided heart failure. Pure right-sided heart failure is infrequent and usually occurs in patients with any one of a variety of disorders affecting the lungs; hence, it is often referred to as *cor pulmonale*. Cor pulmonale is most commonly associated with parenchymal diseases of the lung, but can also arise secondary to disorders that affect the pulmonary vasculature (e.g., primary pulmonary hypertension (Chapter 15), recurrent pulmonary thomboembolism (Chapter 4)), or that merely produce hypoxia (e.g., chronic sleep apnea, altitude sickness), with its associated pulmonary vasoconstriction. *The common feature of these diverse disorders is pulmonary hypertension* (discussed later), which results in hypertrophy and dilation of the right side of the heart. In extreme cases, leftward bulging of the ventricular septum can cause left ventricular dysfunction. The major morphologic and clinical effects of right-sided heart failure differ from those of left-sided heart failure in that pulmonary congestion is minimal, whereas engorgement of the systemic and portal venous systems may be pronounced.

Morphology.

Heart. As in left-heart failure, the morphology varies with cause. Rarely, structural defects such as valvular abnormalities or endocardial fibrosis (as in carcinoid heart disease) may be present. However, since isolated right heart failure is most often caused by lung disease, in a vast majority of cases the only findings are hypertrophy and dilation of the right atrium and ventricle.

Liver and Portal System. Congestion of the hepatic and portal vessels may produce pathologic changes in the liver, the spleen, and the gut. The liver is usually increased in size and weight **(congestive hepatomegaly)** due to prominent **passive congestion** (Chapter 4). Congestion is most prominent around central veins within hepatic lobules, which show red-brown centrilobular discoloration and paler, sometimes fatty, peripheral regions; this combination produces a characteristic appearance that is referred to as "nutmeg liver" (Chapter 4). In some instances, especially when left-sided heart failure is also present, severe central hypoxia produces **centrilobular necrosis**. With longstanding severe right-sided heart failure, the central areas can become fibrotic, creating so-called **cardiac sclerosis** and, in extreme case, **cardiac cirrhosis** (Chapter 18). Portal hypertension produces enlargement of the spleen **(congestive splenomegaly)**, which often weighs from 300 to 500 gm (normal, <150 gm); it can also contribute to chronic congestion and edema of the bowel wall, which may be so severe as to interfere with the absorption of nutrients.

Pleural, Pericardial, and Peritoneal Spaces. Systemic venous congestion can lead to accumulation of fluid in the pleural, pericardial, or peritoneal spaces (effusions). Thus, pulmonary edema and pleural effusions are associated with left-sided heart failure. Large pleural effusions (over 1 liter) can cause portions of the corresponding lung to be poorly inflated (atelectasis). In addition, transudation of fluid into the peritoneal cavity may give rise to **ascites**.

Subcutaneous Tissues. Edema of the peripheral and dependent portions of the body, especially ankle (pedal) and pretibial edema, is a hallmark of right-sided heart filure. In chronically bedridden patients presacral edema may predominate. Generalized massive edema (anasarca) may also occur.

The clinical features of isolated right-sided heart failure are those related to systemic (and portal) venous congestion, and include hepatosplenomegaly, peripheral edema, pleural effusions, and ascites. Organs that are prominently affected in right-sided heart failure include the kidney and the brain. Congestion of the kidneys is more marked with right-sided than left-sided heart failure, leading to greater fluid retention and peripheral edema, and more pronounced azotemia. Venous congestion and hypoxia of the central nervous system can produce deficits of mental function that are essentially identical to those described in left-sided heart failure.

Although we have discussed right and left heart failure separately, it is again worth emphasizing that *in many cases of chronic cardiac decompensation, the patient presents in biventricular CHF with symptoms that encompass the clinical syndromes of both right-sided and left-sided heart failure*. Standard therapy for CHF relies mainly on pharmacologic approaches. Drugs that relieve fluid overload (e.g., diuretics), that block the renin-angiotensin-aldosterone axis (e.g., angiotensin converting enzyme inhibitors), and that lower adrenergic tone (e.g., β_1-adrenergic blockers) are particularly useful. The efficacy of the latter two classes of drugs supports the idea that the neurohumoral changes that are seen in CHF (including elevated circulating levels of norepinephrine and renin) are maladaptive and contribute to heart failure. Newer approaches to improving cardiac function include devices that provide the heart with a mechanical assist, and resynchronization of electrical impulses to maximize cardiac efficiency. Because of the prevalence and severity of CHF, there is considerable interest in novel

therapies, including cell-based approaches.[21] Of note in this regard, a growing body of evidence indicates that the adult heart may have limited capacity for stem cell–mediated self-renewal. Whether and to what extent this potential can be harnessed to therapeutic advantage is not yet known.[22]

3.2.5 Congenital Heart Disease

Congenital heart disease is a general term used to describe abnormalities of the heart or great vessels that are present from birth. Most such disorders arise from faulty embryogenesis during gestational weeks 3 through 8, when major cardiovascular structures form and begin to function. The most severe anomalies are incompatible with intrauterine survival. Congenital heart defects compatible with embryologic maturation and birth generally affect individual chambers or discrete regions of the heart, with the remainder of the heart developing relatively normally. Examples are infants born with a defect in septation ("hole in the heart"), such as an atrial septal defect (ASD) or a ventricular septal defect (VSD), stenotic valvular lesions, or with abnormalities in the coronary arteries.[23] Some forms of congenital heart disease produce clinically important manifestations soon after birth, which are frequently brought on by the change from fetal to postnatal circulatory patterns (with reliance on the lungs for oxygenation birth, rather than the placenta as in intrauterine life). Approximately half of congenital cardiovascular malformations are diagnosed in the first year of life, but some mild forms may not become evident until adulthood (e.g., ASD).

Incidence.

With an incidence of approximately 1% (estimates range from 4 to 50 per 1000 live births), congenital cardiovascular defects are among the most prevalent malformations and are the most common type of heart disease among children.[24] The incidence is higher in premature infants and in stillborns. Twelve disorders account for about 85% of cases; their frequencies are presented in Table 12-2 .

TABLE 12-2 -- Frequencies of Congenital Cardiac Malformations[*]

Malformation	Incidence per Million Live Births	%
Ventricular septal defect	4482	42
Atrial septal defect	1043	10
Pulmonary stenosis	836	8
Patent ductus arteriosus	781	7
Tetralogy of Fallot	577	5
Coarctation of the aorta	492	5
Atrioventricular septal defect	396	4
Aortic stenosis	388	4
Transposition of the great arteries	388	4
Truncus arteriosus	136	1
Total anomalous pulmonary venous connection	120	1
Tricuspid atresia	118	1
TOTAL	9757

[*] Presented as upper quartile of 44 published studies. Percentages do not add up to 100% because of rounding.

The number of individuals who have survived with congenital heart disease into adulthood is increasing rapidly and is presently estimated at nearly 1 million individuals in the United States.[25] Many of those with congenital heart disease have benefited greatly from rapid advances in the surgical and interventional repair of various structural heart defects. Nevertheless, such repairs may not restore the heart to normal; in such instances, patients may suffer from arrhythmias or ventricular dysfunction, and require additional surgery.[26] Other factors that impact the long-term outcome include risks associated with the use of prosthetic materials and devices,[27] such as substitute valves or myocardial patches, and maternal risks associated with childbearing.[28]

Cardiac Development.

The diverse malformations seen in congenital heart disease are caused by errors that occur during cardiac development; thus, a brief review how the heart normally forms is in order before discussing the specific defects (Fig. 12-3). The fine details of this complex process are beyond our scope here. Suffice it to say that the earliest cardiac precursors originate in lateral mesoderm and move to the mid-line in two migratory waves to create a crescent of cells consisting of the first and second heart fields by about day 15 of development.[29,][30] Each heart field is marked by the expression of different sets of genes; for example, the first heart field expresses the transcription factors TBX5 and Hand1, whereas the second heart field expresses the transcription factor Hand2 and fibroblast growth factor-10. Both fields contain multipotent progenitor cells that can produce all of the major cell types of the heart; endocardium, myocardium, and smooth muscle cells. As an aside, there is considerable interest in the therapeutic potential of such early cardiac progenitors, which could conceivably be used to regenerate portions of the adult heart that are damaged or otherwise dysfunctional.

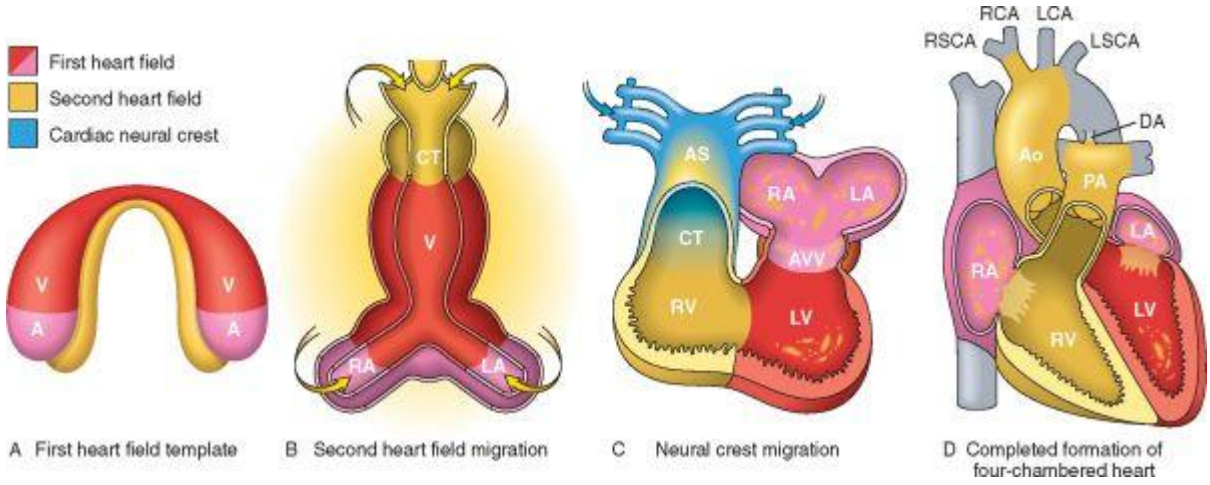

FIGURE 12-3 Human cardiac development, emphasizing the three sources of cells. **A**, Day 15. First heart field (FHF) cells (shown in red) form a crescent shape in the anterior embryo with second heart field (SHF) cells (shown in yellow) near the FHF. **B**, Day 21. SHF cells lie dorsal to the straight heart tube and begin to migrate *(arrows)* into the anterior and posterior ends of the tube to form the right ventricle (RV), conotruncus (CT), and part of the atria (A). **C**, Day 28. Following rightward looping of the heart tube, cardiac neural crest cells (shown in blue) also migrate *(arrow)* into the outflow tract from the neural folds to septate the outflow tract and pattern the bilaterally symmetric aortic arch arteries (III, IV, and VI). **D**, Day 50. Septation of the ventricles, atria, and atrioventricular valves (AVV) results in the appropriately configured four-chambered heart. Ao, aorta; AS, aortic sac; DA, ductus arteriosus; LA, left atrium; LCA, left carotid artery; LSCA, left subclavian artery; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RCA, right carotid artery; RSCA, right subclavian artery; V, ventricle. *(Modified by permission from Srivastava D: Making or breaking the heart: from lineage determination to morphogenesis. Cell 126:1037, 2006.)*

Even at this very early stage of development, each heart field is destined to give rise to particular portions of the heart. Cells derived from the first heart field mainly give rise to the left ventricle, whereas cells derived from the second heart field give rise to the outflow tract, right ventricle, and most of the atria. By day 20, the initial cell crescent develops into a beating tube, which loops to the right and begins to form the heart chambers by day 28. Around this time, two other critical events occur: (1) cells derived from the neural crest migrate into the outflow tract, where they participate in the septation of the outflow tract and the formation of the aortic arches; and (2) the extracellular matrix (ECM) underlying the future atrioventricular canal and outflow tract enlarges to produce swellings known as endocardial cushions. This process depends on the delamination of a subset of endocardial cells, which invade the ECM and subsequently proliferate and differentiate into the mesenchymal cells that are responsible for valve development. By day 50, further septation of the ventricles, atria, and atrioventricular valves produces the fourchambered heart.

Proper orchestration of these remarkable transformations depends on a network of transcription factors that are regulated by a number of signaling pathways, particularly the Wnt, VEGF, bone morphogenetic factor, TGF-β, fibroblast growth factor, and Notch pathways. It should also be remembered that the heart is a mechanical organ that is exposed to flowing blood from its earliest stages of development. It is likely that hemodynamic forces play an important role in cardiac development, just as they influence adaptations in the adult heart such as hypertrophy and dilation. In addition, specific micro-RNAs play critical roles in cardiac development by coordinating patterns and levels of transcription factor expression.[18]

Many of the genetic defects that affect heart development are autosomal dominant mutations that cause partial loss of function in one or another required factor, which are often transcription factors (discussed below). Thus, even relatively minor changes in the activity of one of the many factors necessary for normal development can lead to defects in the final product, the fully developed heart. It can be imagined (but is unproved) that transient environmental stresses during the first trimester of pregnancy that alter the activity of these same genes might give rise to defects resembling those produced by inherited mutations.

Etiology and Pathogenesis.

The main known causes of congenital heart disease consist of sporadic genetic abnormalities, which can take the form of single gene mutations, small chromosomal deletions, and additions or deletions of whole chromosomes (trisomies and monosomies). In the case of single gene mutations, the affected genes encode proteins belonging to several different functional classes, examples of which are provided in Table 12-3 . Many of these mutations affect genes encoding transcription factors that are required for normal heart development. Since the affected patients are heterozygous for these mutations, it follows that a 50% reduction in the activity of these factors is probably sufficient to derange cardiac development. Some of the affected transcription factors appear to work together in large protein complexes, providing an explanation for why mutations in any one of several genes produce similar defects. For example, GATA4, TBX5, and NKX2-5, three transcription factors that are mutated in some patients with atrial and ventricular septal defects, all bind to one another and co-regulate the expression of target genes that are required for the proper development of the heart. Of further interest, GATA4 and TBX20 are also mutated in rare forms of adult-onset cardiomyopathy (discussed later), indicating that they are not only important developmentally but are also needed to maintain the function of the postnatal heart.

TABLE 12-3 -- Selected Examples of Genetic Causes of Congenital Heart Disease

Affected Gene(s)	Normal Function	Syndrome Name	Congenital Cardiac Disease

Affected Gene(s)	Normal Function	Syndrome Name	Congenital Cardiac Disease
Non-syndromic			
NKX2–5	Transcription factor	—	ASD, VSD, conduction defects
GATA-4[*]	Transcription factor	—	ASD, VSD
TBX20[*]	Transcription factor	—	ASD, VSD, valve abnormalities
Syndromic			
TBX5	Transcription factor	Holt-Oram	ASD, VSD, Conduction defects
TBX1	Transcription factor	DiGeorge	Cardiac outflow tract defects
JAG1, NOTCH2	Notch signaling	Alagille	Pulmonary artery stenosis, Tetralogy of Fallot
Fibrillin	Structural protein	Marfan	Aortic aneurysm
	TGFβ signaling		Valve abnormalities

[*] Associated with adult-onset cardiomyopathy. ASD, atrial septal defect; VSD, ventricular septal defect (Modified by permission from Srivastava D: Making or breaking the heart: from lineage determination to morphogenesis. Cell 126:1037, 2006.)

Other single gene mutations associated with congenital heart disease affect proteins within signaling pathways or that have structural roles. Mutations in genes encoding various components of the Notch pathway, such as JAGGED1, NOTCH1, and NOTCH2, are associated with a number of different congenital heart defects, including bicuspid aortic valve (NOTCH1, discussed later) and Tetralogy of Fallot (JAGGED1 and NOTCH2).[29,][30] As you will recall from Chapter 11 , fibrillin mutations underlie Marfan syndrome, which is associated with valvular defects and aortic aneurysms. Although fibrillin was initially described as a structural protein, it is also an important negative regulator of TGFβ signaling, and hyperactive TGFβ signaling is at least partially responsible for the cardiovascular abnormalities in Marfan syndrome.

A notable example of a small chromosomal lesion that causes congenital heart disease is deletion of chromosome 22q11.2, which is found in up to 50% of patients with DiGeorge syndrome. In this syndrome the fourth branchial arch and the derivatives of the third and fourth pharyngeal pouches, which contribute to the formation of the thymus, parathyroids, and heart, develop abnormally. One candidate gene in the deleted region is TBX1, which encodes a transcription factor that regulates the expansion of cardiac progenitors in the second heart field. Other important genetic causes of congenital heart disease include chromosomal aneuplodies, particularly Turner syndrome (monosomy X) and trisomies 13, 18, and 21.[31] Indeed, *the most common genetic cause of congenital heart disease is trisomy 21 (Down syndrome)*,[32] in which about 40% of patients have one or more heart defects, most often affecting structures derived from the endocardial cushions (e.g., the atrioventricular septae and valves). The mechanisms by which aneuploidy leads to congenital heart defects remain largely unknown, but are likely to involve the dysregulated expression of multiple genes.

Beyond these known associations, more subtle forms of genetic variation probably also contribute to congenital heart disease. This assertion is based in part on the recognition that first-degree relatives of affected patients are at increased risk for congenital heart defects compared to the general population. For example, a child of a father with a VSD has a risk of 2%; if the VSD occurred in the mother, the risk to her offspring is 6% to 10%.

Despite these genetic clues, it must be acknowledged that our understanding of the mechanisms that lead to heart defects remains rudimentary. Most affected patients have no identifiable genetic risk factor, and even in those that do, the nature and severity of the defect are highly variable. As a result, it is thought that *environmental factors*, alone or in combination with genetic factors, also contribute to

congenital heart disease and in some cases may be the primary cause. Examples of known exposures that are associated with heart defects include congenital rubella infection, gestational diabetes, and exposure to teratogens (including some therapeutic drugs).[33] There is also great interest in identifying nutritional factors that may modify risk. For instance, intake of multivitamin supplements containing folate may reduce the risk of congenital heart defects.[34]

Clinical Features.

The varied structural anomalies in congenital heart disease fall primarily into three major categories:

- Malformations causing a *left-to-right shunt*
- Malformations causing a *right-to-left shunt*
- Malformations causing an *obstruction*.

A *shunt* is an abnormal communication between chambers or blood vessels. Abnormal channels permit the flow of blood down pressure gradients from the left (systemic) side to the right (pulmonary) side of the circulation or vice versa. When blood from the right side of the circulation flows directly into the left side *(right-to-left shunt)*, hypoxemia and *cyanosis* (a dusky blueness of the skin and mucous membranes) result because of the admixture of poorly oxygenated venous blood with systemic arterial blood (called *cyanotic congenital heart disease*). The most important congenital causes of right-to-left shunts are tetralogy of Fallot, transposition of the great arteries, persistent truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous connection. Moreover, with right-to-left shunts, emboli arising in peripheral veins can bypass the lungs and directly enter the systemic circulation *(paradoxical embolism);* brain infarction and abscess are potential consequences. Severe, long-standing cyanosis also causes *clubbing of the tips of the fingers and toes* (called hypertrophic osteoarthropathy) and polycythemia.

In contrast, *left-to-right shunts* (such as ASD, VSD, and patent ductus arteriosus) increase pulmonary blood flow and are not initially associated with cyanosis. However, leftto-right shunts raise both flow volumes and pressures in the normally low-pressure, low-resistance pulmonary circulation, which can lead to right ventricular hypertrophy and atherosclerosis of the pulmonary vasculature. The muscular pulmonary arteries (<1 mm diameter) first respond to increased pressure and flow by undergoing medial hypertrophy and vasoconstriction, which maintains relatively normal distal pulmonary capillary and venous pressures, and prevents pulmonary edema. Prolonged pulmonary arterial vasoconstriction, however, stimulates the proliferation of the vascular wall cells and the consequent development of irreversible obstructive intimal lesions analogous to the arteriolar changes seen in systemic hypertension (Chapter 11). Eventually, pulmonary vascular resistance approaches systemic levels, thereby producing a new right-to-left shunt that introduces unoxygenated blood into the systemic circulation *(late cyanotic congenital heart disease, or Eisenmenger syndrome)*.

Once irreversible pulmonary hypertension develops, the structural defects of congenital heart disease are considered irreparable. The secondary pulmonary vascular changes can eventually lead to the patient's death. This provides the rationale for early intervention, either surgical or nonsurgical, in those with left-to-right shunts.

Some developmental anomalies of the heart (e.g., coarctation of the aorta, aortic valvular stenosis, and pulmonary valvular stenosis) produce abnormal narrowing of chambers, valves, or blood vessels and therefore are called *obstructive congenital heart disease*. A complete obstruction is called an *atresia*. In some disorders (e.g., Tetralogy of Fallot), an obstruction (pulmonary stenosis) and a shunt (right-to-left through a VSD) are both present.

The altered hemodynamics of congenital heart disease usually cause cardiac dilation or hypertrophy (or both). However, some defects induce a decrease in the volume and muscle mass of a cardiac chamber; this is called *hypo-plasia* if it occurs before birth and *atrophy* if it develops postnatally.

LEFT-TO-RIGHT SHUNTS

The most commonly encountered left-to-right shunts include ASDs, VSDs, patent ductus arteriosus, and atrioventricular septal defects, and are shown in Figure 12-4 .

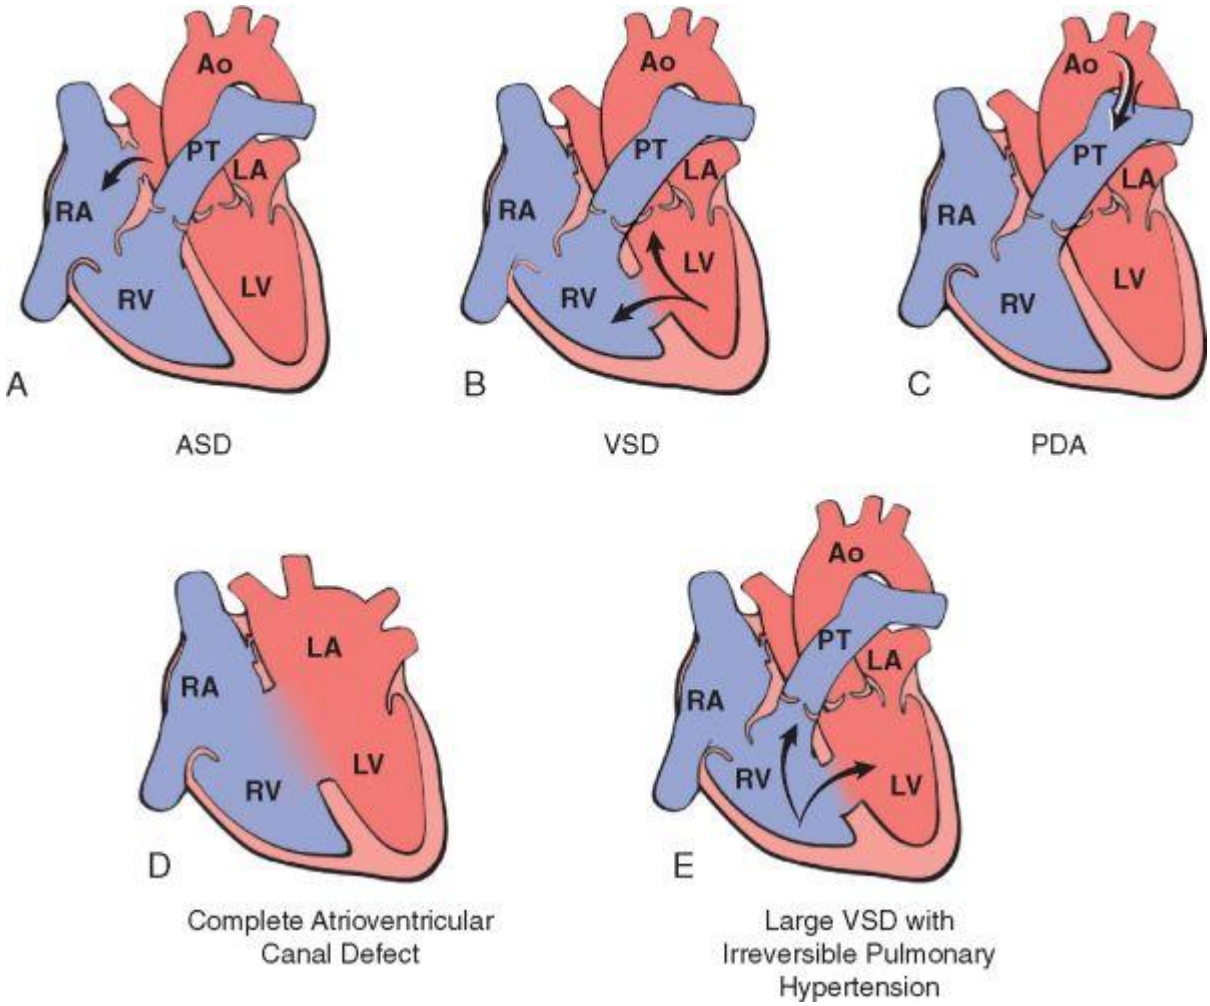

FIGURE 12-4 Schematic of congenital left-to-right shunts. *Arrows* indicate the direction of blood flow. **A**, Atrial septal defect (ASD). **B**, Ventricular septal defect (VSD). With VSD the shunt is left-to-right, and the pressures are the same in both ventricles. Pressure hypertrophy of the right ventricle and volume hypertrophy of the left ventricle are generally present. **C**, Patent ductus arteriosus (PDA). **D**, Atrioventricular septal defect (AVSD). **E**, Large VSD with irreversible pulmonary hypertension. The shunt is right-to-left (shunt reversal). Volume hypertrophy and pressure hypertrophy of the right ventricle are present. The right ventricular pressure is now sufficient to yield a right-to-left shunt. Ao, aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle.

Atrial Septal Defect

An atrial septal defect (ASD) is an abnormal, fixed opening in the atrial septum caused by incomplete tissue formation that allows communication of blood between the left and right atria (not to be confused with patent foramen ovale, see below). ASDs are usually asymptomatic until adulthood (Fig. 12-4A).[35]

Morphology. The three major types of ASDs are classified according to their location as secundum, primum, and sinus venosus. **Secundum ASDs** (90% of all ASDs) result from a deficient or fenestrated oval fossa near the center of the atrial septum. These are usually not associated with other anomalies, and may be of any size, be single or multiple, or be fenestrated. **Primum** anomalies (5% of ASDs) occur adjacent to the AV valves. **Sinus venosus** defects (5%) are located near the entrance of the superior vena cava and may be associated with anomalous pulmonary venous return to the right atrium.

Clinical Features.

ASDs result in a left-to-right shunt, largely because pulmonary vascular resistance is considerably less than systemic vascular resistance and because the compliance (distensibility) of the right ventricle is much greater than that of the left. Pulmonary blood flow may be two to four times normal. A murmur is often present as a result of excessive flow through the pulmonary valve. Despite the right-sided volume overload, ASDs are generally well tolerated and usually do not become symptomatic before age 30; irreversible pulmonary hypertension is unusual. Surgical or catheter-based closure of an ASD reverses the hemodynamic abnormalities and prevents complications, including heart failure, paradoxical embolization, and irreversible pulmonary vascular disease.[36] Mortality is low, and long-term survival is comparable to that of a normal population.

Patent Foramen Ovale

A patent foramen ovale is a small hole created by an open flap of tissue in the atrial septum at the oval fossa.[37] In the fetus, the foramen ovale is an important functional right-to-left shunt that allows oxygen-rich blood from the placenta to bypass the not yet inflated lungs by traveling directly from the right to left atrium. The hole is forced shut at birth as a result of increased blood pressure on the left side of the heart, and the tissue flap closes permanently in approximately 80% of people. In the remaining 20% of people, the unsealed flap can open when there is more pressure on the right side of the heart. Thus, sustained pulmonary hypertension or even transient increases in right-sided pressures, such as occurs during a bowel movement, coughing, or sneezing, can produce brief periods of right-to-left shunting, with the possibility of paradoxical embolism.[38]

Ventricular Septal Defect

Incomplete closure of the ventricular septum, allowing free communication of blood between the left to right ventricles, is the most common form of congenital cardiac anomaly (Fig. 12-4B). Most ventricular septal defects (VSDs) are associated with other congenital cardiac anomalies such as tetralogy of Fallot; only 20% to 30% are isolated.

Morphology. VSDs are classified according to their size and location. Most are about the size of the aortic valve orifice. About 90% involve the region of the membranous interventricular septum (membranous VSD) (Fig. 12-5). The remainder lie below the pulmonary valve (infundibular VSD) or within the muscular septum. Although most VSDs are single, those in the muscular septum may be multiple (so-called “Swiss-cheese” septum).

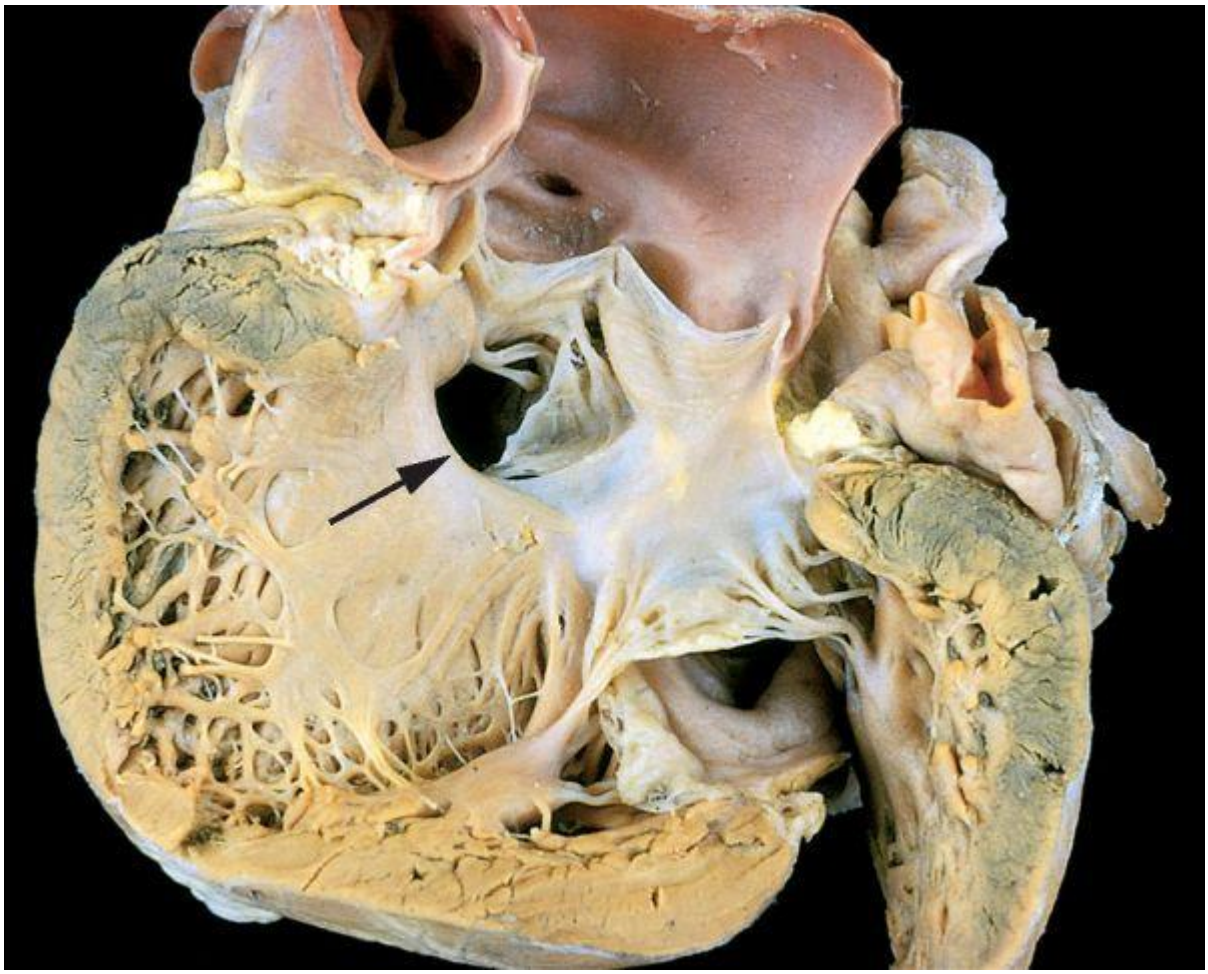

FIGURE 12-5 A ventricular septal defect (membranous type), denoted by the *arrow*. *(Courtesy of William D. Edwards, MD, Mayo Clinic, Rochester, MN.)*

Clinical Features.

The functional consequences of a VSD depend on the size of the defect and whether there are associated with right-sided malformations. Large VSDs cause difficulties virtually from birth; smaller lesions are generally well tolerated for years, and may not be recognized until much later in life. Approximately 50% of small muscular VSDs close spontaneously.[39] Large defects are usually membranous or infundibular, and they generally cause significant left-to-right shunting, leading to right ventricular hypertrophy and pulmonary hypertension virtually from birth. Over time, irreversible pulmonary vascular disease develops in essentially all persons with large unclosed VSDs, ultimately resulting in shunt reversal, cyanosis, and death. Surgical or catheter-based closure of asymptomatic VSDs is generally delayed beyond infancy, in hope of spontaneous closure. Early correction, however, must be performed in babies with large defects to prevent the development of irreversible obstructive pulmonary vascular disease.

Patent Ductus Arteriosus

Patent (also called persistent) ductus arteriosus (PDA) results when the ductus arteriosus, an essential fetal structure that normally spontaneously closes, remains open after birth (see Fig. 12-4C). In the fetal circulation the ductus arteriosus shunts blood from the pulmonary artery to the aorta, which (like the patent foramen ovale) serves to bypass the lungs. About 90% of PDAs occur as an isolated anomaly. The remainder are most often associated with VSD, coarctation of the aorta, or pulmonary or aortic valve stenosis.

PDA produces a characteristic continuous harsh murmur, described as “machinery-like”. The clinical impact of a PDA depends on its diameter and the cardiovascular status of the individual.[40] PDA is usually asymptomatic at birth, and a narrow PDA may have no effect on the child's growth and development. Because the shunt is at first left-to-right, there is no cyanosis, but eventually the additional volume and pressure overload produce obstructive changes in small pulmonary arteries, leading to reversal of flow and its associated consequences.

There is general agreement that an isolated PDA should be closed as early in life as is feasible. Conversely, preservation of ductal patency (by administering prostaglandin E) assumes great importance in the survival of infants with various congenital malformations that obstruct the pulmonary or systemic outflow tracts. For example, in aortic valve atresia a PDA provides the bulk of the systemic blood flow. Depending on the context, therefore, a PDA may be either life-threatening or lifesaving.

Atrioventricular Septal Defect

Atrioventricular septal defect (AVSD, also called complete atrioventricular canal defect) results from the embryologic failure of the superior and inferior endocardial cushions of the AV canal to fuse adequately. The consequence is incomplete closure of the AV septum and malformation of the tricuspid and mitral valves (see Fig. 12-4D). The two most common forms are *partial* AVSD (consisting of a primum ASD and a cleft anterior mitral leaflet, causing mitral insufficiency) and *complete* AVSD (consisting of a large combined AV septal defect and a large common AV valve—essentially a hole in the center of the heart). In the complete form, all four cardiac chambers freely communicate, inducing volume hypertrophy of each. More than one third of all patients with a complete AVSD have Down syndrome. Surgical repair is possible.

RIGHT-TO-LEFT SHUNTS

The diseases in this group cause cyanosis early in postnatal life (*cyanotic* congenital heart disease). Tetralogy of Fallot, the most common in this group, and transposition of the great arteries are illustrated schematically in Figure 12-6 . The others include persistent truncus arteriosus, tricuspid atresia, and total anomalous pulmonary venous connection.

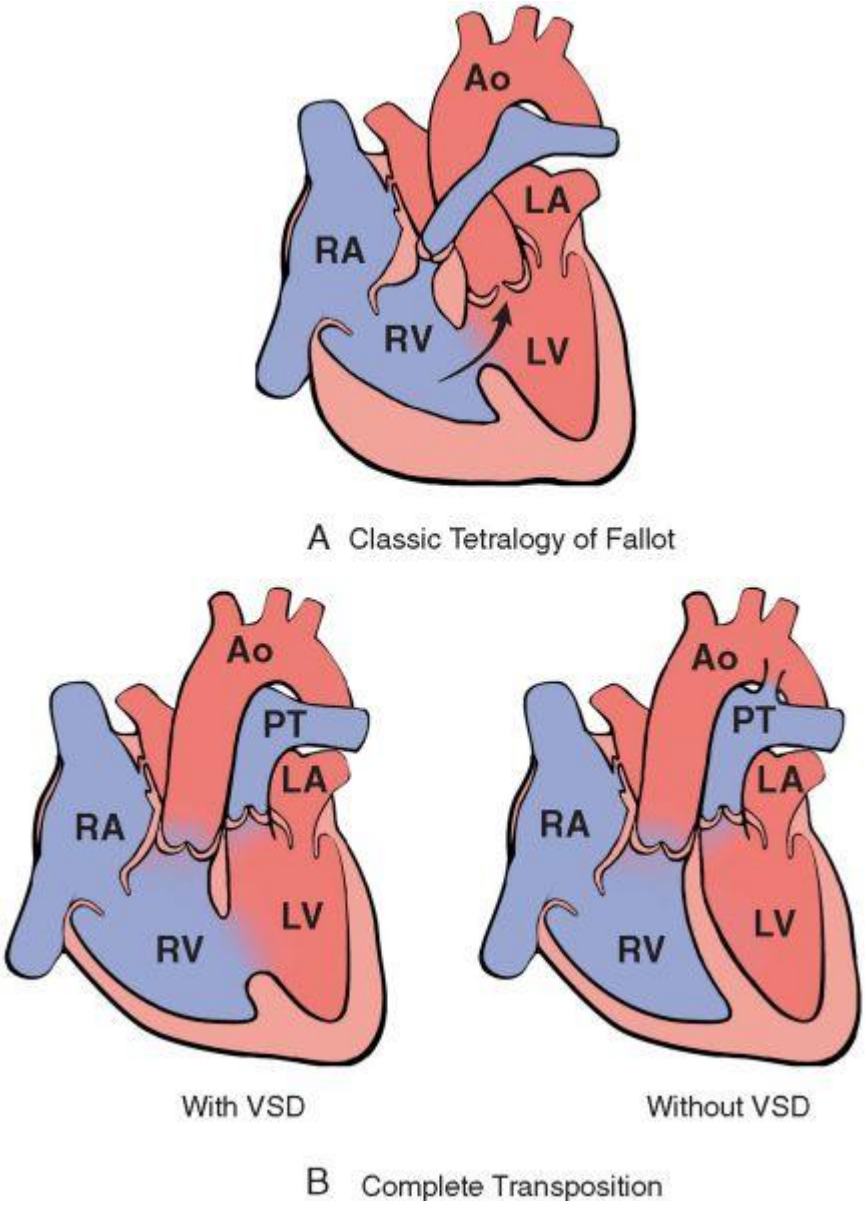

FIGURE 12-6 Schematic of the most important right-to-left shunts *(cyanotic congenital heart disease)*. **A**, Classic tetralogy of Fallot. The direction of shunting across the ventricular septal defect (VSD) depends on the degree of the subpulmonary stenosis; when severe, a right-to-left shunt results (*arrow*). **B**, Transposition of the great arteries with and without VSD. Ao, aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle. *(Courtesy of William D. Edwards, MD, Mayo Clinic, Rochester, MN.)*

Tetralogy of Fallot

The four cardinal features of the tetralogy of Fallot (TOF) are (1) VSD, (2) obstruction of the right ventricular outflow tract (subpulmonary stenosis), (3) an aorta that overrides the VSD, and (4) right ventricular hypertrophy (Fig. 12-6A). All of the features result embryologically from anterosuperior displacement of the infundibular septum.

Morphology. The heart is often enlarged and may be “boot-shaped” as a result of marked right

ventricular hypertrophy, particularly of the apical region. The VSD is usually large. The aortic valve forms the superior border of the VSD, thereby overriding the defect and both ventricular chambers. The obstruction to right ventricular outflow is most often due to narrowing of the infundibulum (subpulmonic stenosis) but can be accompanied by pulmonary valvular stenosis. Sometimes there is complete atresia of the pulmonary valve and variable portions of the pulmonary arteries, such that blood flow through a patent ductus arteriosus, dilated bronchial arteries, or both, is necessary for survival. Aortic valve insufficiency or an ASD may also be present; a right aortic arch is present in about 25% of cases.

Clinical Features.

Even untreated, some patients with TOF survive into adult life (in reports of untreated patients with this condition, 10% were alive at 20 years and 3% at 40 years).[49] The clinical consequences depend primarily on the severity of the subpulmonary stenosis, as this determines the direction of blood flow. If the subpulmonary stenosis is mild, the abnormality resembles an isolated VSD, and the shunt may be left-to-right, without cyanosis (so-called pink tetralogy). As the obstruction increases in severity, there is commensurately greater resistance to right ventricular outflow. *As right-sided pressures approach or exceed left-sided pressures, right-to-left shunting develops, producing cyanosis (classic TOF).* With increasingly severe subpulmonic stenosis, the pulmonary arteries become progressively smaller and thinner walled (hypoplastic), and the aorta grows progressively larger in diameter. As the child grows and the heart increases in size, the pulmonic orifice does not expand proportionally, making the obstruction progressively worse. Most infants with TOF are cyanotic from birth or soon thereafter. The subpulmonary stenosis, however, protects the pulmonary vasculature from pressure overload, and right ventricular failure is rare because the right ventricle is decompressed by the shunting of blood into the left ventricle and aorta. Complete surgical repair is possible for classic TOF but is more complicated for persons with pulmonary atresia and dilated bronchial arteries.

Transposition of the Great Arteries

Transposition of the great arteries (TGA) produces ventriculoarterial discordance: the aorta arises from the right ventricle, and lies anterior and to the right of the pulmonary artery, which emanates from the left ventricle (Fig. 12-7 ; see also Fig. 12-5B). The AV connections are normal (concordant), with the right atrium joining the right ventricle and the left atrium emptying into the left ventricle. The embryologic defect in complete TGA stems from abnormal formation of the truncal and aortopulmonary septa. The result is separation of the systemic and pulmonary circulations, a condition incompatible with postnatal life unless a shunt exists for adequate mixing of blood.

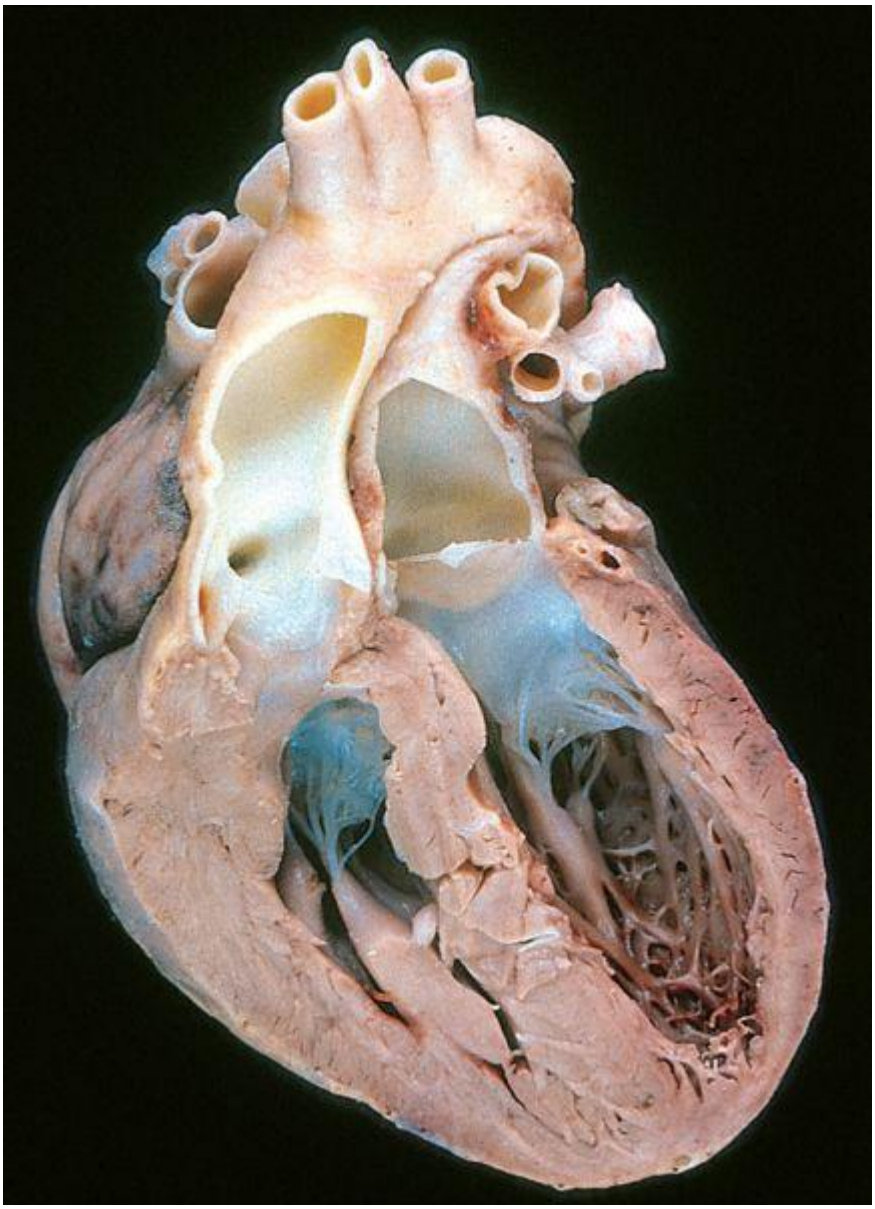

FIGURE 12-7 Transposition of the great arteries. *(Courtesy of William D. Edwards, MD, Mayo Clinic, Rochester, MN.)*

The outlook for infants with TGA depends on the degree of "mixing" of the blood, the magnitude of the tissue hypoxia, and the ability of the right ventricle to maintain the systemic circulation. Patients with TGA and a VSD (~35%) may have a stable shunt. Those with only a patent foramen ovale or ductus arteriosus (~65%), however, have unstable shunts that tend to close and therefore require immediate intervention to create a new shunt (such as balloon atrial septostomy) within the first few days of life. Right ventricular hypertrophy becomes prominent, because this chamber functions as the systemic ventricle. Concurrently, the left ventricle becomes thin-walled (atrophic) as it supports the low-resistance pulmonary circulation. Without surgery, most patients die during the first few months of life. However, as a result of considerable improvements in surgical repair over the past several decades, many persons with TGA now survive to adulthood.[41]

Persistent Truncus Arteriosus

Persistent truncus arteriosus (PTA) arises from a developmental failure of separation of the embryologic truncus arteriosus into the aorta and pulmonary artery. This results in a single great artery that receives blood from both ventricles and gives rise to the systemic, pulmonary, and coronary circulations. Because there is an associated VSD and mixing of blood from the right and left ventricles, PTA produces systemic cyanosis as well as increased pulmonary blood flow, with the danger of irreversible pulmonary hypertension.

Tricuspid Atresia

Complete occlusion of the tricuspid valve orifice is known as *tricuspid atresia*. It results embryologically from unequal division of the AV canal; thus, the mitral valve is larger than normal, and there is almost always underdevelopment (hypoplasia) of the right ventricle. The circulation is maintained to some degree by a right-to-left shunt through an interatrial communication (ASD or patent foramen ovale) and a VSD, which affords communication between the left ventricle and the pulmonary artery that arises from the hypoplastic right ventricle. Cyanosis is present virtually from birth, and there is a high mortality in the first weeks or months of life.

Total Anomalous Pulmonary Venous Connection

Total anomalous pulmonary venous connection (TAPVC), in which the pulmonary veins fail to directly join the left atrium, results embryologically when the common pulmonary vein fails to develop or becomes atretic. Fetal development is made possible by primitive systemic venous channels that usually drain from the lung into the left innominate vein or to the coronary sinus. Either a patent foramen ovale or an ASD is always present, allowing pulmonary venous blood to enter the left atrium. Consequences of TAPVC include volume and pressure hypertrophy and dilation of the right side of the heart, and dilation of the pulmonary trunk. The left atrium is hypoplastic, but the left ventricle is usually normal in size. Cyanosis may be present as a result of mixing of well-oxygenated and poorly oxygenated blood at the site of the anomalous pulmonary venous connection and large right-to-left shunting through an ASD.

OBSTRUCTIVE CONGENITAL ANOMALIES

Congenital obstruction to blood flow may occur at the level of the heart valves or within a great vessel.[42] Relatively common examples include stenosis or atresia of the aortic or pulmonary valves, and coarctation of the aorta. Obstruction can also occur within a chamber, as with subpulmonary stenosis in TOF.

Coarctation of the Aorta

Coarctation (narrowing, constriction) of the aorta ranks high in frequency among the common structural anomalies. Males are affected twice as often as females, although females with Turner syndrome frequently have a coarctation (Chapter 5). Two classic forms have been described: (1) an “infantile” form with tubular hypoplasia of the aortic arch proximal to a patent ductus arteriosus that is often symptomatic in early childhood, and (2) an “adult” form in which there is a discrete ridgelike infolding of the aorta, just opposite the closed ductus arteriosus *(ligamentum arteriosum)* distal to the arch vessels (Fig. 12-8). Encroachment on the aortic lumen is of variable severity, sometimes leaving only a small channel and at other times producing only minimal narrowing. Although coarctation of the aorta may occur as a solitary defect, it is accompanied by a bicuspid aortic valve in 50% of cases and may also be associated with congenital aortic stenosis, ASD, VSD, mitral regurgitation, or berry aneurysms of the circle of Willis in the brain.

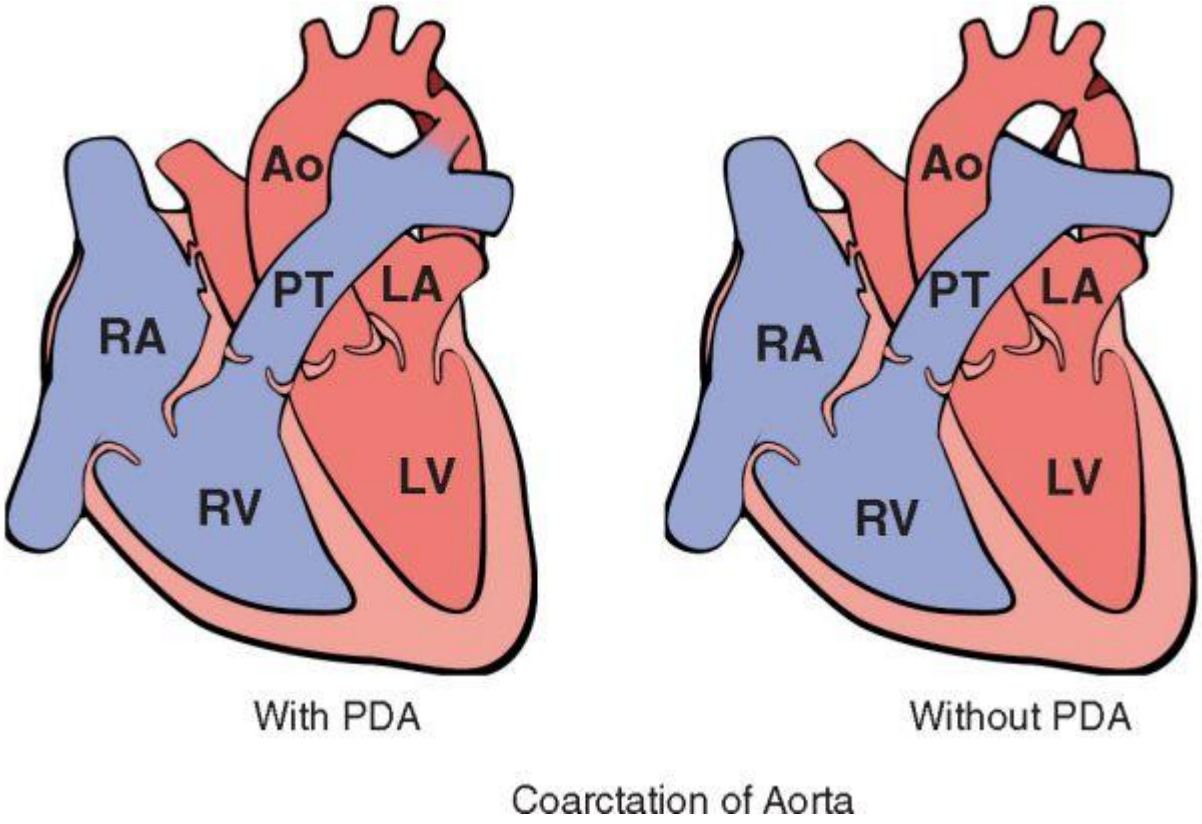

FIGURE 12-8 Diagram showing coarctation of the aorta with and without patent ductus arteriosus (PDA). Ao, aorta; LA, left atrium; LV, left ventricle; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; PDA, patent ductus arteriosus. *(Courtesy of William D. Edwards, MD, Mayo Clinic, Rochester, MN.)*

Clinical manifestations depend on the severity of the narrowing and the patency of the ductus arteriosus. *Coarctation of the aorta with a patent ductus arteriosus* usually leads to manifestations early in life; indeed, it may cause signs and symptoms immediately after birth. Many infants with this anomaly do not survive the neonatal period without surgical or catheter-based intervention. In such cases, the delivery of unsaturated blood through the patent ductus arteriosus produces cyanosis localized to the lower half of the body.

The outlook is different with *coarctation of the aorta without a patent ductus arteriosus*, unless it is very severe. Most children are asymptomatic, and the disease may go unrecognized until well into adult life. Typically there is hypertension in the upper extremities; in contrast, there are weak pulses and hypotension in the lower extremities, associated with manifestations of arterial insufficiency (i.e., claudication and coldness). Particularly characteristic in adults is the development of collateral circulation between the precoarctation arterial branches and the postcoarctation arteries through enlarged intercostal and internal mammary arteries, which produce radiographically visible erosions ("notching") of the undersurfaces of the ribs.

With significant coarctations, murmurs are present throughout systole; sometimes a thrill may be present. There is cardiomegaly due to left ventricular pressure-overload hypertrophy. With uncomplicated coarctation of the aorta, surgical resection and end-to-end anastomosis or replacement of the affected aortic segment by a prosthetic graft yields excellent results.

Pulmonary Stenosis and Atresia

This relatively frequent malformation constitutes an obstruction at the pulmonary valve, which may be mild to severe; the lesion can be isolated or part of a more complex anomaly—either tetralogy of Fallot or transposition of the great arteries. Right ventricular hypertrophy often develops, and there is sometimes poststenotic dilation of the pulmonary artery due to injury of the wall by "jetting" blood. With coexistent subpulmonary stenosis (as in tetralogy of Fallot), the high ventricular pressure is not transmitted to the valve, and the pulmonary trunk is not dilated and may in fact be hypoplastic. When the valve is entirely atretic, there is no communication between the right ventricle and lungs. In such cases the anomaly is associated with a hypoplastic right ventricle and an ASD; blood reaches the lungs through a patent ductus arteriosus. Mild stenosis may be asymptomatic and compatible with long life, whereas symptomatic cases require surgical correction.

Aortic Stenosis and Atresia

Congenital narrowing and obstruction of the aortic valve can occur at three locations: valvular, subvalvular, and supravalvular. With *valvular aortic stenosis* the cusps may be hypoplastic (small), dysplastic (thickened, nodular), or abnormal in number (usually acommissural or unicommissural). In severe congenital aortic stenosis or atresia, obstruction of the left ventricular outflow tract leads to underdevelopment (hypoplasia) of the left ventricle and ascending aorta, sometimes accompanied by dense, porcelain-like left ventricular endocardial fibroelastosis. The ductus must be open to allow blood flow to the aorta and coronary arteries. This constellation of findings, called the *hypoplastic left heart syndrome*, is nearly always fatal in the first week of life, when the ductus closes, unless a palliative procedure is done. Less severe degrees of congenital aortic stenosis may be compatible with long survival. Congenital aortic stenosis is an isolated lesion in 80% of cases.

Subaortic stenosis can be caused by a thickened ring (discrete type) or collar (tunnel type) of dense endocardial fibrous tissue below the level of the cusps. *Supravalvular aortic stenosis* is an inherited form of aortic dysplasia in which the ascending aortic wall is greatly thickened, causing luminal constriction. In some cases it is a component of a multiorgan developmental disorder resulting from deletions on chromosome 7 that include the gene for elastin. Other features of the syndrome include hypercalcemia, cognitive abnormalities, and hallmark facial anomalies (Williams-Beuren syndrome).[43] Mutations in the elastin gene probably cause supravalvular aortic stenosis by disrupting elastin–smooth muscle cell interactions during arterial morphogenesis.

Subaortic stenosis is usually associated with a prominent systolic murmur and sometimes a thrill. Pressure hypertrophy of the left ventricle develops as a consequence of the obstruction to blood flow, but congenital stenoses are well tolerated unless very severe. Mild stenoses can be managed conservatively with antibiotic prophylaxis (to prevent endocarditis) and avoidance of strenuous activity, but owing to left ventricular hypertrophy the threat of sudden death with exertion always looms.

3.2.6 Ischemic Heart Disease

Ischemic heart disease (IHD) is the leading cause of death worldwide for both men and women (7 million total per year). IHD is the generic designation for a group of pathophysiologically related syndromes resulting from *myocardial ischemia*—an imbalance between the supply (perfusion) and demand of the heart for oxygenated blood. Ischemia brings not only an insufficiency of oxygen, but also reduces the availability of nutrients and the removal of metabolites (Chapter 1). For this reason, ischemia is generally less well tolerated by the heart than pure hypoxia, such as may be seen with severe anemia, cyanotic heart disease, or advanced lung disease.

In more than 90% of cases, the cause of myocardial ischemia is reduced blood flow due to obstructive atherosclerotic lesions in the coronary arteries. Thus, IHD is often termed coronary artery disease (CAD) or coronary heart disease. In most cases there is a long period (up to decades) of silent, slow progression of coronary lesions before symptoms appear. Thus, *the syndromes of IHD are only the late manifestations of coronary atherosclerosis that may have started during childhood or adolescence* (Chapter 11).

IHD usually presents as one or more of the following clinical syndromes:

- *Myocardial infarction*, the most important form of IHD, in which ischemia causes the death of heart muscle.
- *Angina pectoris*, in which the ischemia is of insufficient severity to cause infarction, but may be a harbinger of MI.
- *Chronic IHD with heart failure*.
- *Sudden cardiac death*.

In addition to coronary atherosclerosis, myocardial ischemia may be caused by coronary emboli, blockage of small myocardial blood vessels, and lowered systemic blood pressure (e.g., shock). Moreover, in the setting of coronary arterial obstruction, ischemia can be aggravated by an increase in cardiac energy demand (e.g., as occurs with myocardial hypertrophy or increased heart rate *[tachycardia]*), by diminished availability of blood or oxygen due to shock, or by hypoxemia. Some conditions have several deleterious effects; for example, tachycardia increases oxygen demand (because of more contractions per unit time) and decreases supply (by decreasing the relative time spent in diastole, when cardiac perfusion occurs).

Epidemiology.

IHD in its various forms is the leading cause of death for both males and females in the United States and other industrialized nations. Each year nearly 500,000 Americans die of IHD. As troublesome as these numbers may be, they represent an improvement over those that prevailed 2 to 3 decades ago. Since its peak in 1963, the overall death rate from IHD has fallen in the United States by approximately 50%. This remarkable improvement has resulted primarily from (1) *prevention*, achieved by modification of important risk factors, such as smoking, elevated blood cholesterol, and hypertension, and (2) *diagnostic and therapeutic advances*, allowing earlier, more effective, and safer treatments. The latter include new medications, coronary care units, thrombolysis for MI, percutaneous transluminal coronary angioplasty, endovascular stents, coronary artery bypass graft (CABG) surgery, and improved control of heart failure and arrhythmias. Additional risk reduction may potentially be achieved by maintenance of normal blood glucose levels in diabetic patients, control of obesity, and prophylactic anticoagulation of middle-aged men with aspirin. Nevertheless, continuing this encouraging trend in the 21st century will be challenging, in view of the predicted doubling of the number of individuals over age 65 by 2050 and the increased longevity of "baby boomers," the "obesity epidemic," and other factors. Interestingly, the genetic determinants of coronary atherosclerosis and IHD may not be identical, since MI occurs in only a small fraction of individuals with coronary disease. For example, the risk of MI but not coronary atherosclerosis is associated with genetic variants that modify leukotriene B4 metabolism.[44]

Pathogenesis.

The dominant cause of the IHD syndromes is insufficient coronary perfusion relative to myocardial demand, due to chronic, progressive atherosclerotic narrowing of the epicardial coronary arteries, and variable degrees of superimposed acute plaque change, thrombosis, and vasospasm. The individual elements and their interactions are discussed below.

Chronic Atherosclerosis.

More than 90% of patients with IHD have atherosclerosis of one or more of the epicardial coronary arteries. The clinical manifestations of coronary atherosclerosis are generally due to progressive narrowing of the lumen leading to stenosis (“fixed” obstructions) or to acute plaque disruption with thrombosis, both of which compromise blood flow. A fixed lesion obstructing 75% or greater of the lumen is generally required to cause symptomatic ischemia precipitated by exercise (most often manifested as chest pain, known as angina); with this degree of obstruction, compensatory coronary arterial vasodilation is no longer sufficient to meet even moderate increases in myocardial demand. Obstruction of 90% of the lumen can lead to inadequate coronary blood flow even at rest. The progressive myocardial ischemia induced by slowly developing occlusions may stimulate the formation of collateral vessels over time, which can protect against myocardial ischemia and infarction and mitigate the effects of high-grade stenoses.[45]

Although only a single major coronary epicardial trunk may be affected, two or all three—the left anterior descending (LAD), the left circumflex (LCX), and the right coronary artery (RCA)—are often involved by atherosclerosis. Clinically significant stenosing plaques may be located anywhere within these vessels but tend to predominate within the first several centimeters of the LAD and LCX and along the entire length of the RCA. Sometimes the major secondary epicardial branches are also involved (i.e., diagonal branches of the LAD, obtuse marginal branches of the LCX, or posterior descending branch of the RCA), but atherosclerosis of the intramural (penetrating) branches is rare.

Acute Plaque Change.

The risk of an individual developing clinically important IHD depends in part on the number, distribution, structure, and degree of obstruction of atheromatous plaques. However, the varied clinical manifestations of IHD cannot be explained by the anatomic disease burden alone. This is particularly true for the so-called acute coronary syndromes, unstable angina, acute MI, and sudden death. The acute coronary syndromes are typically initiated by an unpredictable and abrupt conversion of a stable atherosclerotic plaque to an unstable and potentially life-threatening atherothrombotic lesion through rupture, superficial erosion, ulceration, fissuring, or deep hemorrhage (Chapter 11). In most instances, the plaque change causes the formation of a superimposed thrombus that partially or completely occludes the affected artery.[46] [47] These acute events are often associated with intralesional inflammation, which you will remember mediates the initiation, progression, and acute complications of atherosclerosis (discussed in Chapter 11). For purposes of simplicity, the spectrum of acute alterations in atherosclerotic lesions will be termed either plaque disruption or plaque change.

Consequences of Myocardial Ischemia.

In each syndrome the critical consequence is downstream myocardial ischemia. *Stable angina* results from increases in myocardial oxygen demand that outstrip the ability of stenosed coronary arteries to increase oxygen delivery; it is usually not associated with plaque disruption. *Unstable angina* is caused by plaque rupture complicated by partially occlusive thrombosis and vasoconstriction, which lead to severe but transient reductions in coronary blood flow. In some cases, microinfarcts can occur distal to disrupted plaques due to thromboemboli. In *MI*, acute plaque change induces total thrombotic occlusion and the subsequent death of heart muscle. Finally, *sudden cardiac death* frequently involves an atherosclerotic lesion in which a disrupted plaque causes regional myocardial ischemia that induces a fatal ventricular arrhythmia. Each of these important syndromes is discussed in detail below, followed by an examination of the important myocardial consequences.

ANGINA PECTORIS

Angina pectoris (literally, chest pain) is characterized by paroxysmal and usually recurrent attacks of substernal or precordial chest discomfort (variously described as constricting, squeezing, choking, or knifelike) caused by transient (15 seconds to 15 minutes) myocardial ischemia that falls short of inducing

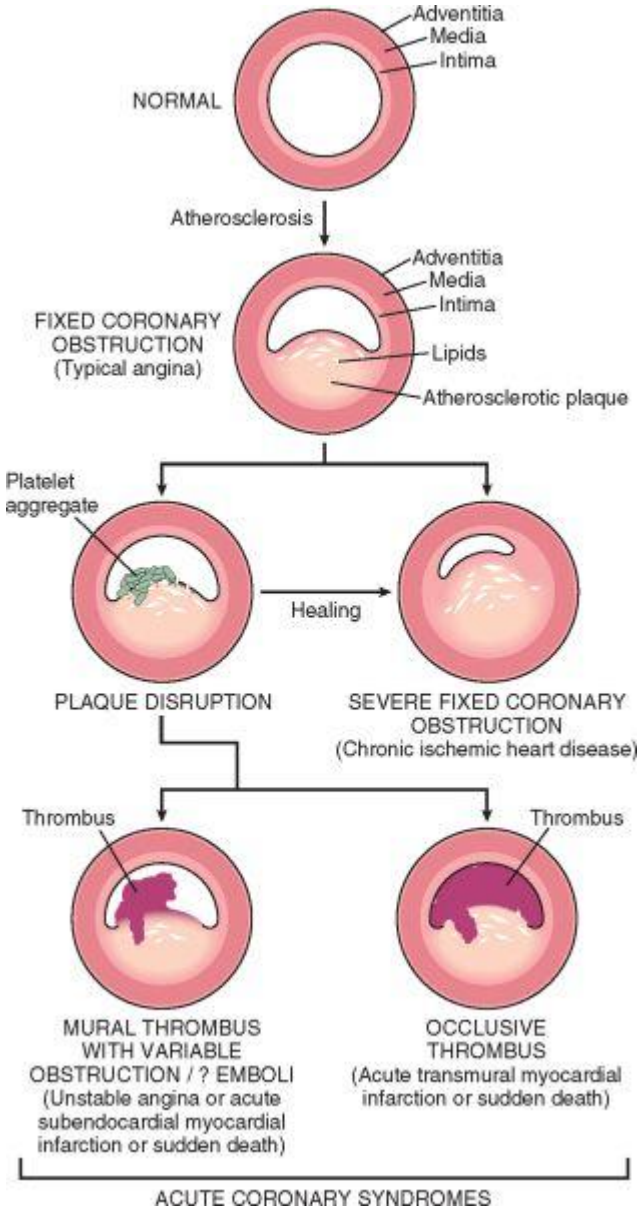

FIGURE 12-9 Schematic of sequential progression of coronary artery lesions and their association with various acute coronary syndromes. *(Modified and redrawn from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989, p 63.)*

myocyte necrosis. The three overlapping patterns of angina pectoris—(1) stable or typical angina, (2) Prinzmetal variant angina, and (3) unstable or crescendo angina—are caused by varying combinations of increased myocardial demand, decreased myocardial perfusion, and coronary arterial pathology. Moreover, not all ischemic events are perceived by patients *(silent ischemia)*.[48]

Stable angina, the most common form, is also called *typical angina pectoris. It is caused by an imbalance in coronary perfusion (due to chronic stenosing coronary atherosclerosis) relative to myocardial demand*, such as that produced by physical activity, emotional excitement, or any other cause of increased cardiac workload. Typical angina pectoris is usually relieved by rest (which decreases demand) or administering nitroglycerin, a strong vasodilator (which increases perfusion).

Prinzmetal variant angina is an uncommon from of episodic myocardial ischemia that is caused by coronary artery spasm. Although individuals with Prinzmetal variant angina may well have significant coronary atherosclerosis, the anginal attacks are unrelated to physical activity, heart rate, or blood pressure. Prinzmetal angina generally responds promptly to vasodilators, such as nitroglycerin and calcium channel blockers.

Unstable or crescendo angina refers to *a pattern of increasingly frequent pain, often of prolonged duration, that is precipitated by progressively lower levels of physical activity or that even occurs at rest*. In most patients, unstable angina is caused by the disruption of an atherosclerotic plaque with superimposed partial (mural) thrombosis and possibly embolization or vasospasm (or both). Unstable angina thus serves as a warning that an acute MI may be imminent; indeed, this syndrome is sometimes referred to as *preinfarction angina*.

MYOCARDIAL INFARCTION (MI)

MI, also known as "heart attack," is the death of cardiac muscle due to prolonged severe ischemia. It is by far the most important form of IHD. About 1.5 million individuals in the United States suffer an MI annually.

Incidence and Risk Factors.

MI can occur at virtually any age, but its frequency rises progressively with increasing age and when predispositions to atherosclerosis are present. Nearly 10% of myocardial infarcts occur in people under age 40, and 45% occur in people under age 65. Blacks and whites are equally affected. Throughout life, men are at significantly greater risk than women.[49] Indeed, except for those having some predisposing atherogenic condition, women are protected against MI and other heart diseases during the reproductive years. However, the decrease of estrogen following menopause is associated with rapid development of CAD, and IHD is the most common cause of death in elderly women. Postmenopausal hormonal replacement therapy is not currently felt to protect against atherosclerosis and IHD (Chapter 11).[50]

Pathogenesis.

We now consider the basis for and consequences of myocardial ischemia.

Coronary Arterial Occlusion.

In the typical case of MI, the following sequence of events is considered most likely (see Chapter 11 for more detail):

- The initial event is a sudden change in an atheromatous plaque, which may consist of intraplaque hemorrhage, erosion or ulceration, or rupture or fissuring.
- When exposed to subendothelial collagen and necrotic plaque contents, platelets adhere, become activated, release their granule contents, and aggregate to form microthrombi.
- Vasospasm is stimulated by mediators released from platelets.
- Tissue factor activates the coagulation pathway, adding to the bulk of the thrombus.
- Frequently within minutes, the thrombus evolves to completely occlude the lumen of the vessel.

Compelling evidence for this sequence has been obtained from (1) autopsy studies of patients dying of acute MI, (2) angiographic studies demonstrating a high frequency of thrombotic occlusion early after MI, (3) the high success rate of coronary revascularization (i.e., thrombolysis, angioplasty, stent placement, and surgery) following MI, and (4) the demonstration of residual disrupted atherosclerotic lesions by angiography after thrombolysis. Coronary angiography performed within 4 hours of the onset of an MI shows a thrombosed coronary artery in almost 90% of cases. However, when angiography is delayed until 12 to 24 hours after onset, occlusion is seen only about 60% of the time, suggesting that some occlusions resolve due to fibrinolysis, relaxation of spasm, or both.

In approximately 10% of cases, transmural MI occurs in the absence of the typical coronary vascular pathology. In such situations, other mechanisms may be responsible for the reduced coronary blood flow, including:

- *Vasospasm* with or without coronary atherosclerosis, perhaps in association with platelet aggregation or due to cocaine abuse
- *Emboli* from the left atrium in association with atrial fibrillation, a left-sided mural thrombus, vegetations of infective endocarditis, intracardiac prosthetic material; or *paradoxical emboli* from the right side of the heart or the peripheral veins, which travel through a patent foramen ovale to the coronary arteries
- *Ischemia without detectable coronary atherosclerosis and thrombosis* may be caused by disorders of small intramural coronary vessels, such as vasculitis, hematologic abnormalities such as sickle cell disease, amyloid deposition in vascular walls, and vascular dissection; lowered systemic blood pressure (shock); or inadequate myocardial “protection” during cardiac surgery

Myocardial Response.

Coronary arterial obstruction compromises the blood supply to a region of myocardium (Fig. 12-10), *causing ischemia*, myocardial dysfunction, and potentially myocyte death. The anatomic region supplied by that artery is referred to as the *area at risk*. The outcome depends predominantly on the severity and duration of flow deprivation (Fig. 12-11).

FIGURE 12-10 Postmortem angiogram showing the posterior aspect of the heart of a patient who died during the evolution of acute myocardial infarction, demonstrating total occlusion of the distal right coronary artery by an acute thrombus *(arrow)* and a large zone of myocardial hypoperfusion involving the posterior left and right ventricles, as indicated by *arrowheads*, and having almost absent filling of capillaries. The heart has been fixed by coronary arterial perfusion with glutaraldehyde and cleared with methyl salicylate, followed by intracoronary injection of silicone polymer (yellow). Philadelphia, WB Saunders, 1989, p. 60.)*

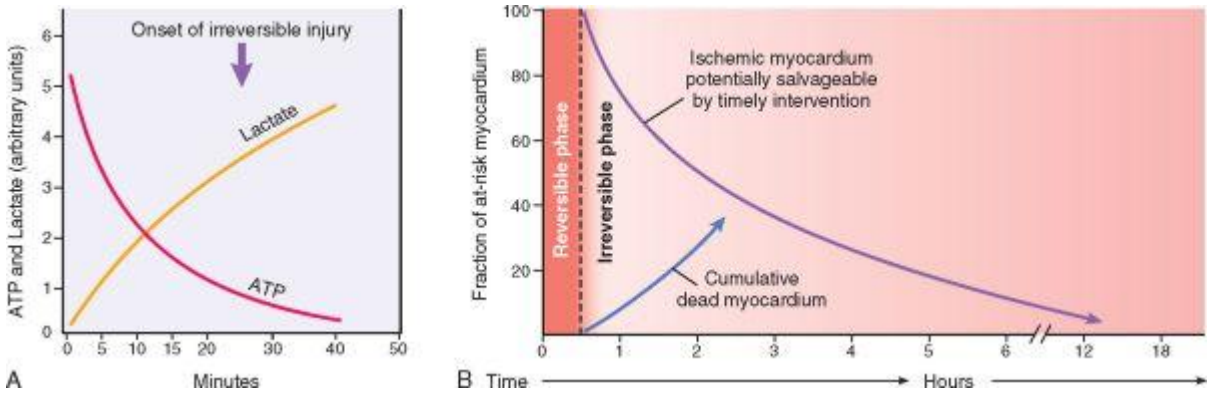

FIGURE 12-11 Temporal sequence of early biochemical findings and progression of necrosis after onset of severe myocardial ischemia. **A**, Early changes include loss of adenosine triphosphate (ATP) and accumulation of lactate. **B**, For approximately 30 minutes after the onset of even the most severe ischemia, myocardial injury is potentially reversible. Thereafter, progressive loss of viability occurs that is complete by 6 to 12 hours. The benefits of reperfusion are greatest when it is achieved early, and are progressively lost when reperfusion is delayed. *(Modified with permission from Antman E: Acute myocardial infarction. In Braunwald E et al. (eds): Heart Disease: A Textbook of Cardiovascular Medicine, 6th ed. Philadelphia, WB Saunders, 2001, pp 1114–1231.)*

The early biochemical consequence of myocardial ischemia is the cessation of aerobic metabolism within seconds, leading to inadequate production of high-energy phosphates (e.g., creatine phosphate and adenosine triphosphate) and accumulation of potentially noxious metabolites (such as lactic acid) (Fig. 12-11A). Because of the exquisite dependence of myocardial function on oxygen, severe ischemia induces loss of contractility within 60 seconds. This cessation of function can precipitate acute heart failure long before myocardial cell death. As detailed in Chapter 1 , ultrastructural changes (including myofibrillar relaxation, glycogen depletion, cell and mitochondrial swelling) also develop within a few minutes of the onset of ischemia. *Nevertheless, these early changes are potentially reversible. As demonstrated both experimentally and in clinical studies, only severe ischemia lasting 20 to 30 minutes or longer leads to irreversible damage (necrosis) of cardiac myocytes*. Ultrastructural evidence of *irreversible* myocyte injury (primary structural defects in the sarcolemmal membrane) develops only after prolonged, severe myocardial ischemia (such as occurs when blood flow is 10% or less of normal).

A key feature that marks the early phases of myocyte necrosis is the disruption of the integrity of the sarcolemmal membrane, which allows intracellular macromolecules to leak out of cells into the cardiac interstitium and ultimately into the microvasculature and lymphatics in the region of the infarct. Tests that measure the levels of myocardial proteins in the blood are important in the diagnosis and management of MI (see later). With prolonged severe ischemia, injury to the microvasculature then follows. The temporal progression of these events is summarized in Table 12-4 .

TABLE 12-4 -- Approximate Time of Onset of Key Events in Ischemic Cardiac Myocytes

Feature	Time
Onset of ATP depletion	Seconds
Loss of contractility	<2 min
ATP reduced	
to 50% of normal	10 min

Feature	Time
to 10% of normal	40 min
Irreversible cell injury	20–40 min
Microvascular injury	>1 hr

ATP, adenosine triphosphate.

In most cases of acute MI, permanent damage to the heart occurs when the perfusion of the myocardium is severely reduced for an extended interval (usually at least 2 to 4 hours), (Fig. 12-11B). *This delay in the onset of permanent myocardial injury provides the rationale for rapid diagnosis in acute MI—to permit early coronary intervention, the purpose of which is to establish reperfusion and salvage as much "at risk" myocardium as possible*.

The progression of ischemic necrosis in the myocardium is summarized in Figure 12-12 . Ischemia is most pronounced in the subendocardium; thus, irreversible injury of ischemic myocytes occurs first in the subendocardial zone. With more extended ischemia, a *wavefront* of cell death moves through the myocardium to involve progressively more of the transmural thickness and breadth of the ischemic zone. The precise location, size, and specific morphologic features of an acute MI depend on:

- The location, severity, and rate of development of coronary obstructions due to atherosclerosis and thromboses
- The size of the vascular bed perfused by the obstructed vessels
- The duration of the occlusion
- The metabolic/oxygen needs of the myocardium at risk
- The extent of collateral blood vessels
- The presence, site, and severity of coronary arterial spasm
- Other factors, such as heart rate, cardiac rhythm, and blood oxygenation

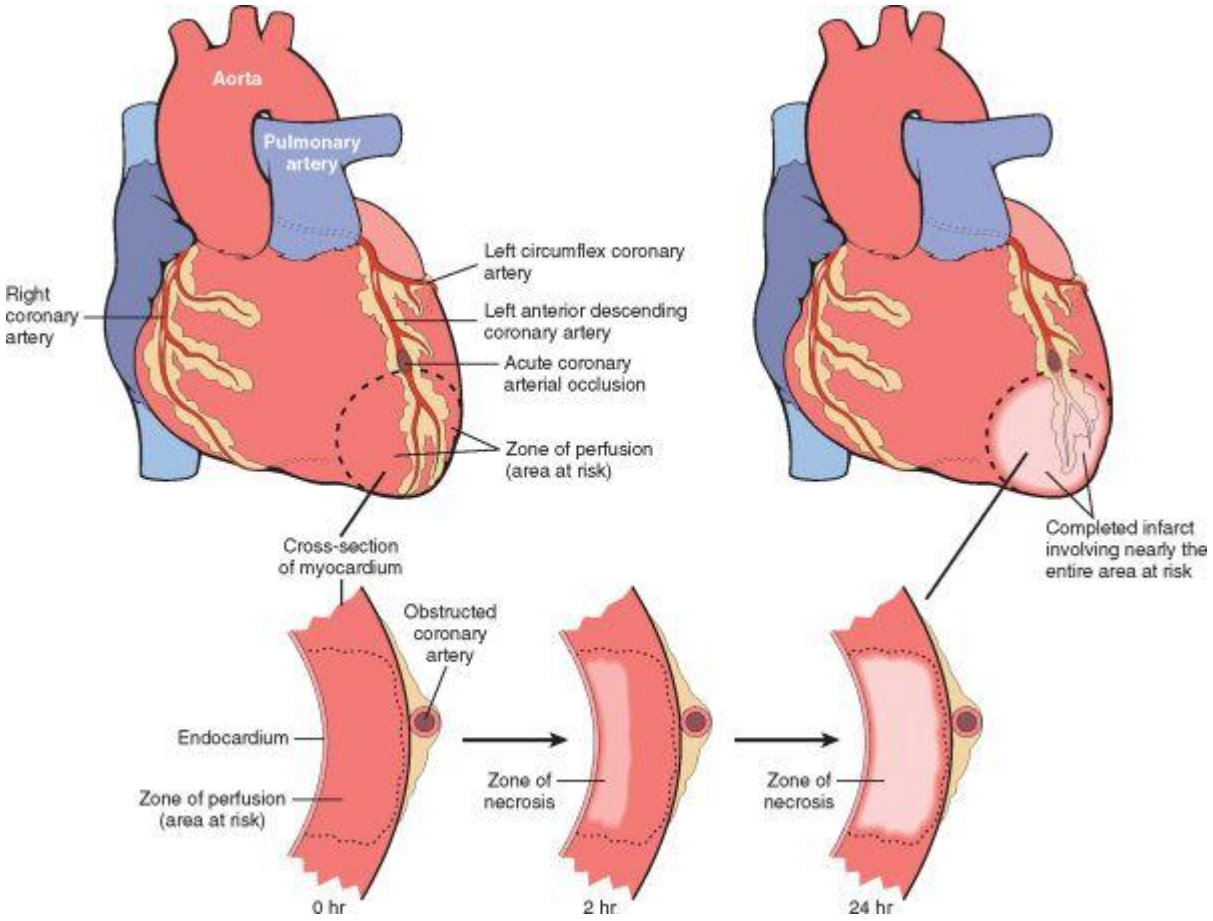

FIGURE 12-12 Progression of myocardial necrosis after coronary artery occlusion. Necrosis begins in a small zone of the myocardium beneath the endocardial surface in the center of the ischemic zone. The area that depends on the occluded vessel for perfusion is the "at risk" myocardium (*shaded*). Note that a very narrow zone of myocardium immediately beneath the endocardium is spared from necrosis because it can be oxygenated by diffusion from the ventricle.

Necrosis is usually complete within 6 hours of the onset of severe myocardial ischemia. However, in instances where the coronary arterial collateral system, stimulated by chronic is-chemia, is better developed and thereby more effective, the progression of necrosis may follow a more protracted course (possibly over 12 hours or longer).

Knowledge of the areas of myocardium perfused by the three major coronary arteries helps correlate sites of vascular obstruction with regions of myocardial infarction. Typically, the left anterior descending branch of the left coronary artery (LAD) supplies most of the apex of the heart (distal end of the ventricles), the anterior wall of the left ventricle, and the anterior two thirds of the ventricular septum. By convention, the coronary artery (either the right coronary artery [RCA] or the left circumflex artery [LCX]) that perfuses the posterior third of the septum is called "dominant" (even though the LAD and LCX collectively perfuse the majority of the left ventricular myocardium). In a right dominant circulation, present in approximately four fifths of individuals, the LCX generally perfuses only the lateral wall of the left ventricle, and the RCA supplies the entire right ventricular free wall, the posterobasal wall of the left ventricle, and the posterior third of the ventricular septum. Thus, occlusions of the RCA (as well as the left coronary artery) can cause left ventricular damage. The right and left coronary arteries function as end arteries, although anatomically most hearts have numerous

intercoronary anastomoses (connections called the collateral circulation). Little blood courses through the collateral circulation in the normal heart. However, when one artery is severely narrowed, blood flows via collaterals from the high- to the low-pressure system, and causes the channels to enlarge. Thus, progressive dilation and growth of collaterals, stimulated by ischemia, may play a role in providing blood flow to areas of the myocardium otherwise deprived of adequate perfusion.

Transmural Versus Subendocardial Infarction.

The distribution of myocardial necrosis correlates with the location and cause of the decreased perfusion (Fig. 12-16). Most myocardial infarcts are *transmural*, in which the ischemic necrosis involves the full or nearly full thickness of the ventricular wall in the distribution of a single coronary artery. This pattern of infarction is usually associated with a combination of chronic coronary atherosclerosis, acute plaque change, and superimposed thrombosis (as discussed previously). In contrast, a *subendocardial (nontransmural) infarct* constitutes an area of ischemic necrosis limited to the inner one third to one half of the ventricular wall. As the subendocardial zone is normally the least perfused region of myocardium, this area is most vulnerable to any reduction in coronary flow. A subendocardial infarct can occur as a result of a plaque disruption followed by a coronary thrombus that becomes lysed before myocardial necrosis extends across the full thickness of the wall; in this case the infarct will be limited to the distribution of the coronary artery that suffered plaque change. However, subendocardial infarcts can also result from prolonged, severe reduction in systemic blood pressure, as in shock superimposed on chronic, otherwise noncritical, coronary stenoses. In the subendocardial infarcts that occur as a result of global hypotension, myocardial damage is usually circumferential, rather than being limited to the distribution of a single major coronary artery. Owing to the characteristic electrocardiographic changes resulting from myocardial ischemia/necrosis in various distributions, transmural infarcts are often referred to as “ST elevation infarcts” and subendocardial infarcts are known as “non-ST elevation infarcts.”

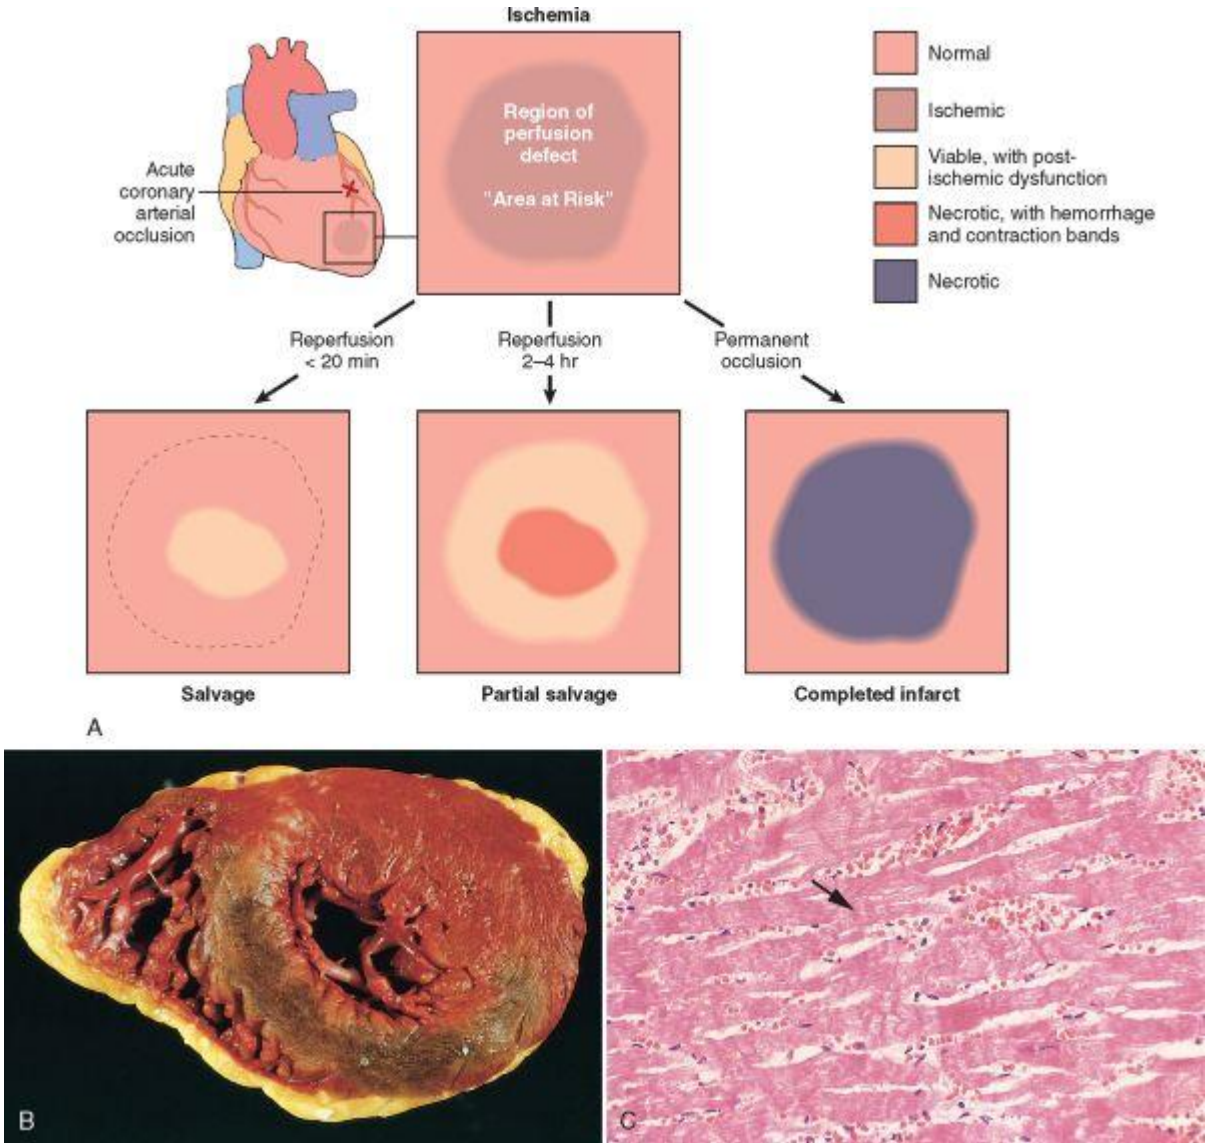

FIGURE 12-16 Consequences of myocardial ischemia followed by reperfusion. **A**, Schematic illustration of the progression of myocardial ischemic injury and its modification by restoration of flow (reperfusion). Hearts suffering brief periods of ischemia of longer than 20 minutes followed by reperfusion do not develop necrosis (reversible injury). Brief ischemia followed by reperfusion results in stunning. If coronary occlusion is extended beyond 20 minutes' duration, a wavefront of necrosis progresses from subendocardium to subepicardium over time. Reperfusion before 3 to 6 hours of ischemia salvages ischemic but viable tissue. This salvaged tissue may also demonstrate stunning. Reperfusion beyond 6 hours does not appreciably reduce myocardial infarct size. **B**, Gross and **C**, microscopic appearance of myocardium modified by reperfusion. **B**, Large, densely hemorrhagic, anterior wall acute myocardial infarction in a patient with left anterior descending artery thrombus treated with streptokinase, a fibrinolytic agent (triphenyl tetrazolium chloride–stained heart slice). Specimen oriented with posterior wall at top. **C**, Myocardial necrosis with hemorrhage and contraction bands, visible as dark bands spanning some myofibers *(arrow)*. This is the characteristic appearance of markedly ischemic myocardium that has been reperfused.

Morphology. The temporal evolution of the morphologic changes in acute MI and subsequent healing are summarized in Table 12-5 .

Nearly all transmural infarcts involve at least a portion of the left ventricle (comprising the free wall and ventricular septum) and encompass nearly the entire perfusion zone of the occluded coronary artery save for a narrow rim (~0.1 mm) of preserved subendocardial myocardium that is sustained by

the diffusion of oxygen and nutrients from the ventricular lumen.

Of MIs caused by a right coronary obstruction, 15% to 30% extend from the posterior free wall of the septal portion of the left ventricle into the adjacent right ventricular wall. Isolated infarction of the right ventricle is unusual (1% to 3% of cases), as is infarction of the atria.

The frequencies of involvement of each of the three main arterial trunks and the corresponding sites of myocardial lesions resulting in infarction (in the typical right dominant heart) are as follows (Fig. 12-13A):

- Left anterior descending coronary artery (40% to 50%): infarcts involving the anterior wall of left ventricle near the apex; the anterior portion of ventricular septum; and the apex circumferentially
- Right coronary artery (30% to 40%): infarcts involving the inferior/posterior wall of left ventricle; posterior portion of ventricular septum; and the inferior/posterior right ventricular free wall in some cases
- Left circumflex coronary artery (15% to 20%): infarcts involving the lateral wall of left ventricle except at the apex

Other locations of critical coronary arterial lesions causing infarcts are sometimes encountered, such as the left main coronary artery, the secondary branches of the left anterior descending coronary artery, or the marginal branches of the left circumflex coronary artery.

The gross and microscopic appearance of an infarct depends on the duration of survival of the patient following the MI. Areas of damage undergo a progressive sequence of morphologic changes that consist of typical ischemic coagulative necrosis (the predominant mechanism of cell death in MI, although apoptosis may also occur), followed by inflammation and repair that closely parallels tissue responses to injury at other sites.

Early recognition of acute MI can be difficult, particularly when death has occurred within a few hours after the onset of symptoms. MIs less than 12 hours old are usually not apparent on gross examination. If the patient died at least 2 to 3 hours after the infarct, however, it is possible to highlight the area of necrosis by immersion of tissue slices in a solution of **triphenyltetrazolium chloride**. This histochemical stain imparts a brick-red color to intact, noninfarcted myocardium where dehydrogenase (e.g., lactate dehydrogenase) activity is preserved. Because dehydrogenases leak out through the damaged membranes of dead cell, an infarct appears as an unstained pale zone (Fig. 12-14). By 12 to 24 hours an infarct can be identified grossly in transverse slices as a reddish-blue area of discoloration caused by stagnated, trapped blood. Thereafter, the infarct becomes progressively more sharply defined, yellow-tan, and soft. By 10 days to 2 weeks, it is rimmed by a hyperemic zone of highly vascularized granulation tissue. Over the succeeding weeks, the injured region evolves to a fibrous scar.

The histopathologic changes also proceed in a fairly predictable sequence (summarized in Fig. 12-15). The typical changes of coagulative necrosis become detectable in the first 6 to 12 hours. “Wavy fibers” may be present at the periphery of the infarct; these changes probably result from the forceful systolic tugs of the viable fibers on immediately adjacent, noncontractile dead fibers, which stretches and folds them. An additional sublethal ischemic change may be seen in the margins of infarcts: so-called vacuolar degeneration or **myocytolysis**, which takes the form of large vacuolar spaces within cells that probably contain water. The necrotic muscle elicits acute inflammation (most prominent between 1 and 3 days). Thereafter macrophages remove the necrotic myocytes (most pronounced at 3 to 7 days), and the damaged zone is progressively replaced by the ingrowth of highly vascularized granulation tissue (most prominent at 1 to 2 weeks); as healing progresses, this is replaced by fibrous tissue. In most instances, scarring is well advanced by the end of the sixth week, but the efficiency of

repair depends on the size of the original lesion.

Since healing requires the participation of inflammatory cells that migrate to the region of damage through intact blood vessels, which often survive only at the infarct margins, the infarct heals from its margins toward its center. Thus, a large infarct may not heal as quickly or as completely as a small one. A healing infarct may appear nonuniform, with the most advanced healing at the periphery. Once a lesion is completely healed, it is impossible to determine its age (i.e., the dense fibrous scar of 8-week-old and 10-year-old infarcts may look identical).

Infarcts may expand beyond their original borders over a period of days to weeks via a process of repetitive necrosis of adjacent regions **(extension)**. In such cases, there is a central zone in which healing is more advanced than the periphery of the infarct. This contrasts with the appearance of a simple infarct described above, in which the most advanced repair is peripheral. Infarct extension may occur because of retrograde propagation of a thrombus, proximal vasospasm, progressively impaired cardiac contractility that renders flow through moderate stenoses insufficient, the deposition of platelet-fibrin microemboli, or an arrhythmia that impairs cardiac function.

TABLE 12-5 -- Evolution of Morphologic Changes in Myocardial Infarction

Time	Gross Features	Light Microscope	Electron Microscope
REVERSIBLE INJURY			
0–½ hr	None	None	Ralaxation of myofibrils; glycogen loss; mitochondrial swelling
IRREVERSIBLE INJURY			
½–4 hr	None	Usually none; variable waviness of fibers at border	Sarcolemmal disruption; mitochondrial amorphous densities
4–12 hr	Dark mottling (occasional)	Early coagulation necrosis; edema; hemorrhage	
12–24 hr	Dark mottling	Ongoing coagulation necrosis; pyknosis of nuclei; myocyte hypereosinophilia; marginal contraction band necrosis; early neutrophilic infiltrate	
1–3 days	Mottling with yellow-tan infarct center	Coagulation necrosis, with loss of nuclei and striations; brisk interstitial infiltrate of neutrophils	
3–7 days	Hyperemic border; central yellow-tan softening	Beginning disintegration of dead myofibers, with dying neutrophils; early phagocytosis of dead cells by macrophages at infarct border	
7–10 days	Maximally yellow-tan and soft, with depressed red-tan margins	Well-developed phagocytosis of dead cells; early formation of fibrovascular granulation tissue at margins	
10–14 days	Red-gray depressed infarct borders	Well-established granulation tissue with new blood vessels and collagen deposition	
2–8 wk	Gray-white scar, progressive from border toward core of infarct	Increased collagen deposition, with decreased cellularity	
>2 mo	Scarring complete	Dense collagenous scar	

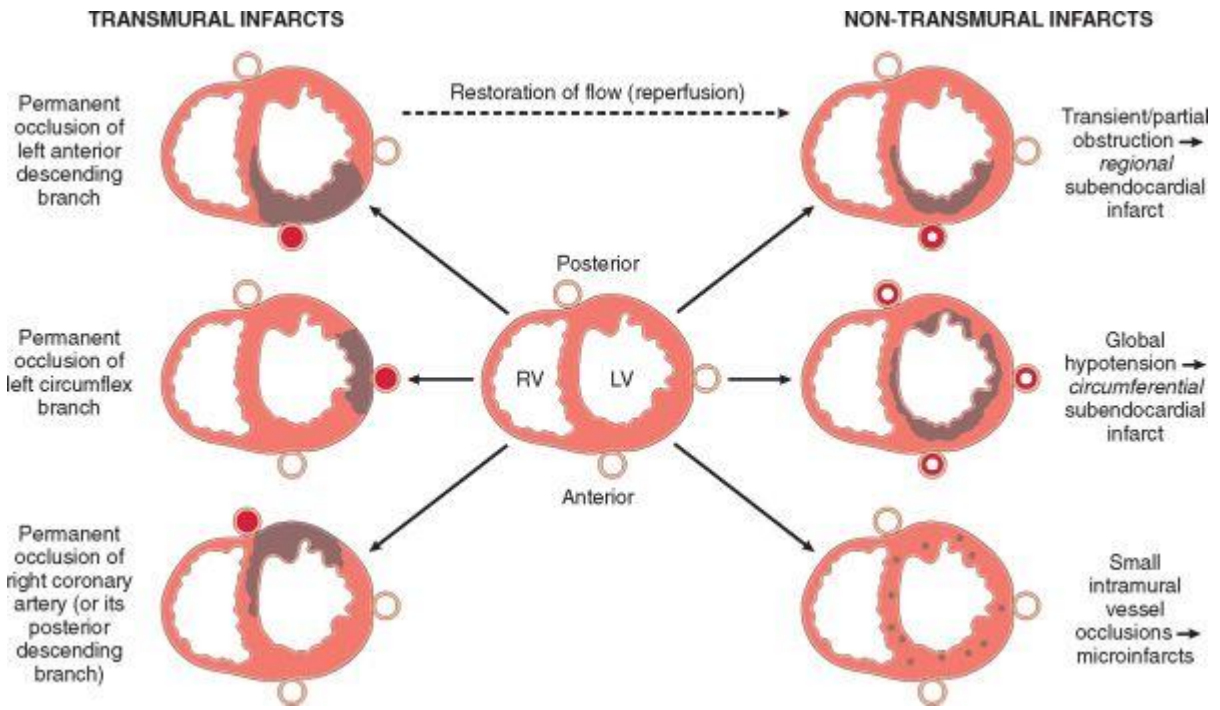

FIGURE 12-13 Distribution of myocardial ischemic necrosis correlated with the location and nature of decreased perfusion. Left, The positions of transmural acute infarcts resulting from occlusions of the major coronary arteries; *top to bottom*, left anterior descending, left circumflex, and right coronary arteries. Right, The types of infarcts that result from a partial or transient occlusion, global hypotension, or intramural small vessel occlusions.

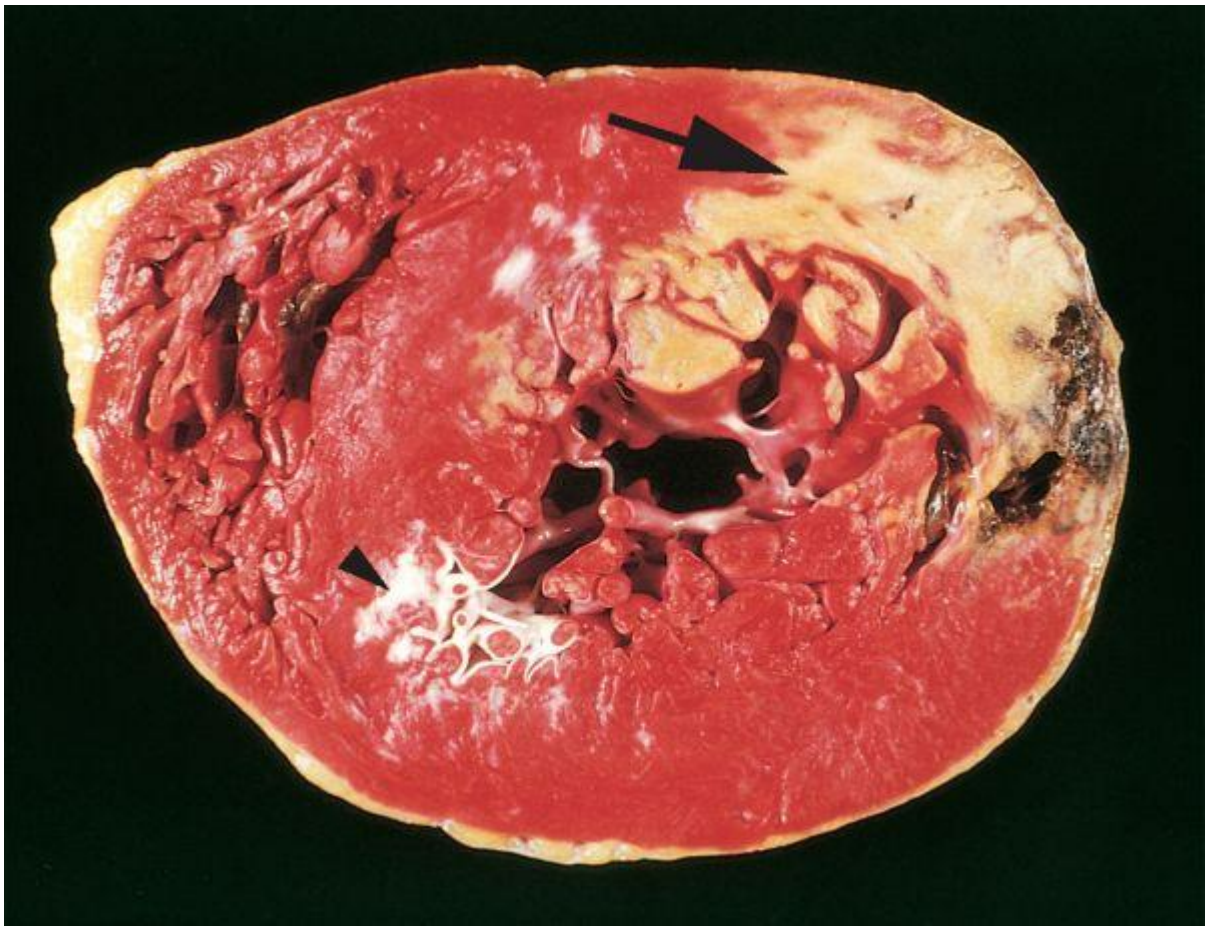

FIGURE 12-14 Acute myocardial infarct, predominantly of the posterolateral left ventricle, demonstrated histochemically by a lack of staining by triphenyltetrazolium chloride in areas of necrosis *(arrow)*. The staining defect is due to the enzyme leakage that follows cell death. Note the myocardial hemorrhage at one edge of the infarct that was associated with cardiac rupture, and the anterior scar *(arrowhead)*, indicative of old infarct. Specimen is oriented with the posterior wall at the top.

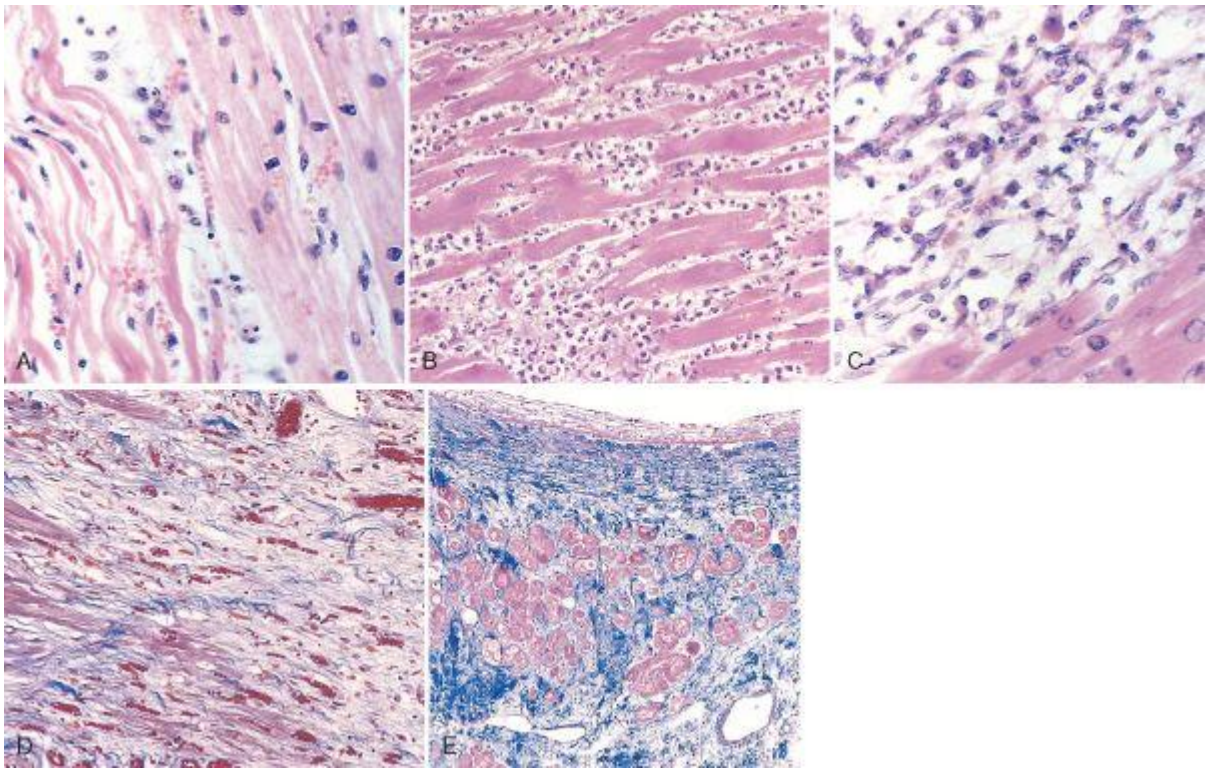

FIGURE 12-15 Microscopic features of myocardial infarction and its repair. **A**, One-day-old infarct showing coagulative necrosis and wavy fibers (elongated and narrow, as compared with adjacent normal fibers *at right*). Widened spaces between the dead fibers contain edema fluid and scattered neutrophils. **B**, Dense polymorphonuclear leukocytic infiltrate in area of acute myocardial infarction of 3 to 4 days' duration. **C**, Nearly complete removal of necrotic myocytes by phagocytosis (approximately 7 to 10 days). **D**, Granulation tissue characterized by loose collagen and abundant capillaries. **E**, Well-healed myocardial infarct with replacement of the necrotic fibers by dense collagenous scar. A few residual cardiac muscle cells are present.

We now consider interventions that seek to limit infarct size by salvaging myocardium that is not yet necrotic.

Infarct Modification by Reperfusion.

The most effective way to "rescue" ischemic myocardium threatened by infarction is to restore myocardial blood flow as rapidly as possible, a process referred to as *reperfusion*.[51] Although this can often be accomplished, reperfusion may also trigger deleterious complications, including arrhythmias, myocardial hemorrhage with contraction bands, irreversible cell damage superimposed on the original ischemic injury *(reperfusion injury)*, microvascular injury, and prolonged ischemic dysfunction *(myocardial stunning);* these are discussed below and summarized in Figures 12-16 and 12-17 . Coronary intervention (i.e., thrombolysis, angioplasty, stent placement, or coronary artery bypass graft [CABG] surgery) is often used in an attempt to dissolve, mechanically alter, or bypass the lesion that initiated the acute MI. The purpose of these treatments is to restore blood flow to the area at risk for infarction and rescue the ischemic (but not yet necrotic) heart muscle. Because loss of myocardial viability in infarction is progressive, occurring over a period of at least several hours (see Fig. 12-11B and Fig. 12-17A), early reperfusion can salvage myocardium and thereby limit infarct size, with consequent improvement in both short- and long-term function and survival. The potential benefit of reperfusion is related to (1) the rapidity with which the coronary obstruction is alleviated (the first 3 to 4 hours following onset are critical) and (2) the extent of correction of the vascular occlusion and the

underlying causal lesion. For example, thrombolysis can remove a thrombus occluding a coronary artery, but does not alter the underlying atherosclerotic plaque that initiated it. In contrast, percutaneous transluminal coronary angioplasty (PTCA) with stent placement not only eliminates a thrombotic occlusion but also can relieve some of the original obstruction and instability caused by the underlying disrupted plaque. CABG provides flow around a blocked vessel.

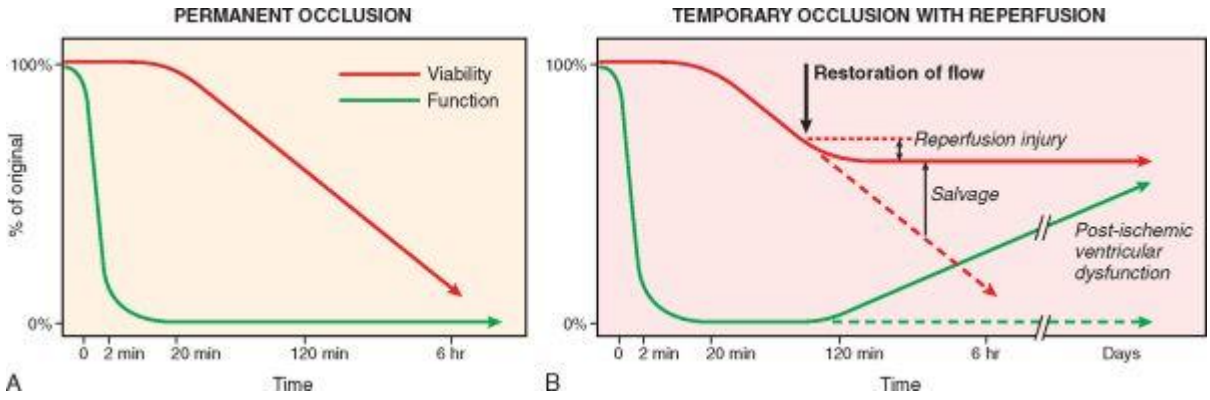

FIGURE 12-17 Effects of reperfusion on myocardial viability and function. Following coronary occlusion, contractile function is lost within 2 minutes and viability begins to diminish after approximately 20 minutes. If perfusion is not restored (**A**), then nearly all myocardium in the affected region will die. **B**, If flow is restored, then some necrosis is prevented, myocardium is salvaged, and at least some function will return. The earlier reperfusion occurs, the greater the degree of salvage. However, the process of reperfusion itself may induce some damage *(reperfusion injury)*, and return of function of salvaged myocardium may be delayed for hours to days *(post-ischemic ventricular dysfunction)*.

Recall that (1) severe ischemia does not cause immediate cell death even in the most severely affected regions of myocardium, and (2) not all regions of myocardium are equally ischemic. Therefore, the outcome following the restoration of blood flow may vary from region to region. As indicated in Figure 12-16A , reperfusion of myocardium within 20 minutes of the onset of ischemia may completely prevent necrosis. Reperfusion after a longer interval may not prevent all necrosis but can salvage at least some myocytes that would have otherwise died.

The typical appearance of reperfused myocardium is illustrated in Figure 12-16B and C. A reperfused infarct is usually hemorrhagic because the vasculature is injured during the period of ischemia and leaks when flow is restored. Microscopic examination reveals that myocytes that were irreversibly injured at the time of reperfusion often contain *contraction bands*, intensely eosinophilic intracellular "stripes" composed of closely packed sarcomeres. These result from the exaggerated contraction of myofibrils when perfusion is reestablished, at which time the interior of dead cells with damaged plasma membranes are exposed to a high concentration of calcium ions from the plasma. Thus, *reperfusion not only salvages reversibly injured cells but also alters the morphology of lethally injured cells*.

In addition to its benefits, reperfusion may also have some deleterious effects on the vulnerable ischemic myocardium (*reperfusion injury;* see Fig. 12-17B).[52] The clinical significance of myocardial reperfusion injury is uncertain. As discussed in Chapter 1 , reperfusion injury may be mediated by oxidative stress, calcium overload, and potentially inflammation initiated during reperfusion. Reperfusion-induced microvascular injury causes not only hemorrhage but also endothelial swelling that occludes capillaries and may limit the reperfusion of critically injured myocardium (called *no-reflow*).

Biochemical abnormalities may also persist for a period of days to several weeks in myocytes that are rescued from ischemia by reperfusion. These are thought to underlie a phenomenon referred to as *stunned myocardium*, a state of reversible cardiac failure that usually recovers after several days.[53] Reperfusion also frequently induces arrhythmias. Myocardium that is subjected to chronic, sublethal ischemia may also enter into a state of lowered metabolism and function that is referred to as *hibernation*.[54] The function of hibernating myocardium may be restored by revascularization (e.g., by CABG surgery, angioplasty, or stenting). Paradoxically, repetitive short-lived transient severe ischemia may protect the myocardium against infarction (a phenomenon known as *preconditioning*) by mechanisms that are not understood.[55]

Clinical Features.

MI is diagnosed by clinical symptoms, laboratory tests for the presence of myocardial proteins in the plasma, and characteristic electrocardiographic changes. Patients with MI often present with a rapid, weak pulse and profuse sweating (diaphoresis). Dyspnea due to impaired contractility of the ischemic myocardium and the resultant pulmonary congestion and edema is common. However, in about 10% to 15% of patients the onset is entirely asymptomatic and the disease is discovered only by electrocardiographic changes or laboratory tests that show evidence of myocardial damage (see below). Such "silent" MIs are particularly common in elderly patients and in the setting of diabetes mellitus.

The laboratory evaluation of MI is based on measuring the blood levels of proteins that leak out of fatally injured myocytes; these molecules include myoglobin, cardiac troponins T and I, the MB fraction of creatine kinase (CK-MB), lactate dehydrogenase, and many others (Fig. 12-18).[56] The diagnosis of myocardial injury is established when blood levels of these cardiac biomarkers are increased in the clinical setting of acute ischemia. The rate of appearance of these markers in the peripheral circulation depends on several factors, including their intracellular location and molecular weight, the blood flow and lymphatic drainage in the area of the infarct, and the rate of elimination of the marker from the blood.

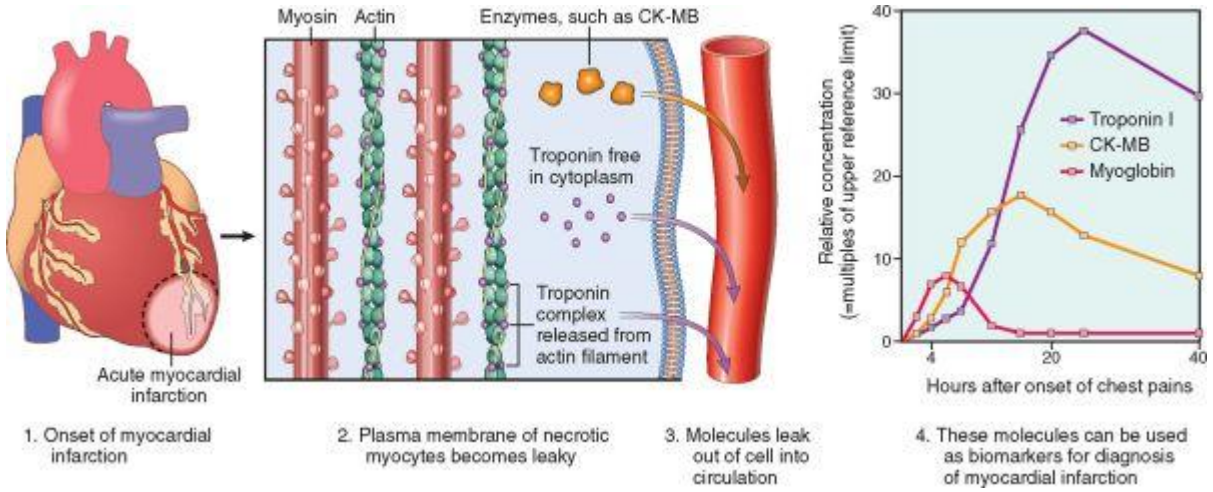

FIGURE 12-18 Release of myocyte proteins in myocardial infarction. Some of these proteins (e.g., troponin I, C, or T and creatine phosphokinase, MB fraction [CK-MB]) are used as diagnostic biomarkers.

The most sensitive and specific biomarkers of myocardial damage are cardiac-specific proteins, particularly Troponins I and T (proteins that regulate calcium-mediated contraction of cardiac and

skeletal muscle). Troponins I and T are not normally detectable in the circulation. Following an MI, levels of both begin to rise at 2 to 4 hours and peak at 48 hours. Formerly the "gold standard," cardiac creatine kinase remains useful. Creatine kinase, an enzyme that is present in brain, myocardium, and skeletal muscle, is a dimer composed of two isoforms designated "M" and "B." MM homodimers are found predominantly in cardiac and skeletal muscle; BB homodimers in brain, lung, and many other tissues; and MB heterodimers principally in cardiac muscle, with lesser amounts also being found in skeletal muscle. As a result, the MB form of creatine kinase (CK-MB) is sensitive but not specific, since it is also elevated when skeletal muscle is injured. CK-MB begins to rise within 2 to 4 hours of the onset of MI, peaks at about 24 hours, and returns to normal within approximately 72 hours. Although the diagnostic sensitivities of cardiac troponin and CK-MB measurements are similar in the early stages of MI, elevated troponin levels persist for approximately 7 to 10 days after acute MI, well after CK-MB levels have returned to normal. Troponin and CK-MB levels peak earlier in patients whose hearts are successfully reperfused, because proteins are washed out of the necrotic tissue more rapidly. *Unchanged levels of CK-MB and troponin over a period of 2 days essentially excludes the diagnosis of MI*.

Consequences and Complications of MI.

Extraordinary progress has been made in the treatment of patients with acute MI. Concurrent with the decrease in the overall mortality of IHD since the 1960s, the in-hospital death rate has declined from around 30% to approximately 7% in patients receiving timely therapy. Half of the deaths associated with acute MI occur within 1 hour of onset; most of these individuals never reach the hospital. Therapies given routinely in the setting of acute MI include aspirin and heparin (to prevent further thrombosis); oxygen (to minimize ischemia); nitrates (to induce vasodilation and reverse vasospasm); beta-adrenergic inhibitors (beta-blockers, to diminish cardiac oxygen demand and decrease the risk of arrythmias); angiotensinogen converting enzyme (ACE) inhibitors (to limit venticular dilation); and maneuvers that aim to open up blocked vessels, including the administration of fibrinolytic agents, coronary angioplasty with or without stenting, and emergent CABG surgery. The choice of therapy depends on the clinical picture and the expertise of the treating institution. Angioplasty is highly effective in skilled hands, while fibinolytic therapy can be given with almost equivalent efficacy by simple infusion. In general, factors associated with a poor prognosis include advanced age, female gender, diabetes mellitus, and, as a result of the cumulative loss of functional myocardium, previous MI.

Despite these interventions, many patients have one or more complications following acute MI, including the following (some of which are illustrated in Fig. 12-19):

- *Contractile dysfunction. Myocardial infarcts produce abnormalities in left ventricular function roughly proportional to their size*. There is usually some degree of left ventricular failure with hypotension, pulmonary vascular congestion, and interstitial pulmonary transudates, which may progress to frank pulmonary edema and respiratory impairment. Severe "pump failure" *(cardiogenic shock)* occurs in 10% to 15% of patients following acute MI, generally those with a large infarct (>40% of the left ventricle). Cardiogenic shock has a nearly 70% mortality rate and accounts for two thirds of in-hospital deaths.
- *Arrhythmias*. Many patients have *myocardial irritability* and/or conduction disturbances following MI that lead to potentially fatal arrhythmias. MI-associated arrhythmias include sinus bradycardia, heart block (asystole), tachycardia, ventricular premature contractions or ventricular tachycardia, and ventricular fibrillation. Because of the location of portions of the atrioventricular conduction system (bundle of His) in the inferoseptal myocardium, infarcts of this region may also be associated with heart block.
- *Myocardial rupture*. The *cardiac rupture syndromes* result from softening and weakening of the necrotic and subsequently inflamed myocardium. They include (1) rupture of the ventricular free wall (most common), with hemopericardium and cardiac tamponade (Fig. 12-19A); (2) rupture of the ventricular septum (less common), leading to an *acute VSD* and left-to-right shunting (Fig. 12-19B); and (3) papillary muscle rupture (least common), resulting in the acute onset of severe mitral regurgitation (Fig. 12-19C). Free-wall rupture is most frequent 3 to 7 days after MI, when coagulative necrosis, neutrophilic infiltration, and lysis of the myocardial connective tissue have appreciably weakened the infarcted myocardium (mean, 4 to 5 days;

range, 1 to 10 days). The anterolateral wall at the midventricular level is the most common site for postinfarction free-wall rupture. Risk factors for free-wall rupture include age over 60, female gender, and preexisting hypertension. This complication occurs less frequently in patients without prior MI because associated fibrotic scarring tends to inhibit myocardial tearing. Acute free-wall ruptures are usually rapidly fatal. However, a fortuitously located pericardial adhesion that partially aborts a rupture may result in a *false aneurysm* (localized hematoma communicating with the ventricular cavity). The wall of a false aneurysm consists only of epicardium and adherent parietal pericardium and thus many still ultimately rupture.

- *Pericarditis*. A fibrinous or fibrinohemorrhagic pericarditis (Dressler syndrome) usually develops about the second or third day following a transmural infarct as a result of underlying myocardial inflammation (Fig. 12-19D).
- *Right ventricular infarction*. Isolated infarction of the right ventricle is unusual, but infarction of some right ventricular myocardium often accompanies ischemic injury of the adjacent posterior left ventricle and ventricular septum. Right ventricular infarcts of either type cause acute right-sided heart failure associated with pooling of blood in the venous circulation and systemic hypotension.
- Infarct *extension*. New necrosis may occur adjacent to an existing infarct.
- Infarct *expansion*. As a result of the weakening of necrotic muscle, there may be disproportionate stretching, thinning, and dilation of the infarct region (especially with anteroseptal infarcts), which is often associated with mural thrombus (Fig. 12-19E).
- *Mural thrombus*. With any infarct, the combination of a local abnormality in contractility (causing stasis) and endocardial damage (creating a thrombogenic surface) can foster *mural thrombosis* (Chapter 4) and potentially *thromboembolism*.
- *Ventricular aneurysm*. In contrast to the *false aneurysms* mentioned above, *true* aneurysms of the ventricular wall are bounded by myocardium that has become scarred. Aneurysms of the ventricular wall are a late complication of large transmural infarcts that experience early expansion. The thin scar tissue wall of an aneurysm paradoxically bulges during systole (Fig. 12-19F). Complications of ventricular aneurysms include mural thrombus, arrhythmias, and heart failure; rupture of the tough fibrotic wall is not a concern.
- *Papillary muscle dysfunction*. As mentioned above, rupture of a papillary muscle may occur following an MI. More frequently, postinfarct mitral regurgitation results from ischemic dysfunction of a papillary muscle and underlying myocardium and later from papillary muscle fibrosis and shortening, or from ventricular dilation (see below).
- *Progressive late heart failure* (chronic IHD is discussed below).

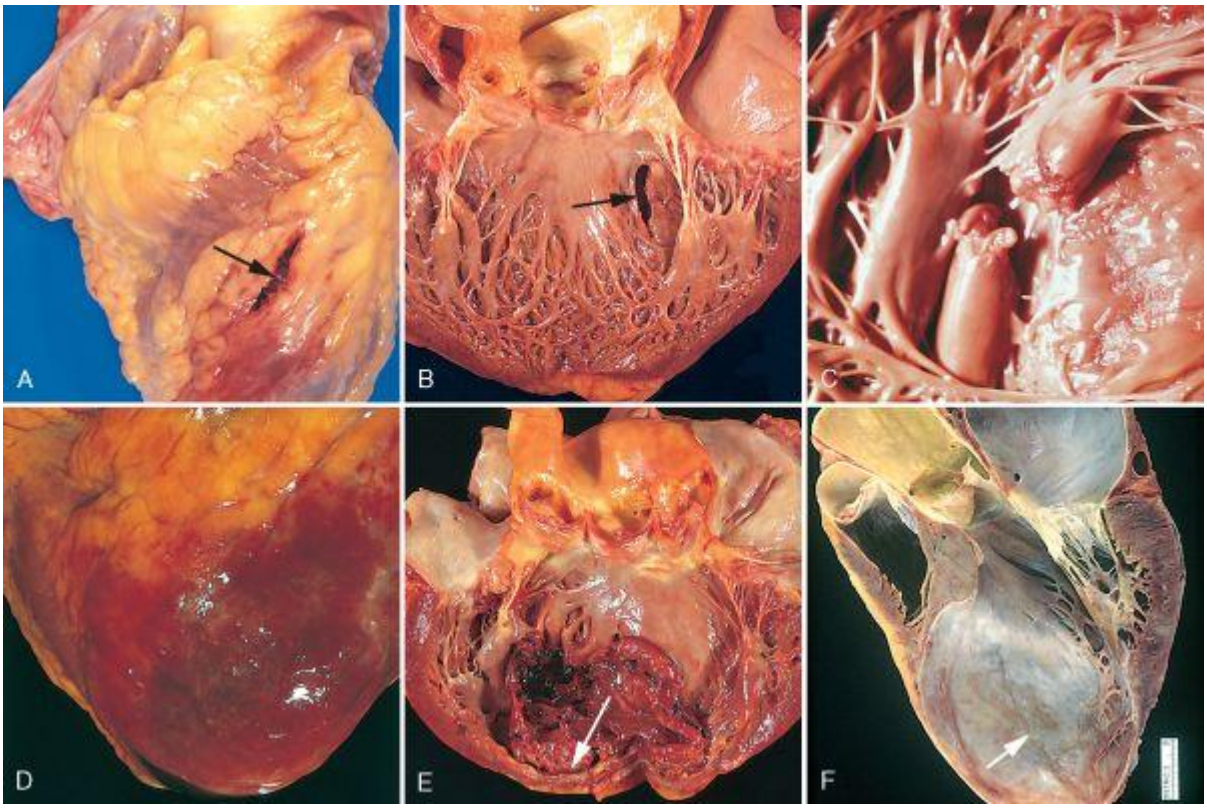

FIGURE 12-19 Complications of myocardial infarction. Cardiac rupture syndromes (**A**–**C**). **A**, Anterior myocardial rupture in an acute infarct *(arrow)*. **B**, Rupture of the ventricular septum *(arrow)*. **C**, Complete rupture of a necrotic papillary muscle. **D**, Fibrinous pericarditis, showing a dark, roughened epicardial surface overlying an acute infarct. **E**, Early expansion of anteroapical infarct with wall thinning *(arrow)* and mural thrombus. **F**, Large apical left ventricular aneurysm. The left ventricle is on the *right* in this apical four-chamber view of the heart. *(**A–E**, Reproduced by permission from Schoen FJ: Interventional and Surgical Cardiovascular Pathology: Clinical Correlations and Basic Principles. Philadelphia, WB Saunders, 1989; **F**, Courtesy of William D. Edwards, MD, Mayo Clinic, Rochester, MN.)*

The risk of specific postinfarct complications and the prognosis depend primarily on the infarct size, location, and thickness (subendocardial or transmural). Large transmural infarcts yield a higher probability of cardiogenic shock, arrhythmias, and late CHF. Patients with anterior transmural infarcts are at greatest risk for free-wall rupture, expansion, mural thrombi, and aneurysm. In contrast, posterior transmural infarcts are more likely to be complicated by conduction blocks, right ventricular involvement, or both; when acute VSDs occur in this area they are more difficult to manage. Overall, however, patients with anterior infarcts have a worse clinical course than those with inferior (posterior) infarcts. With subendocardial infarcts, only rarely do pericarditis, rupture, and aneurysms occur.

In addition to the sequence of repair in the infarcted tissues described above, the noninfarcted segments of the ventricle undergo hypertrophy and dilation; collectively, these changes are termed *ventricular remodeling*. The compensatory hypertrophy of noninfarcted myocardium is initially hemodynamically beneficial. However, this adaptive effect may be overwhelmed by ventricular dilation (with or without ventricular aneurysm) and increased oxygen demand, which can exacerbate ischemia and depress cardiac function. There may also be changes in ventricular shape and stiffening of the ventricle due to scar formation and hypertrophy that further diminish cardiac output. Some of these deleterious effects appear to be reduced by ACE inhibitors, which lessen the ventricular dilation that occurs after MI.

Long-term prognosis after MI depends on many factors, the most important of which are the quality of residual left ventricular function and the extent of vascular obstructions in vessels that perfuse the viable myocardium. The overall total mortality within the first year is about 30%. Thereafter there is a 3% to 4% mortality among survivors with each passing year. Infarct prevention through control of risk factors in individuals who have never experienced MI *(primary prevention)* and prevention of reinfarction in those who have recovered from an acute MI *(secondary prevention)* are important strategies that have received much attention and achieved considerable success.

The relationship of the causes, pathophysiology, and consequences of MI are summarized in Figure 12-20 , including the possible outcomes of chronic IHD and sudden death, to be discussed next.

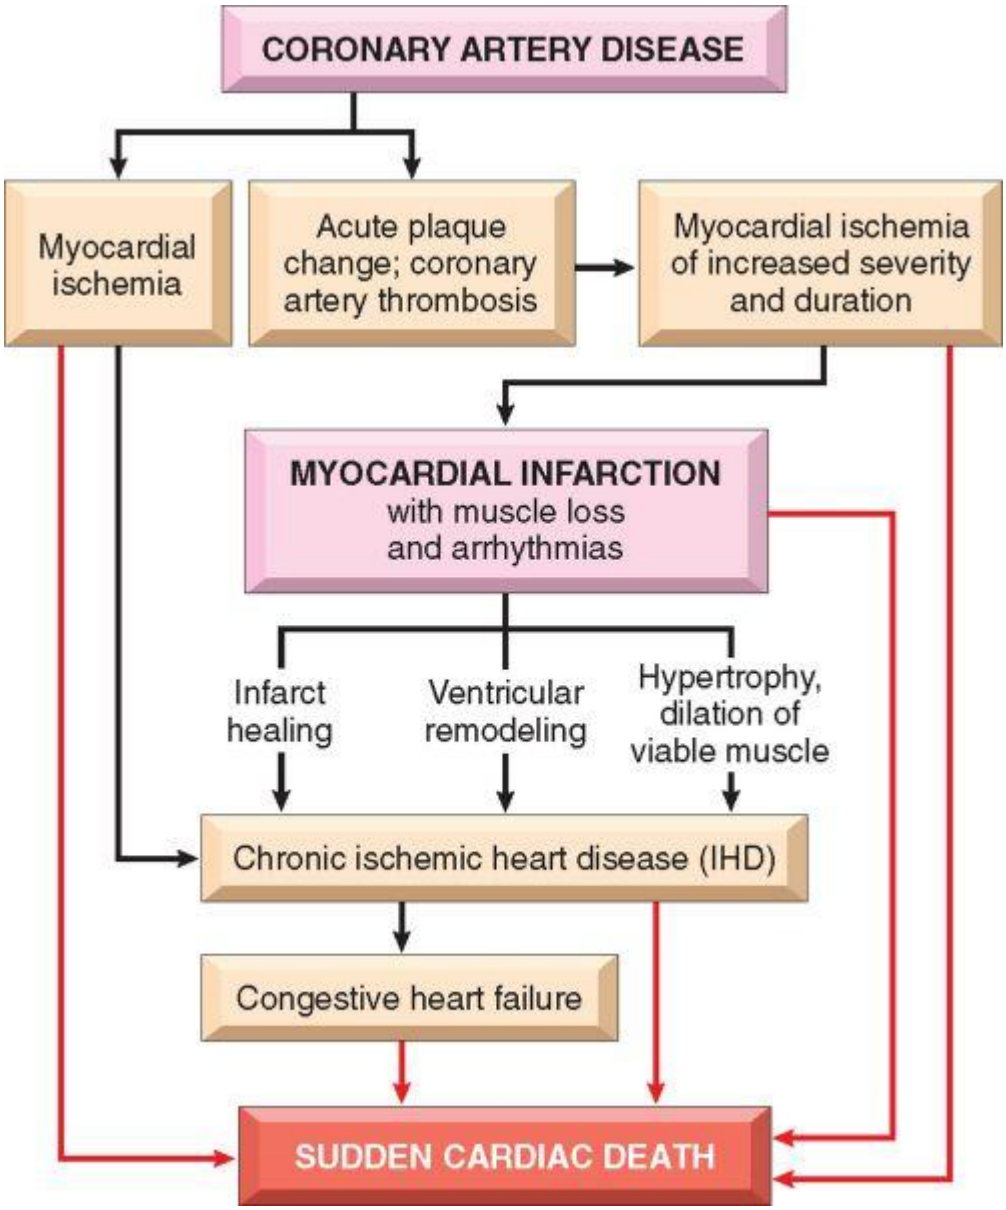

FIGURE 12-20 Schematic of the various pathways in the progression of ischemic heart disease (IHD), showing the interrelationships among coronary artery disease, acute plaque change, myocardial ischemia, myocardial infarction, chronic IHD, congestive heart failure, and sudden cardiac death.

CHRONIC IHD

The designation chronic IHD is used here to describe progressive heart failure as a consequence of ischemic myocardial damage. The term *ischemic cardiomyopathy* is often used by clinicians to describe chronic IHD. In most instances there has been prior MI and sometimes previous coronary arterial interventions and/or bypass surgery. Chronic IHD usually appears postinfarction due to the functional decompensation of hypertrophied noninfarcted myocardium (see earlier discussion of cardiac hypertrophy). However, in other cases severe obstructive coronary artery disease may present as chronic IHD in the absence of prior infarction.

Morphology. Hearts from patients with chronic IHD are usually enlarged and heavy, due to left ventricular hypertrophy and dilation. Invariably there is some degree of obstructive coronary atherosclerosis. Discrete scars representing healed infarcts are usually present. The mural endocardium may have patchy, fibrous thickenings, and mural thrombi may be present. Microscopic findings include myocardial hypertrophy, diffuse subendocardial vacuolization, and fibrosis.

Clinically, progressive CHF may occur in patients who have had past episodes of MI or anginal attacks. In some individuals, however, progressive myocardial damage is silent, and heart failure is the first indication of IHD. The diagnosis rests largely on the exclusion of other cardiac diseases. Patients with chronic IHD account for nearly half of cardiac transplant recipients.

SUDDEN CARDIAC DEATH

Sudden cardiac death (SCD) strikes down about 300,000 to 400,000 individuals annually in the United States. It is defined as unexpected death from cardiac causes in individuals without symptomatic heart disease or early after symptom onset (usually within 1 hour). *SCD is usually the consequence of a lethal arrhythmia (e.g., asystole, ventricular fibrillation).* It most frequently occurs in the setting of IHD; in some cases, SCD is the first clinical manifestation of IHD.

Acute myocardial ischemia is the most common trigger for fatal arrhythmias.[57] Although ischemic injury can affect the conduction system and create electromechanical cardiac instability, fatal arrhythmias usually result from acute ischemia-induced electrical instability of myocardium that is distant from the conduction system. Arrythmogenic foci are often located adjacent to scars left by old MIs.

Nonatherosclerotic conditions associated with SCD include

- Congenital structural or coronary arterial abnormalities
- Aortic valve stenosis
- Mitral valve prolapse
- Myocarditis
- Dilated or hypertrophic cardiomyopathy
- Pulmonary hypertension
- Hereditary or acquired cardiac arrhythmias
- Cardiac hypertrophy of any cause (e.g., hypertension)
- Other miscellaneous causes, such as systemic metabolic and hemodynamic alterations, catecholamines, and drugs of abuse, particularly cocaine and methamphetamine.

Morphology. Marked coronary atherosclerosis with a critical (>75%) stenosis involving one or more of the three major vessels is present in 80% to 90% of SCD victims; only 10% to 20% of cases are of nonatherosclerotic origin. Usually there are high-grade stenoses (>90%); in approximately one half, acute plaque disruption is observed, and in approximately 25% diagnostic changes of acute MI are seen.[58] This suggests that many patients who die suddenly are suffering an MI, but the short interval from onset to death precludes the development of diagnostic myocardial changes. However, in one study of those who had been successfully resuscitated from a sudden cardiac arrest, a new MI occurred in only 39% of the patients.[59] Thus, most SCD is not associated with acute MI; most of these deaths are thought to result from myocardial ischemia–induced irritability that initiates malignant ventricular arrhythmias. Scars of previous infarcts and subendocardial myocyte vacuolization indicative of severe chronic ischemia are common in such patients.

Heritable conditions associated with SCD are of importance, since they may provide a basis for intervention in surviving family members.[60] Some of these disorders are associated with recognizable anatomic abnormalities (e.g., congenital anomalies, hypertrophic cardiomyopathy, mitral valve prolapse). However, other heritable arrhythmias can precipitate sudden death in the absence of structural cardiac pathology (so-called primary electrical disorders). These syndromes can only be diagnosed definitively by genetic testing, which is performed in those with a positive family history or an unexplained nonlethal arrhythmia.

The primary electrical abnormalities of the heart that predispose to SCD include long QT syndrome, Brugada syndrome, short QT syndrome, catecholaminergic polymorphic ventricular tachycardia, Wolff-Parkinson-White syndrome, congenital sick sinus syndrome, and isolated cardiac conduction disease.[61] The most important of these disorders are the so-called *channelopathies*, which are caused by mutations in genes that are required for normal ion channel function.[62] These disorders (mostly with autosomal-dominant inheritance) either involve genes that encode the ion channels (including Na^+, K^+, and Ca^+), or accessory proteins that are essential for the normal function of the same channels, which are responsible for conducting the electrical currents that mediate contraction of the heart. The prototype is the *long QT syndrome*, characterized by prolongation of the QT segment in electrocardiograms and susceptibility to malignant ventricular arrhythmias. Mutations in seven different genes account for the majority of cases of long QT syndrome. The most frequent mutations are in the gene encoding KCNQ1 and result in decreased potassium currents. Ion channels are needed for the normal function of many tissues, and certain channelopathies are also associated with skeletal muscle disorders and diabetes; however, the most common cardiac channelopathies are isolated disorders of the heart.

The prognosis of many patients vulnerable to SCD, including those with chronic IHD, is markedly improved by implantation of a pacemaker or an automatic cardioverter defibrillator, which senses and electrically counteracts an episode of ventricular fibrillation.[63]

3.2.7 Hypertensive Heart Disease

Hypertensive heart disease (HHD) stems from the increased demands placed on the heart by hypertension, which causes pressure overload and ventricular hypertrophy. Although most commonly seen in the left heart as the result of systemic hypertension, pulmonary hypertension can cause right-sided HHD, or *cor pulmonale*.

SYSTEMIC (LEFT-SIDED) HYPERTENSIVE HEART DISEASE

In hypertension, hypertrophy of the heart is an adaptive response to pressure overload that can lead to myocardial dysfunction, cardiac dilation, CHF, and in some cases sudden death. *The minimal criteria*

for the diagnosis of systemic HHD are the following: (1) left ventricular hypertrophy (usually concentric) in the absence of other cardiovascular pathology and (2) a history or pathologic evidence of hypertension. The Framingham Study established unequivocally that even mild hypertension (levels only slightly above 140/90 mm Hg), if sufficiently prolonged, induces left ventricular hypertrophy. Approximately 25% of the population of the United States suffers from hypertension of at least this degree. The pathogenesis of hypertension is discussed in Chapter 11 .

Morphology. Hypertension induces left ventricular pressure overload hypertrophy, initially without ventricular dilation. As a result, the left ventricular wall thickening increases the weight of the heart disproportionately to the increase in overall cardiac size (Fig. 12-21A). The thickness of the left ventricular wall may exceed 2.0 cm, and the heart weight may exceed 500 gm. In time the increased thickness of the left ventricular wall imparts a stiffness that impairs diastolic filling, often inducing left atrial enlargement.

Microscopically, the earliest change of systemic HHD is an increase in the transverse diameter of myocytes, which may be difficult to appreciate on routine microscopy. At a more advanced stage variable degrees of cellular and nuclear enlargement become apparent, often accompanied by interstitial fibrosis. The biochemical, molecular, and morphologic changes that occur in hypertensive hypertrophy are similar to those noted in other conditions associated with myocardial pressure overload.

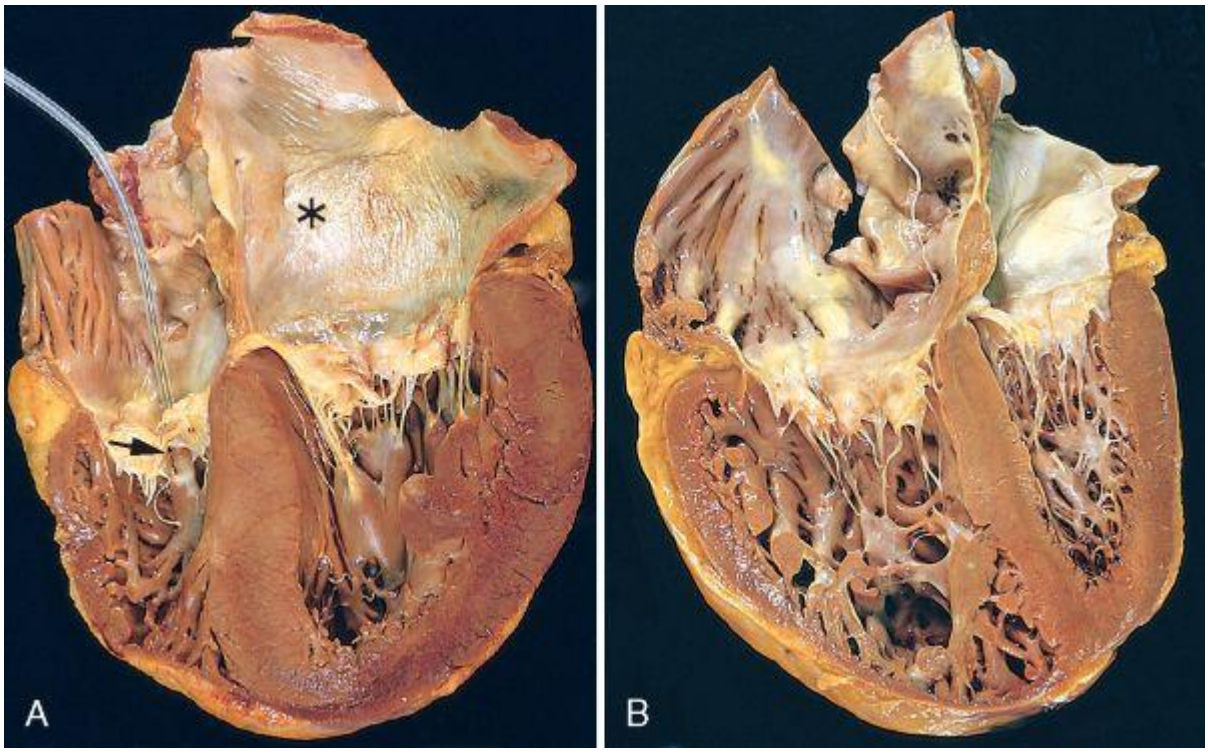

FIGURE 12-21 Hypertensive heart disease, systemic and pulmonary. **A**, Systemic (left-sided) hypertensive heart disease. There is marked concentric thickening of the left ventricular wall causing reduction in lumen size. The left ventricle and left atrium (*asterisk*) is on the *right* in this apical four-chamber view of the heart. A pacemaker is present in the right ventricle *(arrow)*. **B**, Pulmonary (right-sided) hypertensive heart disease (cor pulmonale). The right ventricle is markedly dilated and has a thickened free wall and hypertrophied trabeculae (apical four-chamber view of heart, right ventricle on *left*). The shape of the left ventricle (to the *right*) has been distorted by the enlarged right ventricle.

Compensated systemic HHD may be asymptomatic, producing only electrocardiographic or echocardiographic evidence of left ventricular enlargement. In many patients, systemic HHD comes to attention due to new atrial fibrillation induced by left atrial enlargement or CHF. Depending on the severity, duration, and underlying basis of the hypertension, and on the adequacy of therapeutic control, the patient may (1) enjoy normal longevity and die of unrelated causes, (2) develop IHD due to the potentiating effects of hypertension on coronary atherosclerosis, (3) suffer renal damage or cerebrovascular stroke as direct effects of hypertension, or (4) experience progressive heart failure or SCD. Effective control of hypertension can prevent or lead to regression of cardiac hypertrophy and its associated risks.

PULMONARY (RIGHT-SIDED) HYPERTENSIVE HEART DISEASE (COR PULMONALE)

Normally, because the pulmonary vasculature is the low pressure side of the circulation, the right ventricle has a thinner and more compliant wall than the left ventricle.[64] *Cor pulmonale*, as isolated pulmonary HHD is frequently called, stems from pressure overload of the right ventricle,[65] and is characterized by right ventricular hypertrophy, dilation, and potentially failure secondary to pulmonary hypertension. The most frequent causes are disorders of the lungs, especially chronic respiratory diseases such as emphysema, or primary pulmonary hypertension (Table 12-6). It should be remembered, however, that pulmonary venous hypertension most commonly occurs as a complication of left-sided heart diseases of various etiologies.

TABLE 12-6 -- Disorders Predisposing to Cor Pulmonale

DISEASES OF THE PULMONARY PARENCHYMA
Chronic obstructive pulmonary disease
Diffuse pulmonary interstitial fibrosis
Pneumoconioses
Cystic fibrosis
Bronchiectasis
DISEASES OF THE PULMONARY VESSELS
Recurrent pulmonary thromboembolism
Primary pulmonary hypertension
Extensive pulmonary arteritis (e.g., Wegener granulomatosis)
Drug-, toxin-, or radiation-induced vascular obstruction
Extensive pulmonary tumor microembolism
DISORDERS AFFECTING CHEST MOVEMENT
Kyphoscoliosis
Marked obesity (sleep apnea, pickwickian syndrome)
Neuromuscular diseases
DISORDERS INDUCING PULMONARY ARTERIAL CONSTRICTION
Metabolic acidosis

Hypoxemia
Chronic altitude sickness
Obstruction of major airways
Idiopathic alveolar hypoventilation

Cor pulmonale may be acute or chronic. *Acute cor pulmonale* can follow massive pulmonary embolism. *Chronic cor pulmonale* results from right ventricular hypertrophy (and dilation) secondary to prolonged pressure overload, such as can occur with chronic lung diseases and a variety of other conditions, many of which are discussed in more detail in Chapter 15 .

Morphology. In acute cor pulmonale there is marked dilation of the right ventricle without hypertrophy. On cross-section the normal crescent shape of the right ventricle is transformed to a dilated ovoid. In chronic cor pulmonale the right ventricular wall thickens, sometimes up to 1.0 cm or more (Fig. 12-21B). More subtle right ventricular hypertrophy may take the form of thickening of the muscle bundles in the outflow tract, immediately below the pulmonary valve, or thickening of the moderator band, the muscle bundle that connects the ventricular septum to the anterior right ventricular papillary muscle. Sometimes, the hypertrophied right ventricle compresses the left ventricular chamber, or leads to regurgitation and fibrous thickening of the tricuspid valve. Normally, the myocytes of the right ventricle are haphazardly arranged and the wall contains transmural fat; in right ventricular hypertrophy, fat in the wall disappears and the myocytes align themselves circumferentially.

3.2.8 Valvular Heart Disease

Valvular disease can come to clinical attention due to stenosis, insufficiency (regurgitation or incompetence), or both. *Stenosis is the failure of a valve to open completely, which impedes forward flow. Insufficiency, in contrast, results from failure of a valve to close completely, thereby allowing reversed flow*. These abnormalities can be present alone or coexist, and may involve only a single valve (*isolated disease*) or more than one valve (*combined disease*). *Functional regurgitation* is used to describe the incompetence of a valve stemming from an abnormality in one of its support structures. For example, dilation of the right or left ventricle can pull the ventricular papillary muscles down and outward, thereby preventing proper closure of otherwise normal mitral or tricuspid leaflets. Similarly, dilation of the aortic or pulmonary artery may pull the valve commissures apart and prevent full closure of the aortic or pulmonary valve cusps. Functional mitral valve regurgitation is particularly common in IHD (*ischemic mitral regurgitation*).[66]

The clinical consequences of valve dysfunction vary depending on the valve involved, the degree of impairment, how fast it develops, and the rate and quality of compensatory mechanisms. For example, sudden destruction of an aortic valve cusp by infection (infective endocarditis; see later) can cause acute, massive regurgitation that can be rapidly fatal. In contrast, rheumatic mitral stenosis usually develops indolently over years, and its clinical effects are often remarkably well tolerated. Certain conditions can complicate valvular heart disease by increasing the demands on the heart; for example, pregnancy can exacerbate valve disease and lead to an unfavorable maternal or fetal outcome.[67] Valvular stenosis or insufficiency often produces secondary changes, both proximal and distal to the affected valve. Generally, valvular stenosis leads to pressure overload of the heart, whereas valvular insufficiency leads

to volume overload of the heart. In addition, the ejection of blood through narrowed stenotic valves can produce high speed “jets” of blood that injure the endocardium where they impact.

Valvular abnormalities may be congenital (discussed earlier) or acquired. *Acquired stenoses of the aortic and mitral valves account for approximately two thirds of all cases of valve disease*. Valvular stenosis is almost always due to a chronic abnormality of the valve cusp that becomes clinically evident after many years. Relatively few disorders produce valvular stenosis. In contrast, valvular insufficiency can result from intrinsic disease of the valve cusps or damage to or distortion of the supporting structures (e.g., the aorta, mitral annulus, tendinous cords, papillary muscles, ventricular free wall). Valvular insufficiency has many causes and may appear acutely, as with rupture of the cords, or chronically in disorders associated with leaflet scarring and retraction.

The causes of acquired heart valve diseases are summarized in Table 12-7 and discussed in the following sections. The most frequent causes of the major functional valvular lesions are:

- Aortic stenosis: calcification of anatomically normal and congenitally bicuspid aortic valves
- Aortic insufficiency: dilation of the ascending aorta, usually related to hypertension and aging
- Mitral stenosis: rheumatic heart disease
- Mitral insufficiency: myxomatous degeneration (mitral valve prolapse)

TABLE 12-7 -- Major Etiologies of Acquired Heart Valve Disease

Mitral Valve Disease	Aortic Valve Disease
MITRAL STENOSIS	**AORTIC STENOSIS**
Postinflammatory scarring (rheumatic heart disease)	Postinflammatory scarring (rheumatic heart disease)
	Senile calcific aortic stenosis
	Calcification of congenitally deformed valve
MITRAL REGURGITATION	**AORTIC REGURGITATION**
Abnormalities of Leaflets and Commissures	
Postinflammatory scarring	Postinflammatory scarring (rheumatic heart disease)
Infective endocarditis	Infective endocarditis
Mitral valve prolapse	Marfan syndrome
Drugs (e.g., fen-phen)	
Abnormalities of Tensor Apparatus	***Aortic Disease***
Rupture of papillary muscle	Degenerative aortic dilation
Papillary muscle dysfunction (fibrosis)	Syphilitic aortitis
Rupture of chordae tendineae	Ankylosing spondylitis
	Rheumatoid arthritis
	Marfan syndrome
Abnormalities of Left Ventricular Cavity and/or Annulus	
LV enlargement (myocarditis, dilated cardiomyopathy)	
Calcification of mitral ring

LV, Left ventricular.

VALVULAR DEGENERATION ASSOCIATED WITH CALCIFICATION

Heart valves are subjected to high levels of repetitive mechanical stress, particularly at the hinge points of the cusps and leaflets, as a result of (1) 40 million or more cardiac contractions per year, (2) substantial tissue deformations during each contraction, and (3) transvalvular pressure gradients in the closed phase of each contraction of approximately 120 mm Hg for the mitral and 80 mm Hg for the aortic valve. It is therefore not surprising that these delicate structures can suffer cumulative damage and dystrophic calcification (deposits of calcium phosphate salts) that lead to clinically important dysfunction.[68]

Calcific Aortic Stenosis

The most common of all valvular abnormalities, acquired aortic stenosis, is usually the consequence of age-associated "wear and tear" of either anatomically normal valves or congenitally bicuspid valves (~1% of the population).[69] The prevalence of aortic stenosis, estimated at 2%, is increasing with the rising average age of the population. Aortic stenosis of previously normal valves (termed senile calcific aortic stenosis) usually comes to clinical attention in the seventh to ninth decades of life, whereas stenotic bicuspid valves tend to present in patients 50 to 70 years of age.

Prior work attributed aortic valve calcification to wear and tear degeneration and dystrophic and passive accumulation of hydroxyapatite, the same calcium salt that is found in bone.[70] More recent studies suggest that chronic injury due to hyperlipidemia, hypertension, inflammation, and other factors implicated in atherosclerosis may have a role and perhaps even precede the calcification. It is clear, however, that the valve injury of calcific aortic stenosis differs in some respects from atherosclerosis. Most notably, instead of accumulating smooth muscle cells, the abnormal valves contain cells resembling osteoblasts that synthesize bone matrix proteins and promote the deposition of calcium salts. Bicuspid valves incur greater mechanical stress than normal tricuspid valves, which may explain why they become stenotic more rapidly.

Morphology. The morphologic hallmark of nonrheumatic, calcific aortic stenosis (with either tricuspid or bicuspid valves) is heaped-up calcified masses within the aortic cusps that ultimately protrude through the outflow surfaces into the sinuses of Valsalva, preventing the opening of the cusps. The free edges of the cusps are usually not involved (Fig. 12-22A). The calcific process begins in the valvular fibrosa, at the points of maximal cusp flexion (near the margins of attachment). Microscopically, the layered architecture of the valve is largely preserved. An earlier, hemodynamically inconsequential stage of the calcification process is called **aortic valve sclerosis**. In aortic stenosis the functional valve area is decreased sufficiently by large nodular calcific deposits to cause measurable obstruction to outflow; this subjects the left ventricular myocardium to progressively increasing pressure overload.

In contrast to rheumatic (and congenital) aortic stenosis (see Fig. 12-24E), commissural fusion is not usually seen. The mitral valve is generally normal, although some patients may have direct extension of aortic valve calcific deposits onto the anterior mitral leaflet. In contrast, virtually all patients with rheumatic aortic stenosis also have concomitant and characteristic structural abnormalities of the

mitral valve (see later).

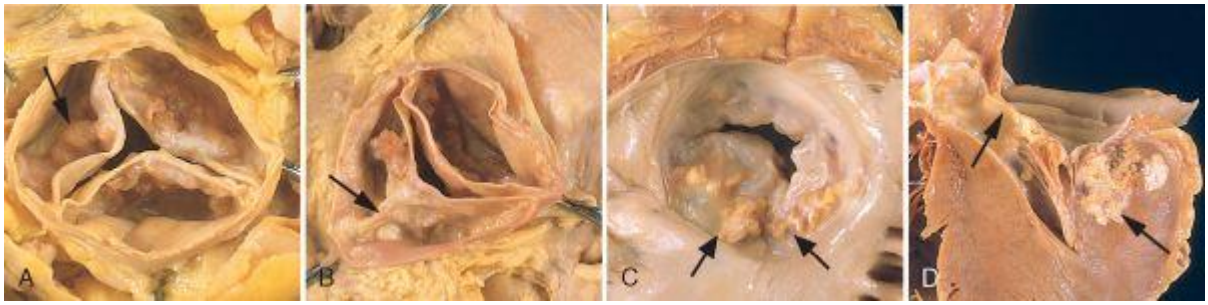

FIGURE 12-22 Calcific valvular degeneration. **A**, Calcific aortic stenosis of a previously normal valve (viewed from aortic aspect). Nodular masses of calcium are heaped up within the sinuses of Valsalva *(arrow)*. Note that the commissures are not fused, as in postrheumatic aortic valve stenosis (see Fig. 12-27E). **B**, Calcific aortic stenosis of a congenitally bicuspid valve. One cusp has a partial fusion at its center, called a *raphe (arrow)*. **C** and **D**, Mitral annular calcification, with calcific nodules at the base (attachment margin) of the anterior mitral leaflet *(arrows)*. **C**, Left atrial view. **D**, Cut section of myocardium.

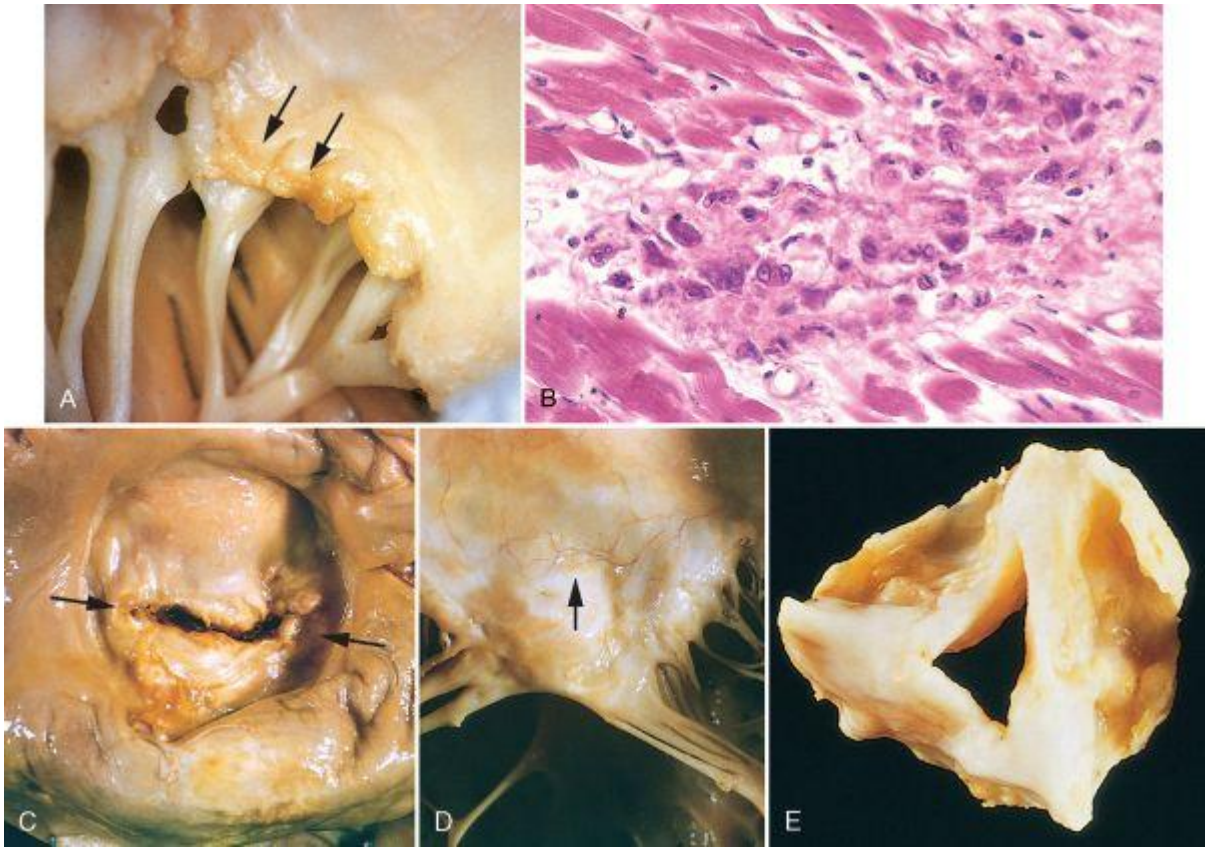

FIGURE 12-24 Acute and chronic rheumatic heart disease. **A**, Acute rheumatic mitral valvulitis superimposed on chronic rheumatic heart disease. Small vegetations (verrucae) are visible along the line of closure of the mitral valve leaflet *(arrows)*. Previous episodes of rheumatic valvulitis have caused fibrous thickening and fusion of the chordae tendineae. **B**, Microscopic appearance of Aschoff body in a patient with acute rheumatic carditis. The myocardial interstitium has a circumscribed collection of mononuclear inflammatory cells, including some large macrophages with prominent nucleoli and a binuclear macrophage, associated with necrosis. **C** and **D**, Mitral stenosis with diffuse fibrous thickening and distortion of the valve leaflets and commissural fusion (*arrows*, C), and thickening of the chordae tendineae (**D**). Note neovascularization of anterior mitral leaflet (*arrow*, D). **E**, Rheumatic aortic stenosis, demonstrating thickening and distortion of the cusps with commissural fusion. *(**E**, Reproduced from Schoen FJ, St. John-Sutton M: Contemporary issues in the*

pathology of valvular heart disease. Hum Pathol 18:568, 1967.)

Clinical Features.

In calcific aortic stenosis (superimposed on a previously normal or bicuspid aortic valve), the obstruction to left ventricular outflow leads to gradual narrowing of the valve orifice (valve area approximately 0.5 to 1 cm^2 in severe aortic stenosis; normal, ~4 cm^2) and an increasing pressure gradient across the calcified valve, reaching 75 to 100 mm Hg in severe cases. Left ventricular pressures rise to 200 mm Hg or more in such instances, producing concentric left ventricular (pressure overload) hypertrophy. The hypertrophied myocardium tends to be ischemic (as a result of diminished microcirculatory perfusion, often complicated by coronary atherosclerosis), and angina pectoris may appear. Both systolic and diastolic myocardial function may be impaired; eventually, cardiac decompensation and CHF may ensue. The onset of symptoms (angina, CHF, or syncope, for which the pathophysiologic basis is poorly understood) in aortic stenosis heralds cardiac decompensation and carries a poor prognosis; ~50% with angina will die within 5 years, and 50% with CHF will die within 2 years, if the obstruction is not alleviated by surgical valve replacement. Medical therapy is ineffective in severe symptomatic aortic stenosis. In contrast, asymptomatic patients with aortic stenosis generally have an excellent prognosis.

Calcific Stenosis of Congenitally Bicuspid Aortic Valve

With a prevalence of approximately 1%, bicuspid aortic valve (BAV) is the most frequent congenital cardiovascular malformation in humans.[71] Although BAV is usually uncomplicated early in life, late complications of BAV include aortic stenosis or regurgitation, infective endocarditis, and aortic dilation and/or dissection. BAVs are predisposed to progressive degenerative calcification, similar to that occurring in aortic valves with initially normal anatomy (see Fig. 12-22B). Bicuspid aortic valves are responsible for approximately 50% of cases of aortic stenosis in adults.[72] Structural abnormalities of the aortic wall commonly accompany BAV, even when the valve is hemodynamically normal, and this may potentiate aortic dilation or aortic dissection (see later). Recent studies have confirmed previous reports of familial clustering of BAV and left ventricular outflow tract obstruction malformations, and their association with other cardiovascular malformations.[73]

In a congenitally bicuspid aortic valve, there are only two functional cusps, usually of unequal size, with the larger cusp having a midline *raphe*, resulting from incomplete commissural separation during development; less frequently the cusps are of equal size and the raphe is absent. The raphe is frequently a major site of calcific deposits. Once stenosis is present, the clinical course is similar to that described above for calcific aortic stenosis. Valves that become bicuspid because of an acquired deformity (e.g., rheumatic valve disease) have a fused commissure that produces a conjoined cusp that is generally twice the size of the nonconjoined cusp. BAVs may also become incompetent as a result of aortic dilation, cusp prolapse, or infective endocarditis. The mitral valve is generally normal in patients with a congenitally bicuspid aortic valve.

Mitral Annular Calcification

Degenerative calcific deposits can develop in the peripheral fibrous ring *(annulus)* of the mitral valve. Grossly, these appear as irregular, stony hard, occasionally ulcerated nodules (2–5 mm in thickness) that lie behind the leaflets (see Fig. 12-22C and D). The process generally does not affect valvular function or otherwise become clinically important. In unusual cases, however, mitral annular calcification may lead to (1) regurgitation by interfering with physiologic contraction of the valve ring, (2) stenosis by

impairing opening of the mitral leaflets, or (3) arrhythmias and occasionally sudden death by penetration of calcium deposits to a depth sufficient to impinge on the atrioventricular conduction system. Because calcific nodules may also provide a site for thrombi that can embolize, patients with mitral annular calcification have an increased risk of stroke, and the calcific nodules can also be the nidus for infective endocarditis. Heavy calcific deposits are sometimes visualized on echocardiography or seen as a distinctive, ringlike opacity on chest radiographs. Mitral annular calcification is most common in women over age 60 and individuals with mitral valve prolapse (see below) or elevated left ventricular pressure (as in systemic hypertension, aortic stenosis, or hypertrophic cardiomyopathy).

MITRAL VALVE PROLAPSE (MYXOMATOUS DEGENERATION OF THE MITRAL VALVE)

In mitral valve prolapse (MVP), one or both mitral valve leaflets are "floppy" and *prolapse*, or balloon back, into the left atrium during systole.[74] The key histologic change in the tissue is called *myxomatous degeneration*. MVP affects approximately 3% of adults in the United States; it is most often an incidental finding on physical examination (particularly in young women), but in a small minority of affected individuals may lead to serious complications.

Morphology. The characteristic anatomic change in MVP is interchordal ballooning (hooding) of the mitral leaflets or portions thereof (Fig. 12-23A –C). The affected leaflets are often enlarged, redundant, thick, and rubbery. The associated tendinous cords may be elongated, thinned, or even ruptured, and the annulus may be dilated. The tricuspid, aortic, or pulmonary valves may also be affected. Histologically, there is attenuation of the collagenous fibrosa layer of the valve, on which the structural integrity of the leaflet depends, accompanied by marked thickening of the spongiosa layer with deposition of mucoid (myxomatous) material (Fig. 12-23E). Secondary changes reflect the stresses and injury incident to the billowing leaflets: (1) fibrous thickening of the valve leaflets, particularly where they rub against each other; (2) linear fibrous thickening of the left ventricular endocardial surface where the abnormally long cords snap or rub against it; (3) thickening of the mural endocardium of the left ventricle or atrium as a consequence of friction-induced injury induced by the prolapsing, hyper-mobile leaflets; (4) thrombi on the atrial surfaces of the leaflets or the atrial walls; and (5) focal calcifications at the base of the posterior mitral leaflet. Mild myxomatous degeneration can also occur in mitral valves secondary to regurgitation of other etiologies (e.g., ischemic dysfunction).

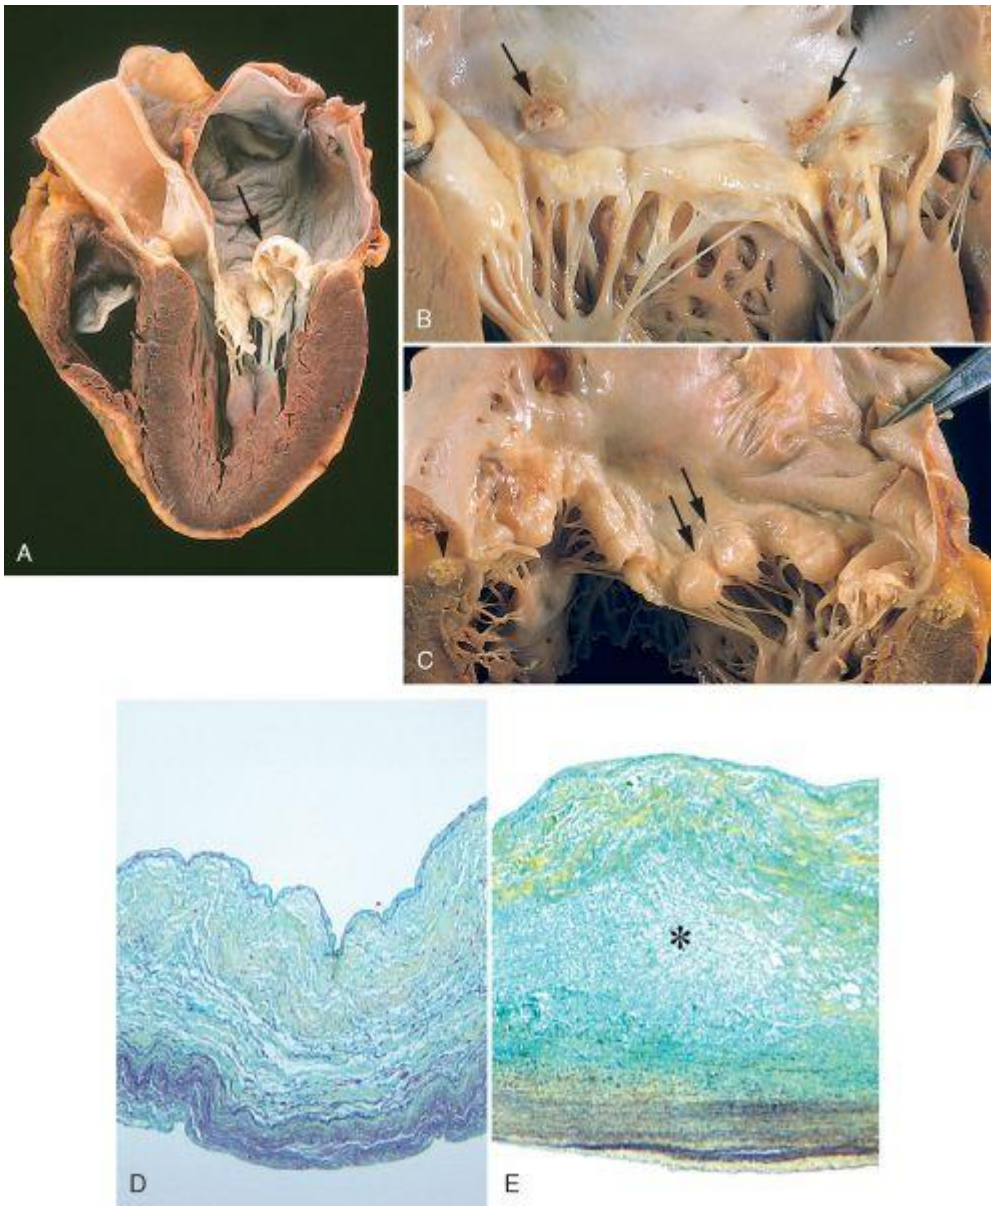

FIGURE 12-23 Myxomatous degeneration of the mitral valve. **A**, Long axis of left ventricle demonstrating hooding with prolapse of the posterior mitral leaflet into the left atrium *(arrow)*. The left ventricle is on right in this apical four-chamber view. **B**, Opened valve, showing pronounced hooding of the posterior mitral leaflet with thrombotic plaques at sites of leaflet–left atrium contact *(arrows)*. **C**, Opened valve with pronounced hooding from patient who died suddenly *(double arrows)*. Note also mitral annular calcification *(arrowhead)*. Normal heart valve **(D)** and myxomatous mitral valve **(E)** (Movat pentachrome stain, in which collagen is yellow, elastin is black, and proteoglycans are blue). In myxomatous valves, collagen in the fibrosa is loose and disorganized, proteolgycans *(asterisk)* are deposited in the spongiosa, and elastin in the atrialis is disorganized. *(**A**, Courtesy of William D. Edwards, MD, Mayo Clinic, Rochester, MN; **D,E**, From Rabkin E, et al: Activated interstitial myofibroblasts express catabolic enzymes and mediate matrix remodeling in myxomatous heart valves. Circulation 104:2525–2532, 2001.)*

Pathogenesis.

The basis for the changes that weaken the valve leaflets and associated structures is unknown in most cases. Uncommonly, MVP is associated with heritable disorders of connective tissue including Marfan syndrome, which is usually caused by mutations in fibrillin-1 (FBN-1) (Chapter 5). As you will recall,

defects in FBN-1 alter cell-matrix interactions and also dysregulate TGF-β signaling.[75] Of interest, mice engineered to express mutated FBN-1 develop a form of mitral valve prolapse that can be prevented by inhibitors of TGF-β,[76] indicating that excess TGF-β can cause the characteristic structural laxity and myxomatous change. Whether similar mechanisms contribute to sporadic MVP is unknown. Studies utilizing genetic linkage analysis have also mapped autosomal-dominant forms of MVP to several other genetic loci that may be involved in remodeling of the valvular extracellular matrix.[77]

Clinical Features.

Most individuals diagnosed with MVP are asymptomatic, and the condition is discovered incidentally by detection of a midsystolic click on physical examination. The diagnosis can be confirmed by echocardiography. Those cases with mitral regurgitation are also associated with a systolic murmur. A minority of patients have chest pain mimicking angina, dyspnea, and fatigue. Although the great majority of persons with MVP have no untoward effects, approximately 3% develop one of four serious complications: (1) infective endocarditis; (2) mitral insufficiency, sometimes with chordal rupture; (3) stroke or other systemic infarct, resulting from embolism of leaflet thrombi; or (4) arrhythmias, both ventricular and atrial.

The risk of complications is very low when MVP is discovered incidentally in young asymptomatic patients, and higher in men, older patients, and those with arrhythmias or mitral regurgitation. For patients with symptoms or at high risk for serious complications, valve surgery is often done; indeed, MVP is presently the most common cause for surgical repair or replacement of the mitral valve.

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever (RF) is an acute, immunologically mediated, multisystem inflammatory disease that occurs a few weeks after an episode of group A streptococcal pharyngitis.[78] Acute rheumatic carditis is a frequent manifestation during the active phase of RF and may progress over time to chronic rheumatic heart disease (RHD), of which valvular abnormalities are key manifestations.

RHD is characterized principally by deforming fibrotic valvular disease, particularly mitral stenosis, of which it is virtually the only cause. The incidence and mortality rate of RF and RHD have declined remarkably in many parts of the world over the past century, as a result of improved socioeconomic conditions and rapid diagnosis and treatment of streptococcal pharyngitis. Nevertheless, in developing countries, and in many crowded, economically depressed urban areas in the Western world, RHD remains an important public health problem, affecting an estimated 15 million people. Rheumatic fever only rarely follows infections by streptococci at other sites, such as the skin.

Morphology. Key pathologic features of acute RF and chronic RHD are shown in Figure 12-24 . During acute RF, focal inflammatory lesions are found in various tissues. Distinctive lesions occur in the heart, called **Aschoff bodies**, which consist of foci of lymphocytes (primarily T cells), occasional plasma cells, and plump activated macrophages called Anitschkow cells (pathognomonic for RF). These macrophages have abundant cytoplasm and central round-toovoid nuclei in which the chromatin is disposed in a central, slender, wavy ribbon (hence the designation **“caterpillar cells”**), and may become multinucleated.

During acute RF, diffuse inflammation and Aschoff bodies may be found in any of the three layers of the heart, causing pericarditis, myocarditis, or endocarditis (**pancarditis**).

Inflammation of the endocardium and the left-sided valves typically results in fibrinoid necrosis within the cusps or along the tendinous cords. Overlying these necrotic foci are small (1- to 2-mm)

vegetations, called **verrucae**, along the lines of closure. These vegetations place RHD within a small group of disorders that are associated with vegetative valve disease, each with its own characteristic morphologic features (Fig. 12-25). Subendocardial lesions, perhaps exacerbated by regurgitant jets, may induce irregular thickenings called **MacCallum plaques**, usually in the left atrium.

The cardinal anatomic changes of the mitral valve in chronic RHD are **leaflet thickening, commissural fusion and shortening, and thickening and fusion of the tendinous cords** (Fig. 12-24D). In chronic disease the mitral valve is virtually always involved. The mitral valve is affected alone in 65% to 70% of cases, and along with the aortic valve in another 25% of cases. Tricuspid valve involvement is infrequent, and the pulmonary valve is only rarely affected. Because of the increase in calcific aortic stenosis (see earlier) and the reduced frequency of RHD, rheumatic aortic stenosis now accounts for less than 10% of cases of acquired aortic stenosis. Fibrous bridging across the valvular commissures and calcification create "fish mouth" or "buttonhole" stenoses. With tight mitral stenosis, the left atrium progressively dilates and may harbor mural thrombi in the appendage or along the wall, either of which can embolize. Long-standing congestive changes in the lungs may induce pulmonary vascular and parenchymal changes and in time lead to right ventricular hypertrophy. The left ventricle is largely unaffected by isolated pure mitral stenosis. Microscopically, in the mitral leaflets there is organization of the acute inflammation and subsequent diffuse fibrosis and neovascularization that obliterate the originally layered and avascular leaflet architecture. Aschoff bodies are rarely seen in surgical specimens or autopsy tissue from patients with chronic RHD, as a result of the long times between the initial insult and the development of the chronic deformity.

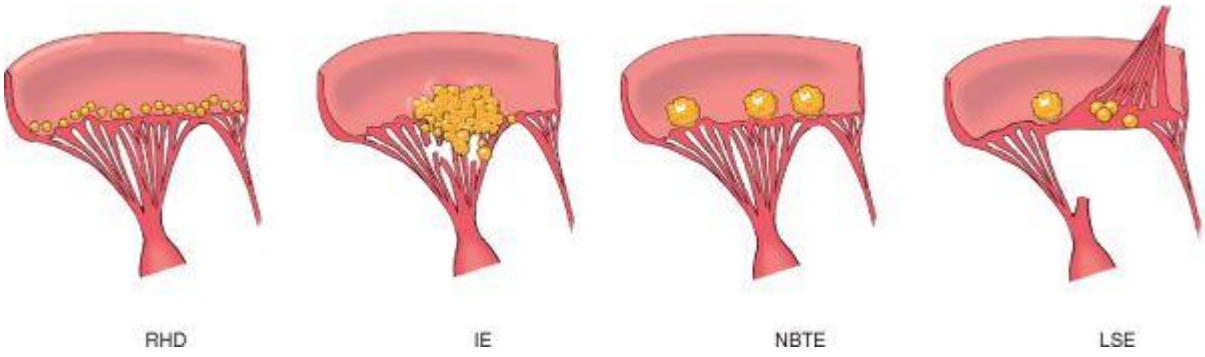

FIGURE 12-25 Comparison of the four major forms of vegetative endocarditis. The rheumatic fever phase of rheumatic heart disease (RHD) is marked by small, warty vegetations along the lines of closure of the valve leaflets. Infective endocarditis (IE) is characterized by large, irregular masses on the valve cusps that can extend onto the chordae (see Fig. 12-25). Nonbacterial thrombotic endocarditis (NBTE) typically exhibits small, bland vegetations, usually attached at the line of closure. One or many may be present (see Fig. 12-27). Libman-Sacks endocarditis (LSE) has small or medium-sized vegetations on either or both sides of the valve leaflets.

Pathogenesis.

Acute rheumatic fever results from immune responses to group A streptococci, which happen to cross-react with host tissues. Antibodies directed against the M proteins of streptococci have been shown to cross-react with self antigens in the heart. In addition, CD4+ T cells specific for streptococcal peptides also react with self proteins in the heart, and produce cytokines that activate macrophages (such as those found in Aschoff bodies). Damage to heart tissue may thus be caused by a combination of antibody- and T cell–mediated reactions (Chapter 6).

Clinical Features.

RF is characterized by a constellation of findings that includes as major manifestations: (1) migratory polyarthritis of the large joints, (2) pancarditis, (3) subcutaneous nodules, (4) erythema marginatum of the skin, and (5) Sydenham chorea, a neurologic disorder with involuntary rapid, purposeless movements. The diagnosis is established by the so-called Jones criteria: evidence of a preceding group A streptococcal infection, with the presence of two of the major manifestations listed above or one major and two minor manifestations (nonspecific signs and symptoms that include fever, arthralgia, or elevated blood levels of acute-phase reactants).[80]

Acute RF typically appears 10 days to 6 weeks after an episode of pharyngitis caused by group A streptococci in about 3% of infected patients. It occurs most often in children between ages 5 and 15, but first attacks can occur in middle to later life. Although pharyngeal cultures for streptococci are negative by the time the illness begins, antibodies to one or more streptococcal enzymes, such as streptolysin O and DNase B, can be detected in the sera of most patients with RF. The predominant clinical manifestations are carditis and arthritis, the latter more common in adults than in children. Clinical features related to *acute carditis* include pericardial friction rubs, weak heart sounds, tachycardia, and arrhythmias. Myocarditis may cause cardiac dilation that can evolve to functional mitral valve insufficiency or even heart failure. Approximately 1% of patients die from fulminant RF. *Arthritis* typically begins with migratory polyarthritis (accompanied by fever) in which one large joint after another becomes painful and swollen for a period of days and then subsides spontaneously, leaving no residual disability.

After an initial attack there is increased vulnerability to reactivation of the disease with subsequent pharyngeal infections, and the same manifestations are likely to appear with each recurrent attack. Damage to the valves is cumulative. Turbulence induced by ongoing valvular deformities begets additional fibrosis. Clinical manifestations appear years or even decades after the initial episode of RF and depend on which cardiac valves are involved. In addition to various cardiac murmurs, cardiac hypertrophy and dilation, and heart failure, individuals with chronic RHD may suffer from arrhythmias (particularly atrial fibrillation in the setting of mitral stenosis), thromboembolic complications, and infective endocarditis (see below). The long-term prognosis is highly variable. Surgical repair or prosthetic replacement of diseased valves has greatly improved the outlook for persons with RHD.

INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) is a serious infection characterized by colonization or invasion of the heart valves or the mural endocardium by a microbe.[81] This leads to the formation of *vegetations* composed of thrombotic debris and organisms, often associated with destruction of the underlying cardiac tissues. The aorta, aneurysmal sacs, other blood vessels, and prosthetic devices can also become infected. Although fungi and other classes of microorganisms can be responsible, most cases are caused by bacterial infections *(bacterial endocarditis)*. Prompt diagnosis and effective treatment of IE is important.

Traditionally, IE has been classified on clinical grounds into acute and subacute forms. This subdivision reflects the range of the disease severity and tempo, which are determined in large part by the virulence of the infecting microorganism and whether underlying cardiac disease is present. *Acute infective endocarditis* is typically caused by infection of a previously normal heart valve by a highly virulent organism that produces necrotizing, ulcerative, destructive lesions. These infections are difficult to cure with antibiotics and usually require surgery. Death within days to weeks ensues in many patients with acute IE, despite treatment. In contrast, in *subacute IE*, the organisms are of lower virulence. These organisms cause insidious infections of deformed valves that are less destructive. In such cases the disease may pursue a protracted course of weeks to months, and cures are often produced with antibiotics.

Etiology and Pathogenesis.

As mentioned above, IE can develop on previously normal valves, especially with highly virulent organisms, but a variety of cardiac and vascular abnormalities predispose to this form of infection. In years past, rheumatic heart disease was the major antecedent disorder, but more common now are mitral valve prolapse, degenerative calcific valvular stenosis, bicuspid aortic valve (whether calcified or not), artificial (prosthetic) valves, and unrepaired and repaired congenital defects.[82] The causative organisms differ somewhat in the major high-risk groups. Endocarditis of native but previously damaged or otherwise abnormal valves is caused most commonly (50% to 60% of cases) by *Streptococcus viridans*, which is part of the normal flora of the oral cavity. In contrast, more virulent *S. aureus* organisms commonly found on the skin can infect either healthy or deformed valves and are responsible for 10% to 20% of cases overall; *S. aureus* is the major offender in intravenous drug abusers with IE. The roster of the remaining bacteria includes enterococci and the so-called HACEK group (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella*, and *Kingella*), all commensals in the oral cavity. Prosthetic valve endocarditis is caused most commonly by coagulase-negative staphylococci (e.g., *S. epidermidis*). Other agents causing endocarditis include gram-negative bacilli and fungi. In about 10% to 15% of all cases of endocarditis, no organism can be isolated from the blood ("culture-negative" endocarditis).

Foremost among the factors predisposing to the development of endocarditis are those that lead to bacteremia. The source of the organism may be an obvious infection elsewhere, a dental or surgical procedure, a contaminated needle shared by intravenous drug users, or seemingly trivial breaks in the epithelial barriers of the gut, oral cavity, or skin. The risk can be lowered in those with predisposing factors (e.g., valve abnormalities, conditions causing bacteremia) by prophylaxis with antibiotics.

Morphology. The hallmark of IE is the presence of friable, bulky, potentially destructive **vegetations** containing fibrin, inflammatory cells, and bacteria or other organisms on the heart valves (Figs. 12-25B and 12-26). The aortic and mitral valves are the most common sites of infection, although the valves of the right heart may also be involved, particularly in intravenous drug abusers. The vegetations may be single or multiple and may involve more than one valve. Vegetations sometimes erode into the underlying myocardium and produce an abscess **(ring abscess)**. **Emboli** may be shed from the vegetations at any time; because the embolic fragments may contain large numbers of virulent organisms, abscesses often develop at the sites where the emboli lodge, leading to sequelae such as **septic infarcts** or mycotic aneurysms.

The vegetations of **subacute endocarditis** are associated with less valvular destruction than those of acute endocarditis, although the distinction between the two forms may blur. Microscopically, the vegetations of typical subacute IE often have granulation tissue indicative of healing at their bases. With time, fibrosis, calcification, and a chronic inflammatory infiltrate can develop.

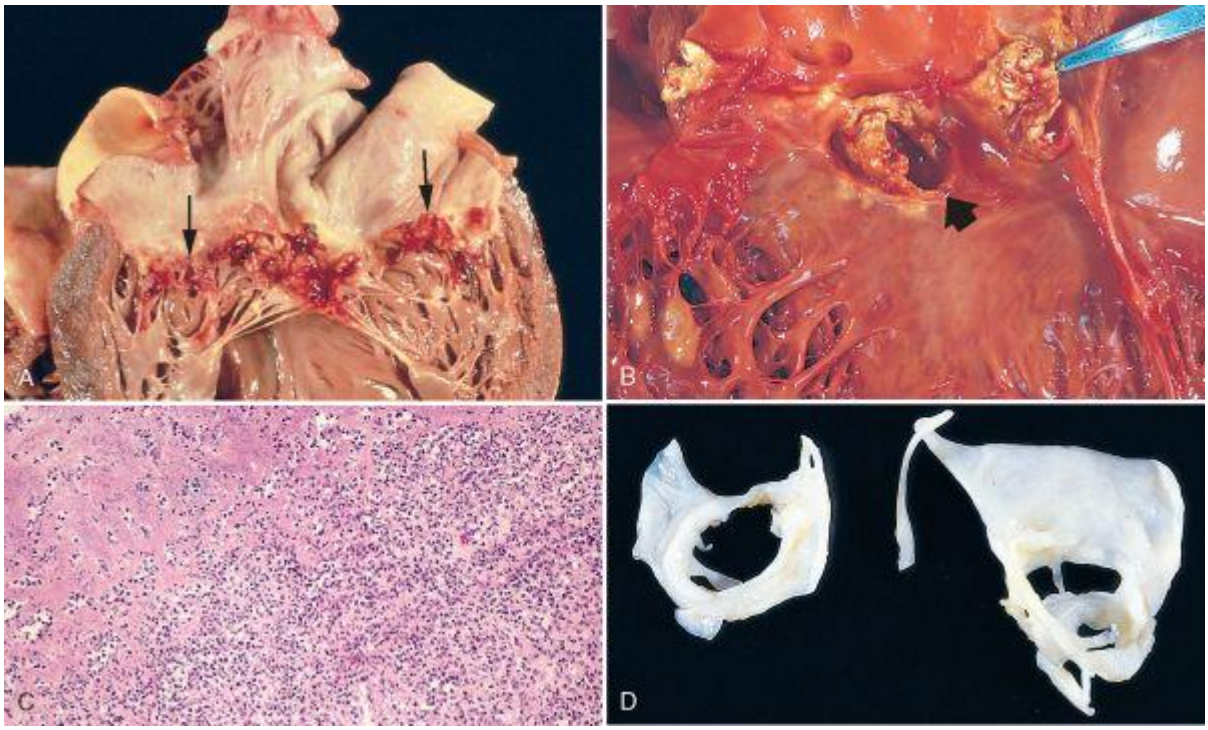

FIGURE 12-26 Infective (bacterial) endocarditis. **A**, Endocarditis of mitral valve (subacute, caused by *Streptococcus viridans*). The large, friable vegetations are denoted by *arrows*. **B**, Acute endocarditis of congenitally bicuspid aortic valve (caused by *Staphylococcus aureus)* with extensive cuspal destruction and ring abscess *(arrow)*. **C**, Histologic appearance of vegetation of endocarditis with extensive acute inflammatory cells and fibrin. Bacterial organisms were demonstrated by tissue Gram stain. **D**, Healed endocarditis, demonstrating mitral valvular destruction but no active vegetations. *(**C**, Reproduced from Schoen FJ: Surgical pathology of removed natural and prosthetic heart valves. Hum Pathol 18:558, 1987.)*

Clinical Features.

Fever is the most consistent sign of IE. Acute endocarditis has a stormy onset with rapidly developing fever, chills, weakness, and lassitude. However, fever may be slight or absent, particularly in the elderly, and the only manifestations may be nonspecific fatigue, loss of weight, and a flu-like syndrome. Complications of IE generally begin within the first few weeks of onset. They may be immunologically mediated, as exemplified by glomerulonephritis caused by the deposition of antigen-antibody complexes (Chapter 20). Murmurs are present in 90% of patients with left-sided IE and may stem from a new valvular defect or represent a preexisting abnormality. The so-called Duke criteria (Table 12-8) provide a standardized assessment of individuals with suspected IE that takes into account predisposing factors, physical findings, blood culture results, echocardiographic findings, and laboratory information.[83] Earlier diagnosis and effective treatment has nearly eliminated some previously common clinical manifestations of long-standing IE—for example, micro-thromboemboli (manifest as splinter or subungual hemorrhages), erythematous or hemorrhagic nontender lesions on the palms or soles (Janeway lesions), subcutaneous nodules in the pulp of the digits (Osler nodes), and retinal hemorrhages in the eyes (Roth spots).

TABLE 12-8 -- Diagnostic Criteria for Infective Endocarditis[*]

PATHOLOGIC CRITERIA

Microorganisms, demonstrated by culture or histologic examination, in a vegetation, embolus from a vegetation, or intracardiac abscess
Histologic confirmation of active endocarditis in vegetation or intracardiac abscess
CLINICAL CRITERIA
Major
Blood culture(s) positive for a characteristic organism or persistently positive for an unusual organism
Echocardiographic identification of a valve-related or implant-related mass or abscess, or partial separation of artificial valve
New valvular regurgitaion
Minor
Predisposing heart lesion or intravenous drug use
Fever
Vascular lesions, including arterial petechiae, subungual/splinter hemorrhages, emboli, septic infarcts, mycotic aneurysm, intracranial hemorrhage, Janeway lesions[†]
Immunological phenomena, including glomerulonephritis, Osler nodes,[‡] Roth spots,[§] rheumatoid factor
Microbiologic evidence, including a single culture positive for an unusual organism
Echocardiographic findings consistent with but not diagnostic of endocarditis, including worsening or changing of a preexistent murmur

Modified from Durack DT et al: Am J Med, 96:200, 1994 and Karchmer AW: In Braunwald E, Zipes DP, Libby P (eds): Heart Disease. A Textbook of Cardiovascular Medicine, 6th ed. Philadelphia, WB Saunders, 2001, p 1723.

[*] Diagnosis by these guidelines, often called the Duke Criteria, requires either pathologic or clinical criteria; if clinical criteria are used, 2 major, 1 major + 3 minor, or 5 minor criteria are required for diagnosis.

[†] Janeway lesions are small erythematous or hemorrhagic, macular, nontender lesions on the palms and soles and are the consequence of septic embolic events.

[‡] Osler nodes are small, tender subcutaneous nodules that develop in the pulp of the digits or occasionally more proximally in the fingers and persist for hours to several days.

[§] Roth spots are oval retinal hemorrhages with pale centers.

NONINFECTED VEGETATIONS

Noninfected (sterile) vegetations are caused by nonbacterial thrombotic endocarditis and the endocarditis of systemic lupus erythematosus (SLE), called Libman-Sacks endocarditis (see below).

Nonbacterial Thrombotic Endocarditis (NBTE)

NBTE is characterized by the deposition of small sterile thrombi on the leaflets of the cardiac valves (Figs. 12-25C and 12-27). The lesions are 1 mm to 5 mm in size, and occur singly or multiply along the line of closure of the leaflets or cusps. Histologically they are composed of bland thrombi that are loosely attached to the underlying valve. The vegetations are not invasive and do not elicit any inflammatory reaction. Thus, the local effect of the vegetations is usually unimportant, but they may be the source of systemic emboli that produce infarcts in the brain, heart, or elsewhere.

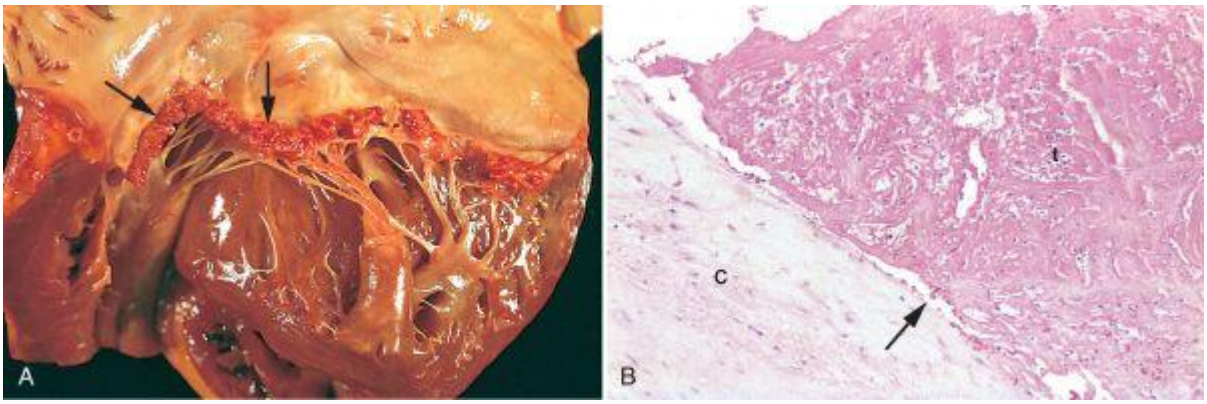

FIGURE 12-27 Nonbacterial thrombotic endocarditis (NBTE). **A**, Nearly complete row of thrombotic vegetations along the line of closure of the mitral valve leaflets *(arrows)*. **B**, Photomicrograph of NBTE, showing bland thrombus, with virtually no inflammation in the valve cusp (c) or the thrombotic deposit (t). The thrombus is only loosely attached to the cusp *(arrow)*.

NBTE is often encountered in debilitated patients, such as those with cancer or sepsis—hence the previously used term *marantic endocarditis*. It frequently occurs concomitantly with deep venous thromboses, pulmonary emboli, or other findings consistent with an underlying systemic hypercoagulable state (Chapter 4). Indeed, there is a striking association with mucinous adenocarcinomas, which may relate to the procoagulant effects of tumor-derived mucin or tissue factor, and NBTE can be a part of the Trousseau syndrome of migratory thrombophlebitis (Chapter 7). Endocardial trauma, as from an indwelling catheter, is another well-recognized predisposing condition, and right-sided valvular and endocardial thrombotic lesions frequently track along the course of Swan-Ganz pulmonary artery catheters.

Endocarditis of Systemic Lupus Erythematosus (Libman-Sacks Disease)

Mitral and tricuspid valvulitis with small, sterile vegetations, called *Libman-Sacks endocarditis*, is occasionally encountered in SLE. The lesions are small (1–4 mm in diameter) single or multiple, sterile, pink vegetations that often have a warty (verrucous) appearance. They may be located on the undersurfaces of the atrioventricular valves, on the valvular endocardium, on the chords, or on the mural endocardium of atria or ventricles. Histologically the vegetations consist of a finely granular, fibrinous eosinophilic material that may contain hematoxylin bodies, homogeneous remnants of nuclei damaged by anti-nuclear antigen bodies (see Chapter 6). An intense valvulitis may be present, characterized by fibrinoid necrosis of the valve substance that is often contiguous with the vegetation. Active leaflet vegetations can be difficult to distinguish from those of infective endocarditis (see Fig. 12-25); fibrosis and serious deformities can result that resemble chronic rheumatoid heart disease and require surgery.

Thrombotic heart valve lesions with sterile vegetations or rarely fibrous thickening commonly occur with the antiphospholipid syndrome (discussed in Chapter 4), which you will recall can also lead to a hypercoagulable state.[84] The mitral valve is more frequently involved than the aortic valve; regurgitation is the usual functional abnormality.

CARCINOID HEART DISEASE

Carcinoid heart disease is the cardiac manifestation of the systemic syndrome caused by carcinoid tumors. It generally involves the endocardium and valves of the right heart. Cardiac lesions are present

in one half of patients with the *carcinoid syndrome*, which is characterized by *episodic flushing of the skin, cramps, nausea, vomiting, and diarrhea* (see Chapter 17).

Morphology. The cardiovascular lesions associated with the carcinoid syndrome are distinctive, consisting of firm plaquelike endocardial fibrous thickenings on the inside surfaces of the cardiac chambers and the tricuspid and pulmonary valves; occasionally they involve the major blood vessels of the right side, the inferior vena cava and the pulmonary artery (Fig. 12-28). The plaquelike thickenings are composed predominantly of smooth muscle cells and sparse collagen fibers embedded in an acid mucopolysaccharide-rich matrix material. Elastic fibers are not present in the plaques. Structures underlying the plaques are intact.

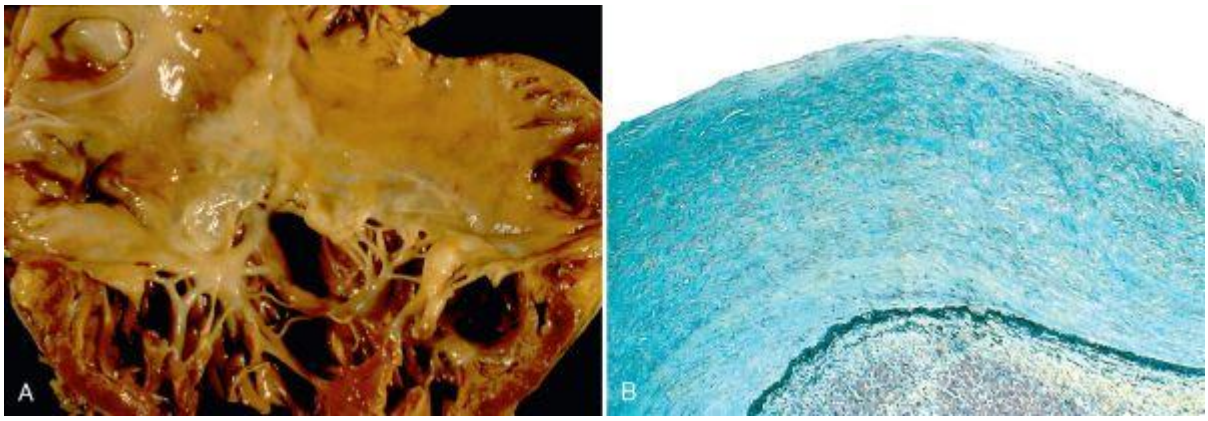

FIGURE 12-28 Carcinoid heart disease. **A**, Characteristic endocardial fibrotic lesion involving the right ventricle and tricuspid valve. **B**, Microscopic appearance of carcinoid heart disease with intimal thickening. Movat stain shows myocardial elastic tissue (black) underlying the acid mucopolysaccharide-rich lesion (blue-green).

Although the mechanisms of the fibrosis are not understood, it appears that the clinical and pathologic findings relate to the elaboration by carcinoid tumors of a variety of bioactive products, such as serotonin (5-hydroxytryptamine), kallikrein, bradykinin, histamine, prostaglandins, and tachykinins. Plasma levels of serotonin and urinary excretion of the serotonin metabolite 5-hydroxyindoleacetic acid correlate with the severity of the right heart lesions.

The key bioactive mediators released into the portal circulation by gut carcinoid tumors are readily metabolized by the liver and do not reach the heart in high concentration. Thus, gastrointestinal carcinoids (with venous drainage via the portal system) do not usually induce carcinoid heart disease, unless there are extensive hepatic metastases that release the relevant mediators directly into the interior vena cava. Restriction of the cardiac changes to the right side of the heart is explained by inactivation of both serotonin and bradykinin during passage through the lungs by monoamine oxidase present in the pulmonary vascular endothelium. In contrast, primary carcinoid tumors in organs outside of the portal system of venous drainage that empty directly into the inferior vena cava (e.g., ovary and lung) can induce the syndrome in the absence of hepatic metastases.

The most common cardiac manifestation is tricuspid insufficiency, followed by pulmonary valve insufficiency, which usually occurs in combination with tricuspid disease. Stenoses of the right-sided valves may also develop, whereas left-sided valvular disease is only seen under unusual circumstances,

such as when there is patent foramen ovale with right to left shunting or primary or metastatic carcinoid tumor involving the lung. Left-sided valvular abnormalities with pathologic features similar to those seen in the carcinoid syndrome have been reported to complicate the use of drugs that have serotonergic activity. These include fenfluramine (part of the "fen-phen" combination of appetite suppressants), some antiparkinsonian drugs, and methysergide or ergotamine, used to treat migraine headaches.[85]

COMPLICATIONS OF ARTIFICIAL VALVES

Replacement of damaged cardiac valves with prostheses is a common and often lifesaving mode of therapy.[86] Artificial valves are primarily of two types: (1) *mechanical prostheses*, consisting of different kinds of rigid mechanical valves, such as caged balls, tilting disks, or hinged semicircular flaps that are composed of nonphysiologic material; and (2) *tissue valves*, usually *bioprostheses*, consisting of chemically treated animal tissue, especially porcine aortic valve tissue, which has been preserved in a dilute glutaraldehyde solution and subsequently mounted on a prosthetic frame. Tissue valves are flexible and function similarly to natural semilunar valves.

Approximately 60% of substitute valve recipients develop a serious prosthesis-related problem within 10 years postoperatively. The *nature* of these complications differs among types (Table 12-9 and Fig. 12-29).[87]

- *Thromboembolic complications*, either local obstruction of the prosthesis by thrombus or distant thromboemboli, are the major problem with mechanical valves (Fig. 12-29A). This complication necessitates long-term anticoagulation in all individuals with mechanical valves, with its attendant risk of hemorrhagic stroke or other forms of serious bleeding.
- *Infective endocarditis* is a potentially serious complication of valve replacement. The vegetations of prosthetic valve endocarditis are usually located at the prosthesis-tissue interface, and often cause the formation of a ring abscess, which can eventually lead to a paravalvular regurgitant blood leak if the prosthetic valve-tissue junction is disrupted. In addition, vegetations may directly involve the tissue of bioprosthetic valvular cusps. The major organisms causing such infections are staphylococcal skin contaminants (e.g., *S. epidermidis*), *S. aureus*, streptococci, and fungi.
- *Structural deterioration* rarely causes failure of contemporary mechanical valves. However, bioprostheses often eventually become incompetent due to calcification and/or tearing (Fig. 12-29B).[88]
- Other complications include intravascular hemolysis due to high shear forces, paravalvular leak due to inadequate healing, or obstruction due to overgrowth of fibrous tissue during the healing process.

TABLE 12-9 -- Complications of Cardiac Valve Prostheses

Thrombosis/thromboembolism
Anticoagulant-related hemorrhage
Prosthetic valve endocarditis
Structural deterioration (intrinsic)
Wear, fracture, poppet failure in ball valves, cuspal tear, calcification
Other forms of dysfunction
Inadequate healing (paravalvular leak), exuberant healing (obstruction), disproportion, hemolysis, noise

3.2.9 Cardiomyopathies

The term *cardiomyopathy* (literally, heart muscle disease) is used to describe *heart disease resulting from an abnormality in the myocardium*.[89,][90] Diseases of the myocardium usually produce abnormalities in cardiac wall thickness and chamber size, and mechanical and/or electrical dysfunction, and are associated with significant morbidity and mortality. Although chronic myocardial dysfunction secondary to ischemia, valvular abnormalities, or hypertension can cause ventricular dysfunction (see previous sections of this chapter), these conditions are not considered to be cardiomyopathies.

Clinical manifestations associated with the cardiomyopathies are either confined to the heart or can be a part of a generalized systemic disorder; in either situation, cardiac dysfunction is a key problem. *Primary* cardiomyopathies are diseases predominantly confined to the heart muscle, whereas *secondary* cardiomyopathies have myocardial involvement as a component of a systemic or multiorgan disorder. In most cases the mechanism by which the noncardiac problem affects the heart is well understood. In other disorders such as diabetes, the pathogenesis of the cardiac dysfunction is less obvious.[91] A major advance in our understanding of cardiomyopathies is the increasing appreciation that many cases have underlying genetic causes,[91,][92] which we will discuss as we review the major categories of cardiomyopathy.

Cardiomyopathies of diverse etiology may have a similar morphologic appearance, and a clinician encountering a person with myocardial disease is usually unaware of the underlying cause. Hence the clinical approach is largely determined by which one of three clinical, functional, and pathologic patterns is present (Fig. 12-30 and Table 12-10): (1) dilated cardiomyopathy (DCM), (2) hypertrophic cardiomyopathy (HCM), or (3) restrictive cardiomyopathy. Another rare form of cardiomyopathy, left ventricular noncompaction, is characterized by a distinctive “spongy” appearance of the left ventricular myocardium. This congenital disorder is frequently associated with heart failure or arrhythmias and other clinical symptomatology; it may be diagnosed in children or adults as either an isolated finding or associated with other congenital heart anomalies, such as complex cyanotic congenital heart disease.[93] Gene mutations affecting myocardial ion channel function have also been included in recent

classifications of primary cardiomyopathy (this group of disorders has been discussed in the context of sudden cardiac death). For the purposes of this discussion, arrhythmogenic right ventricular cardiomyopathy (arrhythmogenic right ventricular dysplasia), discussed below, is considered a variant of DCM.

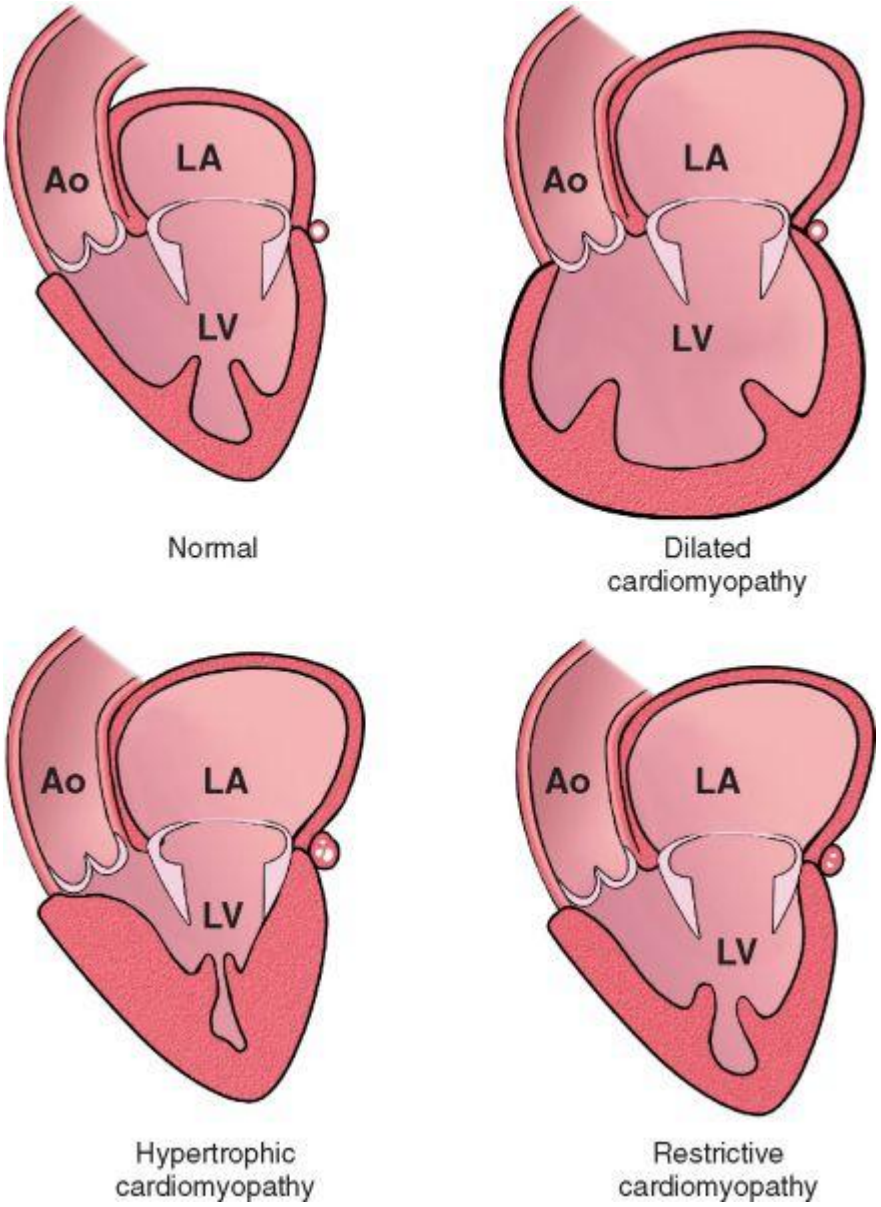

FIGURE 12-30 Representations of the three distinctive forms of myocardial disease. Ao, aorta; LA, left atrium; LV, left ventricle.

TABLE 12-10 -- Cardiomyopathy and Indirect Myocardial Dysfunction: Functional Patterns and Causes

Functional Pattern	Left Ventricular Ejection Fraction[*]	Mechanisms of Heart Failure	Causes of Phenotype	Indirect Myocardial Dysfunction (Mimicking Cardiomyopathy)
Dilated	<40%	Impairment of contractility	Genetic; alcohol; peripartum; myocarditis; hemochromatosis;	Ischemic heart disease; valvular heart disease;

Functional Pattern	Left Ventricular Ejection Fraction[*]	Mechanisms of Heart Failure	Causes of Phenotype	Indirect Myocardial Dysfunction (Mimicking Cardiomyopathy)
		(systolic dysfunction)	chronic anemia; doxorubicin (Adriamycin); sarcoidosis; idiopathic	hypertensive heart disease; congenital heart disease
Hypertrophic	50% to 80%	Impairment of compliance (diastolic dysfunction)	Genetic; Friedreich ataxia; storage diseases; infants of diabetic mother	Hypertensive heart disease; aortic stenosis
Restrictive	45% to 90%	Impairment of compliance (diastolic dysfunction)	Amyloidosis; radiation-induced fibrosis; idiopathic	Pericardial constriction

[*] Normal, approximately 50% to 65%.

Within the hemodynamic patterns of myocardial dysfunction, there is a spectrum of clinical severity, and overlap of clinical features often occurs between groups. Moreover, each of these patterns can be either idiopathic or due to one of numerous specific identifiable causes (Table 12-11).

TABLE 12-11 -- Conditions Associated with Heart Muscle Diseases

CARDIAC INFECTIONS
Viruses
Chlamydia
Rickettsia
Bacteria
Fungi
Protozoa
TOXINS
Alcohol
Cobalt
Catecholamines
Carbon monoxide
Lithium
Hydrocarbons
Arsenic
Cyclophosphamide
Doxorubicin (Adriamycin) and daunorubicin
METABOLIC
Hyperthroidism
Hypothyroidism

Hyperkalemia
Hypokalemia
Nutritional deficiency (protein, thiamine, other avitaminoses)
Hemochromatosis
NEUROMUSCULAR DISEASE
Friedreich ataxia
Muscular dystrophy
Congenital atrophies
STORAGE DISORDERS AND OTHER DEPOSITIONS
Hunter-Hurler syndrome
Glycogen storage disease
Fabry disease
Amyloidosis
INFILTRATIVE
Leukemia
Carcinomatosis
Sarcoidosis
Radiation-induced fibrosis
IMMUNOLOGICAL
Myocarditis (several forms)
Post-transplant rejection

Endomyocardial biopsies are used in the diagnosis and management of individuals with myocardial disease and in cardiac transplant recipients.[94,][95] Endomyocardial biopsy involves inserting a device (called a *bioptome*) transvenously into the right side of the heart and using its jaws to snip a small piece of septal myocardium, which is then analyzed by a pathologist.

DILATED CARDIOMYOPATHY

The term *dilated cardiomyopathy* (DCM) is applied to a form of cardiomyopathy characterized by *progressive cardiac dilation and contractile (systolic) dysfunction*, usually with concomitant hypertrophy. It is sometimes called congestive cardiomyopathy.

Morphology. In DCM the heart is usually enlarged, heavy (often weighing two to three times normal), and flabby, due to dilation of all chambers (Fig. 12-31). Mural thrombi are common and may be a source of thromboemboli. There are no primary valvular alterations, and mitral (or tricuspid) regurgitation, when present, results from left (or right) ventricular chamber dilation (functional regurgitation). Either the coronary arteries are free of significant narrowing or the obstructions present are insufficient to explain the degree of cardiac dysfunction.

The histologic abnormalities in DCM are nonspecific and usually do not point to a specific etiologic agent. Moreover, the severity of morphologic changes may not reflect either the degree of dysfunction or the patient's prognosis. Most muscle cells are hypertrophied with enlarged nuclei, but some are attenuated, stretched, and irregular. Interstitial and endocardial fibrosis of variable degree is present, and small subendocardial scars may replace individual cells or groups of cells, probably reflecting healing of previous ischemic necrosis of myocytes caused by hypertrophy-induced imbalance between perfusion and demand.

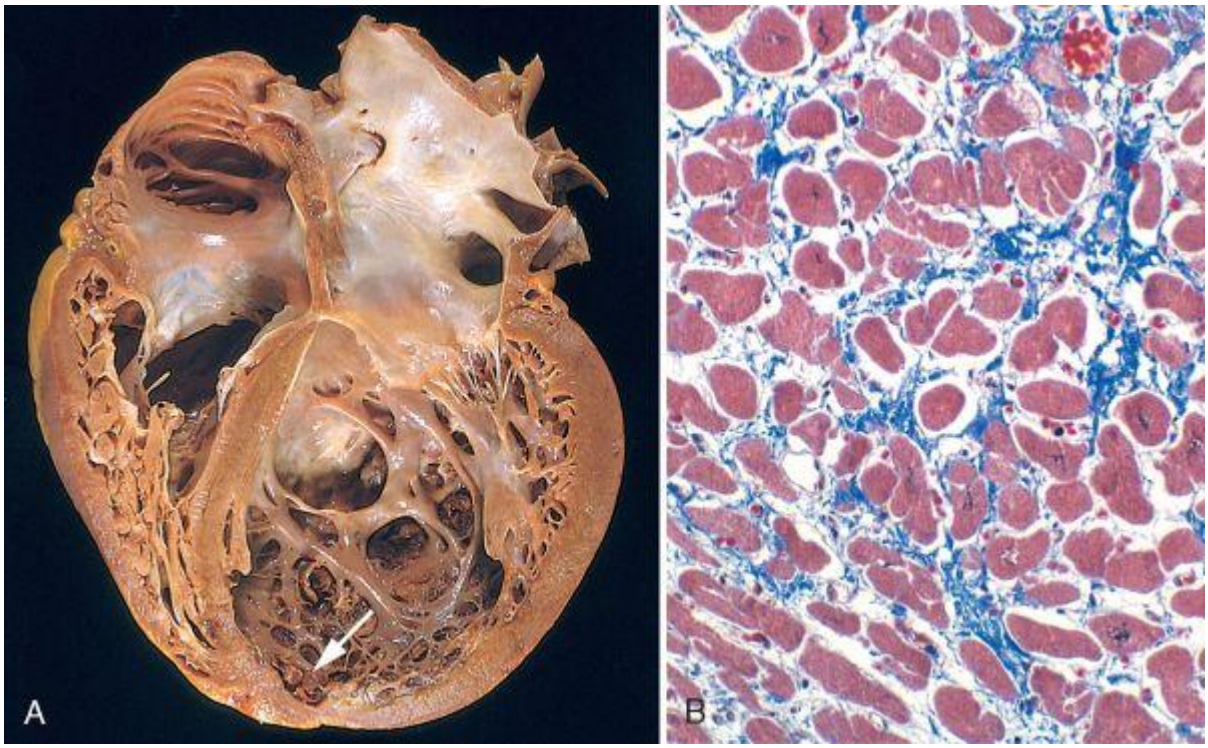

FIGURE 12-31 Dilated cardiomyo-pathy. **A**, Four-chamber dilatation and hypertrophy are evident. There is granular mural thrombus (*arrow*) at the apex of the left ventricle (on the *right* in this apical four-chamber view). The coronary arteries were patent. **B**, Histologic section demonstrating variable myocyte hypertrophy and interstitial fibrosis (collagen is highlighted as blue in this Masson trichrome stain).

Pathogenesis.

Although many individuals with DCM have a familial (genetic) form, DCM can also result from various acquired myocardial insults or interactions of genetics and the environment that ultimately may yield a similar clinicopathologic pattern.[96] These include (1) myocarditis (an inflammatory disorder that precedes the development of cardiomyopathy in at least some cases, and is sometimes caused by viral infections), (2) toxicities (including adverse effects of chemotherapeutic agents and chronic alcoholism, a history of which can be elicited in 10% to 20% of patients), and (3) childbirth. Each of these subgroups are summarized in Figure 12-32 and described below.

- *Genetic influences*. In 20% to 50% of cases, DCM is familial and caused by inherited genetic abnormalities.[97] In the genetic forms of DCM, autosomal-dominant inheritance is the predominant pattern; X-linked, autosomal-recessive, and mitochondrial inheritance are less common. The genetic abnormalities identified as causes of familial DCM in humans most commonly affect genes that encode cytoskeletal proteins expressed by myocytes (Fig. 12-33).[98] In some families there are deletions in mitochondrial

genes that result in defects in oxidative phosphorylation; in others there are mutations in genes encoding enzymes involved in beta-oxidation of fatty acids.[99] The mitochondrial defects most frequently cause dilated cardiomyopathy in children. X-linked dilated cardiomyopathy typically presents in the teenage years or in the early 20s and is usually rapidly progressive. X-linked cardiomyopathy is associated with mutations in the gene that encodes dystrophin, a cell membrane–associated cytoskeletal protein that plays a critical role in couping the internal cytoskeleton to the extracellular matrix; recall that dystrophin is mutated in the most common skeletal myopathies (i.e., Duchenne and Becker muscular dystrophies, see Chapter 27). Some patients and families with dystrophin gene mutations have DCM as the primary clinical feature. Other forms of DCM are associated with mutations in genes encoding cardiac α-actin (which links the sarcomere with dystrophin), desmin, and the nuclear lamina proteins, lamin A and lamin C. Interestingly, and probably resulting from the common developmental origin of contractile myocytes and conduction elements, congenital abnormalities of conduction may also be associated with DCM.[100]

- *Myocarditis*. Clinical studies using sequential endomyocardial biopsies have demonstrated progression from myocarditis to DCM; in other studies, *viral nucleic acids* from coxsackievirus B and other enteroviruses have been detected in the myocardium of patients with DCM. This suggests that, in at least some cases, DCM is a consequence of myocarditis. Myocarditis is discussed in more detail below.
- *Alcohol and other toxins*. *Alcohol abuse* is strongly associated with the development of DCM, raising the possibility that ethanol toxicity (Chapter 9) or a secondary nutritional disturbance may be the cause of the myocardial injury.[101] Alcohol or its metabolites (especially acetaldehyde) have a direct toxic effect on the myocardium; however, no morphologic features serve to distinguish *alcoholic cardiomyopathy* from DCM of other etiologies. Moreover, chronic alcoholism may be associated with thiamine deficiency, which can lead to beriberi heart disease (also indistinguishable from DCM) (see Chapter 9). In yet other cases a nonalcoholic *toxic insult* is the cause of the myocardial failure. Particularly important in this last group is myocardial injury caused by certain chemotherapeutic agents, including doxorubicin (Adriamycin), discussed later. In the past, cobalt has also caused DCM.
- *Childbirth*. A special form of DCM, termed *peripartum cardiomyopathy*, can occur late in pregnancy or several weeks to months postpartum. The cause of peripartum cardiomyopathy is poorly understood but is probably multifactorial.[102] Pregnancy-associated hypertension, volume overload, nutritional deficiency, other metabolic derangements, or an as yet poorly characterized immunological reaction have been proposed as causes. Recent work suggests a relationship between elevated levels of an anti-angiogenic cleavage product of the hormone prolactin (which rises late in pregnancy) and peripartum cardiomyopathy.[103] Blocking prolactin secretion by bromocriptine in mouse models prevents peripartum cardiomyopathy, suggesting a potential novel therapeutic strategy.

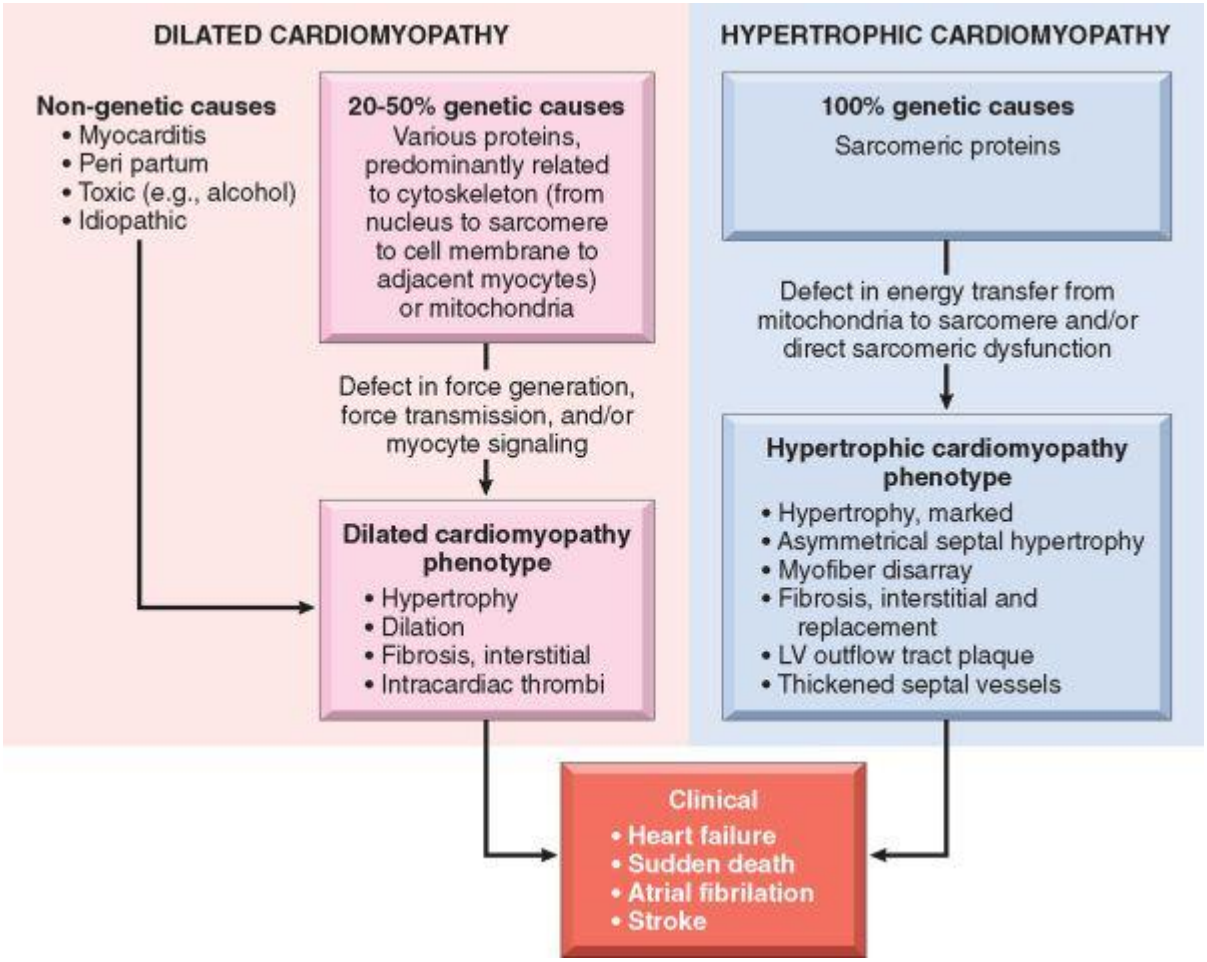

FIGURE 12-32 Causes and consequences of dilated and hypertrophic cardiomyopathy. Some dilated cardiomyopathies and virtually all hypertrophic cardiomyopathies are genetic in origin. The genetic causes of dilated cardiomyopathy involve mutations in any of a wide variety of proteins, predominantly of the cytoskeleton, but also the sarcomere, mitochondria, and nuclear envelope. In contrast, the mutated genes that cause hypertrophic cardiomyopathy encode proteins of the sarcomere. Although these two forms of cardiomyopathy differ greatly in subcellular basis and morphologic phenotypes, they share a common set of clinical complications. LV, left ventricle.

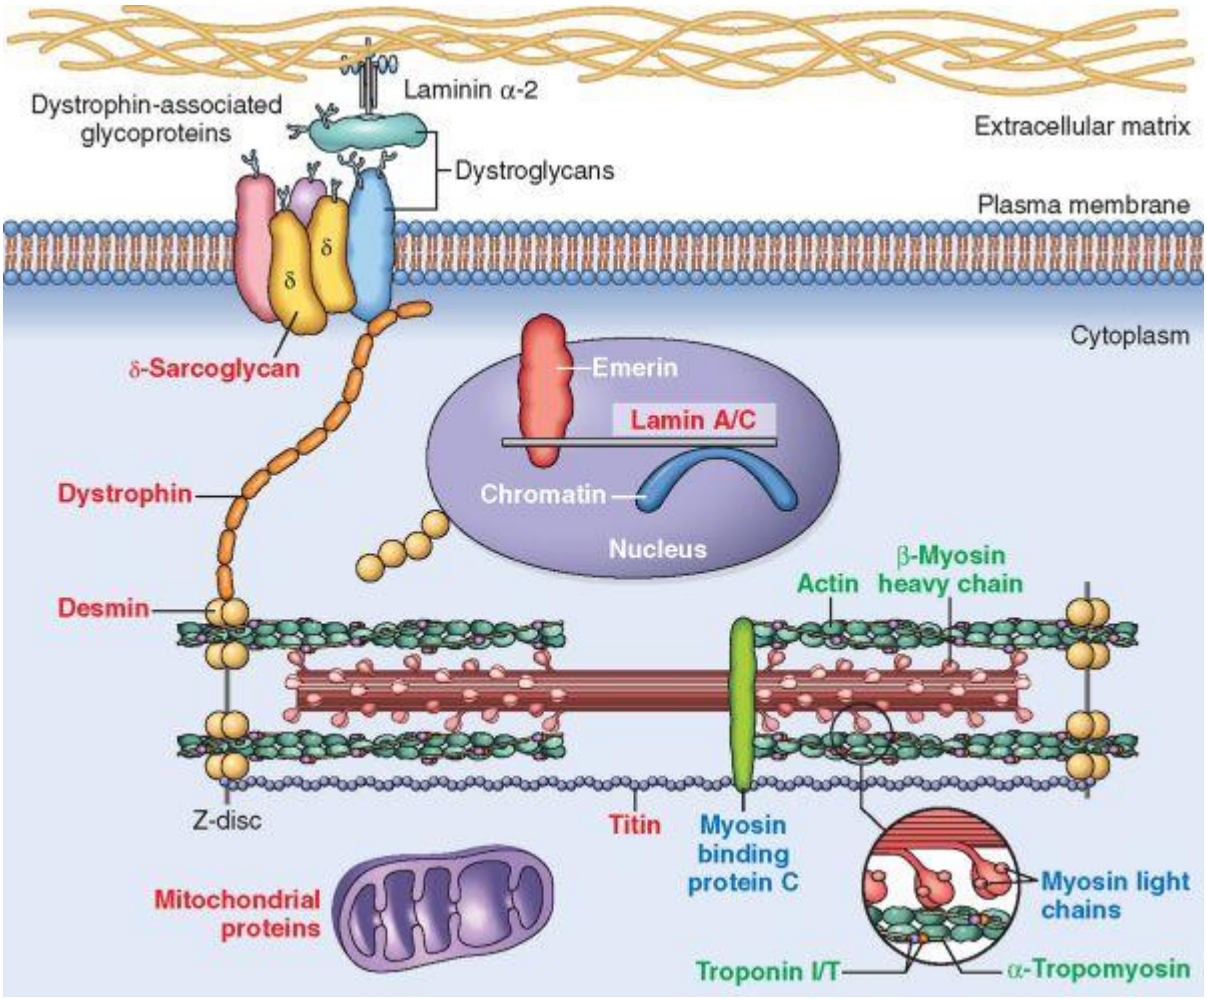

FIGURE 12-33 Schematic of a myocyte, showing key proteins mutated in dilated cardiomyopathy (red), hypertrophic cardiomyopathy (blue), or both (green).

Clinical Features.

DCM may occur at any age, including in childhood, but it most commonly affects individuals between the ages of 20 and 50. It presents with slowly progressive signs and symptoms of CHF such as shortness of breath, easy fatigability, and poor exertional capacity. In the end stage, patients often have ejection fractions of less than 25% (normal, ~50% to 65%). Fifty percent of patients die within 2 years, and only 25% survive longer than 5 years, but some severely affected patients may unexpectedly improve on therapy. Secondary mitral regurgitation and abnormal cardiac rhythms are common. Death is usually attributable to progressive cardiac failure or arrhythmia and can occur suddenly. Embolism from dislodgment of an intracardiac thrombus can occur. Cardiac transplantation is frequently done, and long-term ventricular assist may be beneficial in some patients. Interestingly, mechanical cardiac assist may induce lasting regression of cardiac dysfunction in some patients.[104]

Arrhythmogenic Right Ventricular Cardiomyopathy (Arrhythmogenic Right Ventricular Dysplasia)

Arrhythmogenic right ventricular cardiomyopathy (ARVC), or *arrhythmogenic right ventricular dysplasia*, is an inherited disease of the cardiac muscle that causes right ventricular failure and various rhythm disturbances, particularly ventricular tachycardia or fibrillation that can lead to sudden death,

primarily in young people.[105] Left-sided involvement with left-sided heart failure may also occur. Morphologically, the right ventricular wall is severely thinned because of loss of myocytes, with extensive fatty infiltration and fibrosis (Fig. 12-34). The condition appears to have autosomal-dominant inheritance and variable penetrance. The disease seems to be related to defective cell adhesion proteins in the desmosomes that link adjacent cardiac myocytes. *Naxos syndrome* is a disorder characterized by arrhythmogenic right ventricular cardiomyopathy and hyperkeratosis of plantar palmar skin surfaces that is associated with mutations in the gene encoding plakoglobin.[106]

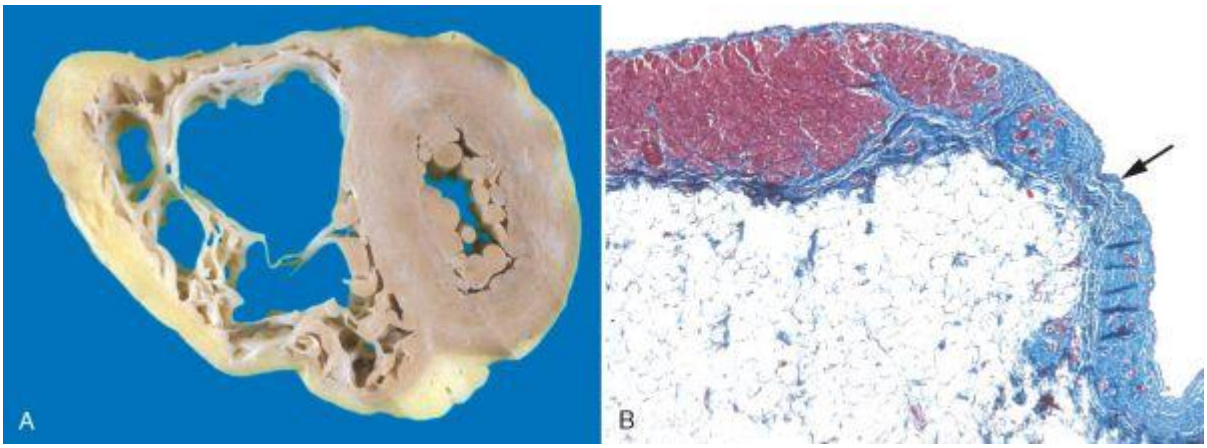

FIGURE 12-34 Arrhythmogenic right ventricular cardiomyopathy. **A**, Gross photograph, showing dilation of the right ventricle and near-transmural replacement of the right ventricular free-wall by fat and fibrosis. The left ventricle has a virtually normal configuration. **B**, Histologic section of the right ventricular free wall, demonstrating replacement of myocardium (red) by fibrosis (blue, *arrow*) and fat (Masson trichrome stain).

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by *myocardial hypertrophy*, poorly compliant left ventricular myocardium *leading to abnormal diastolic filling*, and in about one third of cases, *intermittent ventricular outflow obstruction*. It is the leading cause of left ventricular hypertrophy unexplained by other clinical or pathologic causes.[107] As discussed below, HCM is caused by mutations in genes encoding sarcomeric proteins. Since the incidence of unexplained cardiac hypertrophy is approximately 1 in 500, HCM may be the most common cardiovascular disorder caused by single gene mutations. The heart is thick-walled, heavy, and *hyper*contracting, in striking contrast to the flabby, *hypo*contracting heart of DCM. HCM causes primarily diastolic dysfunction; systolic function is usually preserved. The two most common diseases that must be distinguished clinically from HCM are deposition diseases of the heart (e.g., amyloidosis, Fabry's disease) and hypertensive heart disease coupled with age-related subaortic septal hypertrophy (see “Hypertensive Heart Disease”). Occasionally, valvular or congenital subvalvular aortic stenosis can also mimic HCM.

Morphology. The essential feature of HCM is massive myocardial hypertrophy, usually without ventricular dilation (Fig. 12-35). The classic pattern is disproportionate thickening of the ventricular septum as compared with the free wall of the left ventricle (with a ratio greater than 1 : 3), frequently termed asymmetric septal hypertrophy. In about 10% of cases, however, the hypertrophy is symmetrical throughout the heart. On cross-section, the ventricular cavity loses its usual round-to-ovoid shape and may be compressed into a “banana-like” configuration by bulging of the ventricular septum into the lumen (Fig. 12-35A). Although marked hypertrophy can involve the entire septum,

it is usually most prominent in the subaortic region. Often present are endocardial thickening or mural plaque formation in the left ventricular outflow tract and thickening of the anterior mitral leaflet. Both findings are a result of contact of the anterior mitral leaflet with the septum during ventricular systole, and they correlate with echocardiographically demonstrated functional left ventricular outflow tract obstruction during midsystole.

The most important histologic features of the myocardium in HCM are (1) extensive myocyte hypertrophy to a degree unusual in other conditions, with transverse myocyte diameters frequently greater than 40 μm (normal, ~15 μm); (2) haphazard disarray of bundles of myocytes, individual myocytes, and contractile elements in sarcomeres within cells (termed **myofiber disarray**); and (3) interstitial and replacement fibrosis (Fig. 12-35B).

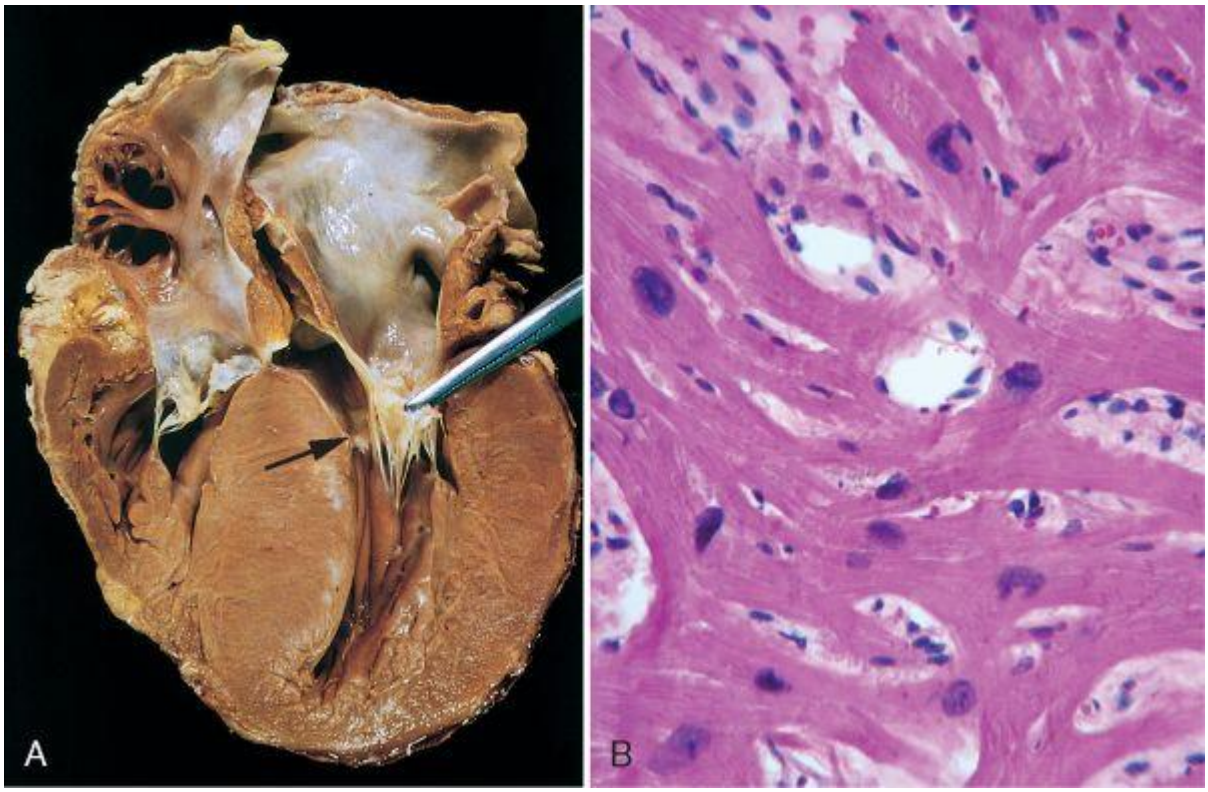

FIGURE 12-35 Hypertrophic cardiomyopathy with asymmetric septal hypertrophy. **A**, The septal muscle bulges into the left ventricular outflow tract, and the left atrium is enlarged. The anterior mitral leaflet has been moved away from the septum to reveal a fibrous endocardial plaque *(arrow)* (see text). **B**, Histologic appearance demonstrating disarray, extreme hypertrophy, and branching of myocytes as well as the characteristic interstitial fibrosis (collagen is blue in this Masson trichrome stain).

Pathogenesis.

HCM is caused by mutations in any one of several genes that encode sarcomeric proteins.[108] In most cases the pattern of transmission is autosomal dominant with variable penetrance. Remaining cases seem to be sporadic. More than 400 different mutations have been found in nine different genes in HCM, most being missense mutations. Mutations causing HCM are found most commonly in the gene encoding β-myosin heavy chain (β-MHC), with the genes for cardiac TnT, α-tropomyosin, and myosin-binding protein C (MYBP-C) being the next most frequently mutated. Mutations in β-MHC, MYBP-C, and TnT account for 70% to 80% of all cases of HCM. Different affected families may have distinct

mutations involving the same protein. For example, approximately 50 different mutations of β-MHC are known to cause HCM. The prognosis of HCM varies widely and correlates strongly with specific mutations. Although it is clear that these genetic defects are critical to the etiology of HCM, the sequence of events leading from mutations to disease is still poorly understood. To make matters even more complicated, changes in certain genes, depicted in Figure 12-33 , can give rise to both HCM and DCM.

Clinical Features.

The basic physiologic abnormality in HCM is reduced stroke volume due to *impaired diastolic filling, which results from the reduced chamber size and compliance of the massively hypertrophied left ventricle*. In addition, approximately 25% of patients with HCM have dynamic obstruction to the left ventricular outflow. The limitation of cardiac output and a secondary increase in pulmonary venous pressure cause exertional dyspnea. Auscultation discloses a *harsh systolic ejection murmur*, caused by ventricular outflow obstruction as the anterior mitral leaflet moves toward the ventricular septum during systole. Because of the massive hypertrophy, high left ventricular chamber pressure, and frequently abnormal intramural arteries, focal myocardial ischemia commonly results, even in the absence of concomitant coronary artery disease; thus, anginal pain is frequent. The major clinical problems in HCM are atrial fibrillation, mural thrombus formation leading to embolization and possible stroke, intractable cardiac failure, ventricular arrhythmias, and, not infrequently, sudden death, especially in some affected families. Indeed, HCM is one of the most common causes of sudden, otherwise unexplained death in young athletes.[109]

The natural history of HCM is highly variable. Most patients can be helped by treatment with drugs that decrease heart rate and contractility, such as β-adrenergic blockers. Some benefit may also be gained from reduction of the mass of the septum, which relieves the outflow tract obstruction. This can be achieved either by surgical excision of muscle or carefully controlled septal infarction, which is induced by infusion of alcohol through a catheter.

As discussed above, HCM is a disease caused by mutations in proteins of the sarcomere, and DCM is mostly associated with abnormalities of cytoskeletal proteins (Fig. 12-33). DCM seems to be a disease of abnormal force generation, force transmission, or myocyte signaling. In the past, HCM has been considered a disorder of sarcomeres that impairs cardiac function and induces a compensatory hypertrophic response. However, recent evidence suggests that HCM may stem from a defect in energy transfer from its source of generation (mitochondria) to its site of use (sarcomeres), leading to subcellular energy deficiency. Despite these etiologic differences, there are some common mechanistic and clinicopathologic threads between HCM and the genetic and acquired forms of DCM, as summarized in Figure 12-32 .

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy is a disorder characterized by a *primary decrease in ventricular compliance, resulting in impaired ventricular filling during diastole*. Because the contractile (systolic) function of the left ventricle is usually unaffected, the functional abnormality can be confused with that of constrictive pericarditis or HCM.[110] Restrictive cardiomyopathy may be idiopathic or associated with distinct diseases or processes that affect the myocardium, principally radiation fibrosis, amyloidosis, sarcoidosis, metastatic tumors, or the deposition of metabolites that accumulate due to inborn errors of metabolism.

Morphology. The ventricles are of approximately normal size or slightly enlarged, the cavities are

not dilated, and the myocardium is firm and noncompliant. Biatrial dilation is commonly observed. Microscopically, there may be only patchy or diffuse interstitial fibrosis, which can vary from minimal to extensive. However, endomyocardial biopsy will often reveal a specific etiology. An important specific subgroup is amyloidosis (described later).

Several other restrictive conditions require brief mention. *Endomyocardial fibrosis* is principally a disease of children and young adults in Africa and other tropical areas, characterized by fibrosis of the ventricular endocardium and subendocardium that extends from the apex upward, often involving the tricuspid and mitral valves. The fibrous tissue markedly diminishes the volume and compliance of affected chambers and so induces a restrictive functional defect. Ventricular mural thrombi sometimes develop, and indeed there is a suggestion that the fibrous tissue results from the organization of mural thrombi. The etiology is unknown.

Loeffler endomyocarditis also results in endomyocardial fibrosis, typically with large mural thrombi. It is similar in morphology to the tropical disease, but in addition to the cardiac changes, there is often a peripheral eosinophilia (i.e., elevated blood eosinophils) and eosinophilic infiltrates in other organs. The release of toxic products of eosinophils, especially major basic protein, is postulated to initiate endomyocardial necrosis, followed by scarring of the necrotic area, layering of the endocardium by thrombus, and finally organization of the thrombus. It is now recognized that some patients with Loeffler endomyocarditis have a myeloproliferative disorder associated with chromosomal rearrangements involving either the PDGFRα or PDGFRβ genes (Chapter 13). These rearrangements produce fusion genes that encode constitutively active PDGFR tyrosine kinases. Treatment of such patients with the tyrosine kinase inhibitor imatinib has resulted in hematologic remissions associated with reversal of the endomyocarditis, which otherwise is often rapidly fatal.

Endocardial fibroelastosis is an uncommon heart disease of obscure etiology characterized by focal or diffuse fibroelastic thickening usually involving the mural left ventricular endocardium. It is most common in the first 2 years of life, and is accompanied by aortic valve obstruction or other congenital cardiac anomalies in about one third of cases. Diffuse involvement may be responsible for rapid and progressive cardiac decompensation and death.

MYOCARDITIS

Under the designation myocarditis are a diverse group of pathologic entities in which infectious microorganisms and/or an inflammatory process cause myocardial injury.[111] These disorders must be distinguished from conditions, such as ischemic heart disease, in which injuries caused by other mechanisms lead to inflammation secondarily.

Etiology and Pathogenesis.

In the United States, *viral infections* are the most common cause of myocarditis. *Coxsackieviruses A* and *B* and other enteroviruses probably account for most of the cases. Other less common etiologic agents include cytomegalovirus, HIV, and a host of other agents (listed in Table 12-12). The responsible virus can sometimes be identified by serologic studies or, more recently, identification of viral nucleic acids (DNA or RNA) in myocardial biopsies. Whether viruses cause the myocardial injury directly or initiate a destructive immune response is unclear.

TABLE 12-12 -- Major Causes of Myocarditis

INFECTIONS

Viruses (e.g., coxsackievirus, ECHO, influenza, HIV, cytomegalovirus)
Chlamydiae (e.g., *C. psittaci*)
Rickettsiae (e.g., *R. typhi*, typhus fever)
Bacteria (e.g., *Corynebacterium diphtheriae, Neisseria meningococcus, Borrelia* (Lyme disease)
Fungi (e.g., *Candida*)
Protozoa (e.g., *Trypanosoma cruzi* [Chagas disease], toxoplasmosis)
Helminths (e.g. trichinosis)
IMMUNE-MEDIATED REACTIONS
Postviral
Poststreptococcal (rheumatic fever)
Systemic lupus erythematosus
Drug hypersensitivity (e.g., methyldopa, sulfonamides)
Transplant rejection
UNKNOWN
Sarcoidosis
Giant cell myocarditis

HIV, human immunodeficiency virus.

Nonviral agents are also important causes of infectious myocarditis, particularly the protozoa *Trypanosoma cruzi*, the agent of Chagas disease.[112] Chagas disease is endemic in some regions of South America; myocardial involvement is present in most infected individuals. About 10% of patients die during an acute attack; others develop a chronic immune-mediated myocarditis that may progress to cardiac insufficiency 10 to 20 years later. Trichinosis is the most common helminthic disease associated with myocarditis. Parasitic diseases, including toxoplasmosis, and bacterial infections, including Lyme disease and diphtheria, can also cause myocarditis. In the case of diphtheritic myocarditis, toxins released by *Corynebacterium diphtheriae* seem to be responsible for the myocardial injury. Myocarditis occurs in approximately 5% of patients with Lyme disease, a systemic illness caused by the bacterial spirochete *Borrelia burgdorferi* (Chapter 8). Lyme myocarditis manifests primarily as a self-limited conduction system disorder that frequently requires a temporary pacemaker. Myocarditis occurs in many patients with AIDS. Two types have been identified: (1) inflammation and myocyte damage without a clear etiologic agent and (2) myocarditis caused by HIV directly or by an opportunistic pathogen.

There are also noninfectious causes of myocarditis. Myocarditis can be caused by hypersensitivity reactions *(hypersensitivity myocarditis)*, often to drugs such as antibiotics, diuretics, or antihypertensive agents. Myocarditis can also be associated with systemic diseases of immune origin, such as rheumatic fever, systemic lupus erythematosus, and polymyositis. Cardiac sarcoidosis and rejection of a transplanted heart (see Figure 12-40) are also considered forms of myocarditis.

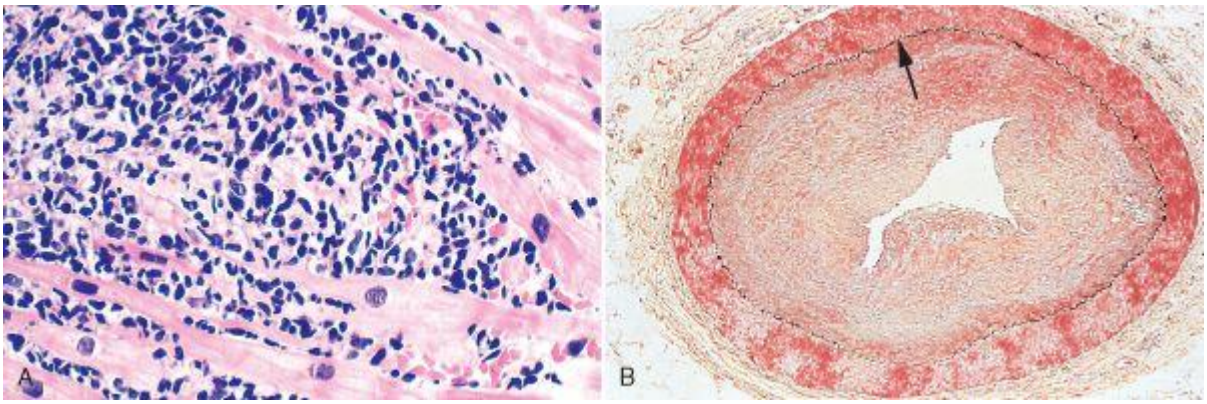

FIGURE 12-40 Complications of heart transplantation. **A**, Cardiac allograft rejection typified by lymphocytic infiltrate, with associated damage to cardiac myocytes. **B**, Graft coronary arteriosclerosis, demonstrating severe diffuse concentric intimal thickening producing critical stenosis. The internal elastic lamina *(arrow)* and media are intact (Movat pentachrome stain, elastin black). *(**B**, Reproduced by permission from Salomon RN et al.: Human coronary transplantation-associated arteriosclerosis. Evidence for chronic immune reaction to activated graft endothelial cells. Am J Pathol 138:791, 1991.)*

Morphology. During the active phase of myocarditis the heart may appear normal or dilated; some hypertrophy may be present depending on disease duration. In advanced stages the ventricular myocardium is flabby and often mottled by either pale foci or minute hemorrhagic lesions. Mural thrombi may be present in any chamber.

During active disease, myocarditis is most frequently characterized by an interstitial inflammatory infiltrate associated with focal myocyte necrosis (Fig. 12-36). A diffuse, mononuclear, predominantly lymphocytic infiltrate is most common (Fig. 12-36A). Although endomyocardial biopsies are diagnostic in some cases, they can be spuriously negative because inflammatory involvement of the myocardium may be focal or patchy. If the patient survives the acute phase of myocarditis, the inflammatory lesions either resolve, leaving no residual changes, or heal by progressive fibrosis.

Hypersensitivity myocarditis has interstitial infiltrates, principally perivascular, composed of lymphocytes, macrophages, and a high proportion of eosinophils (Fig. 12-36B). A morphologically distinctive form of myocarditis of uncertain cause, called **giant-cell myocarditis**, is characterized by a widespread inflammatory cellular infiltrate containing multinucleate giant cells interspersed with lymphocytes, eosinophils, plasma cells, and macrophages. Focal to frequently extensive necrosis is present (see Fig. 12-36C). This variant carries a poor prognosis.

The myocarditis of **Chagas disease** is rendered distinctive by parasitization of scattered myofibers by trypanosomes accompanied by an inflammatory infiltrate of neutrophils, lymphocytes, macrophages, and occasional eosinophils (see Fig. 12-36D).

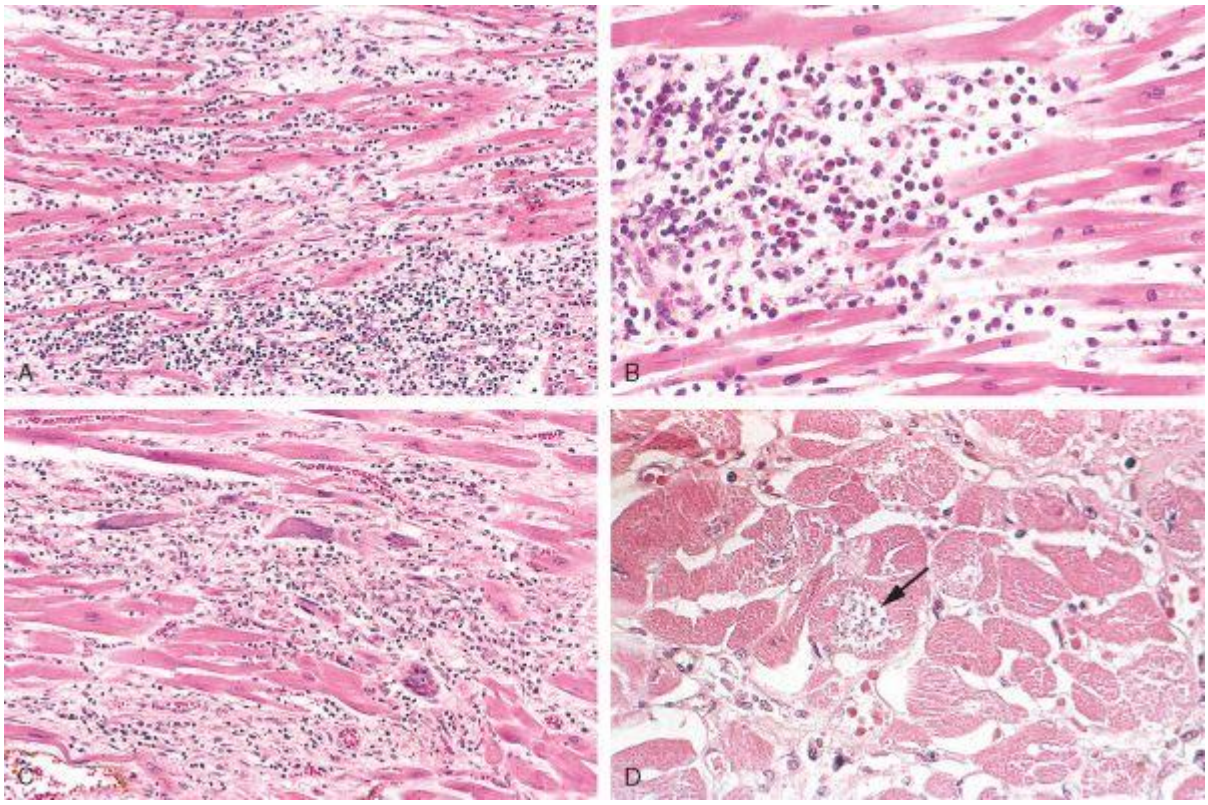

FIGURE 12-36 Myocarditis. **A**, Lymphocytic myocarditis, associated with myocyte injury. **B**, Hypersensitivity myocarditis, characterized by interstitial inflammatory infiltrate composed largely of eosinophils and mononuclear inflammatory cells, predominantly localized to perivascular and expanded interstitial spaces. **C**, Giant-cell myocarditis, with mononuclear inflammatory infiltrate containing lymphocytes and macrophages, extensive loss of muscle, and multinucleated giant cells. **D**, The myocarditis of Chagas disease. A myofiber distended with trypanosomes *(arrow)* is present along with inflammation and necrosis of individual myofibers.

Clinical Features.

The clinical spectrum of myocarditis is broad. At one end the disease is entirely asymptomatic, and such patients recover completely without sequelae; at the other extreme is the precipitous onset of heart failure or arrhythmias, occasionally with sudden death. Between these extremes are the many levels of involvement associated with symptoms such as fatigue, dyspnea, palpitations, precordial discomfort, and fever. The clinical features of myocarditis can mimic those of acute MI. Occasionally, patients develop dilated cardiomyopathy as a late complication of myocarditis.

OTHER CAUSES OF MYOCARDIAL DISEASE

Cardiotoxic Drugs.

Cardiac complications of cancer therapy are an important clinical problem.[113] Cardiotoxicity can be associated with conventional chemotherapeutic agents, targeted drugs such as tyrosine kinase inhibitors, and certain forms of immunotherapy.[114,][115] The anthracyclines doxorubicin and daunorubicin are the chemotherapeutic agents that are most often associated with toxic myocardial injury, which often leads to a dilated cardiomyopathy and heart failure. Anthracycline toxicity is dose-dependent (cardiotoxicity becomes progressively more frequent above a total dose of 500 mg/m^2) and is attributed primarily to peroxidation of lipids in myocyte membranes.

Many other pharmaceuticals and other agents, such as lithium, phenothiazines, chloroquine, and cocaine, have been implicated in myocardial injury and sometimes sudden death. Common findings in hearts injured by many of these chemicals and drugs (including diphtheria exotoxin and doxorubicin) are myofiber swelling, cytoplasmic vacuolization, and fatty change. With discontinuance of the toxic agent these changes may resolve completely, leaving no apparent sequelae. Sometimes, however, more extensive damage produces myocyte necrosis, which can evolve to a dilated cardiomyopathy.

Catecholamines.

Foci of myocardial necrosis with contraction bands, often associated with a sparse mononuclear inflammatory infiltrate consisting mostly of macrophages, can occur in individuals with a pheochromocytoma, a tumor that elaborates catecholamines (Chapter 24). This is considered to be a manifestation of the general problem of "catecholamine effect," also seen in association with intense autonomic stimulation (secondary to intracranial lesions or stress), or the exogenous administration of large doses of vasopressor agents such as dopamine.[116] Sudden, intense emotional or physical stress can also induce acute left ventricular dysfunction due to myocardial stunning, a phenomenon known as Takotsubo cardiomyopathy.[117] Cocaine also causes similar catecholamine-mediated damage. The mechanism of catecholamine cardiotoxicity is uncertain, but it seems to relate either to direct toxicity of catecholamines to cardiac myocytes via calcium overload or to focal vasoconstriction in the coronary arterial macro- or microcirculation in the face of an increased heart rate. The mononuclear cell infiltrate is probably a secondary reaction to the foci of myocyte cell death. Similar changes may be encountered in individuals who have recovered from hypotensive episodes or have been resuscitated from a cardiac arrest; in such cases the damage is a result of ischemia-reperfusion (see earlier) with subsequent inflammation.

Amyloidosis.

Amyloidosis is a prototypical myocardial disorder caused by deposition of an abnormal substance in the heart. Amyloidosis (Chapter 6) is caused by insoluble extracellular fibrillar deposits of protein fragments that are prone to forming β-pleated sheets.[118] Cardiac amyloidosis may appear along with systemic amyloidosis or be restricted to the heart, particularly in the aged (senile cardiac amyloidosis).[119] In senile cardiac amyloidosis, the amyloid deposits generally occur in the ventricles and atria. Senile cardiac amyloidosis occurs in older individuals and is caused by the deposition of transthyretin, a normal serum protein synthesized in the liver that is responsible for transporting thyroxine and retinol-binding protein. Senile cardiac amyloidosis[120] has a far better prognosis than systemic amyloidosis. Mutant forms of transthyretin can accelerate cardiac (and associated systemic) amyloidosis. For example, the risk of isolated cardiac amyloidosis is four times greater in African Americans than in Caucasians after 60 years of age because 4% of African Americans have a transthyretin mutation leading to the substitution of isoleucine for valine at position 122. This substitution produces an amyloidogenic form of transthyretin (responsible for autosomal-dominant familial transthyretin amyloidosis). Isolated atrial amyloidosis can also occur secondary to deposition of atrial natriuretic peptide, but its clinical significance is uncertain.

Cardiac amyloidosis most frequently produces a restrictive cardiomyopathy, but it can also be asymptomatic or manifest as dilation, arrhythmias, or symptoms mimicking those of ischemic or valvular disease. These varied presentations depend on the predominant location of the deposits, which can be found in the interstitium, conduction system, vasculature, or valves.

Morphology. The heart varies in consistency from normal to firm and rubbery. Usually the chambers are of normal size, but in some cases they are dilated and have thickened walls. Numerous small,

semitranslucent nodules resembling drips of wax may be seen at the atrial endocardial surface, particularly on the left. Eosinophilic deposits of amyloid may be found in the interstitium, conduction tissue, valves, endocardium, pericardium, and small intramural coronary arteries; they can be distinguished from other hyaline deposits by special stains such as Congo red, which produces classic apple-green birefringence when viewed under polarized light (Fig. 12-37). Amyloid deposits often form rings around cardiac myocytes and capillaries. Intramural arteries and arterioles may have sufficient amyloid in their walls to compress and occlude their lumens, inducing myocardial ischemia ("small-vessel disease").

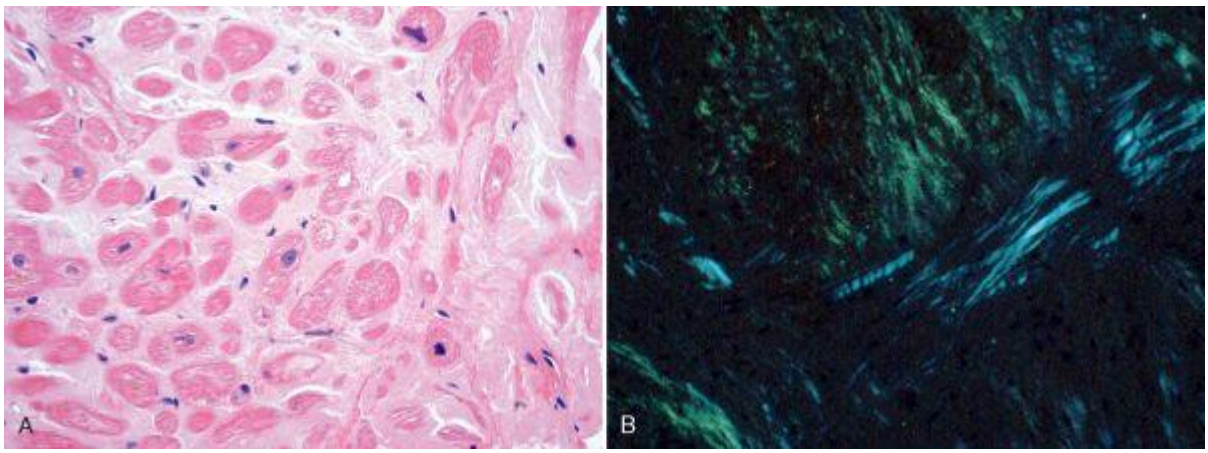

FIGURE 12-37 Cardiac amyloidosis. **A**, Hematoxylin and eosin stain, showing amyloid appearing as amorphous pink material around myocytes. **B**, Congo red stain viewed under polarized light, in which amyloid shows characteristic apple-green birefringence (compared with collagen, which appears white).

Iron Overload.

Iron overload can result from either hereditary hemochromatosis (Chapter 18) or multiple blood transfusions (hemosiderosis). The heart in each is usually dilated. Iron deposition is more prominent in ventricles than atria and in the myocardium than in the conduction system. It is thought that iron causes systolic dysfunction by interfering with metal-dependent enzyme systems or by inducing oxygen free-radical injury.

Morphology. Grossly, the myocardium of the iron-overloaded heart is rust-brown in color but is usually otherwise indistinguishable from that of idiopathic dilated cardiomyopathy. Microscopically, there is marked accumulation of hemosiderin within cardiac myocytes, particularly in the perinuclear region, demonstrable with a Prussian blue stain. This is associated with varying degrees of cellular degeneration and fibrosis. Ultrastructurally, the cardiac myocytes contain abundant perinuclear siderosomes (ironcontaining lysosomes).

Hyperthyroidism and Hypothyroidism.

Cardiac manifestations are among the earliest, most consistent features of hyperthyroidism and hypothyroidism, and they reflect direct and indirect effects of thyroid hormones on the cells of the heart.[121] In *hyperthyroidism* (Chapter 24), tachycardia, palpitations, and cardiomegaly are common; supraventricular arrhythmias occasionally appear. Cardiac failure is uncommon; when it occurs in this

setting, it is usually superimposed on other cardiac diseases. In *hypothyroidism* (Chapter 24), cardiac output is decreased, due to reductions in stroke volume and heart rate. Increased peripheral vascular resistance and decreased blood volume result in narrowing of the pulse pressure, prolongation of circulation time, and decreased flow to peripheral tissues.

Morphology. In hyperthyroidism the gross and histologic features are those of nonspecific hypertrophy and can also include ischemic foci. In well-advanced hypothyroidism (myxedema) the heart is flabby, enlarged, and dilated. Histologic features of hypothyroidism include myofiber swelling with loss of striations and basophilic degeneration, accompanied by interstitial mucopolysaccharide-rich edema fluid. A similar fluid sometimes accumulates within the pericardial sac. The term **myxedema heart** has been applied to these changes.

3.2.10 Pericardial Disease

The most important pericardial disorders cause fluid accumulation, inflammation, fibrous constriction, or some combination of these processes, usually in association with disease elsewhere in the heart or a systemic disease; isolated pericardial disease is unusual.[122]

PERICARDIAL EFFUSION AND HEMOPERICARDIUM

Normally, there are about 30 to 50 mL of thin, clear, straw-colored fluid in the pericardial sac. Under various circumstances the parietal pericardium may be distended by serous fluid *(pericardial effusion)*, blood (hemopericardium), or pus (purulent pericarditis). With long-standing pressure or volume overload, the pericardium dilates. This permits a slowly accumulating pericardial effusion to become quite large without interfering with cardiac function. Thus, with chronic effusions of less than 500 mL in volume, the only clinical significance is a characteristic globular enlargement of the heart shadow on chest radiographs. In contrast, rapidly developing fluid collections of as little as 200 to 300 mL—for example, due to hemopericardium caused by a ruptured MI or aortic dissection—may produce compression of the thin-walled atria and venae cavae, or the ventricles themselves. As a consequence, cardiac filling is restricted, producing potentially fatal *cardiac tamponade*.

PERICARDITIS

Pericardial inflammation may occur secondary to a variety of cardiac diseases, thoracic or systemic disorders, metastases from neoplasms arising in remote sites, or a surgical procedure on the heart. Primary pericarditis is unusual and almost always of viral origin. The major causes of pericarditis are listed in Table 12-13 . Most evoke an acute pericarditis, but a few, such as tuberculosis and fungi, produce chronic reactions.

TABLE 12-13 -- Causes of Pericarditis

INFECTIOUS AGENTS
Viruses
Pyogenic becteria
Tuberculosis
Fungi
Other parasites

PRESUMABLY IMMUNOLOGICALLY MEDIATED
Rheumatic fever
Systemic lupus erythematosus
Scleroderma
Postcardiotomy
Postmyocardial infarction (Dressler) syndrome
Drug hypersensitivity reaction
MISCELLANEOUS

Uremia
Following cardiac surgery
Neoplasia
Trauma
Radiation

Acute Pericarditis
Serous Pericarditis.

This is characteristically produced by noninfectious inflammatory diseases, such as rheumatic fever, SLE, and scleroderma, tumors, and uremia. An infection in the tissues contiguous to the pericardium—for example, a bacterial pleuritis—may incite sufficient irritation of the parietal pericardial serosa to cause a sterile serous effusion that may progress to serofibrinous pericarditis and ultimately to a frank suppurative reaction. In some instances a well-defined viral infection elsewhere—upper respiratory tract infection, pneumonia, parotitis—antedates the pericarditis and serves as the primary focus of infection. Infrequently, usually in young adults, a viral pericarditis occurs as an apparent primary infection that may be accompanied by myocarditis *(myopericarditis)*. Histologically, there is a mild inflammatory infiltrate in the epipericardial fat consisting predominantly of lymphocytes. Organization into fibrous adhesions rarely occurs.

Fibrinous and Serofibrinous Pericarditis.

These two anatomic forms are *the most frequent type of pericarditis* and are composed of serous fluid mixed with a fibrinous exudate. Common causes include acute MI (recall Fig. 12-19D), the postinfarction (Dressler) syndrome (probably an autoimmune condition appearing several weeks after an MI), uremia, chest radiation, rheumatic fever, SLE, and trauma. A fibrinous reaction also follows routine cardiac surgery.

Morphology. In fibrinous pericarditis the surface is dry, with a fine granular roughening. In serofibrinous pericarditis a more intense inflammatory process induces the accumulation of larger amounts of yellow to browen turbid fluid, which is made brown and cloudy by the presence of leukocytes and red cells (which may give the fluid a visibly bloody appearance), and often fibrin. As with all inflammatory exudates, fibrin may be lysed with resolution of the exudate, or it may become organized (see Chapter 3).

From the clinical standpoint *the development of a loud pericardial friction rub is the most striking characteristic of fibrinous pericarditis*, and pain, systemic febrile reactions, and signs suggestive of cardiac failure may be present. However, the collection of serous fluid may sometimes prevent rubbing by separating the two layers of the pericardium.

Purulent or Suppurative Pericarditis.

This form of pericarditis is caused by invasion of the pericardial space by microbes, which may reach the pericardial cavity by several routes: (1) direct extension from neighboring infections, such as an empyema of the pleural cavity, lobar pneumonia, mediastinal infections, or extension of a ring abscess through the myocardium or aortic root; (2) seeding from the blood; (3) lymphatic extension; or (4) direct introduction during cardiotomy. Immunosuppression predisposes to infection by all of these pathways. The exudate ranges from a thin cloudy fluid to frank pus up to 400 to 500 mL in volume. The serosal surfaces are reddened, granular, and coated with the exudate (Fig. 12-38). Microscopically there is an acute inflammatory reaction, which sometimes extends into surrounding structures to induce *mediastinopericarditis*. Complete resolution is infrequent, and organization by scarring is the usual outcome. The intense inflammatory response and the subsequent scarring frequently produce *constrictive pericarditis*, a serious consequence (see later).

FIGURE 12-38 Acute suppurative pericarditis arising from direct extension of a pneumonia. Extensive purulent exudate is evident.

The clinical findings in the active phase are essentially the same as those present in fibrinous pericarditis, but signs of systemic infection are usually marked: for example, spiking temperatures, chills, and fever.

Hemorrhagic Pericarditis.

In this type of pericarditis the exudate is composed of blood mixed with a fibrinous or suppurative effusion; it is most commonly caused by the spread of a malignant neoplasm to the pericardial space. In such cases, cytologic examination of fluid removed through a pericardial tap often reveals the presence of neoplastic cells. Hemorrhagic pericarditis can also be found in bacterial infections, in persons with an underlying bleeding diathesis, and in tuberculosis. Hemorrhagic pericarditis often follows cardiac surgery and is occasionally responsible for significant blood loss or even tamponade, requiring a

"second-look" operation. The clinical significance is similar to that of fibrinous or suppurative pericarditis.

Caseous Pericarditis.

This rare type of pericarditis is, until proved otherwise, tuberculous in origin; infrequently, fungal infections evoke a similar reaction. Pericardial involvement occurs by direct spread from tuberculous foci within the tracheobronchial nodes. Caseous pericarditis is a frequent antecedent of disabling, fibrocalcific, chronic constrictive pericarditis.

Chronic or Healed Pericarditis

In some cases organization merely produces plaquelike fibrous thickenings of the serosal membranes ("soldier's plaque") or thin, delicate adhesions of obscure origin that are observed fairly frequently at autopsy and rarely cause impairment of cardiac function. In other cases, fibrosis in the form of delicate, stringy adhesions completely obliterates the pericardial sac. In most instances, this *adhesive pericarditis* has no effect on cardiac function.

Adhesive mediastinopericarditis may follow infectious pericarditis, previous cardiac surgery, or irradiation to the mediastinum. The pericardial sac is obliterated, and adherence of the external aspect of the parietal layer to surrounding structures produces a great strain on cardiac function. With each systolic contraction, the heart pulls not only against the parietal pericardium but also against the attached surrounding structures. Systolic retraction of the rib cage and diaphragm, pulsus paradoxus, and a variety of other characteristic clinical findings may be observed. The increased workload causes cardiac hypertrophy and dilation, which may be substantial in severe cases.

In *constrictive pericarditis* the heart is encased in a dense, fibrous or fibrocalcific scar that limits diastolic expansion and cardiac output, features that mimic a restrictive cardiomyopathy. A prior history of pericarditis may or may not be present. The scar, often 0.5 to 1.0 cm thick, obliterates the pericardial space and sometimes calcifies; in extreme cases it can resemble a plaster mold *(concretio cordis)*. Because of the dense enclosing scar, cardiac hypertrophy and dilation cannot occur. Cardiac output may be reduced at rest, but more importantly the heart has little if any capacity to increase its output in response to increased peripheral needs. Heart sounds are understandably distant or muffled. Treatment consists of surgical removal of the shell of constricting fibrous tissue (pericardiectomy).

HEART DISEASE ASSOCIATED WITH RHEUMATOLOGIC DISORDERS

Paradoxically, the prevalence and importance of cardiovascular manifestations of rheumatologic diseases (including rheumatoid arthritis, SLE, systemic sclerosis, ankylosing spondylitis, and psoriatic arthritis) has increased as a result of the longer life expectancy of persons with these disorders and enhanced detection of milder cases.[123] Inflammatory mechanisms may cause vascular, myocardial, valvular, and pericardial manifestations. In addition, ischemic heart disease seems to be accelerated in individuals with inflammatory rheumatic conditions.

Rheumatoid arthritis is mainly a disorder of the joints, but it is also associated with many extra-articular features (e.g., subcutaneous rheumatoid nodules, acute vasculitis, and Felty syndrome; see Chapter 26). The heart is also involved in 20% to 40% of cases of severe prolonged rheumatoid arthritis. The most common finding is a *fibrinous pericarditis* that may progress to fibrous thickening of the visceral and parietal pericardium and dense adhesions. Granulomatous rheumatoid nodules resembling those that occur subcutaneously may also be identifiable in the myocardium. Much less frequently, rheumatoid nodules involve the endocardium, valves of the heart, and root of the aorta. *Rheumatoid valvulitis* can lead to marked fibrous thickening and secondary calcification of the aortic valve cusps, producing

changes resembling those of chronic rheumatic valvular disease. The valvular lesions associated with SLE were discussed previously under “Valvular Heart Disease.”

3.2.11 Tumors of the Heart

Primary tumors of the heart are rare; in contrast, metastatic tumors to the heart occur in about 5% of persons dying of cancer. The most common primary cardiac tumors, in descending order of frequency (overall, including adults and children), are myxomas, fibromas, lipomas, papillary fibroelastomas, rhabdomyomas, angiosarcomas, and other sarcomas. The five most common tumors are all benign and collectively account for 80% to 90% of primary tumors of the heart.

PRIMARY CARDIAC TUMORS

Myxoma

Myxomas are the most common primary tumor of the heart in adults (Fig. 12-39). They are benign neoplasms often associated with clonal abnormalities of chromosomes 12 and 17 that are thought to arise from primitive multipotent mesenchymal cells. Although they may arise in any of the four chambers or, rarely, on the heart valves, about 90% are located in the atria *(atrial myxomas)*, with a left-to-right ratio of approximately 4 : 1.

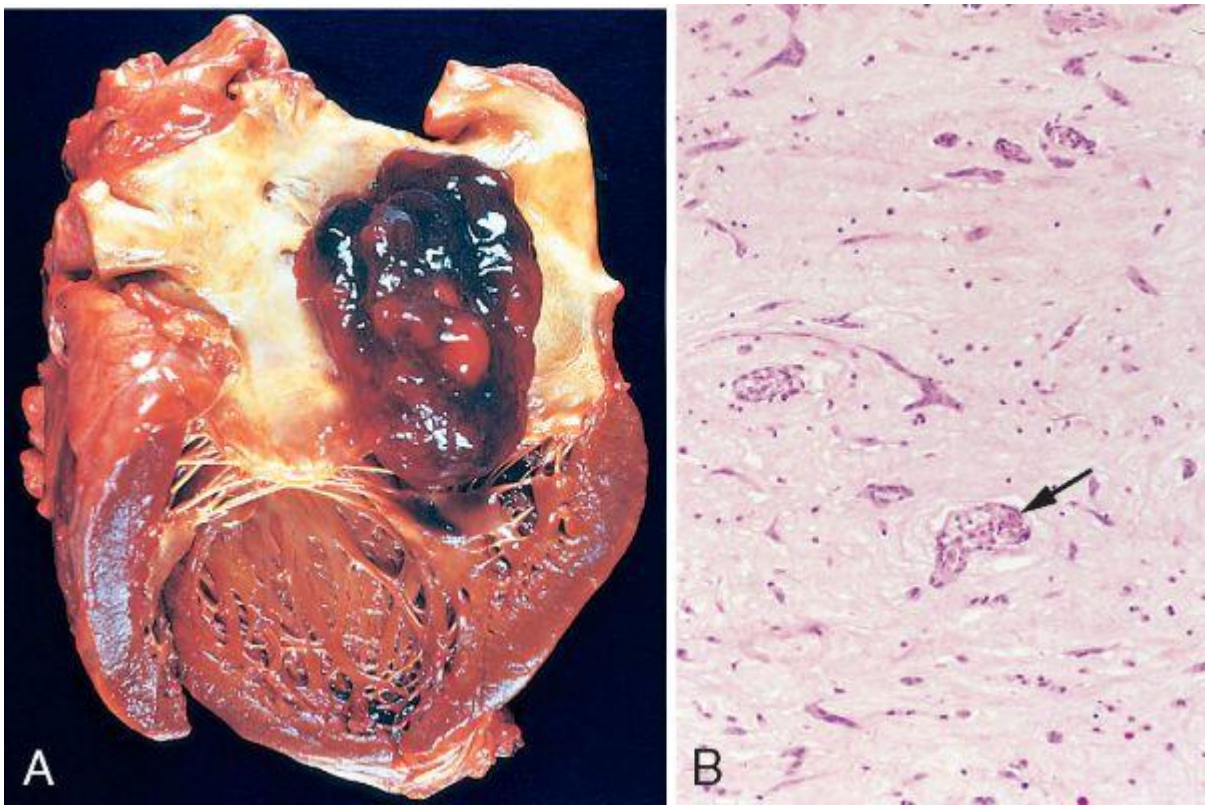

FIGURE 12-39 Left atrial myxoma. **A**, Gross photograph showing large pedunculated lesion arising from the region of the fossa ovalis and extending into the mitral valve orifice. **B**, Microscopic appearance, with abundant amorphous extracellular matrix in which there are scattered collections of myxoma cells in various groupings, including abnormal vessel-like formations *(arrow)*.

Morphology. The tumors are usually single, but rarely several occur simultaneously. The region of

the fossa ovalis in the atrial septum is the favored site of origin. Myxomas range in size from small (<1 cm) to large (≥10 cm). They are sessile or pedunculated lesions (Fig. 12-39A) that vary from globular hard masses mottled with hemorrhage to soft, translucent, papillary, or villous lesions having a gelatinous appearance. The pedunculated form is often sufficiently mobile to move into or even through the AV valves during systole, causing intermittent obstruction that may be position-dependent. Sometimes mobile tumors exert a "wrecking-ball" effect, causing damage to the valve leaflets.

Histologically, myxomas are composed of stellate or globular myxoma cells embedded within an abundant acid mucopolysaccharide ground substance (Fig. 12-39B). Peculiar vessel-like or gland-like structures are characteristic. Hemorrhage and mononuclear inflammation are usually present.

The major clinical manifestations are due to valvular "ball-valve" obstruction, embolization, or a syndrome of constitutional symptoms, such as fever and malaise. Sometimes fragmentation and systemic embolization calls attention to these lesions. Constitutional symptoms are probably due to the elaboration by some myxomas of the cytokine IL-6, a major mediator of the acute-phase response. Echocardiography provides the opportunity to identify these masses noninvasively. Surgical removal is usually curative; rarely, the neoplasm recurs months to years later.

Approximately 10% of individuals with myxoma have a familial syndrome (known as *Carney complex*) characterized by autosomal-dominant transmission, multiple cardiac and often extracardiac (e.g., skin) myxomas, pigmented skin lesions, and endocrine overactivity. A careful history and physical examination in persons with cardiac myxoma is important to identify the extra-cardiac signs of the Carney complex, since this diagnosis carries implications for family members of the patient. The gene *PRKAR1* on chromosome 17 (encoding a regulatory subunit of cyclic adenosine monophosphate–dependent protein kinase A, possibly a tumor suppressor gene) is mutated in most Carney complex kindreds; other kindreds have abnormalities in a locus at chromosome 2p16.[124]

Lipoma

Lipomas are localized, well-circumscribed, benign tumors composed of mature fat cells that may occur in the subendocardium, subepicardium, or myocardium. They may be asymptomatic, or produce ball-valve obstructions or arrhythmias. Lipomas are most often located in the left ventricle, right atrium, or atrial septum and are not necessarily neoplastic. In the atrial septum, non-neoplastic depositions of fat sometimes occur that are called "lipomatous hypertrophy."

Papillary Fibroelastoma

Papillary fibroelastomas are curious, usually incidental, sea-anemone-like lesions, most often identified at autopsy. They may embolize and thereby become clinically important. Clonal cytogenetic abnormalities have been reported, suggesting that fibroelastomas are unusual benign neoplasms. They resemble the much smaller, usually trivial, *Lambl excrescences* that are frequently found on the aortic valves of older individuals.

Morphology. Papillary fibroelastomas are generally located on valves, particularly the ventricular surfaces of semilunar valves and the atrial surfaces of atrioventricular valves. They consist of a distinctive cluster of hairlike projections up to 1 cm in length, and several centimeters in diameter. Histologically, the projections are composed of a core of myxoid connective tissue containing

abundant mucopolysaccharide matrix and elastic fibers that is covered by a surface endothelium.

Rhabdomyoma

Rhabdomyomas are the most frequent primary tumor of the heart in infants and children and are frequently discovered in the first years of life because of obstruction of a valvular orifice or cardiac chamber. Cardiac rhabdomyomas are often associated with tuberous sclerosis (see Chapter 28), which is caused by defects in the TSC1 or TSC2 tumor suppressor genes. The TSC1 and TSC2 proteins work together in a complex that inhibits the activity of the mammalian target of rapamycin (mTOR), a kinase that stimulates cell growth and regulates cell size. TSC1 or TSC2 expression is often completely lost in rhadmyosarcomas that occur in the setting of tuberous sclerosis, providing a mechanism for the myocyte overgrowth. Because they often regress spontaneously, rhabdomyomas are considered by some to be hamartomas rather than true neoplasms.

Morphology. Rhabdomyomas are generally small, gray-white myocardial masses up to several centimeters in diameter. They are usually multiple in number and involve the ventricles preferentially, often protruding into the chambers. Histologically they are composed of bizarre, markedly enlarged myocytes. In sections the abundant myocyte cytoplasm is often reduced to thin webs or strands that extend to cell membranes, an appearance referred to as **spider cells**.

Sarcoma

Cardiac *angiosarcomas* and other sarcomas are not clinically or morphologically distinctive from their counterparts in other locations (see Fig. 11-35 and Chapter 26) and so require no further comment here.

CARDIAC EFFECTS OF NONCARDIAC NEOPLASMS

With enhanced patient survival due to diagnostic and therapeutic advances, significant cardiovascular effects of noncardiac neoplasms and their therapy are now commonly encountered (Table 12-14). Pathology derives from infiltration by tumor, circulating mediators, and complications of therapy.

TABLE 12-14 -- Cardiovascular Effects of Noncardiac Neoplasms

Chemotherapy
Radiation therapy

Modified from Schoen FJ, et al: Cardiac effects of non-cardiac neoplasms. Cardiol Clin 2:657, 1984.

The most frequent metastatic tumors involving the heart are carcinomas of the lung and breast, melanomas, leukemias, and lymphomas. Metastases can reach the heart and pericardium by retrograde lymphatic extension (most carcinomas), by hematogenous seeding (many tumors), by direct contiguous extension (primary carcinoma of the lung, breast, or esophagus), or by venous extension (tumors of the kidney or liver). Clinical symptoms are most often associated with pericardial spread, which can cause symptomatic pericardial effusions or a mass-effect that is sufficient to restrict cardiac filling. Myocardial metastases are usually clinically silent or have nonspecific features, such as a generalized defect in ventricular contractility or compliance. Bronchogenic carcinoma or malignant lymphoma may infiltrate the mediastinum extensively, causing encasement, compression, or invasion of the superior vena cava with resultant obstruction to blood coming from the head and upper extremities *(superior vena cava syndrome)*. Renal cell carcinoma often invades the renal vein, and may grow as a frond of tissue up the inferior vena cava and into the right atrium, blocking venous return to the heart.

Noncardiac tumors may also affect cardiac function indirectly, sometimes via circulating tumor-derived substances (e.g., nonbacterial thrombotic endocarditis, carcinoid heart disease, pheochromocytoma-associated myocardial damage, multiple myeloma–associated AL amyloidosis; all described earlier).

Complications of chemotherapy were discussed earlier in this chapter. Radiation used to treat breast, lung, or mediastinal neoplasms can cause pericarditis, pericardial effusion, myocardial fibrosis, and chronic pericardial disorders. Other cardiac effects of radiation therapy include accelerated coronary artery disease and mural and valvular endocardial fibrosis.

3.2.12 Cardiac Transplantation

Transplantation of cardiac allografts is now frequently performed (~3000 per year worldwide) for severe, intractable heart failure of diverse causes, the two most common being dilated cardiomyopathy and ischemic heart disease. Three major factors have contributed to the improved outcome of cardiac transplantation since the first human to human transplant in 1967: (1) more effective immunosuppressive therapy (including the use of cyclosporin A, glucocorticoids, and other agents), (2) careful selection of candidates, and (3) early histopathologic diagnosis of acute allograft rejection by endomyocardial biopsy.[125]

Of the major complications, allograft rejection is the primary problem requiring surveillance; scheduled endomyocardial biopsy is the only reliable means of diagnosing acute cardiac rejection before substantial myocardial damage has occurred and at a stage that is reversible in the majority of instances. Rejection is characterized by interstitial lymphocytic inflammation that, in its more advanced stages, damages adjacent myocytes; the histology resembles myocarditis (Fig. 12-40A). When myocardial injury is not extensive, the “rejection episode” is usually either self-limited or successfully reversed by increased immunosuppressive therapy. Advanced rejection may be irreversible and fatal if it is not promptly treated.

The major current limitation to the long-term success of cardiac transplantation is diffuse stenosing intimal proliferation of the coronary arteries, which may involve intramural vessels extensively *(graft arteriopathy)* (Fig. 12-40B). Because the transplanted heart is often denervated, patients with this disorder may not experience ischemic chest pain, and this vexing problem may lead to silent MI; in severe graft arteriopathy, CHF or sudden death is the usual outcome. The pathogenesis of these arterial lesions is uncertain. Low-level, chronic rejection reactions may induce inflammatory cells and vascular wall cells to secrete growth factors that promote the recruitment and proliferation of intimal smooth

muscle cells and the synthesis of extracellular matrix, thereby expanding the intima (Chapter 6). Other postoperative problems include infection and malignancies, particularly Epstein-Barr virus-associated B cell lymphomas that arise in the setting of T-cell immunosuppression. Despite these problems, the overall outlook is good; the 1-year survival is 70% to 80% and 5-year survival is greater than 60%.

3.3 13. Diseases of White Blood Cells, Lymph Nodes, Spleen & Thymus

3.3.1 Development & Maintenance of Hematopoietic Tissues

The components of the hematopoietic system have been traditionally divided into the *myeloid tissues*, which include the bone marrow and the cells derived from it (e.g., red cells, platelets, granulocytes, and monocytes), and the *lymphoid tissues*, consisting of the thymus, lymph nodes, and spleen. It is important to recognize, however, that this subdivision is artificial with respect to both the normal physiology of hematopoietic cells and the diseases affecting them. For example, although bone marrow contains relatively few lymphocytes, it is the source of all lymphoid progenitors. Similarly, neoplastic disorders of myeloid progenitor cells (myeloid leukemias) originate in the bone marrow but secondarily involve the spleen and (to a lesser degree) the lymph nodes. Some red cell disorders (such as immunohemolytic anemia, discussed in Chapter 14) result from the formation of autoantibodies, signifying a primary disorder of lymphocytes. Thus, it is not possible to draw neat lines between diseases involving the myeloid and lymphoid tissues. Recognizing this difficulty, we somewhat arbitrarily divide diseases of the hematopoietic tissues into two chapters. In this chapter we discuss white cell diseases and disorders affecting the spleen and thymus. In Chapter 14 we consider diseases of red cells and those affecting hemostasis. Before delving into specific diseases, we will briefly discuss the origins of hematopoietic cells, since many disorders of white cells and red cells involve disturbances of their normal development and maturation.

Development and Maintenance of Hematopoietic Tissues

Blood cell progenitors first appear during the third week of embryonic development in the yolk sac, but definitive *hematopoietic stem cells* (HSCs) are believed to arise several weeks later in the mesoderm of the intraembryonic aorta/gonad/mesonephros region.[1] During the third month of embryogenesis, HSCs migrate to the liver, which becomes the chief site of blood cell formation until shortly before birth. By the fourth month of development, HSCs begin to shift in location yet again, this time to the bone marrow. By birth, marrow throughout the skeleton is hematopoietically active and hepatic hematopoiesis dwindles to a trickle, persisting only in widely scattered foci that become inactive soon after birth. Until puberty, hematopoietically active marrow is found throughout the skeleton, but soon thereafter it becomes restricted to the axial skeleton. Thus, in normal adults, only about half of the marrow space is hematopoietically active.

The formed elements of blood—red cells, granulocytes, monocytes, platelets, and lymphocytes—have a common origin from HSCs, pluripotent cells that sit at the apex of a hierarchy of bone marrow progenitors (Fig. 13-1). Most evidence supporting this scheme comes from studies in mice, but human hematopoiesis is believed to proceed in a similar way. HSCs give rise to two kinds of multipotent cells, the common lymphoid and common myeloid progenitors. The common lymphoid progenitor is the source of T-cell, B-cell, and natural killer (NK) cell precursors. We will return to the origins of lymphoid cells when we discuss tumors derived from these cells. From the common myeloid progenitors arise various kinds of committed progenitors restricted to differentiation along particular lineages. These cells are referred to as colony-forming units (CFUs) (see Fig. 13-1), because they give rise to colonies composed of specific kinds of mature cells when grown in culture. From the various committed progenitors are derived the morphologically recognizable precursors, such as myeloblasts, proerythroblasts, and megakaryoblasts, which in turn give rise to mature granulocytes, red cells, and platelets.

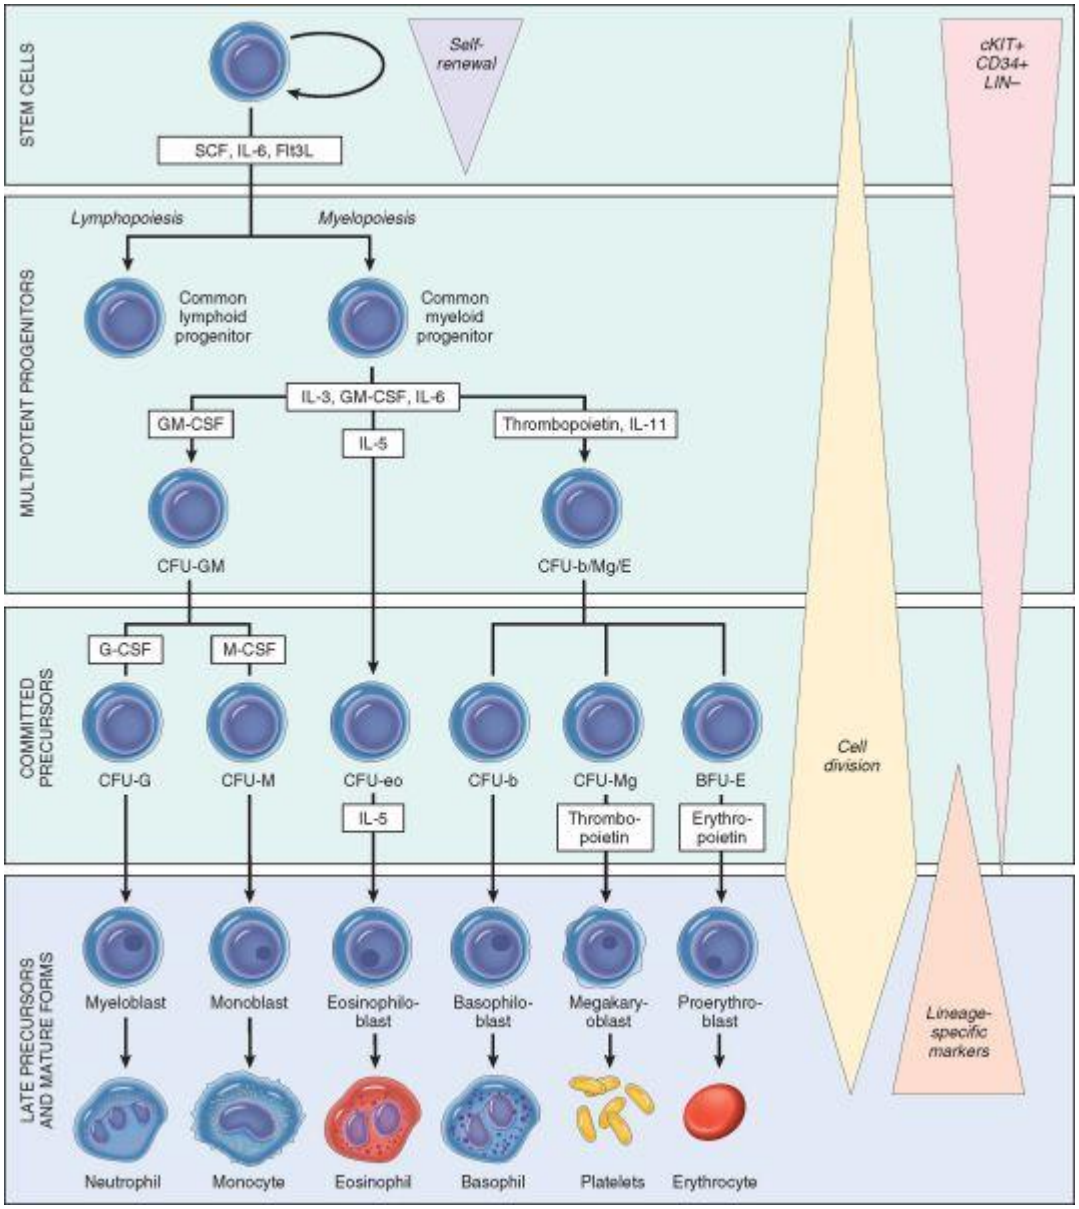

FIGURE 13-1 Differentiation of blood cells. CFU, colony forming unit; SCF, stem cell factor; Flt3L, Flt3 ligand; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; LIN–, negative for lineage-specific markers; M-CSF,

macrophage colony-stimulating factor.

HSCs have two essential properties that are required for the maintenance of hematopoiesis: pluripotency and the capacity for self-renewal. Pluripotency refers to the ability of a single HSC to generate all mature hematopoietic cells. When an HSC divides at least one daughter cell must self-renew to avoid stem cell depletion. Self-renewing divisions are believed to occur within a specialized marrow niche, in which stromal cells and secreted factors nurture and somehow maintain the HSCs.[2] As you may have already surmised from their ability to migrate during embryonic development, HSCs are not sessile. Particularly under conditions of marked stress, such as severe anemia, HSCs are mobilized from the bone marrow and appear in the peripheral blood. In such circumstances, additional HSC niches are sometimes induced or "unveiled" in other tissues, such as the spleen and liver, which can then become sites of extramedullary hematopoiesis.

The marrow response to short-term physiologic needs is regulated by hematopoietic growth factors through effects on the committed progenitors. Since mature blood elements are terminally differentiated cells with finite life spans, their numbers must be constantly replenished. In at least some divisions of HSCs, a single daughter cell begins to differentiate. Once past this threshold, these newly committed cells lose the capacity for self-renewal and commence an inexorable journey down a road that leads to terminal differentiation and death. However, as these progenitors differentiate they also begin to express receptors for lineage-specific growth factors, which stimulate their short-term growth and survival. Some growth factors, such as stem cell factor (also called *c-KIT ligand*) and FLT3-ligand, act on very early committed progenitors. Others, such as erythropoietin, granulocyte-macrophage colonystimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and thrombopoietin, act on committed progenitors with more restricted potentials. Feedback loops that are mediated through growth factors tune the marrow output, allowing the numbers of formed blood elements (red cells, white cells, and platelets) to be maintained within appropriate ranges (given in Table 13-1).

TABLE 13-1 -- Adult Reference Ranges for Blood Cells[*]

Cell Type	
White cells (× 10^3/μL)	4.8–10.8
Granulocytes (%)	40–70
Neutrophils (× 10^3/μL)	1.4–6.5
Lymphocytes (× 10^3/μL)	1.2–3.4
Monocytes (× 10^3/μL)	0.1–0.6
Eosinophils (× 10^3/μL)	0–0.5
Basophils (× 10^3/μL)	0–0.2
Red cells (× 10^3/μL)	4.3–5, men; 3.5–5.0, women
Platelets (× 10^3/μL)	150–450

[*] Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used.

Many diseases alter the production of blood cells. The marrow is the ultimate source of all cells of the innate and adaptive immune system and responds to infectious or inflammatory challenges by increasing its output of granulocytes under the direction of specific growth factors and cytokines. Conversely, other disorders are associated with defects in hematopoiesis that lead to deficiencies of one

or more type of blood cell. Primary tumors of hematopoietic cells are among the most important diseases that interfere with marrow function, but specific genetic diseases, infections, toxins, and nutritional deficiencies, as well as chronic inflammation of any cause, can also decrease the production of blood cells by the marrow.

Tumors of hematopoietic origin are often associated with mutations that block progenitor cell maturation or abrogate their growth factor dependence. The net effect of such derangements is an unregulated clonal expansion of hematopoietic elements, which replace normal marrow progenitors and often spread to other hematopoietic tissues. In some instances, these tumors originate from transformed HSCs that retain the ability to differentiate along multiple lineages, whereas in other instances the origin is a more differentiated progenitor that has acquired an abnormal capacity for self-renewal. Whether this latter situation merely reflects a block in differentiation, or derives instead from the reactivation of a program of gene expression that supports the self-renewal of normal stem cells, is an area of current investigation.

Morphology. The bone marrow is a unique microenvironment that supports the orderly proliferation, differentiation, and release of blood cells. It is filled with a network of thin-walled sinusoids lined by a single layer of endothelial cells, which are underlaid by a discontinuous basement membrane and adventitial cells. Within the interstitium lie clusters of hematopoietic cells and fat cells. Differentiated blood cells enter the circulation by transcellular migration through the endothelial cells.

The normal marrow is organized in subtle, but important, ways. For example, normal megakaryocytes lie next to sinusoids and extend cytoplasmic processes that bud off into the bloodstream to produce platelets, while red cell precursors often surround macrophages (so-called **nurse cells**) that provide some of the iron needed for the synthesis of hemoglobin. Diseases that distort the marrow architecture, such as deposits of metastatic cancer or granulomatous disease, can cause the abnormal release of immature precursors into the peripheral blood, a finding that is referred to as **leukoerythroblastosis**.

Marrow aspirate smears provide the best assessment of the morphology of hematopoietic cells. The most mature marrow precursors can be identified based on their morphology alone. Immature precursors ("blast" forms) of different types are morphologically similar and must be identified definitively using lineage-specific antibodies and histochemical markers (described later under white cell neoplasms). Biopsies are a good means for estimating marrow activity. In normal adults, the ratio of fat cells to hematopoietic elements is about 1 : 1. In hypoplastic states (e.g., aplastic anemia) the proportion of fat cells is greatly increased; conversely, fat cells often disappear when the marrow is involved by hematopoietic tumors and in diseases characterized by compensatory hyperplasias (e.g., hemolytic anemias), and neoplastic proliferations such as leukemias. Other disorders (such as metastatic cancers and granulomatous diseases) induce local marrow fibrosis. Such lesions are usually inaspirable and best seen in biopsies.

3.3.2 Disorders of White Cells

Disorders of white blood cells can be classified into two broad categories: *proliferative disorders*, in which there is an expansion of leukocytes, and *leukopenias*, which are defined as a deficiency of leukocytes. Proliferations of white cells can be *reactive* or *neoplastic*. Since the major function of leukocytes is host defense, reactive proliferation in response to an underlying primary, often microbial, disease is fairly common. Neoplastic disorders, though less frequent, are much more important

clinically. In the following discussion we will first describe the leukopenic states and summarize the common reactive disorders, and then consider in some detail the malignant proliferations of white cells.

3.3.2.1 Leukopenia

The number of circulating white cells may be markedly decreased in a variety of disorders. An abnormally low white cell count *(leukopenia)* usually results from reduced numbers of neutrophils *(neutropenia, granulocytopenia)*. *Lymphopenia* is less common; in addition to congenital immunodeficiency diseases (see Chapter 6), it is most commonly observed in advanced human immunodeficiency virus (HIV) infection, following therapy with glucocorticoids or cytotoxic drugs, autoimmune disorders, malnutrition, and certain acute viral infections. In the latter setting lymphopenia actually stems from lymphocyte activation rather than a true decrease in the number of lymphocytes in the body. You will recall that acute viral infections induce production of type I interferons, which activate T lymphocytes and change the expression of a number of surface proteins that regulate T cell migration. These changes result in the sequestration of activated T cells in lymph nodes and increased adherence to endothelial cells, both of which contribute to lymphopenia. Granulocytopenia is more common and is often associated with significantly decreased granulocyte function, and thus merits further discussion.

NEUTROPENIA, AGRANULOCYTOSIS

Neutropenia, a reduction in the number of neutrophils in the blood, occurs in a wide variety of circumstances. *Agranulocytosis*, a clinically significant reduction in neutrophils, has the serious consequence of making individuals susceptible to bacterial and fungal infections.

Pathogenesis.

A reduction in circulating granulocytes occurs if there is (1) inadequate or ineffective granulopoiesis, or (2) accelerated removal of neutrophils from the blood. *Inadequate or ineffective granulopoiesis* is observed in the setting of

- *Suppression of hematopoietic stem cells*, as occurs in aplastic anemia (see Chapter 14) and a variety of infiltrative marrow disorders (tumors, granulomatous disease, etc.); in these conditions granulocytopenia is accompanied by anemia and thrombocytopenia
- *Suppression of committed granulocytic precursors* by exposure to certain drugs (discussed below)
- Disease states associated with *ineffective hematopoiesis*, such as megaloblastic anemias (Chapter 14) and myelodysplastic syndromes, where defective precursors die in the marrow
- Rare *congenital conditions* (such as Kostmann syndrome) in which inherited defects in specific genes impair granulocytic differentiation

Accelerated removal or destruction of neutrophils occurs with

- *Immunologically mediated injury* to neutrophils, which can be idiopathic, associated with a well-defined immunological disorder (e.g., systemic lupus erythematosus), or caused by exposure to drugs
- *Splenomegaly*, in which splenic sequestration of neutrophils leads to excessive destruction, usually associated with increased destruction of red cells and platelets as well
- *Increased peripheral utilization*, which can occur in overwhelming bacterial, fungal, or rickettsial infections

The most common cause of agranulocytosis is drug toxicity. Certain drugs, such as alkylating agents and antimetabolites used in cancer treatment, produce agranulocytosis in a predictable, dose-related fashion. Because such drugs cause a generalized suppression of the bone marrow, production of red cells and

platelets is also affected. Agranulocytosis can also occur as an idiosyncratic reaction to a large variety of agents. The roster of implicated drugs includes aminopyrine, chloramphenicol, sulfonamides, chlorpromazine, thiouracil, and phenylbutazone. The neutropenia induced by chlorpromazine and related phenothiazines results from a toxic effect on granulocytic precursors in the bone marrow. In contrast, agranulocytosis following administration of aminopyrine, thiouracil, and certain sulfonamides probably stems from antibody-mediated destruction of mature neutrophils through mechanisms similar to those involved in drug-induced immunohemolytic anemias (Chapter 14).

In some patients with acquired idiopathic neutropenia, autoantibodies directed against neutrophil-specific antigens are detected. Severe neutropenia can also occur in association with monoclonal proliferations of large granular lymphocytes (so-called LGL leukemia).[3] The mechanism of this neutropenia is not clear; suppression of marrow granulocytic progenitors by products of the neoplastic cell (usually a CD8+ cytotoxic T cell) is considered most likely.

Morphology. The alterations in the bone marrow vary with cause. With excessive destruction of neutrophils in the periphery, the marrow is usually hypercellular due to a compensatory increase in granulocytic precursors. Hypercellularity is also the rule with neutropenias caused by ineffective granulopoiesis, as occurs in megaloblastic anemias and myelodysplastic syndromes. Agranulocytosis caused by agents that suppress or destroy granulocytic precursors is understandably associated with marrow hypocellularity.

Infections are a common consequence of agranulocytosis. Ulcerating necrotizing lesions of the gingiva, floor of the mouth, buccal mucosa, pharynx, or elsewhere in the oral cavity (agranulocytic angina) are quite characteristic. These are typically deep, undermined, and covered by gray to green-black necrotic membranes from which numerous bacteria or fungi can be isolated. Less frequently, similar ulcerative lesions occur in the skin, vagina, anus, or gastrointestinal tract. Severe life-threatening invasive bacterial or fungal infections may occur in the lungs, urinary tract, and kidneys. The neutropenic patient is at particularly high risk for deep fungal infections caused by *Candida* and *Aspergillus*. Sites of infection often show a massive growth of organisms with little leukocytic response. In the most dramatic instances, bacteria grow in colonies (botryomycosis) resembling those seen on agar plates.

Clinical Features.

The symptoms and signs of neutropenia are related to infection, and include malaise, chills, and fever, often followed by marked weakness and fatigability. With agranulocytosis, infections are often overwhelming and may cause death within hours to days.

Serious infections are most likely when the neutrophil count falls below 500 per mm^3. Because infections are often fulminant, broad-spectrum antibiotics must be given expeditiously whenever signs or symptoms appear. In some instances, such as following myelosuppressive chemotherapy, neutropenia is treated with G-CSF, a growth factor that stimulates the production of granulocytes from marrow precursors.

3.3.2.2 Reactive (Inflammatory) Proliferations of White Cells & Lymph Nodes

LEUKOCYTOSIS

Leukocytosis refers to an increase in the number of white cells in the blood. It is a common reaction to a variety of inflammatory states.

Pathogenesis.

The peripheral blood leukocyte count is influenced by several factors, including

- The size of the myeloid and lymphoid precursor and storage cell pools in the bone marrow, thymus, circulation, and peripheral tissues
- The rate of release of cells from the storage pools into the circulation
- The proportion of cells that are adherent to blood vessel walls at any time (the marginal pool)
- The rate of extravasation of cells from the blood into tissues

As was discussed in Chapter 2 , leukocyte homeostasis is maintained by cytokines, growth factors, and adhesion molecules through their effects on the commitment, proliferation, differentiation, and extravasation of leukocytes and their progenitors. Table 13-2 summarizes the major mechanisms of neutrophilic leukocytosis and its causes, the most important of which is infection. In acute infection there is a rapid increase in the egress of mature granulocytes from the bone marrow pool. If the infection is prolonged, the release of interleukin-1 (IL-1), tumor necrosis factor (TNF), and other inflammatory cytokines stimulates bone marrow stromal cells and T cells to produce increased amounts of hematopoietic growth factors, which enhance the proliferation and differentiation of committed granulocytic progenitors and, over several days, cause a sustained increase in neutrophil production.

TABLE 13-2 -- Mechanisms and Causes of Leukocytosis

INCREASED PRODUCTION IN THE MARROW
Chronic infection or inflammation (growth factor-dependent)
Paraneoplastic (e.g., Hodgkin lymphoma; growth factor-dependent)
Myeloproliferative disorders (e.g., chronic myeloid leukemia; growth factor-independent)
INCREASED RELEASE FROM MARROW STORES
Endotoxemia
Infection
Hypoxia
DECREASED MARGINATION
Exercise
Catecholamines
DECREASED EXTRAVASATION INTO TISSUES
Glucocorticoids

Some growth factors preferentially stimulate the production of a single type of leukocyte. For example, IL-5 mainly stimulates eosinophil production, while G-CSF induces neutrophilia. Such factors are differentially produced in response to various pathogenic stimuli and, as a result, the five principal types of leukocytosis (neutrophilia, eosinophilia, basophilia, monocytosis, and lymphocytosis) tend to be observed in different clinical settings (summarized in Table 13-3).

TABLE 13-3 -- Causes of Leukocytosis

Type of Leukocytosis	Causes

Type of Leukocytosis	Causes
Neutrophilic leukocytosis	Acute bacterial infections, especially those caused by pyogenic organisms; sterile inflammation caused by, for example, tissue necrosis (myocardial infarction, burns)
Eosinophilic leukocytosis (eosinophilia)	Allergic disorders such as asthma, hay fever; certain skin diseases (e.g., pemphigus, dermatitis herpetiformis); parasitic infestations; drug reactions; certain malignancies (e.g., Hodgkin and some non-Hodgkin lymphomas); collagen vascular disorders and some vasculitides; atheroembolic disease (transient)
Basophilic leukocytosis (basophilia)	Rare, often indicative of a myeloproliferative disease (e.g., chronic myeloid leukemia)
Monocytosis	Chronic infections (e.g., tuberculosis), bacterial endocarditis, rickettsiosis, and malaria; collagen vascular diseases (e.g., systemic lupus erythematosus); inflammatory bowel diseases (e.g., ulcerative colitis)
Lymphocytosis	Accompanies monocytosis in many disorders associated with chronic immunological stimulation (e.g., tuberculosis, brucellosis); viral infections (e.g., hepatitis A, cytomegalovirus, Epstein-Barr virus); *Bordetella pertussis* infection

In sepsis or severe inflammatory disorders (such as Kawasaki disease), leukocytosis is often accompanied by morphologic changes in the neutrophils, such as toxic granulations, Döhle bodies, and cytoplasmic vacuoles (Fig. 13-2). *Toxic granules*, which are coarser and darker than the normal neutrophilic granules, represent abnormal azurophilic (primary) granules. *Döhle bodies* are patches of dilated endoplasmic reticulum that appear as sky-blue cytoplasmic "puddles."

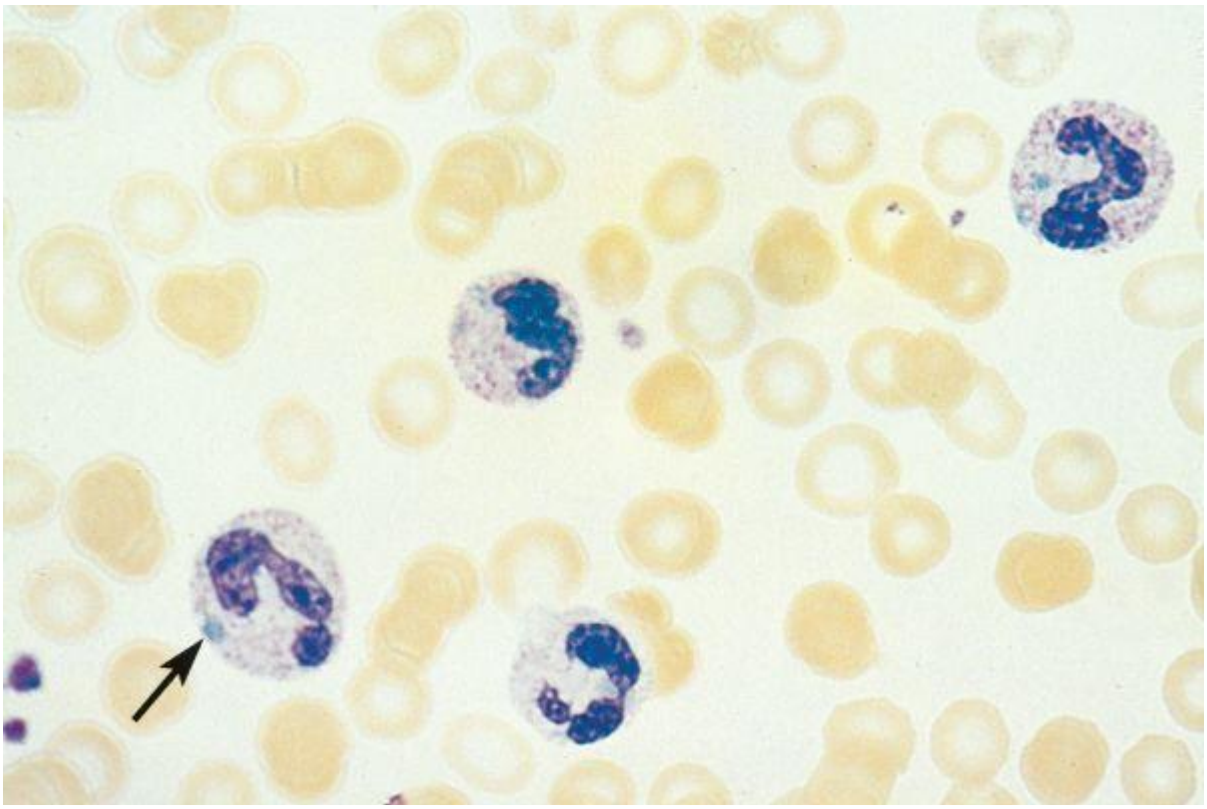

FIGURE 13-2 Reactive changes in neutrophils. Neutrophils containing coarse purple cytoplasmic granules (toxic granulations) and blue cytoplasmic patches of dilated endoplasmic reticulum (Döhle bodies, *arrow*) are observed in this peripheral blood smear prepared from a

patient with bacterial sepsis.

In most instances it is not difficult to distinguish reactive and neoplastic leukocytoses, but uncertainties may arise in two settings. Acute viral infections, particularly in children, can cause the appearance of large numbers of activated lym phocytes that resemble neoplastic lymphoid cells. At other times, particularly in severe infections, many immature granulocytes appear in the blood, simulating a myeloid leukemia *(leukemoid reaction)*. Special laboratory studies (discussed later) are helpful in distinguishing reactive and neoplastic leukocytoses.

LYMPHADENITIS

Following their initial development from precursors in the bone marrow (B cells) and the thymus (T cells), lymphocytes circulate through the blood and, under the influence of specific cytokines and chemokines, home to lymph nodes, spleen, tonsils, adenoids, and Peyer's patches, which constitute the peripheral lymphoid tissues. Lymph nodes, the most widely distributed and easily accessible lymphoid tissue, are frequently examined for diagnostic purposes. They are discrete encapsulated structures that contain well-organized B-cell and T-cell zones, which are richly invested with phagocytes and antigen-presenting cells (Fig. 6-6 , Chapter 6).

The activation of resident immune cells leads to morphologic changes in lymph nodes. Within several days of antigenic stimulation, the primary follicles enlarge and are transformed into pale-staining *germinal centers*, highly dynamic structures in which B cells acquire the capacity to make high-affinity antibodies against specific antigens. Paracortical T-cell zones may also undergo hyperplasia. The degree and pattern of the morphologic changes are dependent on the inciting stimulus and the intensity of the response. Trivial injuries and infections induce subtle changes, while more significant infections inevitably produce nodal enlargement and sometimes leave residual scarring. For this reason, lymph nodes in adults are almost never “normal” or “resting,” and it is often necessary to distinguish morphologic changes secondary to past experience from those related to present disease. Infections and inflammatory stimuli often elicit regional or systemic immune reactions within lymph nodes. Some that produce distinctive morphologic patterns are described in other chapters. Most, however, cause stereotypical patterns of lymph node reaction designated acute and chronic nonspecific lymphadenitis.

Acute Nonspecific Lymphadenitis

Acute lymphadenitis in the cervical region is most often due to microbial drainage from infections of the teeth or tonsils, while in the axillary or inguinal regions it is most often caused by infections in the extremities. Acute lymphadenitis also occurs in mesenteric lymph nodes draining acute appendicitis. Unfortunately, other self-limited infections may also cause acute mesenteric adenitis and induce symptoms mimicking acute appendicitis, a differential diagnosis that plagues the surgeon. Systemic viral infections (particularly in children) and bacteremia often produce acute generalized lymphadenopathy.

Morphology. Grossly, the nodes are swollen, gray-red, and engorged. Microscopically, there is prominence of large reactive germinal centers containing numerous mitotic figures. Macrophages often contain particulate debris derived from dead bacteria or necrotic cells. When pyogenic organisms are the cause, the centers of the follicles may undergo necrosis; sometimes the entire node is converted into a bag of pus. With less severe reactions, scattered neutrophils infiltrate about the follicles and accumulate within the lymphoid sinuses. The endothelial cells lining the sinuses undergo

hyperplasia.

Nodes involved by acute lymphadenitis are enlarged and painful. When abscess formation is extensive the nodes become fluctuant. The overlying skin is red. Sometimes, suppurative infections penetrate through the capsule of the node and track to the skin to produce draining sinuses. Healing of such lesions is associated with scarring.

Chronic Nonspecific Lymphadenitis

Chronic immunological stimuli produce several different patterns of lymph node reaction.

Morphology.

Follicular hyperplasia is caused by stimuli that activate humoral immune responses. It is defined by the presence of large oblong germinal centers (secondary follicles), which are surrounded by a collar of small resting naive B cells (the mantle zone) (Fig. 13-3). Germinal centers are normally polarized into two distinct regions: (1) a dark zone containing proliferating blastlike B cells (centroblasts) and (2) a light zone composed of B cells with irregular or cleaved nuclear contours (centrocytes). Interspersed between the germinal B centers is an inconspicuous network of antigen-presenting follicular dendritic cells and macrophages (often referred to as **tingible-body macrophages**) containing the nuclear debris of B cells, which undergo apoptosis if they fail to produce an antibody with a high affinity for antigen.

Causes of follicular hyperplasia include rheumatoid arthritis, toxoplasmosis, and early stages of infection with HIV. This form of hyperplasia is morphologically similar to follicular lymphoma (discussed later). Features favoring a reactive (non-neoplastic) hyperplasia include (1) preservation of the lymph node architecture, including the interfollicular T-cell zones and the sinusoids; (2) marked variation in the shape and size of the follicles; and (3) the presence of frequent mitotic figures, phagocytic macrophages, and recognizable light and dark zones, all of which tend to be absent from neoplastic follicles.

Paracortical hyperplasia is caused by stimuli that trigger T cell–mediated immune responses, such as acute viral infections (e.g., infectious mononucleosis). The T-cell regions typically contain immunoblasts, activated T cells three to four times the size of resting lymphocytes that have round nuclei, open chromatin, several prominent nucleoli, and moderate amounts of pale cytoplasm. The expanded T-cell zones encroach on and, in particularly exuberant reactions, efface the B-cell follicles. In such cases immunoblasts may be so numerous that special studies are needed to exclude a lymphoid neoplasm. In addition, there is often a hypertrophy of sinusoidal and vascular endothelial cells, sometimes accompanied by infiltrating macrophages and eosinophils.

Sinus histiocytosis (also called reticular hyperplasia) refers to an increase in the number and size of the cells that line lymphatic sinusoids. Although nonspecific, this form of hyperplasia may be particularly prominent in lymph nodes draining cancers such as carcinoma of the breast. The lining lymphatic endothelial cells are markedly hypertrophied and macrophages are greatly increased in numbers, resulting in the expansion and distension of the sinuses.

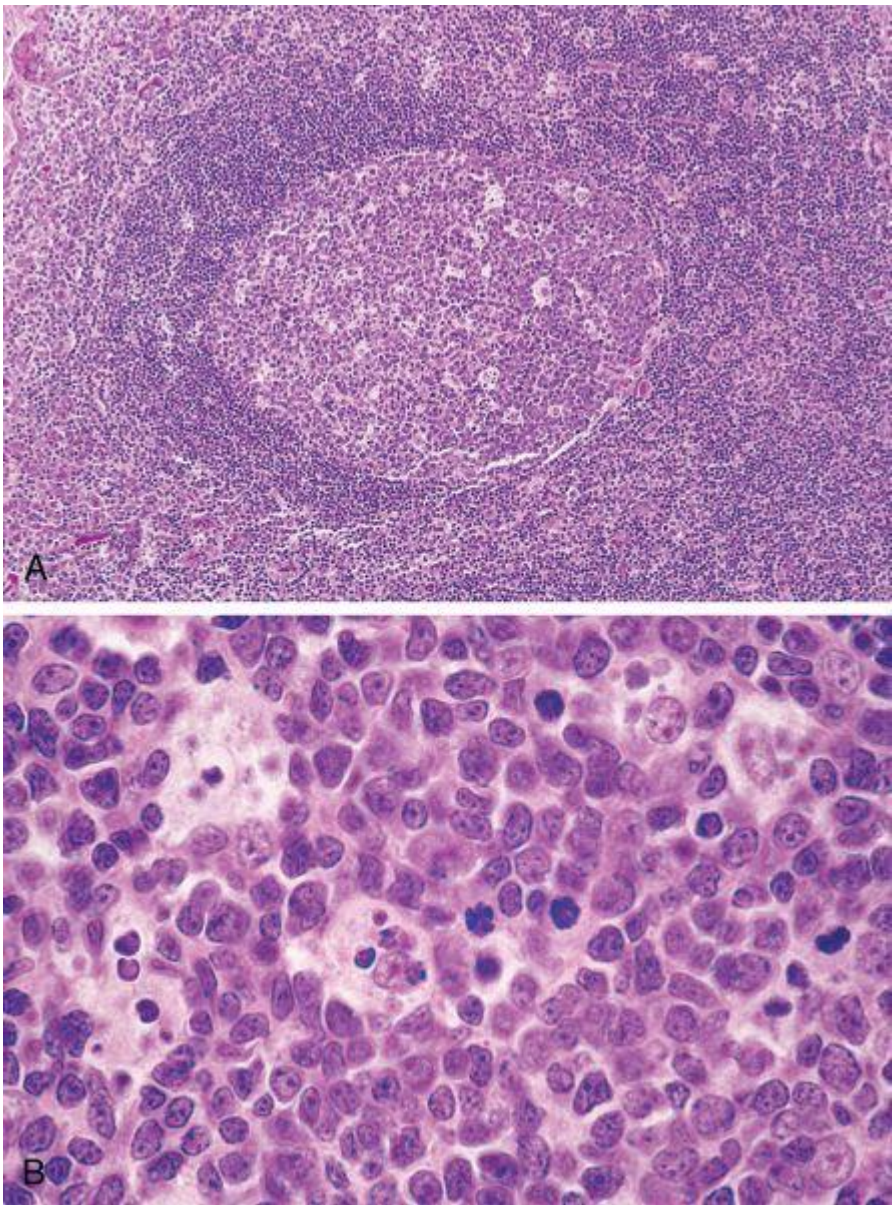

FIGURE 13-3 Follicular hyperplasia. **A**, Low-power view showing a reactive follicle and surrounding mantle zone. The dark-staining mantle zone is more prominent adjacent to the germinal-center light zone in the left half of the follicle. The right half of the follicle consists of the dark zone. **B**, High-power view of the dark zone shows several mitotic figures and numerous macrophages containing phagocytosed apoptotic cells (tingible bodies).

Characteristically, lymph nodes in chronic reactions are nontender, because nodal enlargement occurs slowly over time. Chronic lymphadenitis is particularly common in inguinal and axillary nodes, which drain relatively large areas of the body and are challenged frequently.

Before leaving the reactive disorders of lymphocytes, it is worth pointing out that chronic immune reactions can promote the appearance of organized collections of immune cells in nonlymphoid tissues. A classic example is seen in chronic gastritis caused by *Helicobacter pylori*, in which aggregates of mucosal lymphocytes are seen that simulate the appearance of Peyer's patches. A similar phenomenon occurs in rheumatoid athritis, in which B-cell follicles often appear in the inflamed synovium.

Lymphotoxin, a cytokine required for the formation of normal Peyer's patches, is probably involved in the establishment of these “extranodal” inflammation-induced collections of lymphoid cells.[4]

3.3.2.3 Neoplastic Proliferations of White Cells

Malignancies are clinically the most important disorders of white cells. These diseases fall into several broad categories:

- *Lymphoid neoplasms* include a diverse group of tumors of B-cell, T-cell, and NK-cell origin. In many instances the phenotype of the neoplastic cell closely resembles that of a particular stage of normal lymphocyte differentiation, a feature that is used in the diagnosis and classification of these disorders.
- *Myeloid neoplasms* arise from early hematopoietic progenitors. Three categories of myeloid neoplasia are recognized: *acute myeloid leukemias*, in which immature progenitor cells accumulate in the bone marrow; *myelodysplastic syndromes*, which are associated with ineffective hematopoiesis and resultant peripheral blood cytopenias; and *chronic myeloproliferative disorders*, in which increased production of one or more terminally differentiated myeloid elements (e.g., granulocytes) usually leads to elevated peripheral blood counts.
- The *histiocytoses* are uncommon proliferative lesions of macrophages and dendritic cells. Although “histiocyte” (literally, “tissue cell”) is an archaic morphologic term, it is still often used. A special type of immature dendritic cell, the Langerhans cell, gives rise to a spectrum of neoplastic disorders referred to as the *Langerhans cell histiocytoses*.

ETIOLOGIC AND PATHOGENETIC FACTORS IN WHITE CELL NEOPLASIA: OVERVIEW

As we will see in the following sections, the neoplastic disorders of white cells are extremely varied. Before we delve into this complexity, it is worth considering a few themes of general relevance to their etiology and pathogenesis.

Chromosomal Translocations and Other Acquired Mutations.

Nonrandom chromosomal abnormalities, most commonly translocations, are present in the majority of white cell neoplasms. As was discussed briefly in Chapter 7 , many specific rearrangements are associated with particular neoplasms, suggesting a critical role in their genesis.

- *The genes that are mutated or otherwise altered often play crucial roles in the development, growth, or survival of the normal counterpart of the malignant cell*. In some instances, the result of the aberration is to produce a “dominant- negative” protein that interferes with a normal function (a loss of function); in others the result is an inappropriate increase in some normal activity (a gain of function). In certain tumors, different aberrations have the same functional consequence as a result of their convergence on a common critical signaling pathway or transcription factor. An example of this is seen in so-called “MALTomas” (see also Chapter 17), B-cell lymphomas occurring in extranodal mucosal sites, which are often associated with translocations involving either the *MALT1* or the *BCL10* gene. The MALT1 and BCL10 proteins bind one another in a protein complex that regulates NF-κB, a transcription factor with important pro-survival functions in normal lymphocytes. The net effect of translocations involving either *MALT1* and *BCL10* is the same—a dysregulation of the MALT1/BCL10 complex that causes the constitutive activation of NF-κB,[5] which (as we will see) plays a role in the pathogenesis of many lymphoid malignancies.[6]
- *Oncoproteins created by genomic aberrations often block normal maturation*. Many oncoproteins cause an arrest in differentiation, often at a stage when cells are proliferating rapidly. The importance of this block in maturation is most evident in the acute leukemias, in which dominant-negative mutations involving transcription factors that interfere with early stages of lymphoid or myeloid cell differentiation often collaborate with activating mutations in tyrosine kinases that increase cell survival and proliferation (Fig. 13-4). However, this theme also applies to more mature lymphoid tumors. For example, *BCL6* encodes a transcription factor that is expressed in germinal center B cells. Without *BCL6*, germinal center B cells cannot form; however, *BCL6* must be turned off for germinal cell B cells to mature into memory B cells or plasma cells. As we will discuss, aberrations that up-regulate *BCL6* expression and prevent its down-regulation are very common in certain types of lymphomas derived from germinal center B cells.[7]

- *Proto-oncogenes are often activated in lymphoid cells by errors that occur during antigen receptor gene rearrangement and diversification*. Among lymphoid cells, *potentially oncogenic mutations occur most frequently in germinal center B cells during attempted antibody diversification*. After antigen stimulation, B cells enter germinal centers and upregulate the expression of activation-induced cytosine deaminase (AID), a specialized DNA-modifying enzyme that is essential for two types of Ig gene modifications: class switching, an intragenic recombination event in which the IgM heavy-chain constant gene segment is replaced with a different constant segment (e.g., IgG_3), thus allowing an isotype switch of antibody class; and somatic hypermutation, which creates point mutations within Ig genes that may by chance increase antibody affinity for antigen (Chapter 6). Certain proto-oncogenes, such as *c-MYC*, are activated in germinal center B-cell lymphomas by chromosomal translocations involving class switch regions. Remarkably, AID expression is sufficient to induce *c-MYC/Ig* translocations in normal germinal center B cells,[8,][9] apparently because it creates lesions in DNA that lead to chromosomal breaks. Parenthetically, it follows that even activation of a strong oncogene like *c-MYC* is not sufficient to cause transformation, emphasizing that (like other cancers) lymphomas arise due to a combination of multiple genetic lesions. Other proto-oncogenes, such as *BCL6*, are more commonly activated in germinal center B-cell lymphomas by point mutations,[10] which also seem to stem from “mistargeting” of AID. Undoubtedly, the selective advantage offered by antibody diversification against infection far outweighs the price that is paid in terms of potentially oncogenic mutations, but this is of little solace to individuals afflicted with tumors of germinal center B-cell origin, which include the most common and clinically important lymphoid neoplasms. A different type of regulated genomic instability is unique to precursor B and T cells, which express a V(D)J recombinase that cuts DNA at specific sites within the immunoglobulin (Ig) and T-cell receptor loci, respectively. This process is essential for the assembly of productive antigen receptor genes, but sometimes goes awry, leading to the joining of portions of other genes to antigen receptor gene regulatory elements. Particularly in tumors of precursor T cells, proto-oncogenes are often deregulated by their involvement in such aberrant recombination events.

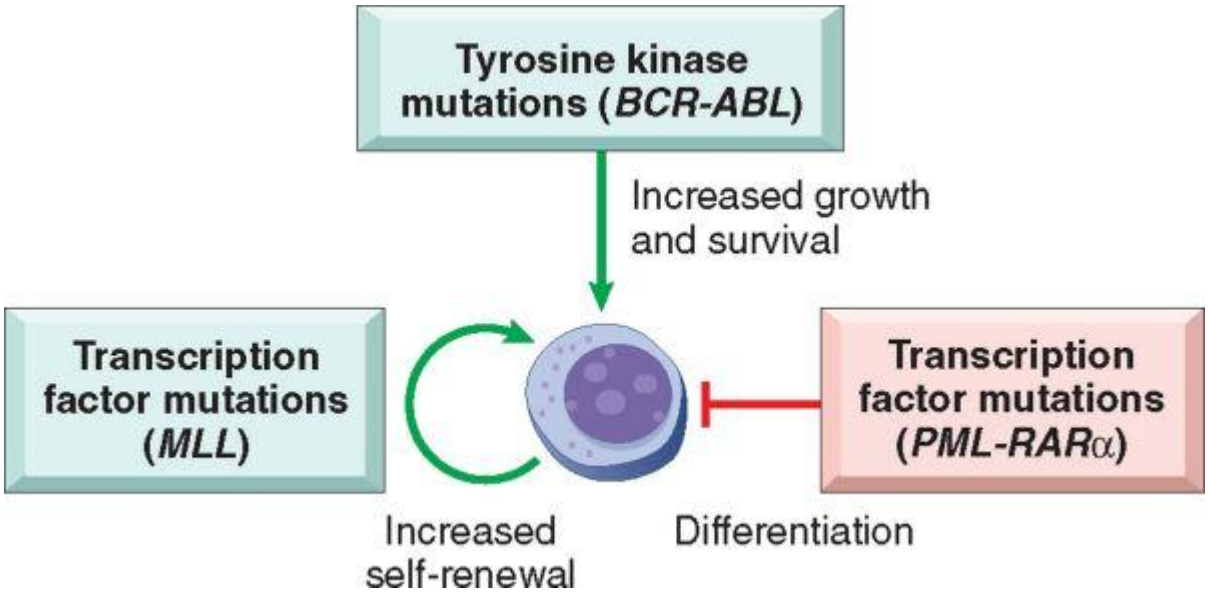

FIGURE 13-4 Molecular pathogenesis of acute leukemia. Acute leukemias arise from complementary mutations that block differentiation at early stages of white cell development, enhance self-renewal, and increase growth and survival. Important examples of each type of mutation are listed. BCR-ABL, breakpoint chromosomal region–Abelson kinase fusion gene; MLL, mixed-lineage leukemia gene; PML-RARα, promyelocytic leukemia–retinoic acid receptor α fusion gene.

Inherited Genetic Factors.

As was discussed in Chapter 7 , individuals with genetic diseases that promote genomic instability, such as Bloom syndrome, Fanconi anemia, and ataxia telangiectasia, are at increased risk of acute leukemia. In addition, both Down syndrome (trisomy 21) and type I neurofibromatosis are associated with an increased incidence of childhood leukemia.

Viruses.

Three lymphotropic viruses—human T-cell leukemia virus-1 (HTLV-1), Epstein-Barr virus (EBV), and Kaposi sarcoma herpesvirus/human herpesvirus-8 (KSHV/HHV-8)—have been implicated as causative agents in particular lymphomas. The possible mechanisms of transformation by viruses were discussed in Chapter 7 . HTLV-1 is associated with adult T-cell leukemia/lymphoma. EBV is found in a subset of Burkitt lymphoma, 30% to 40% of Hodgkin lymphoma (HL), many B-cell lymphomas arising in the setting of T-cell immunodeficiency, and rare NK-cell lymphomas. In addition to Kaposi sarcoma, KSHV is uniquely associated with an unusual B-cell lymphoma that presents as a malignant effusion, often in the pleural cavity.

Chronic Immune Stimulation.

Several environmental agents that cause localized chronic immune stimulation predispose to lymphoid neoplasia, which almost always arises within the inflamed tissue. Examples include the associations between *H. pylori* infection and gastric B-cell lymphomas (Chapter 17), and gluten-sensitive enteropathy and intestinal T-cell lymphomas. This can be contrasted with HIV infection, which is associated with an increased risk of B-cell lymphomas that may arise within virtually any organ. Early in the course, T-cell dysregulation by HIV infection causes a systemic hyperplasia of germinal center B cells that is associated with an increased incidence of germinal center B-cell lymphomas. In advanced infection (acquired immunodeficiency syndrome), severe T-cell immunodeficiency further elevates the risk for B-cell lymphomas, particularly those associated with EBV and KSHV/HHV-8.

Iatrogenic Factors.

Ironically, radiation therapy and certain forms of chemotherapy used to treat cancer increase the risk of subsequent myeloid and lymphoid neoplasms. This association stems from the mutagenic effects of ionizing radiation and chemotherapeutic drugs on hematolymphoid progenitor cells.

Smoking.

The incidence of acute myeloid leukemia is increased 1.3- to 2-fold in smokers, presumably because of exposure to carcinogens, such as benzene, in tobacco smoke.

LYMPHOID NEOPLASMS

Definitions and Classifications

One confusing aspect of the lymphoid neoplasms concerns the use of the terms *lymphocytic leukemia* and *lymphoma*. *Leukemia* is used for neoplasms that present with widespread involvement of the bone marrow and (usually, but not always) the peripheral blood. *Lymphoma* is used for proliferations that arise as discrete tissue masses. Originally these terms were attached to what were considered distinct entities, but with time and increased understanding these divisons have blurred. Many entities called “lymphoma” occasionally have leukemic presentations, and evolution to “leukemia” is not unusual during the progression of incurable “lymphomas.” Conversely, tumors identical to “leukemias” sometimes arise as soft-tissue masses unaccompanied by bone marrow disease. Hence, when applied to particular neoplasms, the terms *leukemia* and *lymphoma* merely reflect the usual tissue distribution of each disease at presentation.

Within the large group of lymphomas, *Hodgkin lymphoma* is segregated from all other forms, which constitute the *non-Hodgkin lymphomas (NHLs)*. As will be seen, Hodgkin lymphoma has distinctive pathologic features and is treated in a unique fashion. The other important group of lymphoid tumors is the *plasma cell neoplasms*. These most often arise in the bone marrow and only infrequently involve lymph nodes or the peripheral blood. Taken together, the diverse lymphoid neoplasms constitute a

complex, clinically important group of cancers, with about 100,000 new cases being diagnosed each year in the United States.

The clinical presentation of the various lymphoid neoplasms is most often determined by the anatomic distribution of disease. Two thirds of NHLs and virtually all Hodgkin lymphomas present as enlarged nontender lymph nodes (often >2 cm). The remaining one third of NHLs present with symptoms related to the involvement of extranodal sites (e.g., skin, stomach, or brain). The lymphocytic leukemias most often come to attention because of signs and symptoms related to the suppression of normal hematopoiesis by tumor cells in the bone marrow. Finally, the most common plasma cell neoplasm, multiple myeloma, causes bony destruction of the skeleton and often presents with pain due to pathologic fractures. However, it should also be kept in mind that *certain lymphoid tumors cause symptoms through the secretion of circulating factors*. Specific examples include the plasma cell tumors, in which much of the pathophysiology is related to the secretion of whole antibodies or Ig fragments; and Hodgkin lymphoma, which is often associated with fever related to the release of inflammatory cytokines.

Historically, few areas of pathology evoked as much controversy as the classification of lymphoid neoplasms, but this situation has improved greatly because of advances in the use of objective molecular diagnostic tools. The current World Health Organization (WHO) classification scheme (Table 13-4) uses morphologic, immunophenotypic, genotypic, and clinical fea tures to sort the lymphoid neoplasms into five broad categories,[11] which are separated according to the cell of origin:

1. Precursor B-cell neoplasms (neoplasms of immature B cells)
2. Peripheral B-cell neoplasms (neoplasms of mature B cells)
3. Precursor T-cell neoplasms (neoplasms of immature T cells)
4. Peripheral T-cell and NK-cell neoplasms (neoplasms of mature T cells and NK cells)
5. Hodgkin lymphoma (neoplasms of Reed-Sternberg cells and variants)

TABLE 13-4 -- The WHO Classification of the Lymphoid Neoplasms

I. PRECURSOR B-CELL NEOPLASMS
B-cell acute lymphoblastic leukemia/lymphoma (B-ALL)
II. PERIPHERAL B-CELL NEOPLASMS
Chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Lymphoplasmacytic lymphoma
Splenic and nodal marginal zone lymphomas
Extranodal marginal zone lymphoma
Mantle cell lymphoma
Follicular lymphoma
Marginal zone lymphoma
Hairy cell leukemia
Plasmacytoma/plasma cell myeloma
Diffuse large B-cell lymphoma
Burkitt lymphoma
III. PRECURSOR T-CELL NEOPLASMS

T-cell acute lymphoblastic leukemia/lymphoma (T-ALL)
IV. PERIPHERAL T-CELL AND NK-CELL NEOPLASMS
T-cell prolymphocytic leukemia
Large granular lymphocytic leukemia
Mycosis fungoides/Sézary syndrome
Peripheral T-cell lymphoma, unspecified
Anaplastic large-cell lymphoma
Angioimmunoblastic T-cell lymphoma
Enteropathy-associated T-cell lymphoma
Panniculitis-like T-cell lymphoma
Hepatosplenic γδ T-cell lymphoma
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma
NK-cell leukemia
V. HODGKIN LYMPHOMA
Classical subtypes
Nodular sclerosis
Mixed cellularity
Lymphocyte-rich
Lymphocyte depletion
Lymphocyte predominance

NK, natural killer.

Before we discuss the specific entities of the WHO classification, some important principles relevant to the lymphoid neoplasms should be emphasized.

- Lymphoid neoplasia can be suspected from the clinical features, but *histologic examination of lymph nodes or other involved tissues is required for diagnosis*.
- *In most lymphoid neoplasms, antigen receptor gene rearrangement precedes transformation; hence, all of the daughter cells derived from the malignant progenitor share the same antigen receptor gene configuration and sequence, and synthesize identical antigen receptor proteins* (either Igs or T-cell receptors). In contrast, normal immune responses comprise polyclonal populations of lymphocytes that express many different antigen receptors. Thus, analyses of antigen receptor genes and their protein products can be used to distinguish reactive (polyclonal) and malignant (monoclonal) lymphoid proliferations. In addition, each antigen receptor gene rearrangement produces a unique DNA sequence that constitutes a highly specific clonal marker, which can be used to detect small numbers of residual malignant lymphoid cells after therapy.[12,][13]
- *The vast majority (85% to 90%) of lymphoid neoplasms are of B-cell origin, with most of the remainder being T-cell tumors; only rarely are tumors of NK cell origin encountered*. Most lymphoid neoplasms resemble some recognizable stage of B- or T-cell differentiation (Fig. 13-5), a feature that is used in their

classification. Markers recognized by antibodies that are helpful in the characterization of lymphomas and leukemias are listed in Table 13-5 .

- *Lymphoid neoplasms are often associated with immune abnormalities*. Both a loss of protective immunity (susceptibility to infection) and a breakdown of tolerance (autoimmunity) can be seen, sometimes in the same patient. In a further ironic twist, individuals with inherited or acquired immunodeficiency are themselves at high risk of developing certain lymphoid neoplasms, particularly those caused by oncogenic viruses (e.g., EBV).
- *Neoplastic B and T cells tend to recapitulate the behavior of their normal counterparts*. Like normal lymphocytes, neoplastic B and T cells home to certain tissue sites, leading to characteristic patterns of involvement. For example, follicular lymphomas home to germinal centers in lymph nodes, whereas cutaneous T-cell lymphomas home to the skin. Like their normal counterparts, particular adhesion molecules and chemokine receptors govern the homing of the neoplastic lymphoid cells. Variable numbers of neoplastic B and T lymphoid cells also recirculate through the lymphatics and peripheral blood to distant sites; as a result most lymphoid tumors are widely disseminated at the time of diagnosis. Notable exceptions to this rule include Hodgkin lymphomas, which are sometimes restricted to one group of lymph nodes, and marginal zone B-cell lymphomas, which are often restricted to sites of chronic inflammation.
- *Hodgkin lymphoma spreads in an orderly fashion*. In contrast, most forms of NHL spread widely early in their course in a less predictable fashion. Hence, while lymphoma staging provides generally useful prognostic information, it is of most utility in guiding therapy in Hodgkin lymphoma.

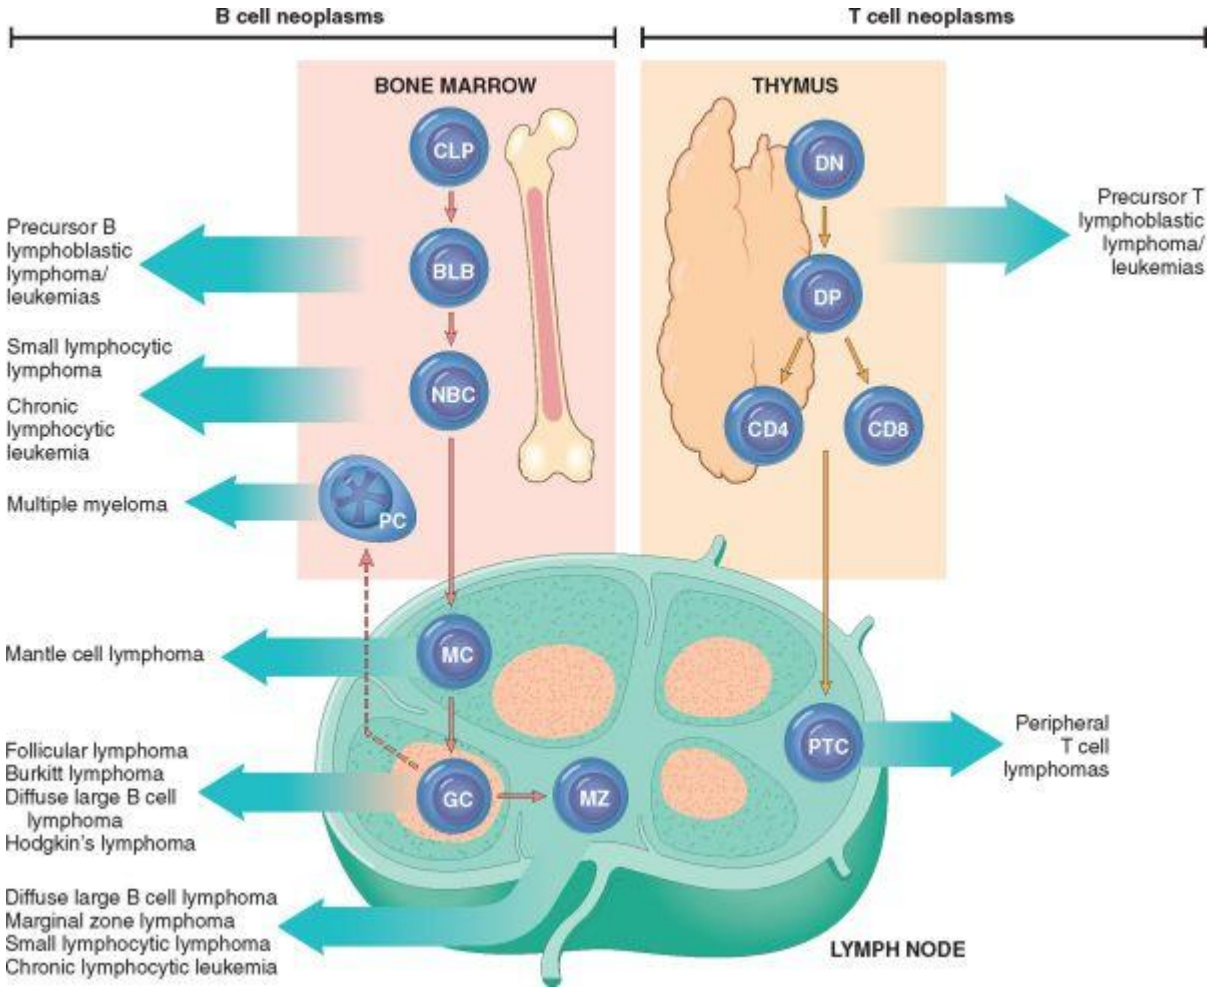

FIGURE 13-5 Origin of lymphoid neoplasms. Stages of B- and T-cell differentiation from which specific lymphoid tumors emerge are shown. CLP, common lymphoid precursor; BLB, pre-B lymphoblast; DN, CD4/CD8 double-negative pro-T cell; DP, CD4/CD8 double-positive pre-T cell; GC, germinal-center B cell; MC, mantle B cell; MZ, marginal zone B cell; NBC, naive B cell; PTC, peripheral T cell.

TABLE 13-5 -- Some Immune Cell Antigens Detected by Monoclonal Antibodies

Antigen Designation	Normal Cellular Distribution
PRIMARILY T-CELL ASSOCIATED	
CD1	Thymocytes and Langerhans cells
CD3	Thymocytes, mature T cells
CD4	Helper T cells, subset of thymocytes
CD5	T cells and a small subset of B cells
CD8	Cytotoxic T cells, subset of thymocytes, and some NK cells
PRIMARILY B-CELL ASSOCIATED	
CD10	Pre-B cells and germinal-center B cells; also called CALLA
CD19	Pre-B cells and mature B cells but not plasma cells
CD20	Pre-B cells after CD19 and mature B cells but not plasma cells
CD21	EBV receptor; mature B cells and follicular dendritic cells
CD23	Activated mature B cells
CD79a	Marrow pre-B cells and mature B cells
PRIMARILY MONOCYTE- OR MACROPHAGE-ASSOCIATED	
CD11c	Granulocytes, monocytes, and macrophages; also expressed by hairy cell leukemias
CD13	Immature and mature monocytes and granulocytes
CD14	Monocytes
CD15	Granulocytes; Reed-Sternberg cells and variants
CD33	Myeloid progenitors and monocytes
CD64	Mature myeloid cells
PRIMARILY NK-CELL ASSOCIATED	
CD16	NK cells and granulocytes
CD56	NK cells and a subset of T cells
PRIMARILY STEM CELL–AND PROGENITOR CELL–ASSOCIATED	
CD34	Pluripotent hematopoietic stem cells and progenitor cells of many lineages
ACTIVATION MARKERS	
CD30	Activated B cells, T cells, and monocytes; Reed-Sternberg cells and variants
PRESENT ON ALL LEUKOCYTES	
CD45	All leukocytes; also known as leukocyte common antigen (LCA)

CALLA, common acute lymphoblastic leukemia antigen; CD, cluster designation; EBV, Epstein-Barr virus; NK, natural killer.

We now turn to the specific entities of the WHO classification. We will begin with neoplasms of immature lymphoid cells and then move on to neoplasms of B cells, plasma cells, T cells, and NK cells.

Some of the most salient molecular and clinical features of the group of neoplasms, which includes the lymphoid leukemias, non-Hodgkin lymphomas, and plasma cell tumors, are summarized in Table 13-6 . We will then finish with a discussion of Hodgkin lymphoma. Throughout, the most common (and thus most important) entities will be emphasized.

TABLE 13-6 -- Summary of Major Types of Lymphoid Leukemias and Non-Hodgkin Lymphomas

Diagnosis	Cell of Origin	Genotype	Salient Clinical Features
NEOPLASMS OF IMMATURE B AND T CELLS			
B-cell acute lymphoblastic leukemia/lymphoma	Bone marrow precursor B cell	Diverse chromosomal translocations; t(12;21) involving *CBF*α and *ETV*6 present in 25%	Predominantly children; symptoms relating to marrow replacement and pancytopenia; aggressive
T-cell acute lymphoblastic leukemia/lymphoma	Precursor T cell (often of thymic origin)	Diverse chromosomal translocations, *NOTCH1* mutations (50% to 70%)	Predominantly adolescent males; thymic masses and variable bone marrow involvement; aggressive
NEOPLASMS OF MATURE B CELLS			
Burkitt lymphoma	Germinal-center B cell	Translocations involving c-*MYC* and Ig loci, usually t(8;14); subset EBV-associated	Adolescents or young adults with extranodal masses; uncommonly presents as “leukemia”; aggressive
Diffuse large B-cell lymphoma	Germinal-center or post–germinal-center B cell	Diverse chromosomal rearrangements, most often of *BCL6* (30%), *BCL2* (10%), or c-*MYC* (5%)	All ages, but most common in adults; often appears as a rapidly growing mass; 30% extranodal; aggressive
Extranodal marginal zone lymphoma	Memory B cell	t(11;18), t(1;14), and t(14;18) creating *MALT1-IAP2*, *BCL10-IgH*, and *MALT1-IgH* fusion genes, respectively	Arises at extranodal sites in adults with chronic inflammatory diseases; may remain localized; indolent
Follicular lymphoma	Germinal-center B cell	t(14;18) creating *BCL2-IgH* fusion gene	Older adults with generalized lymphadenopathy and marrow involvement; indolent
Hairy cell leukemia	Memory B cell	No specific chromosomal abnormality	Older males with pancytopenia and splenomegaly; indolent
Mantle cell lymphoma	Naive B cell	t(11;14) creating *CyclinD1-IgH* fusion gene	Older males with disseminated disease; moderately aggressive
Multiple myeloma/solitary plasmacytoma	Post–germinal-center bone marrow homing plasma cell	Diverse rearrangements involving *IgH*; 13q deletions	Myeloma: older adults with lytic bone lesions, pathologic fractures, hypercalcemia, and renal failure; moderately aggressive
			Plasmacytoma: isolated plasma cell masses in bone or soft tissue; indolent
Small lymphocytic lymphoma/chronic lymphocytic leukemia	Naive B cell or memory B cell	Trisomy 12, deletions of 11q, 13q, and 17p	Older adults with bone marrow, lymph node, spleen, and liver disease; autoimmune hemolysis and thrombocytopenia in a minority; indolent
NEOPLASMS OF MATURE T CELLS OR NK CELLS			
Adult T-cell leukemia/lymphoma	Helper T cell	HTLV-1 provirus present in tumor cells	Adults with cutaneous lesions, marrow involvement, and hypercalcemia; occurs mainly in Japan, West Africa, and the Caribbean; aggressive

Diagnosis	Cell of Origin	Genotype	Salient Clinical Features
Peripheral T-cell lymphoma, unspecified	Helper or cytotoxic T cell	No specific chromosomal abnormality	Mainly older adults; usually presents with lymphadenopathy; aggressive
Anaplastic large-cell lymphoma	Cytotoxic T cell	Rearrangements of *ALK*	Children and young adults, usually with lymph node and soft-tissue disease; aggressive
Extranodal NK/T-cell lymphoma	NK-cell (common) or cytotoxic T cell (rare)	EBV-associated; no specific chromosomal abnormality	Adults with destructive extranodal masses, most commonly sinonasal; aggressive
Mycosis fungoides/Sézary syndrome	Helper T cell	No specific chromosomal abnormality	Adult patients with cutaneous patches, plaques, nodules, or generalized erythema; indolent
Large granular lymphocytic leukemia	Two types: cytotoxic T cell and NK cell	No specific chromosomal abnormality	Adult patients with splenomegaly, neutropenia, and anemia, sometimes, accompanied by autoimmune disease

EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; Ig, immunoglobulin; NK, natural killer.

Precursor B- and T-Cell Neoplasms

Acute Lymphoblastic Leukemia/Lymphoma

Acute lymphoblastic leukemia/lymphomas (ALLs) are neoplasms composed of immature B (pre-B) or T (pre-T) cells, which are referred to as lymphoblasts. *About 85% are B-ALLs, which typically manifest as childhood acute "leukemias."*; The less common *T-ALLs tend to present in adolescent males as thymic "lymphomas."*; There is, however, considerable overlap in the clinical behavior of B- and T-ALL; for example, B-ALL uncommonly presents as a mass in the skin or a bone, and many T-ALLs present with or evolve to a leukemic picture. Because of their morphologic and clinical similarities, the various forms of ALL will be considered here together.

ALL is the most common cancer of children. Approximately 2500 new cases are diagnosed each year in the United States, most occurring in individuals under 15 years of age. ALL is almost three times as common in whites as in blacks, and slightly more frequent in boys than in girls. Hispanics have the highest incidence of any ethnic group. B-ALL peaks in incidence at about the age of 3, perhaps because the number of normal bone marrow pre-B cells (the cell of origin) is greatest very early in life. Similarly the peak incidence of T-ALL is in adolescence, the age when the thymus reaches its maximal size. B- and T-ALL also occur less frequently in adults of all ages.

Morphology. In leukemic presentations, the marrow is hypercellular and packed with lymphoblasts, which replace the normal marrow elements. Mediastinal thymic masses occur in 50% to 70% of T-ALLs, which are also more likely to be associated with lymphadenopathy and splenomegaly. In both B- and T-ALL, the tumor cells have scant basophilic cytoplasm and nuclei somewhat larger than those of small lymphocytes (Fig. 13-6A). The nuclear chromatin is delicate and finely stippled, and nucleoli are either absent or inconspicuous. In many cases the nuclear membrane is deeply subdivided, imparting a convoluted appearance. In keeping with the aggressive clinical behavior, the mitotic rate is high. As with other rapidly growing lymphoid tumors, interspersed macrophages ingesting apoptotic tumor cells may impart a "starry sky" appearance (shown in Fig. 13-15).

Because of differing responses to chemotherapy, ALL must be distinguished from acute myeloid leukemia (AML), a neoplasm of immature myeloid cells that can cause identical signs and symptoms. Compared with myeloblasts, lymphoblasts have more condensed chromatin, less conspicuous nucleoli, and smaller amounts of cytoplasm that usually lacks granules. However, these morphologic distinctions are not absolute and definitive diagnosis relies on stains performed with antibodies specific for B- and T-cell antigens (Fig. 13-6B and C). Histochemical stains are also helpful, in that (in contrast to myeloblasts) lymphoblasts are myeloperoxidase-negative and often contain periodic acid–Schiff-positive cytoplasmic material.

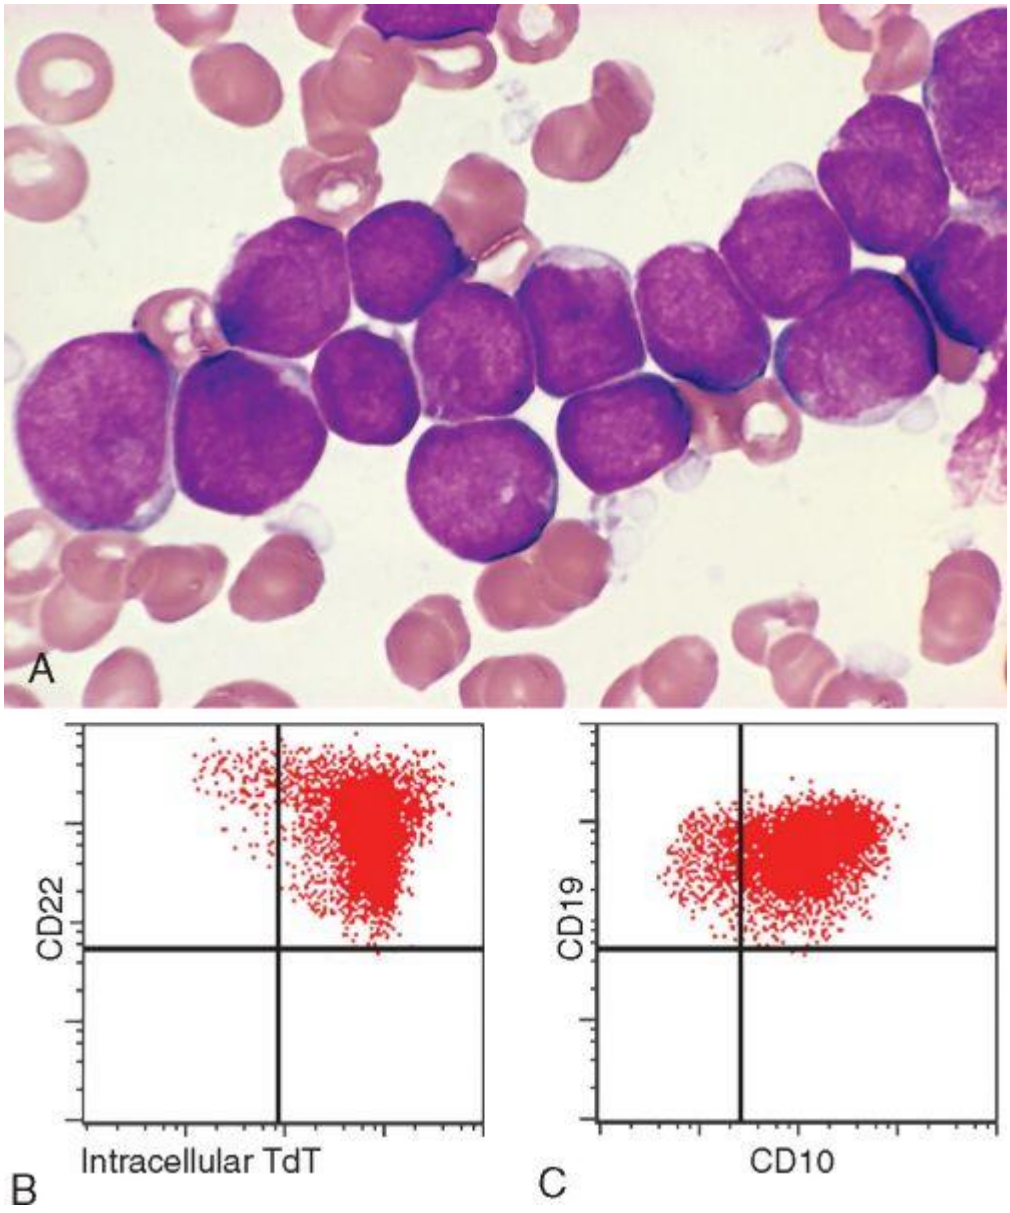

FIGURE 13-6 **A**, Acute lymphoblastic leukemia/lymphoma. Lymphoblasts with condensed nuclear chromatin, small nucleoli, and scant agranular cytoplasm. **B** and **C** represent the phenotype of the ALL shown in **A**, analyzed by flow cytometry. **B**, Note that the lymphoblasts represented by the red dots express terminal deoxynucleotidyl-transferase (TdT) and the B-cell marker CD22. **C**, The same cells are positive for two other markers, CD10 and CD19, commonly expressed on pre-B lymphoblasts. Thus, this is a B-ALL. *(**A**, Courtesy of Dr. Robert W. McKenna; Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX; **B** and **C**, courtesy of Dr. Louis Picker, Oregon Health Science Center, Portland, OR.)*

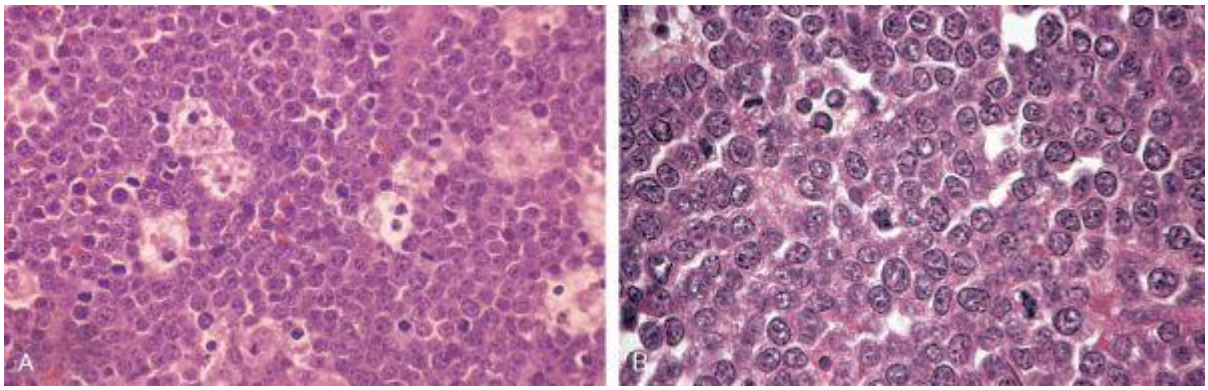

FIGURE 13-15 Burkitt lymphoma. **A**, At low power, numerous pale tingible body macrophages are evident, producing a "starry sky" appearance. **B**, At high power, tumor cells have multiple small nucleoli and high mitotic index. The lack of significant variation in nuclear shape and size lends a monotonous appearance. ***(B**, Courtesy of Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Immunophenotype.

Immunostaining for terminal deoxynucleotidyl-transferase (TdT), a specialized DNA polymerase that is expressed only in pre-B and pre-T lymphoblasts, is positive in more than 95% of cases (Fig. 13-6B). B- and T-ALLs are distinguished with stains for B- and T-cell–specific markers (summarized below).

B-ALLs are arrested at various stages of pre-B cell development. The lymphoblasts usually express the pan B-cell marker CD19 and the transcription factor PAX5, as well as CD10. In very immature B-ALLs, CD10 is negative. Alternatively, more mature "late pre-B" ALLs express CD10, CD19, CD20, and cytoplasmic IgM heavy chain (μ chain).

Similarly, T-ALLs are arrested at various stages of pre-T cell development. In most cases the cells are positive for CD1, CD2, CD5, and CD7. The more immature tumors are usually negative for surface CD3, CD4, and CD8, whereas "late" pre-T cell tumors are positive for these markers.

Molecular Pathogenesis.

Approximately 90% of ALLs have numerical or structural chromosomal changes. Most common is hyperploidy (>50 chromosomes), but hypoploidy and a variety of balanced chromosomal translocations are also seen. These alterations frequently correlate with immunophenotype and sometimes prognosis. For example, hyperdiploidy and hypodiploidy are seen only in B-ALL. In addition, B- and T-ALL are associated with completely different sets of translocations, indicating that they are pathogenetically distinct. RNA profiling using "gene chips" has also shown that certain chromosomal translocations correlate with unique patterns of gene expression.

Many of the chromosomal aberrations seen in ALL dysregulate the expression and function of transcription factors that are required for normal B- and T-cell development. Up to 70% of T-ALLs have gain-of-function mutations in *NOTCH1*, a gene that is essential for T-cell development.[14] On the other hand, a high fraction of B-ALLs have loss-of-function mutations in genes that are required for B-cell development, such as *PAX5*, *E2A*, and *EBF*,[15] or a balanced t(12;21) involving the genes *TEL* and

AML1, two genes that are needed in very early hematopoietic precursors. All of these varied mutations seem to disturb the differentiation of lymphoid precursors and promote maturation arrest. As we will see, similar themes are relevant in the genesis of AML.

In keeping with the multistep origin of cancer (Chapter 7), *single mutations are not sufficient to produce ALL*. This conclusion stems in part from studies of identical twins with concordant B-ALL.[16] In these rare cases, the ALLs in both twins share a common chromosomal aberration and are derived from a single clone transmitted from one twin to the other by transfusion in utero. Despite the presence of the leukemogenic aberration at birth, ALL most often makes its clinical appearance in such patients between 4 and 12 years of age. This lengthy prodrome is most consistent with the existence of a "pre-leukemic" clone that must acquire additional mutations before ALL can develop. The identity of these complementary mutations is incomplete, but aberrations that increase growth and survival, such as activating mutations in tyrosine kinases, are commonly present.

Clinical Features.

It should be emphasized that although ALL and AML are genetically and immunophenotypically distinct, they are clinically very similar. In both, the accumulation of neoplastic "blasts" in the bone marrow suppresses normal hematopoiesis by physical crowding, competition for growth factors, and other poorly understood mechanisms. The common features and those more characteristic of ALL are the following:

- *Abrupt stormy onset* within days to a few weeks of the first symptoms
- *Symptoms related to depression of marrow function*, including fatigue due to anemia; fever, reflecting infections secondary to neutropenia; and bleeding due to thrombocytopenia
- *Mass effects caused by neoplastic infiltration* (which are more common in ALL), including bone pain resulting from marrow expansion and infiltration of the subperiosteum; generalized lymphadenopathy, splenomegaly, and hepatomegaly; testicular enlargement; and in T-ALL, complications related to compression of large vessels and airways in the mediastinum
- *Central nervous system manifestations* such as headache, vomiting, and nerve palsies resulting from meningeal spread, all of which are also more common in ALL

Prognosis.

Pediatric ALL is one of the great success stories of oncology. With aggressive chemotherapy about 95% of children with ALL obtain a complete remission, and 75% to 85% are cured. Despite these achievements, however, ALL remains the leading cause of cancer deaths in children, and only 35% to 40% of adults are cured. *Several factors have been consistently associated with a worse prognosis: (1) age under 2*, largely because of the strong association of infantile ALL with translocations involving the *MLL* gene; *(2) presentation in adolescence or adulthood; (3) peripheral blood blast counts greater than 100,000*, which probably reflects a high tumor burden; and *(4) the presence of particular cytogenetic aberrations such as the t(9;22) (the Philadelphia chromosome)*.[17] The t(9;22) is present in only 3% of childhood ALL, but up to 25% of adult cases, which partially explains the poor outcome in adults. Favorable prognostic markers include (1) an age of 2 to 10 years, (2) a low white cell count, (3) hyperploidy, (4) trisomy of chromosomes 4, 7, and 10, and (5) the presence of a t(12;21).[17] Notably, the molecular detection of residual disease after therapy is predictive of a worse outcome in both B- and T-ALL and is being used to guide new clinical trials.[12]

Although most chromosomal aberrations in ALL alter the function of transcription factors, the t(9;22) instead creates a fusion gene that encodes a constitutively active BCR-ABL tyrosine kinase (described in more detail under chronic myeloid leukemia). In B-ALL, the BCR-ABL protein is usually 190 kDa in size and has stronger tyrosine kinase activity than the form of BCR-ABL that is found in chronic

myeloid leukemia, in which a BCR-ABL protein of 210 kDa in size is usually seen. Treatment of t(9;22)-positive ALLs with BCR-ABL kinase inhibitors leads to clinical responses, but patients relapse quickly because of acquired mutations in BCR-ABL that render the tumor cells drug-resistant.[18] BCR-ABL-positive B-ALL generates mutations at a high rate, a phenomenon referred to as genomic instability that contributes to the clinical progression and therapeutic resistance of many aggressive malignant tumors.

Peripheral B-Cell Neoplasms

Chronic Lymphocytic Leukemia (CLL)/Small Lymphocytic Lymphoma (SLL)

These two disorders differ only in the degree of peripheral blood lymphocytosis. Most affected patients have sufficient lymphocytosis to fulfill the diagnostic requirement for CLL (absolute lymphocyte count >4000 per mm^3). CLL is the most common leukemia of adults in the Western world. There are about 15,000 new cases of CLL each year in the United States. The median age at diagnosis is 60 years, and there is a 2 : 1 male predominance. In contrast, SLL constitutes only 4% of NHLs. CLL/SLL is much less common in Japan and other Asian countries than in the West.

Morphology. Lymph nodes are diffusely effaced by an infiltrate of predominantly small lymphocytes 6 to 12 μm in diameter with round to slightly irregular nuclei, condensed chromatin, and scant cytoplasm (Fig. 13-7). Admixed are variable numbers of larger activated lymphocytes that often gather in loose aggregates referred to as **proliferation centers**, which contain mitotically active cells. When present, **proliferation centers are pathognomonic for CLL/SLL**. The blood contains large numbers of small round lymphocytes with scant cytoplasm (Fig. 13-8). Some of these cells are usually disrupted in the process of making smears, producing so-called **smudge cells**. The bone marrow is almost always involved by interstitial infiltrates or aggregates of tumor cells. Infiltrates are also virtually always seen in the splenic white and red pulp and the hepatic portal tracts (Fig. 13-9).

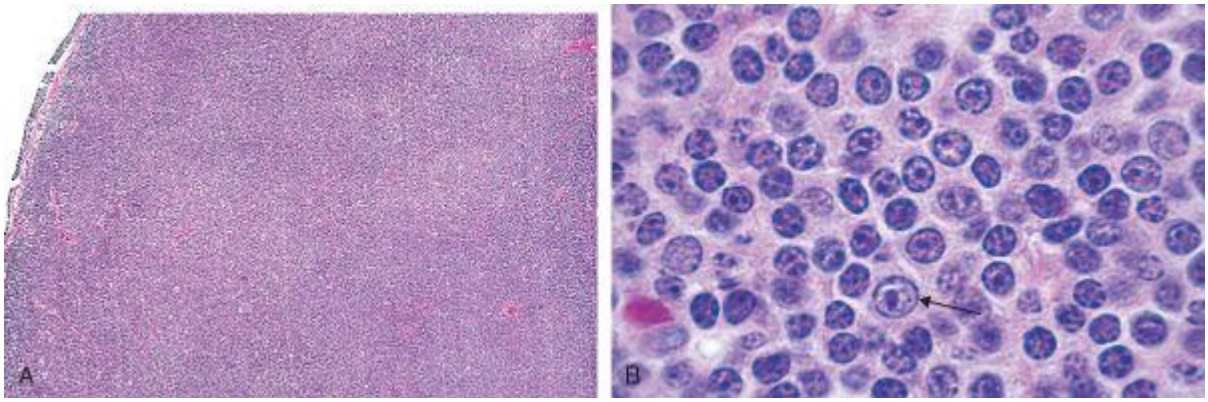

FIGURE 13-7 Small lymphocytic lymphoma/chronic lymphocytic leukemia (lymph node). **A**, Low-power view shows diffuse effacement of nodal architecture. **B**, At high power the majority of the tumor cells are small round lymphocytes. A "prolymphocyte," a larger cell with a centrally placed nucleolus, is also present in this field *(arrow)*. *(**A**, Courtesy of Dr. José Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

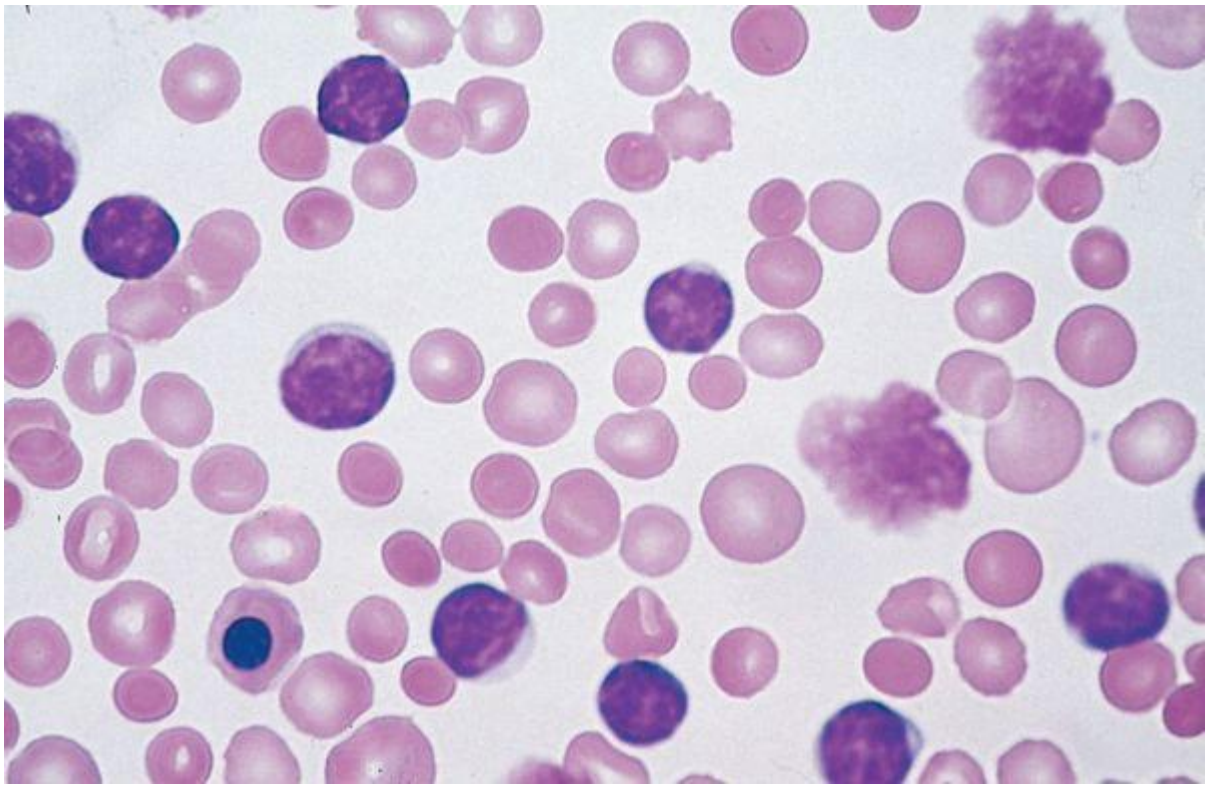

FIGURE 13-8 Chronic lymphocytic leukemia. This peripheral blood smear is flooded with small lymphocytes with condensed chromatin and scant cytoplasm. A characteristic finding is the presence of disrupted tumor cells (smudge cells). A coexistent autoimmune hemolytic anemia (Chapter 14) explains the presence of spherocytes (hyperchromatic, round erythrocytes). A nucleated erythroid cell is present in the lower left-hand corner of the field. In this setting, circulating nucleated red cells could stem from premature release of progenitors in the face of severe anemia, marrow infiltration by tumor (leukoerythroblastosis), or both.

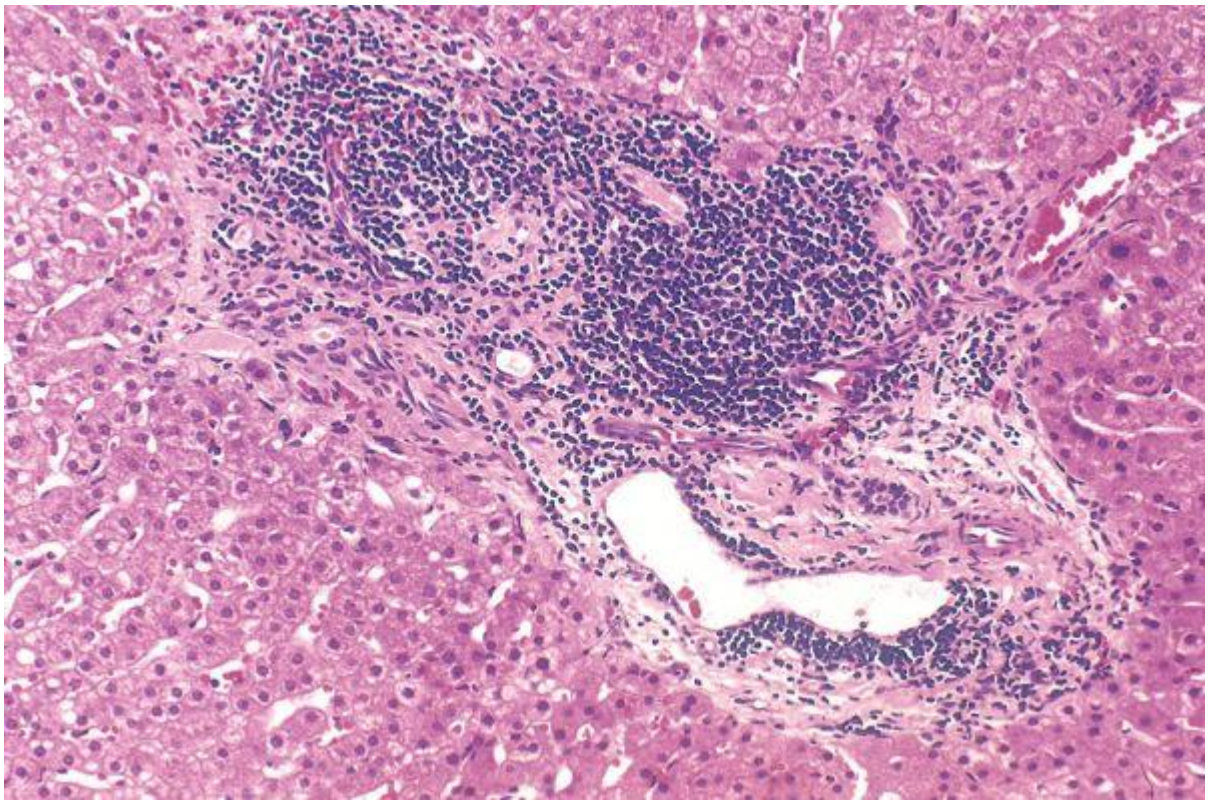

FIGURE 13-9 Small lymphocytic lymphoma/chronic lymphocytic leukemia involving the liver. Low-power view of a typical periportal lymphocytic infiltrate. *(Courtesy of Dr. Mark Fleming, Department of Pathology, Children's Hospital, Boston, MA.)*

Immunophenotype.

CLL/SLL has a distinctive immunophenotype. The tumor cells express the pan-B cell markers CD19 and CD20, as well as CD23 and CD5, the latter a marker that is found on a small subset of normal B cells. Low-level expression of surface Ig (usually IgM or IgM and IgD) is also typical.

Molecular Pathogenesis.

Unlike most other lymphoid malignancies, chromosomal translocations are rare in CLL/SLL. The most common findings are deletions of 13q14.3, 11q, and 17p, and trisomy 12q. Molecular characterization of the region deleted on chromosome 13 has implicated two microRNAs, miR-15a and miR-16-1, as possible tumor suppressor genes.[19] DNA sequencing has revealed that the Ig genes of some CLL/SLL are somatically hypermutated, whereas others are not, suggesting that the cell of origin may be either a postgerminal center memory B cell or a naive B cell. For unclear reasons, tumors with unmutated Ig segments (those putatively of naive B-cell origin) pursue a more aggressive course.[20]

The growth of CLL/SLL cells is largely confined to proliferation centers, where tumor cells must receive critical cues from the microenvironment. Stromal cells in proliferation centers seem to express a variety of factors that stimulate the activity of the transcription factor NF-κB,[21] which promotes cell growth and survival.

Clinical Features.

Patients are often asymptomatic at diagnosis. When symptoms appear, they are nonspecific and include easy fatigability, weight loss, and anorexia. Generalized lymphadenopathy and hepatosplenomegaly are present in 50% to 60% of symptomatic patients. The leukocyte count is highly variable; leukopenia can be seen in individuals with SLL and marrow involvement, while counts in excess of 200,000 per mm^3 are sometimes seen in CLL patients with heavy tumor burdens. At the other end of the spectrum are asymptomatic patients that have in their peripheral blood monoclonal CD5+ B cells in numbers that are too few to merit the diagnosis of CLL. These abnormal B cells often have some of the same chromosomal aberrations that are seen in CLL, such as 13q deletions and trisomy 12, yet only about 1% of such patients progress to symptomatic CLL per year, presumably due to acquisition of additional genetic lesions that have yet to be identified. A small monoclonal Ig "spike" is present in the blood of some patients.

CLL/SLL disrupts normal immune function through uncertain mechanisms. Hypogammaglobulinemia is common and contributes to an increased susceptibility to infections, particularly those caused by bacteria. Conversely, 10% to 15% of patients develop hemolytic anemia or thrombocytopenia due to autoantibodies made by non-neoplastic B cells.

The course and prognosis are extremely variable and depend primarily on the clinical stage. Overall median survival is 4 to 6 years, but over 10 years in individuals with minimal tumor burdens at diagnosis. Other variables that correlate with a worse outcome include (1) the presence of deletions of 11q and 17p, (2) a lack of somatic hypermutation, and (3) the expression of ZAP-70, a protein that augments signals produced by the Ig receptor.[19] Patients are generally treated with "gentle" chemotherapy to control symptoms. Immunotherapy with antibodies against proteins found on the surface of CLL/SLL cells, such as CD20 and CD52, is finding increasing use.[22] Bone marrow transplantation is being offered to the relatively young.

An additional factor in patient survival is the tendency of CLL/SLL to transform to more aggressive tumors. Most commonly this takes the form of a prolymphocytic transform-ation (15% to 30% of patients) or a transformation to diffuse large B-cell lymphoma, so-called *Richter syndrome* (~5% to 10% of patients). Prolymphocytic transformation is marked by worsening cytopenias, increasing splenomegaly, and the appearance of increased numbers of "prolymphocytes" (large cells with a single prominent, centrally placed nucleolus) in the peripheral blood. Transformation to diffuse large B-cell lymphoma is often heralded by the development of a rapidly enlarging mass within a lymph node or the spleen. These transformations probably stem from the acquisition of additional, still unknown mutations that increase growth. Both prolymphocytic and large-cell transformation are ominous events, with most patients surviving less than 1 year.[23]

Follicular Lymphoma

Follicular lymphoma is the most common form of indolent NHL in the United States, affecting 15,000 to 20,000 individuals per year. It usually presents in middle age and afflicts males and females equally. It is less common in Europe and rare in Asian populations. *The tumor likely arises from germinal center B cells and is strongly associated with chromosomal translocations involving BCL2*.

Morphology. In most cases, at low magnification, a predominantly nodular or nodular and diffuse growth pattern is observed in involved lymph nodes (Fig. 13-10A). **Two principal cell types are present in varying proportions: (1) small cells with irregular or cleaved nuclear contours and scant cytoplasm, referred to as centrocytes (small cleaved cells); and (2) larger cells with open nuclear chromatin, several nucleoli, and modest amounts of cytoplasm, referred to as centroblasts** (Fig. 13-10B). In most follicular lymphomas, small cleaved cells are in the majority.

Peripheral blood involvement sufficient to produce lymphocytosis (usually under 20,000 cells per mm^3) is seen in about 10% of cases. Bone marrow involvement occurs in 85% of cases and characteristically takes the form of paratrabecular lymphoid aggre gates. The splenic white pulp (Fig. 13-11) and hepatic portal triads are also frequently involved.

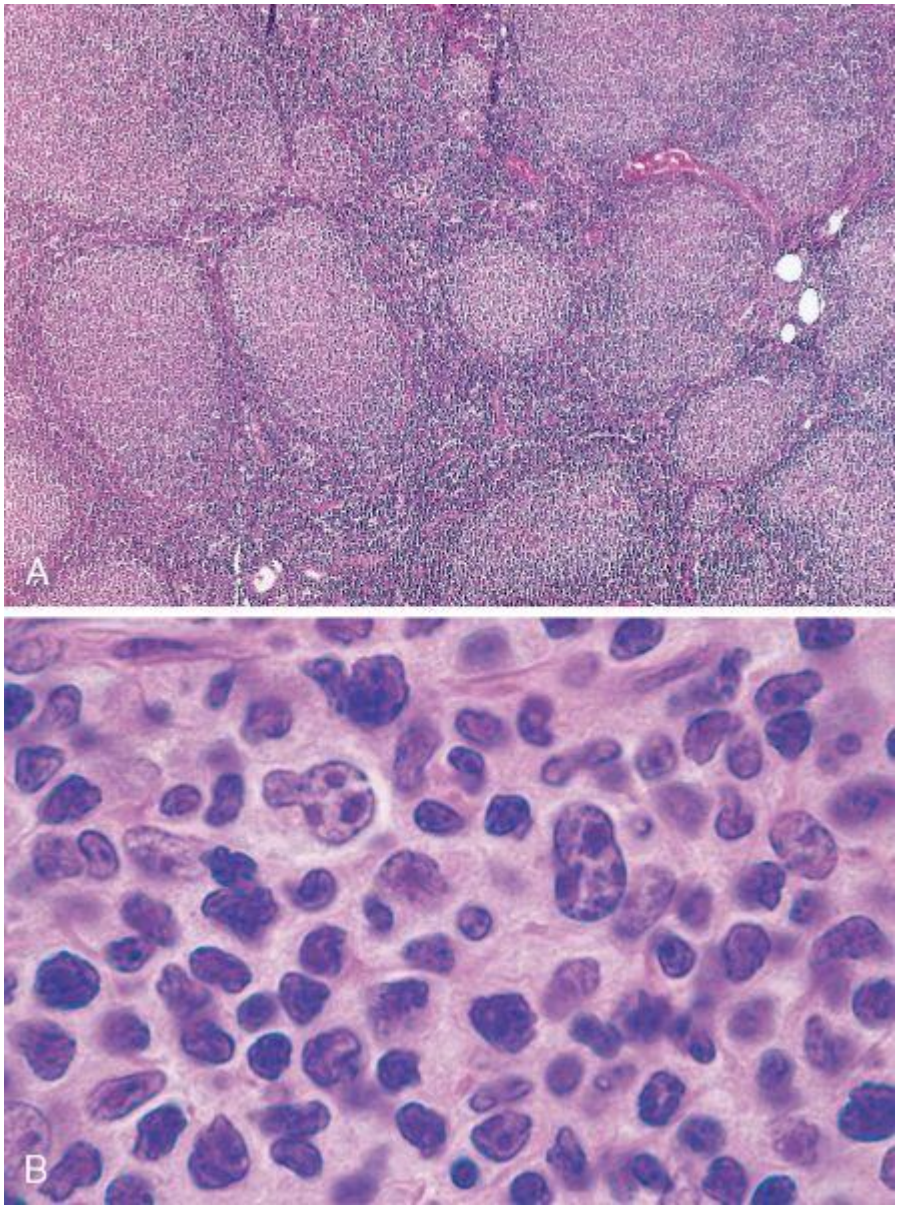

FIGURE 13-10 Follicular lymphoma (lymph node). **A**, Nodular aggregates of lymphoma cells are present throughout lymph node. **B**, At high magnification, small lymphoid cells with condensed chromatin and irregular or cleaved nuclear outlines (centrocytes) are mixed with a population of larger cells with nucleoli (centroblasts). *(**A**, Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

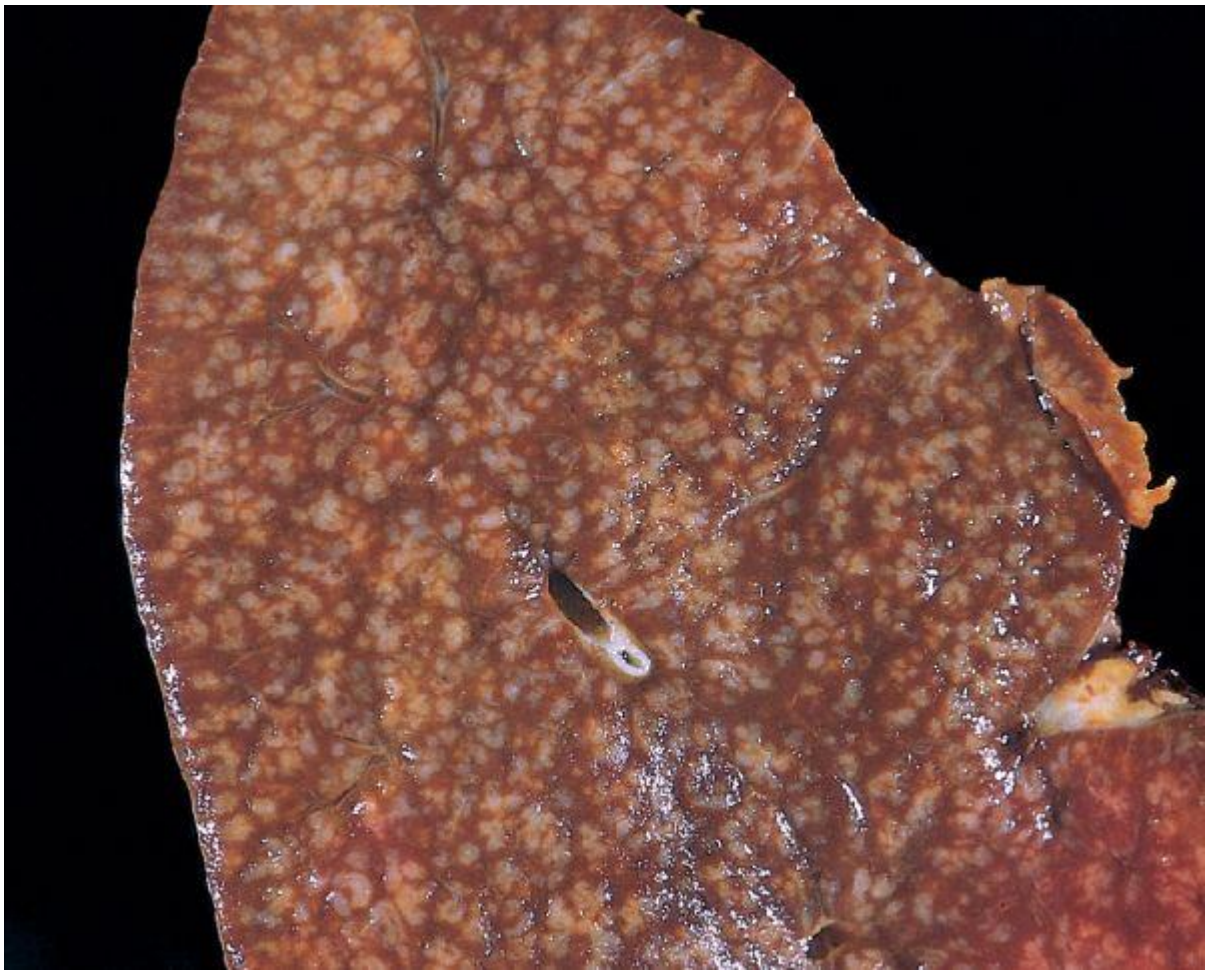

FIGURE 13-11 Follicular lymphoma (spleen). Prominent nodules represent white pulp follicles expanded by follicular lymphoma cells. Other indolent B-cell lymphomas (small lymphocytic lymphoma, mantle cell lymphoma, marginal zone lymphoma) can produce an identical pattern of involvement. *(Courtesy of Dr. Jeffrey Jorgenson, Department of Hematopathology, M.D. Anderson Cancer Center, Houston, TX.)*

Immunophenotype.

The neoplastic cells closely resemble normal germinal center B cells, expressing CD19, CD20, CD10, surface Ig, and BCL6. Unlike CLL/SLL and mantle cell lymphoma, CD5 is not expressed. BCL2 is expressed in more than 90% of cases, in distinction to normal follicular center B cells, which are BCL2-negative (Fig. 13-12).

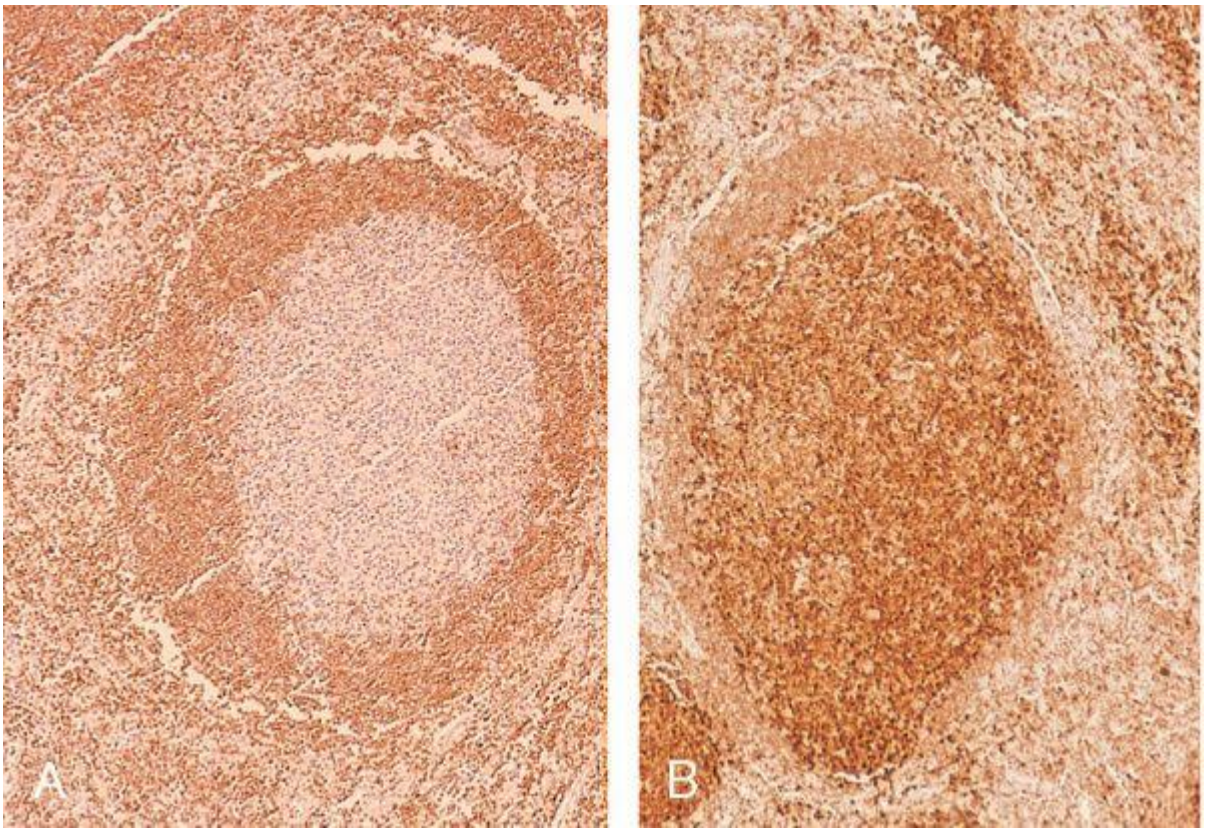

FIGURE 13-12 BCL2 expression in reactive and neoplastic follicles. BCL2 protein was detected by using an immunohistochemical technique that produces a brown stain. In reactive follicles (**A**), BCL2 is present in mantle zone cells but not follicular-center B cells, whereas follicular lymphoma cells (**B**) show strong BCL2 staining. *(Courtesy of Dr. Jeffrey Jorgenson, Department of Hematopathology, M.D. Anderson Cancer Center, Houston, TX.)*

Molecular Pathogenesis.

The hallmark of follicular lymphoma is a (14;18) translocation that juxtaposes the IgH locus on chromosome 14 and the BCL2 locus on chromosome 18. The t(14;18) is seen in up to 90% of follicular lymphomas, and leads to overexpression of BCL2 (see Fig. 13-12). BCL2 antagonizes apoptosis (Chapter 7) and promotes the survival of follicular lymphoma cells. Notably, while normal germinal centers contain numerous B cells undergoing apoptosis, follicular lymphoma is characteristically devoid of apoptotic cells.

Particularly early in the disease, follicular lymphoma cells growing in lymph nodes are found within a network of reactive follicular dendritic cells admixed with macrophages and T cells. Expression profiling studies have shown that differences in the genes expressed by these reactive cells are predictive of outcome, implying that the response of follicular lymphoma cells to therapy is somehow influenced by the surrounding microenvironment.[24,][25]

Clinical Features.

Follicular lymphoma tends to present with painless, generalized lymphadenopathy. Involvement of extranodal sites, such as the gastrointestinal tract, central nervous system, or testis, is relatively uncommon. Although incurable, it usually follows an indolent waxing and waning course. Survival (median, 7–9 years) is not improved by aggressive therapy; hence, the usual approach is to palliate

patients with low-dose chemotherapy or immunotherapy (such as anti-CD20 antibody) when they become symptomatic.

Histologic transformation occurs in 30% to 50% of follicular lymphomas, most commonly to diffuse large B-cell lymphoma. Less commonly, tumors resembling Burkitt lymphoma emerge that are associated with chromosomal translocations involving *c-MYC*. Like normal germinal center B cells, follicular lymphomas have ongoing somatic hypermutation, which may promote transformation by causing point mutations or chromosomal aberrations. The median survival is less than 1 year after transformation.

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) is the most common form of NHL. Each year in the United States there are about 25,000 new cases. There is a slight male predominance. The median patient age is about 60 years, but DLBCL also occurs in young adults and children.

Morphology. The common features are a relatively large cell size (usually four to five times the diameter of a small lymphocyte) and a diffuse pattern of growth (Fig. 13-13). In other respects, substantial morphologic variation is seen. Most commonly, the tumor cells have a round or oval nucleus that appears vesicular due to margination of chromatin to the nuclear membrane, but large multilobated or cleaved nuclei are prominent in some cases. Nucleoli may be two to three in number and located adjacent to the nuclear membrane, or single and centrally placed. The cytoplasm is usually moderately abundant and may be pale or basophilic. More anaplastic tumors may even contain multinucleated cells with large inclusion-like nucleoli that resemble Reed-Sternberg cells (the malignant cell of Hodgkin lymphoma).

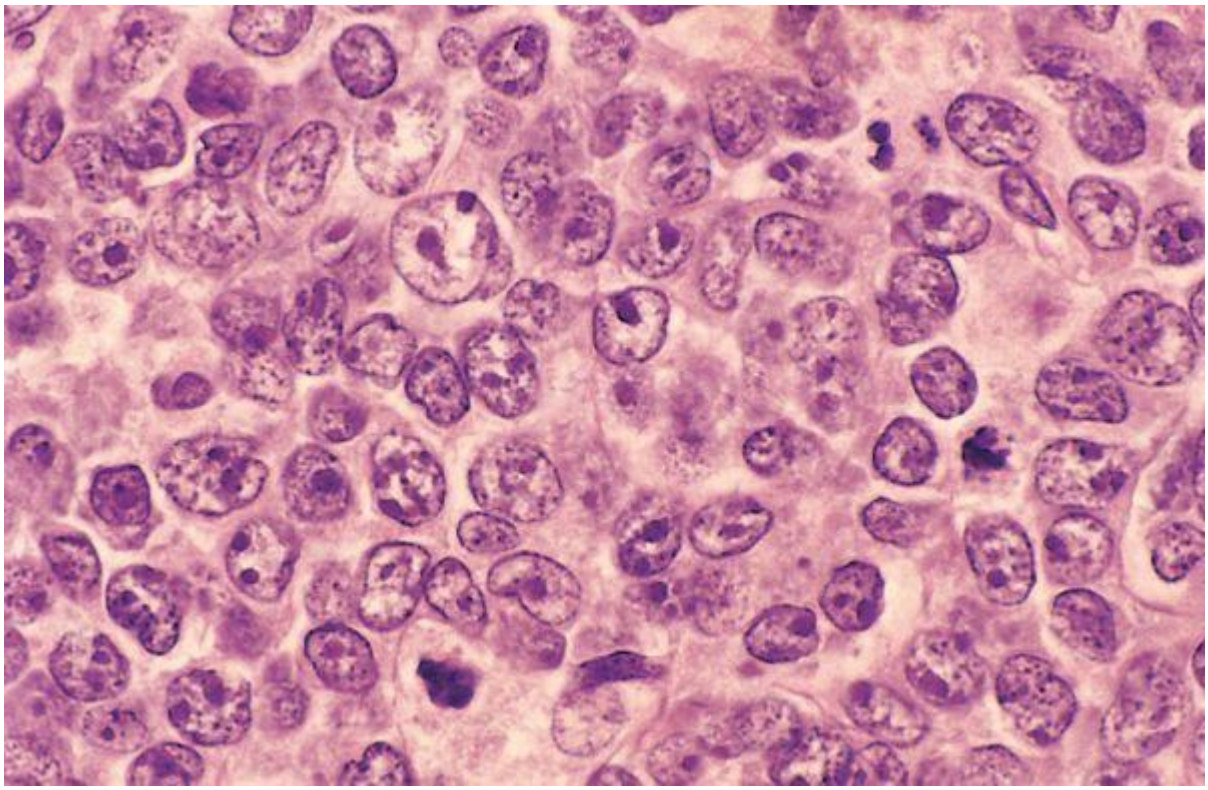

FIGURE 13-13 Diffuse large B-cell lymphoma. Tumor cells have large nuclei, open chromatin, and prominent nucleoli. *(Courtesy of Dr.*

Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)

Immunophenotype.

These mature B-cell tumors express CD19 and CD20 and show variable expression of germinal center B-cell markers such as CD10 and BCL6. Most have surface Ig.

Molecular Pathogenesis.

Cytogenetic, gene expression profiling, and immunohistochemical studies indicate that DLBCL is heterogeneous.[26,][27] One frequent pathogenic event is dysregulation of BCL6, a DNA-binding zinc-finger transcriptional repressor that is required for the formation of normal germinal centers. About 30% of DLBCLs contain various translocations that have in common a breakpoint in *BCL6* at chromosome 3q27. Acquired mutations in *BCL6* promoter sequences that abrogate *BCL6* autoregulation (an important negative-regulatory mechanism) are seen even more frequently. It is hypothesized that both types of lesions are inadvertent byproducts of somatic hypermutation that result in overexpression of *BCL6*, which has several important consequences. BCL6 represses the expression of factors that promote germinal center B-cell differentiation and growth arrest, and thereby holds cells in a relatively undifferentiated, proliferative state.[28,][29] BCL6 can also silence the expression of p53, the "guardian of the genome" (Chapter 7).[30] This "anti-p53" activity may serve to prevent the activation of DNA repair mechanisms in germinal center B cells undergoing somatic hypermutation and class switch recombination. Each of these activities is believed to contribute to the development of DLBCL. Mutations similar to those found in *BCL6* are also seen in multiple other oncogenes, including *c-MYC*,[10] suggesting that somatic hypermutation in DLBCL cells is "mistargeted" to a wide variety of loci.

Another 10% to 20% of tumors are associated with the t(14;18), which (as discussed under follicular lymphoma) leads to the overexpression of the anti-apoptotic protein BCL2. Tumors with *BCL2* rearrangements almost always lack *BCL6* rearrangements, suggesting that these rearrangements define two distinct molecular classes of DLBCL. Some tumors with *BCL2* rearrangements may arise from unrecognized underlying follicular lymphomas, which (as discussed already) frequently transform to DLBCL.

Special Subtypes Associated with Oncogenic Herpesviruses.

Several other subtypes of DLBCL are sufficiently distinctive to merit brief discussion.

- *Immunodeficiency-associated large B-cell lymphoma* occurs in the setting of severe T-cell immunodeficiency (e.g., advanced HIV infection and allogeneic bone marrow transplantation). *The neoplastic B cells are usually infected with* EBV, which plays a critical pathogenic role. Restoration of T-cell immunity may lead to regression of these proliferations.
- *Primary effusion lymphoma* presents as a malignant pleural or ascitic effusion, mostly in patients with advanced HIV infection or the elderly. The tumor cells are often anaplastic in appearance and typically fail to express surface B- or T-cell markers, but have clonal IgH gene rearrangements. *In all cases the tumor cells are infected with KSHV/HHV-8*, which appears to have a causal role.

Clinical Features.

DLBCL typically presents as a rapidly enlarging mass at a nodal or extranodal site. It can arise virtually anywhere in the body. Waldeyer ring, the oropharyngeal lymphoid tissue that includes the tonsils and adenoids, is involved commonly. Primary or secondary involvement of the liver and spleen

may take the form of large destructive masses (Fig. 13-14). Extranodal sites include the gastrointestinal tract, skin, bone, brain, and other tissues. Bone marrow involvement is relatively uncommon and usually occurs late in the course. Rarely, a leukemic picture emerges.

FIGURE 13-14 Diffuse large B-cell lymphoma involving the spleen. The isolated large mass is typical. In contrast, indolent B-cell lymphomas usually produce multifocal expansion of white pulp (see Fig. 13-11). *(Courtesy of Dr. Mark Fleming, Department of Pathology, Children's Hospital, Boston, MA.)*

DLBCLs are aggressive tumors that are rapidly fatal without treatment. With intensive combination chemotherapy, 60% to 80% of patients achieve a complete remission, and 40% to 50% are cured. Immunotherapy with anti-CD20 antibody seems to improve both the initial response and the overall outcome, particularly in the elderly. Individuals with limited disease fare better than those with widespread disease or bulky tumor masses. Expression profiling has identified distinct molecular subtypes with differing clinical outcomes and led to new targeted therapeutic approaches directed at components of the NF-κB and B cell receptor signaling pathways.[26,][27]

Burkitt Lymphoma

Within this category fall (1) African (endemic) Burkitt lymphoma, (2) sporadic (nonendemic) Burkitt lymphoma, and (3) a subset of aggressive lymphomas occurring in individuals infected with HIV. Burkitt lymphomas occurring in each of these settings are histologically identical but differ in some clinical, genotypic, and virologic characteristics.

Morphology. Involved tissues are effaced by a diffuse infiltrate of intermediate-sized lymphoid cells 10 to 25 μm in diameter with round or oval nuclei, coarse chromatin, several nucleoli, and a moderate amount of cytoplasm (Fig. 13-15). **The tumor exhibits a high mitotic index and contains numerous apoptotic cells**, the nuclear remnants of which are phagocytosed by interspersed benign

macrophages. These phagocytes have abundant clear cytoplasm, creating a characteristic **"starry sky" pattern**. When the bone marrow is involved, aspirates reveal tumor cells with slightly clumped nuclear chromatin, two to five distinct nucleoli, and royal blue cytoplasm containing clear cytoplasmic vacuoles.

Immunophenotype.

These are tumors of mature B cells that express surface IgM, CD19, CD20, CD10, and BCL6, a phenotype consistent with a germinal center B-cell origin. Unlike other tumors of germinal center origin, Burkitt lymphoma almost always fails to express the anti-apoptotic protein BCL2.

Molecular Pathogenesis.

All forms of Burkitt lymphoma are associated with translocations of the c-MYC gene on chromosome 8. The translocation partner is usually the IgH locus [t(8;14)] but may also be the Ig κ [t(2;8)] or γ [t(8;22)] light-chain loci. The breakpoints in the IgH locus in sporadic Burkitt lymphoma are usually found in the class switch regions, whereas the breakpoints in endemic Burkitt lymphoma tend to lie within more 5′ V(D)J sequences. The basis for this subtle molecular distinction is not known, but both types of translocations can be induced in germinal center B cells by AID,[8,][9] which you will recall is a specialized DNA-modifying enzyme that is required for both Ig class switching and somatic hypermutation. The net effect of these translocations is similar; the *c-MYC* coding sequence is repositioned adjacent to strong Ig promoter and enhancer elements, which drive increased *c-MYC* expression. In addition, the translocated *c-MYC* allele often harbors point mutations that further increase its activity.[31] Burkitt lymphomas also commonly have mutations that inactivate p53, an event that increases the frequency of *c-MYC* translocations in germinal center B cells.[9] Hence, it is possible that pre-existent defects in p53 set the stage for the acquisition of *c-MYC* translocations.

Essentially all endemic tumors are latently infected with EBV, which is also present in about 25% of HIV-associated tumors and 15% to 20% of sporadic cases. The configuration of the EBV DNA is identical in all tumor cells within individual cases, indicating that infection precedes transformation. Although this places EBV at the "scene of the crime," its precise role in the genesis of Burkitt lymphoma remains poorly understood.

About 5% of DLBCLs have *c-MYC* translocations, and in such instances DLBCL may be difficult to distinguish from Burkitt lymphoma by conventional diagnostic tests. This distinction can be important, since DLBCL and Burkitt lymphoma are often treated with different chemotherapeutic regimens. Gene expression profiling may provide a more accurate assay for differentiating between these two tumors in difficult cases.[32]

Clinical Features.

Both endemic and sporadic Burkitt lymphomas are found mainly in children or young adults; overall, it accounts for about 30% of childhood NHLs in the United States. *Most tumors manifest at extranodal sites*. Endemic Burkitt lymphoma often presents as a mass involving the mandible and shows an unusual predilection for involvement of abdominal viscera, particularly the kidneys, ovaries, and adrenal glands. In contrast, sporadic Burkitt lymphoma most often appears as a mass involving the ileocecum and peritoneum. Involvement of the bone marrow and peripheral blood is uncommon, especially in endemic cases. Burkitt lymphoma is very aggressive but responds well to intensive chemotherapy. Most children and young adults can be cured. The outcome is more guarded in older adults.

Plasma Cell Neoplasms and Related Disorders

These B-cell proliferations contain neoplastic plasma cells that virtually always secrete a monoclonal Ig or Ig fragment. Collectively, the plasma cell neoplasms (often referred to as dyscrasias) account for about 15% of the deaths caused by lymphoid neoplasms. The most common and deadly of these neoplasms is multiple myeloma, of which there are about 15,000 new cases per year in the United States.

A monoclonal Ig identified in the blood is referred to as an M component, in reference to myeloma. Since complete M components have molecular weights of 160,000 or higher, they are restricted to the plasma and extracellular fluid and excluded from the urine in the absence of glomerular damage. However, unlike normal plasma cells, in which the production and coupling of heavy and light chains are tightly balanced, *neoplastic plasma cells often synthesize excess light or heavy chains along with complete Igs*. Occasionally only light chains or heavy chains are produced. The free light chains are small enough to be excreted in the urine, where they are called *Bence-Jones proteins*. Free light chains can be detected and measured in the urine or the blood, the latter with new, highly sensitive tests that are in the process of being evaluated.

Terms used to describe the abnormal Igs include monoclonal gammopathy, dysproteinemia, and paraproteinemia. The following clinicopathologic entities are associated with monoclonal gammopathies.

- *Multiple myeloma (plasma cell myeloma)*, the most important monoclonal gammopathy, usually presents as tumorous masses scattered throughout the skeletal system. *Solitary myeloma* (*plasmacytoma*) is an infrequent variant that presents as a single mass in bone or soft tissue. *Smoldering myeloma* refers to another uncommon variant defined by a lack of symptoms and a high plasma M component.
- *Waldenström macroglobulinemia* is a syndrome in which high levels of IgM lead to symptoms related to hyperviscosity of the blood. It occurs in older adults, most commonly in association with lymphoplasmacytic lymphoma.
- *Heavy-chain disease* is a rare monoclonal gammopathy that is seen in association with a diverse group of disorders, including lymphoplasmacytic lymphoma and an unusual small bowel marginal zone lymphoma that occurs in malnourished populations (so-called Mediterranean lymphoma). The common feature is the synthesis and secretion of free heavy-chain fragments.
- *Primary or immunocyte-associated amyloidosis* results from a monoclonal proliferation of plasma cells secreting light chains (usually of γ isotype) that are deposited as amyloid. Some patients have overt multiple myeloma, but others have only a minor clonal population of plasma cells in the marrow.
- *Monoclonal gammopathy of undetermined significance (MGUS)* is applied to patients without signs or symptoms who have small to moderately large M components in their blood. MGUS is very common in the elderly and has a low but constant rate of transformation to symptomatic monoclonal gammopathies, most often multiple myeloma.

With this background, we now turn to some of the specific clinicopathologic entities. Primary amyloidosis was discussed along with other disorders of the immune system in Chapter 6 .

Multiple Myeloma.

Multiple myeloma is a plasma cell neoplasm characterized by multifocal involvement of the skeleton. Although bony disease dominates, it can spread late in its course to lymph nodes and extranodal sites such as the skin. Multiple myeloma causes 1% of all cancer deaths in Western countries. Its incidence is higher in men and people of African descent. It is chiefly a disease of the elderly, with a peak age of incidence of 65 to 70 years.

Molecular Pathogenesis.

The Ig genes in myeloma cells always show evidence of somatic hypermutation. On this basis, the cell of origin is considered to be a post-germinal center B cell that homes to the bone marrow and has

differentiated into a plasma cell. Of interest, some studies suggest that the tumor originates in and is maintained by stem-like cells resembling small B lymphocytes that rely on signals generated by the "hedgehog" pathway for self-renewal.[33,][34]

The proliferation and survival of myeloma cells are dependent on several cytokines, most notably IL-6. IL-6 is an important growth factor for plasma cells that is produced by the tumor cells themselves and resident marrow stromal cells. High serum levels of IL-6 are seen in patients with active disease and are associated with a poor prognosis. Myeloma cell growth and survival are also augmented by direct physical interactions with bone marrow stromal cells, which is a focus of new therapeutic approaches.[35]

Factors produced by neoplastic plasma cells mediate bone destruction, the major pathologic feature of multiple myeloma. Of particular importance, myeloma-derived MIP1α upregulates the expression of the receptor activator of NF-κB ligand (RANKL) by bone marrow stromal cells, which in turn activates osteoclasts.[36] Other factors released from tumor cells, such as modulators of the Wnt pathway, are potent inhibitors of osteoblast function. The net effect is a marked increase in bone resorption, which leads to hypercalcemia and pathologic fractures.[37]

Many myelomas have rearrangements involving the Ig heavy-chain gene on chromosome 14q32.[38,][39] Common translocation partners include *FGFR3* (fibroblast growth factor receptor 3) on chromosome 4p16, a gene encoding a tyrosine kinase receptor implicated in the control of cellular proliferation; the cell cycle–regulatory genes cyclin D1 on chromosome 11q13 and cyclin D3 on chromosome 6p21; the gene for the transcription factor *c-MAF* on chromosome 16q23; and the gene encoding the transcription factor *MUM1/IRF4* on chromosome 6p25. As may be gathered from the involvement of two different D cyclin genes, dysreglation of D cyclins is a common feature.[38] The other most frequent karyotypic abnormalities are deletions of 13q. Consistent with the diversity of chromosomal aberrations, gene expression profiling studies suggest that myeloma is molecularly quite heterogeneous.[40]

Morphology. Multiple myeloma usually presents as destructive plasma cell tumors (plasmacytomas) involving the axial skeleton. The bones most commonly affected (in descending order of frequency) are the vertebral column, ribs, skull, pelvis, femur, clavicle, and scapula. Lesions begin in the medullary cavity, erode cancellous bone, and progressively destroy the bony cortex, often leading to pathologic fractures; these are most common in the vertebral column, but may occur in any affected bone. **The bone lesions appear radiographically as punched-out defects, usually 1 to 4 cm in diameter** (Fig. 13-16), and grossly consist of soft, gelatinous, red tumor masses. Less commonly, widespread myelomatous bone disease produces diffuse demineralization (osteopenia) rather than focal defects.

Even away from overt tumor masses, the marrow contains an increased number of plasma cells, which usually constitute more than 30% of the cellularity. The plasma cells may infiltrate the interstitium or be present in sheets that completely replace normal elements. Like their benign counterparts, malignant plasma cells have a perinuclear clearing due to a prominent Golgi apparatus and an eccentrically placed nucleus (Fig. 13-17). Relatively normal-appearing plasma cells, **plasmablasts** with vesicular nuclear chromatin and a prominent single nucleolus, or **bizarre, multinucleated cells** may predominate. Other cytologic variants stem from the dysregulated synthesis and secretion of Ig, which often leads to intracellular accumulation of intact or partially degraded protein. Such variants include **flame cells** with fiery red cytoplasm, **Mott cells** with multiple grapelike cytoplasmic droplets, and cells containing a variety of other inclusions, including **fibrils, crystalline rods, and globules**. The globular inclusions are referred to as **Russell bodies** (if cytoplasmic) or **Dutcher bodies** (if nuclear). In advanced disease, plasma cell infiltrates may be present in the spleen, liver, kidneys, lungs, lymph nodes, and other soft tissues.

Commonly, the high level of M proteins causes red cells in peripheral blood smears to stick to one another in linear arrays, a finding referred to as **rouleaux formation**. Rouleaux formation is characteristic but not specific, in that it may be seen in other conditions in which Ig levels are elevated, such as lupus erythematosus and early HIV infection. Rarely, tumor cells flood the peripheral blood, giving rise to **plasma cell leukemia**.

Bence Jones proteins are excreted in the kidney and contribute to a form of renal disease called **myeloma kidney**. This important complication is discussed in detail in Chapter 20 .

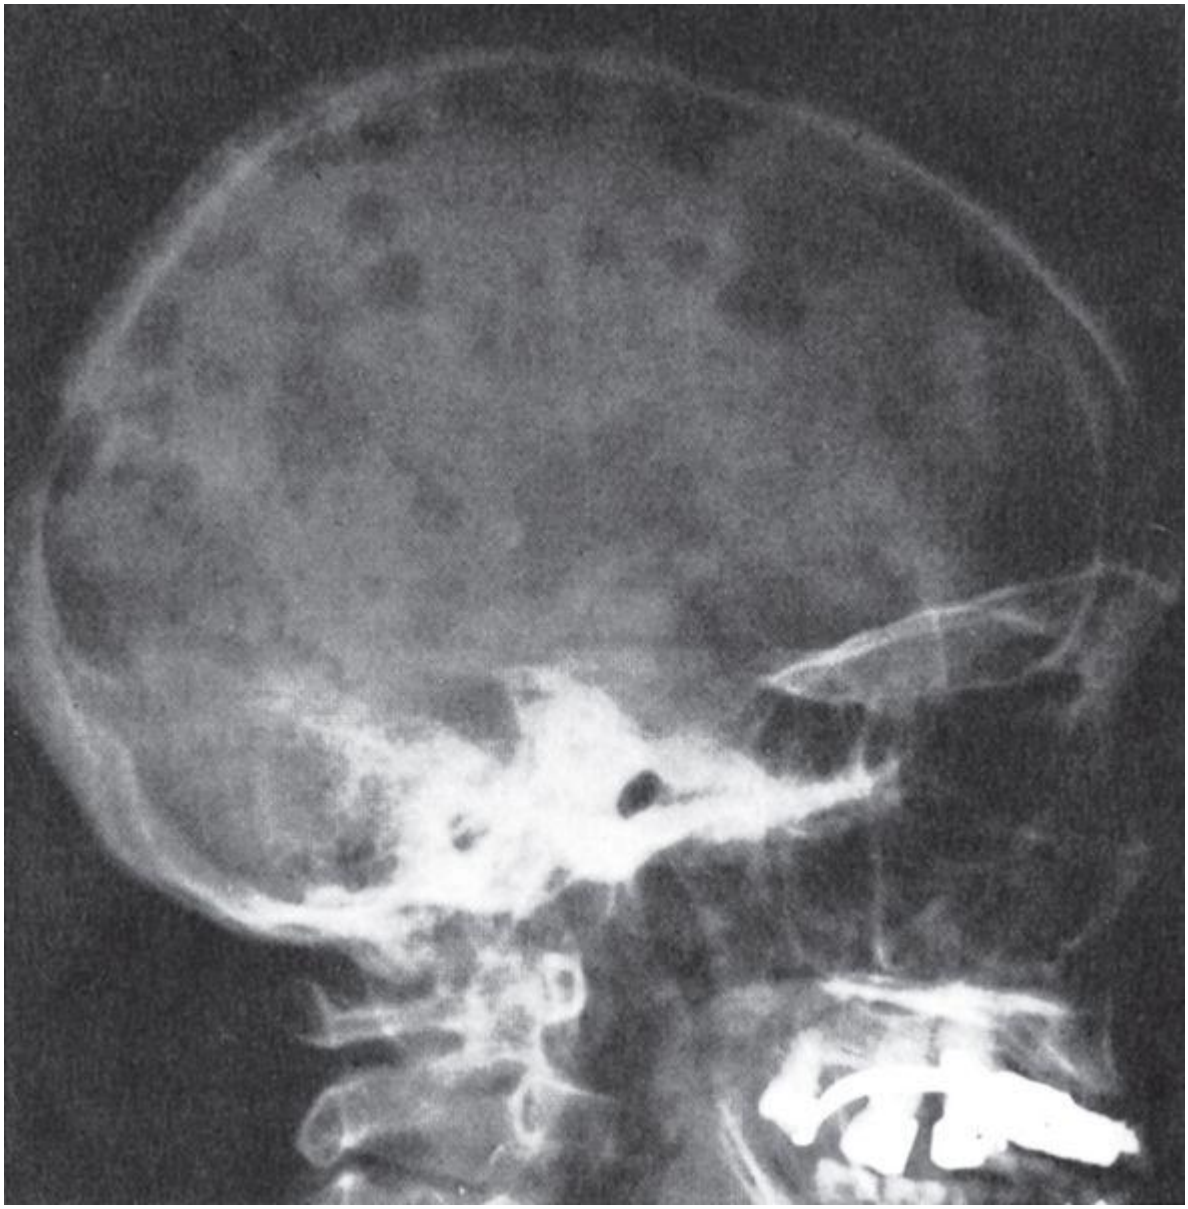

FIGURE 13-16 Multiple myeloma of the skull (radiograph, lateral view). The sharply punched-out bone lesions are most obvious in the calvarium.

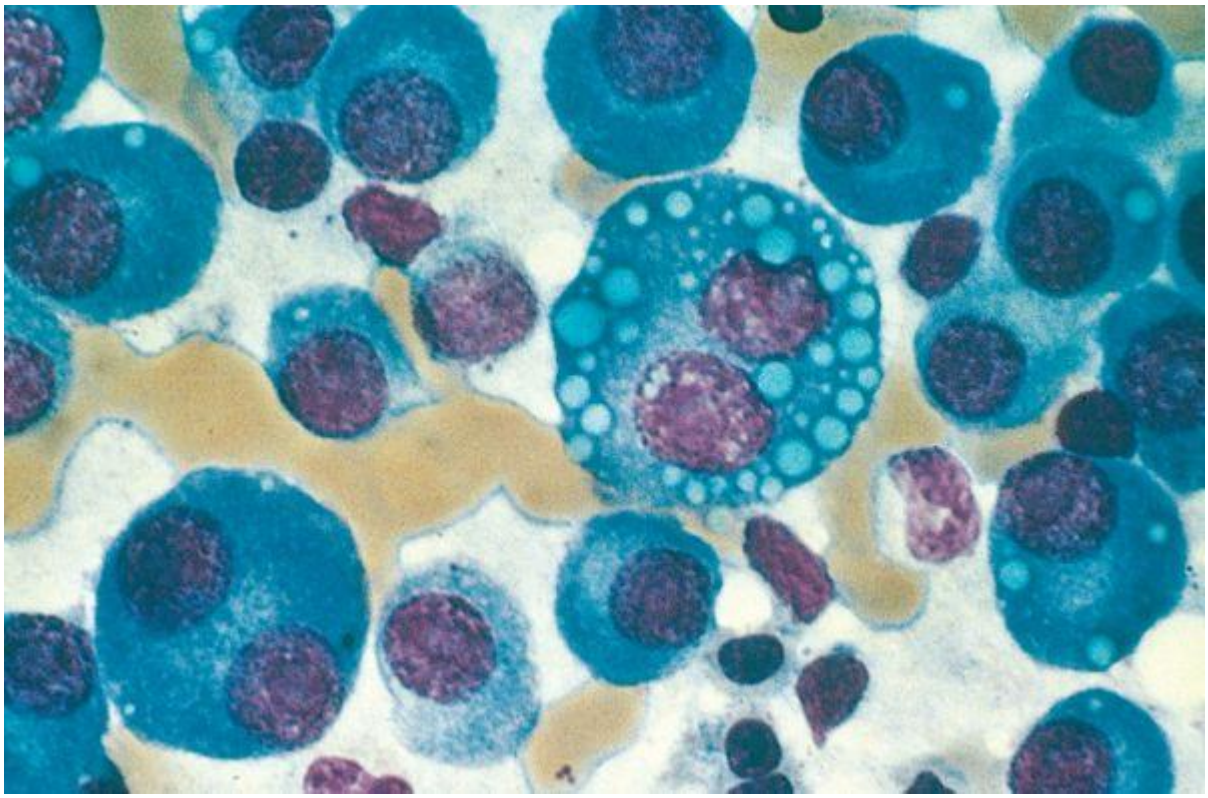

FIGURE 13-17 Multiple myeloma (bone marrow aspirate). Normal marrow cells are largely replaced by plasma cells, including forms with multiple nuclei, prominent nucleoli, and cytoplasmic droplets containing Ig.

Clinical Features.

The clinical features of multiple myeloma stem from (1) the effects of plasma cell growth in tissues, particularly the bones; (2) the production of excessive Igs, which often have abnormal physicochemical properties; and (3) the suppression of normal humoral immunity.

Bone resorption often leads to pathologic fractures and chronic pain. The attendant *hypercalcemia* can give rise to neurologic manifestations, such as confusion, weakness, lethargy, constipation, and polyuria, and contributes to renal dysfunction. Decreased production of normal Igs sets the stage for *recurrent bacterial infections*. Cellular immunity is relatively unaffected. *Of great significance is renal insufficiency, which trails only infections as a cause of death*. The pathogenesis of renal failure (discussed in Chapter 20), which occurs in up to 50% of patients, is multifactorial. However, the single most important factor seems to be *Bence Jones proteinuria*, since the excreted light chains are toxic to renal tubular epithelial cells. Certain light chains (particularly those of the γ6 and γ3 families) are prone to cause *amyloidosis* of the AL type (Chapter 6), which can exacerbate renal dysfunction and deposit in other tissue as well.

In 99% of patients, laboratory analyses reveal increased levels of Igs in the blood and/or light chains (Bence Jones proteins) in the urine. The monoclonal Igs are usually first detected as abnormal protein "spikes" in serum or urine electrophoresis and then further characterized by immunofixation (Fig. 13-18). Most myelomas are associated with more than 3 gm/dL of serum Ig and/or more than 6 gm/dL of urine Bence Jones protein. The most common monoclonal Ig ("M protein") is IgG (~55% of patients), followed by IgA (~25% of cases). Myelomas expressing IgM, IgD, or IgE occur but are rare. Excessive

production and aggregation of M proteins, usually of the IgA and or IgG_3 subtype, leads to symptoms related to hyperviscosity (described under lymphoplasmacytic lymphoma) in about 7% of patients. Both free light chains and a serum M protein are observed together in 60% to 70% of patients. However, in about 20% of patients only free light chains are present. Around 1% of myelomas are nonsecretory; hence, the absence of detectable M proteins does not completely exclude the diagnosis.

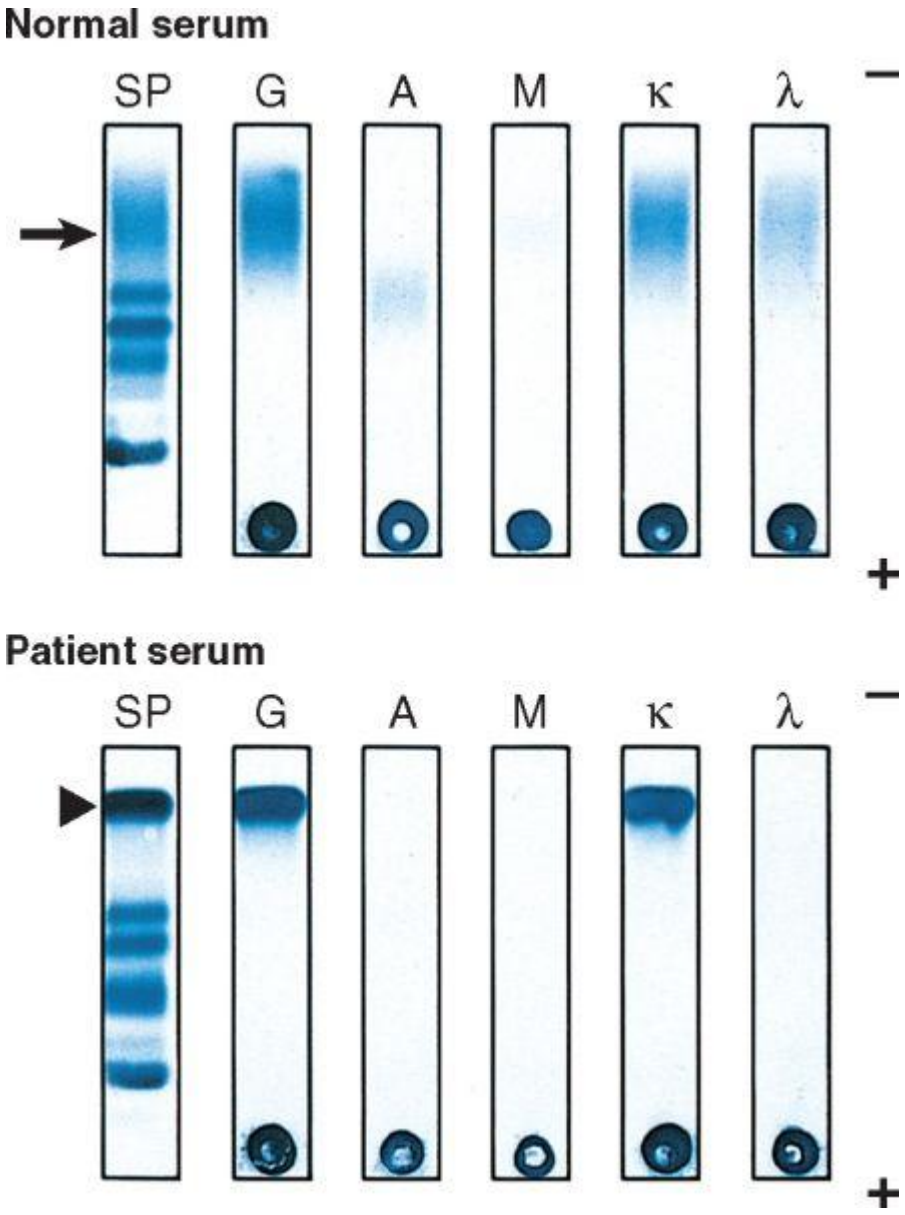

FIGURE 13-18 M protein detection in multiple myeloma. Serum protein electrophoresis (SP) is used to screen for a monoclonal immunoglobulin (M protein). Polyclonal IgG in normal serum (denoted by the *arrow*) appears as a broad band; in contrast, serum from a patient with multiple myeloma contains a single sharp protein band (denoted by the *arrowhead*) in this region of the electropherogram. The suspected monoclonal Ig is confirmed and characterized by immunofixation. In this procedure, proteins separated by electrophoresis within a gel are reacted with specific antisera. After extensive washing, proteins that are cross-linked by antisera are retained and detected with a protein stain. Note the sharp band in the patient serum is cross-linked by antisera specific for IgG heavy chain (G) and kappa light chain (κ), indicating the presence of an IgGκ M protein. Levels of polyclonal IgG, IgA (A), and lambda light chain (γ) are also decreased in the patient serum relative to normal, a finding typical of multiple myeloma. *(Courtesy of Dr. David Sacks, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

The clinicopathologic diagnosis of multiple myeloma rests on radiographic and laboratory findings. It can be strongly suspected when the distinctive radiographic changes are present, but definitive diagnosis requires a bone marrow examination. Marrow involvement often gives rise to a normocytic normochromic anemia, sometimes accompanied by moderate leukopenia and thrombocytopenia.

The prognosis is variable but generally poor. The median survival is 4 to 6 years, and cures have yet to be achieved. Patients with multiple bony lesions, if untreated, rarely survive for more than 6 to 12 months, whereas patients with "smoldering myeloma" may be asymptomatic for many years. Translocations involving cyclin D1 are associated with a good outcome, whereas deletions of 13q, deletions of 17p, and the t(4;14) all portend a more aggressive course.[41]

Cytotoxic agents induce remission in 50% to 70% of patients, and new therapeutic approaches are bringing hope. Myeloma cells are sensitive to inhibitors of the proteasome,[42] a cellular organelle that degrades unwanted and misfolded proteins. You will recall from Chapter 1 that misfolded proteins activate apoptotic pathways. Myeloma cells are prone to the accumulation of misfolded, unpaired Ig chains. Proteasome inhibitors may induce cell death by exacerbating this inherent tendency, and also seem to retard bone resorption through effects on stromal cells.[43] Thalidomide and related compounds also have activity against myeloma, apparently by altering interactions between myeloma cells and bone marrow stromal cells and by inhibiting angiogenesis.[35] Biphosphonates, drugs that inhibit bone resorption, reduce pathologic fractures and limit the hypercalcemia. Bone marrow transplantation prolongs life but has not yet proven to be curative.

Solitary Myeloma (Plasmacytoma).

About 3% to 5% of plasma cell neoplasms present as a solitary lesion of bone or soft tissue. The bone lesions tend to occur in the same locations as in multiple myeloma. Extra-osseous lesions are often located in the lungs, oronasopharynx, or nasal sinuses. Modest elevations of M proteins in the blood or urine may be found in some patients. Solitary osseous plasmacytoma almost inevitably progresses to multiple myeloma, but this can take 10 to 20 years or longer. In contrast, extra-osseous plasmacytomas, particularly those involving the upper respiratory tract, are frequently cured by local resection.

Smoldering Myeloma.

This entity defines a middle ground between multiple myeloma and monoclonal gammopathy of uncertain significance. Plasma cells make up 10% to 30% of the marrow cellularity, and the serum M protein level is greater than 3 gm/dL, but patients are asymptomatic. About 75% of patients progress to multiple myeloma over a 15-year period.[44]

Monoclonal Gammopathy of Uncertain Significance (MGUS).

MGUS is the most common plasma cell dyscrasia,[45] occurring in about 3% of persons older than 50 years of age and in about 5% of individuals older than 70 years of age. By definition, patients are asymptomatic and the serum M protein level is less than 3 gm/dL. *Approximately 1% of patients with MGUS develop a symptomatic plasma cell neoplasm, usually multiple myeloma, per year*,[46] a rate of conversion that remains roughly constant over time. Of pathogenic interest, the clonal plasma cells in MGUS often contain the same chromosomal translocations and deletions that are found in full-blown multiple myeloma,[47] indicating that MGUS is an early stage of myeloma development. As in patients with smoldering myeloma, progression to multiple myeloma is unpredictable; hence, periodic assessment of serum M component levels and Bence Jones proteinuria is warranted.

Lymphoplasmacytic Lymphoma.

Lymphoplasmacytic lymphoma is a B-cell neoplasm of older adults that usually presents in the sixth or seventh decade of life. Although bearing a superficial resemblance to CLL/SLL, it differs in that a substantial fraction of the tumor cells undergo terminal differentiation to plasma cells. *Most commonly, the plasma cell component secretes monoclonal IgM, often in amounts sufficient to cause a hyperviscosity syndrome known as Waldenström macroglobulinemia*. Unlike multiple myeloma, heavy- and light-chain synthesis is usually balanced and complications stemming from the secretion of free light chains (e.g., renal failure and amyloidosis) are rare. A further important distinction is that bone destruction is not observed in this disease.

Morphology. Typically, the marrow contains a diffuse sparse-to-heavy infiltrate of lymphocytes, plasma cells, and plasmacytoid lymphocytes in varying proportions, often accompanied by mast cell hyperplasia (Fig. 13-19). Some tumors also contain a population of larger lymphoid cells with more vesicular nuclear chromatin and prominent nucleoli. Periodic acid–Schiff-positive inclusions containing Ig are frequently seen in the cytoplasm (**Russell bodies**) or the nucleus (**Dutcher bodies**) of some of the plasma cells. At diagnosis the tumor has usually disseminated to the lymph nodes, spleen, and liver. Infiltration of the nerve roots, meninges, and more rarely the brain can also occur with disease progression.

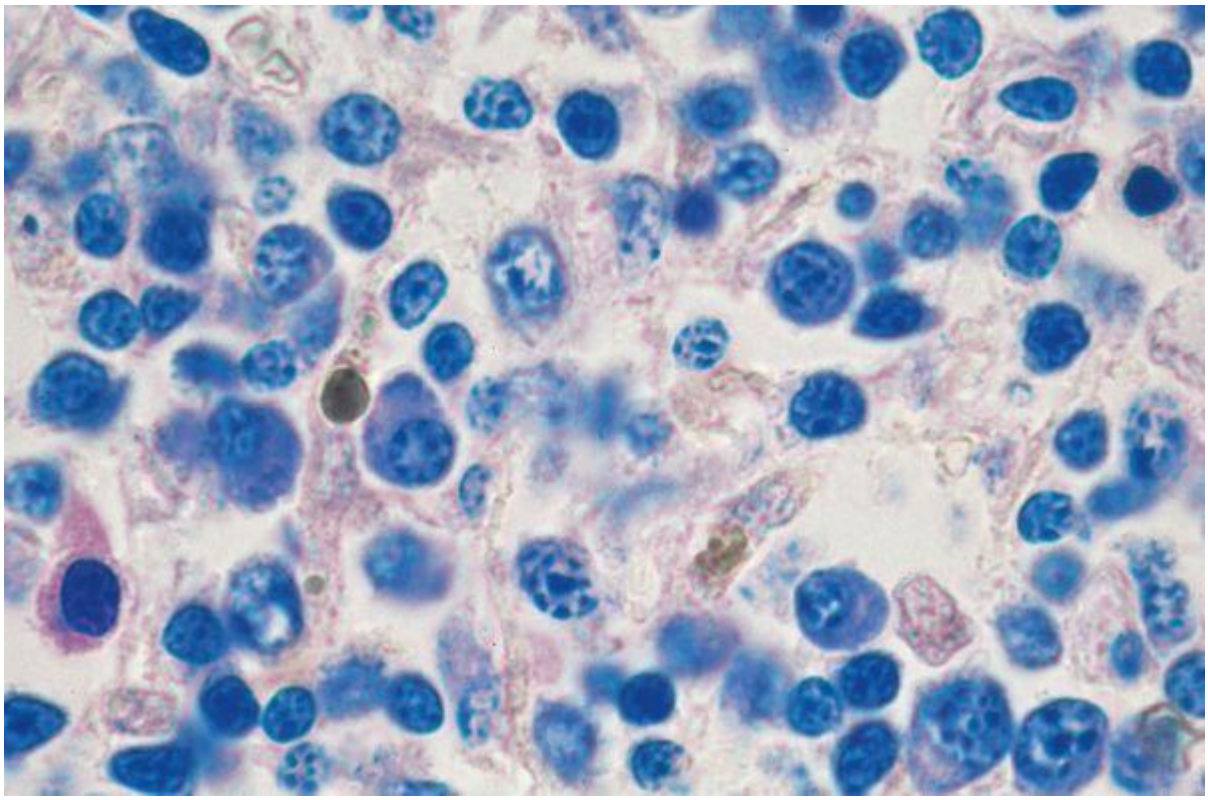

FIGURE 13-19 Lymphoplasmacytic lymphoma. Bone marrow biopsy shows a characteristic mixture of small lymphoid cells exhibiting various degrees of plasma cell differentiation. In addition, a mast cell with purplish red cytoplasmic granules is present at the left-hand side of the field.

Immunophenotype and Molecular Pathogenesis.

The lymphoid component expresses B-cell markers such as CD20 and surface Ig, whereas the plasma cell component secretes the same Ig that is expressed on the surface of the lymphoid cells. This is usually IgM but can also be IgG or IgA. These tumors usually lack chromosomal translocations; the most common cytogenetic abnormality is a deletion involving chromosome 6q.

Clinical Features.

The dominant presenting complaints are nonspecific and include weakness, fatigue, and weight loss. Approximately half the patients have *lymphadenopathy, hepatomegaly, and splenomegaly*. Anemia caused by marrow infiltration is common. About 10% of patients have *autoimmune hemolysis* caused by *cold agglutinins*, IgM antibodies that bind to red cells at temperatures of less than 37°C (described in Chapter 14).

Patients with IgM-secreting tumors have additional complaints stemming from the physicochemical properties of IgM. Because of its large size, at high concentrations IgM greatly increases the viscosity of the blood, giving rise to a *hyperviscosity syndrome* characterized by the following:

- *Visual impairment* associated with venous congestion, which is reflected by striking tortuosity and distention of retinal veins; retinal hemorrhages and exudates can also contribute to the visual problems
- *Neurologic problems* such as headaches, dizziness, deafness, and stupor, all stemming from sluggish blood flow and sludging
- *Bleeding* related to the formation of complexes between macroglobulins and clotting factors as well as interference with platelet functions
- *Cryoglobulinemia* resulting from the precipitation of macroglobulins at low temperatures, which produces symptoms such as Raynaud phenomenon and cold urticaria

Lymphoplasmacytic lymphoma is an incurable progressive disease. Since most IgM is intravascular, symptoms caused by the high IgM levels (such as hyperviscosity and hemolysis) can be alleviated by plasmapheresis. Tumor growth can be controlled for a time with low doses of chemotherapeutic drugs and immunotherapy with anti-CD20 antibody. Transformation to large-cell lymphoma occurs but is uncommon. Median survival is about 4 years.

Mantle Cell Lymphoma

Mantle cell lymphoma is an uncommon lymphoid neoplasm that makes up about 2.5% of NHL in the United States and 7% to 9% of NHL in Europe. It usually presents in the fifth to sixth decades of life and shows a male predominance. As the name implies, *the tumor cells closely resemble the normal mantle zone B cells that surround germinal centers*.

Morphology. Nodal tumor cells may surround reactive germinal centers to produce a nodular appearance at low power, or diffusely efface the node. **Typically, the proliferation consists of a homogeneous population of small lymphocytes with irregular to occasionally deeply clefted (cleaved) nuclear contours** (Fig. 13-20). Large cells resembling centroblasts and proliferation centers are absent, distinguishing mantle cell lymphoma from follicular lymphoma and CLL/SLL, respectively. In most cases the nuclear chromatin is condensed, nucleoli are inconspicuous, and the cytoplasm is scant. Occasionally, tumors composed of intermediate-sized cells with more open chromatin and a brisk mitotic rate are observed; immunophenotyping is necessary to distinguish these "blastoid" variants of mantle cell lymphoma from ALL.

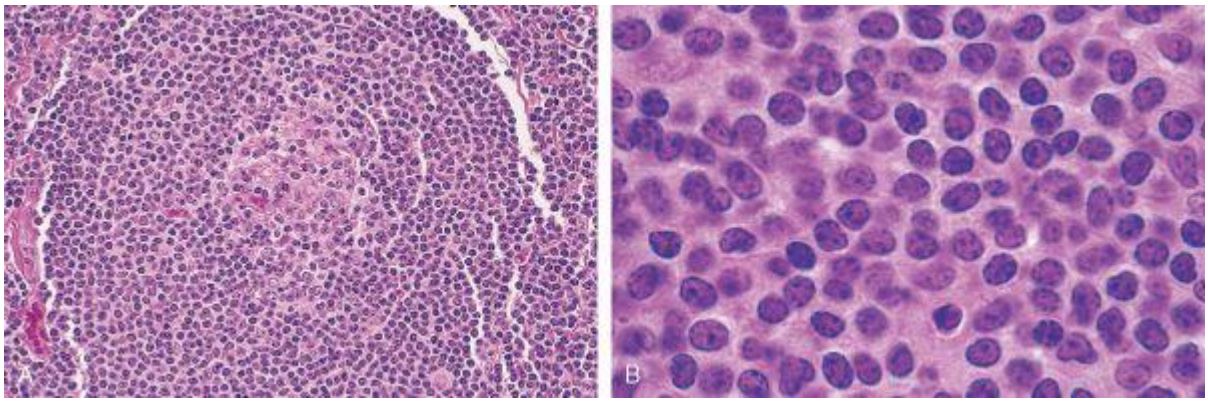

FIGURE 13-20 Mantle cell lymphoma. **A**, At low power, neoplastic lymphoid cells surround a small, atrophic germinal center, producing a mantle zone pattern of growth. **B**, High-power view shows a homogeneous population of small lymphoid cells with somewhat irregular nuclear outlines, condensed chromatin, and scant cytoplasm. Large cells resembling prolymphocytes (seen in chronic lymphocytic leukemia) and centroblasts (seen in follicular lymphoma) are absent.

At diagnosis the majority of patients have generalized lymphadenopathy, and 20% to 40% have peripheral blood involvement. Frequent sites of extranodal involvement include the bone marrow, spleen, liver, and gut. Occasionally, mucosal involvement of the small bowel or colon produces polyp-like lesions (lymphomatoid polyposis); of all forms of NHL, mantle cell lymphoma is most likely to spread in this fashion.

Immunophenotype.

Mantle cell lymphomas express high levels of cyclin D1. Most tumors are also express CD19, CD20, and moderately high levels of surface Ig (usually IgM and IgD with κ or γ light chain). It is usually CD5+ and CD23-, which helps to distinguish it from CLL/SLL. The IgH genes lack somatic hypermutation, supporting an origin from a naive B cell.

Molecular Pathogenesis.

Cyclin D1 overexpression is caused by an (11;14) translocation involving the IgH locus on chromosome 14 and the cyclin D1 locus on chromosome 11. This translocation is detected in about 70% of cases by standard karyotyping and in virtually all tumors by fluorescence in situ hybridization. The resulting up-regulation of cyclin D1 promotes G1- to S-phase progression during the cell cycle, as was described in Chapter 7 .

Clinical Features.

The most common presentation is painless lymphadenopathy. Symptoms related to involvement of the spleen (present in ~50% of cases) and the gut are also common. The prognosis is poor; the median survival is only 3 to 4 years. This lymphoma is not curable with conventional chemotherapy, and most patients eventually succumb to organ dysfunction caused by tumor infiltration. The blastoid variant and a "proliferative" expression profiling signature are associated with even shorter survivals.[26] Bone marrow transplantation and proteasome inhibitors are new therapeutic approaches showing some promise.

Marginal Zone Lymphomas

The category of marginal zone lymphoma encompasses a heterogeneous group of B-cell tumors that arise within lymph nodes, spleen, or extranodal tissues. The extranodal tumors were initially recognized at mucosal sites and are often referred to as mucosa-associated lymphoid tumors (or "maltomas"). In most cases, the tumor cells show evidence of somatic hypermutation and are considered to be of memory B-cell origin.

Although all marginal zone lymphomas share certain features, those occurring at extranodal sites deserve special attention because of their unusual pathogenesis and three exceptional characteristics.

- *They often arise within tissues involved by chronic inflammatory disorders of autoimmune or infectious etiology*; examples include the salivary gland in Sjögren disease, the thyroid gland in Hashimoto thyroiditis, and the stomach in *Helicobacter* gastritis.
- *They remain localized for prolonged periods, spreading systemically only late in their course*.
- *They may regress if the inciting agent (e.g., Helicobacter pylori) is eradicated*.

These characteristics suggest that extranodal marginal zone lymphomas arising in chronically inflamed tissues lie on a continuum between reactive lymphoid hyperplasia and full-blown lymphoma. The disease begins as a polyclonal immune reaction. With the acquisition of still-unknown initiating mutations, a B-cell clone emerges that still depends on antigen-stimulated T-helper cells for signals that drive growth and survival. At this stage, withdrawal of the responsible antigen causes tumor involution. A clinically relevant example is found in gastric "maltoma," in which antibiotic therapy directed against *H. pylori* often leads to tumor regression (Chapter 17). With time, however, tumors may acquire additional mutations that render their growth and survival antigen-independent, such as the (11;18), (14;18), or (1;14) chromosomal translocations, which are relatively specific for extranodal marginal zone lymphomas. All of these translocations up-regulate the expression and function of BCL10 or MALT1, protein components of a signaling complex that activates NF-κB and promotes the growth and survival of B cells.[5] With further clonal evolution, spread to distant sites and transformation to diffuse large B-cell lymphoma may occur. This theme of polyclonal to monoclonal transition during lymphomagenesis is also applicable to the pathogenesis of EBV-induced lymphoma and is discussed more fully in Chapter 7 .

Hairy Cell Leukemia

This rare but distinctive B-cell neoplasm constitutes about 2% of all leukemias. It is predominantly a disease of middle-aged white males, with a median age of 55 and a male-to-female ratio of 5 : 1.

Morphology. Hairy cell leukemia derives its picturesque name from the appearance of the leukemic cells, which have fine hairlike projections that are best recognized under the phase-contrast microscope (Fig. 13-21). On routine peripheral blood smears, hairy cells have round, oblong, or reniform nuclei and moderate amounts of pale blue cytoplasm with threadlike or bleblike extensions. The number of circulating cells is highly variable. The marrow is involved by a diffuse interstitial infiltrate of cells with oblong or reniform nuclei, condensed chromatin, and pale cytoplasm. Because these cells are enmeshed in an extracellular matrix composed of reticulin fibrils, they usually cannot be aspirated (a clinical difficulty referred to as a **"dry tap"**) and are only seen in marrow biopsies. The splenic red pulp is usually heavily infiltrated, leading to obliteration of white pulp and a beefy red gross appearance. Hepatic portal triads are also involved frequently.

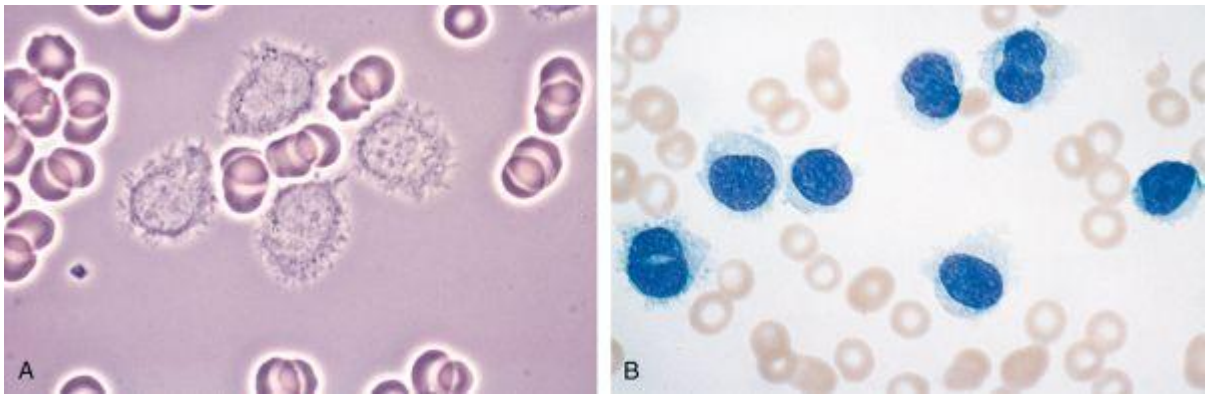

FIGURE 13-21 Hairy cell leukemia (peripheral blood smear). **A**, Phase-contrast microscopy shows tumor cells with fine hairlike cytoplasmic projections. **B**, In stained smears, these cells have round or folded nuclei and modest amounts of pale blue, agranular cytoplasm.

Immunophenotype and Molecular Pathogenesis.

Hairy cell leukemias typically express the pan-B-cell markers CD19 and CD20, surface Ig (usually IgG), and certain relatively distinctive markers, such as CD11c, CD25, and CD103. Analysis of Ig gene sequences has revealed a high incidence of somatic hypermutation, suggesting a post-germinal center memory B-cell origin.

Clinical Features.

Clinical manifestations result largely from infiltration of the bone marrow, liver, and spleen. *Splenomegaly*, often massive, is the most common and sometimes the only abnormal physical finding. *Hepatomegaly* is less common and not as marked; lymphadenopathy is rare. *Pancytopenia* resulting from marrow involvement and splenic sequestration is seen in more than half the cases. About one third of those affected present with *infections*. There is an increased incidence of atypical mycobacterial infections, possibly related to frequent unexplained monocytopenia.

Hairy cell leukemia follows an indolent course. For unclear reasons, this tumor is exceptionally sensitive to "gentle" chemotherapeutic regimens, which produce long-lasting remissions. Tumors often relapse after 5 or more years, yet generally respond well when retreated with chemotherapy. The overall prognosis is excellent.

Peripheral T-Cell and NK-Cell Neoplasms

These categories include a heterogeneous group of neoplasms having phenotypes resembling mature T cells or NK cells. Peripheral T-cell tumors make up about 5% to 10% of NHLs in the United States and Europe, but are more common in Asia. NK-cell tumors are rare in the West, but also more common in the Far East. Only the most common diagnoses and those of particular pathogenetic interest will be discussed.

Peripheral T-Cell Lymphoma, Unspecified

Although the WHO classification includes a number of distinct peripheral T-cell neoplasms, many of these lymphomas are not easily categorized and are lumped into a "wastebasket" diagnosis, *peripheral T-cell lymphoma, unspecified*. As might be expected, no morphologic feature is pathognomonic, but

certain findings are characteristic. These tumors efface lymph nodes diffusely and are typically composed of a pleomorphic mixture of variably sized malignant T cells (Fig. 13-22). There is often a prominent infiltrate of reactive cells, such as eosinophils and macrophages, probably attracted by tumor-derived cytokines. Brisk neoangiogenesis may also be seen.

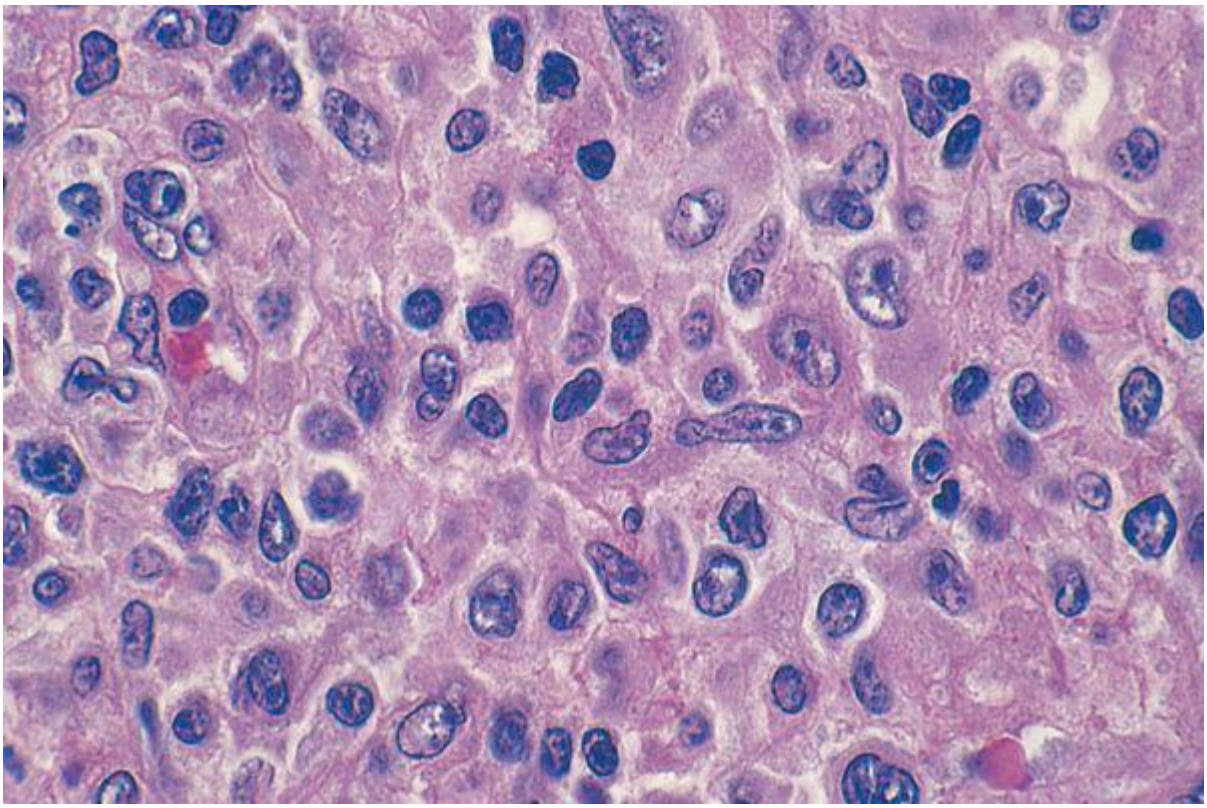

FIGURE 13-22 Peripheral T-cell lymphoma, unspecified (lymph node). A spectrum of small, intermediate, and large lymphoid cells, many with irregular nuclear contours, is visible.

The diagnosis requires immunophenotyping. By definition, all peripheral T-cell lymphomas have a mature T-cell phenotype. They usually express CD2, CD3, CD5, and either αβ or γδ T-cell receptors. Some also express CD4 or CD8; such tumors are taken to be of helper or cytotoxic T-cell origin, respectively. However, many tumors have phenotypes that do not resemble any known normal T cell. In difficult cases where the differential diagnosis lies between lymphoma and a florid reactive process, DNA analysis can be used to confirm the presence of clonal T-cell receptor rearrangements.

Most patients present with generalized lymphadenopathy, sometimes accompanied by eosinophilia, pruritus, fever, and weight loss. Although cures of peripheral T-cell lymphoma have been reported, these tumors have a significantly worse prognosis than comparably aggressive mature B-cell neoplasms (e.g., diffuse large B-cell lymphoma).

Anaplastic Large-Cell Lymphoma (ALK Positive)

This uncommon entity is defined by the presence of rearrangements in the ALK gene on chromosome 2p23. These rearrangements break the *ALK* locus and lead to the formation of chimeric genes encoding

ALK fusion proteins, constitutively active tyrosine kinases that trigger a number of signaling pathways, including the JAK/STAT pathway.[48]

As the name implies, this tumor is typically composed of large anaplastic cells, some containing horseshoe-shaped nuclei and voluminous cytoplasm (so-called hallmark cells) (Fig. 13-23A). The tumor cells often cluster about venules and infiltrate lymphoid sinuses, mimicking the appearance of metastatic carcinoma. ALK is not expressed in normal lymphocytes or other lymphomas; thus, the detection of ALK protein in tumor cells (Fig. 13-23B) is a reliable indicator of an *ALK* gene rearrangement.

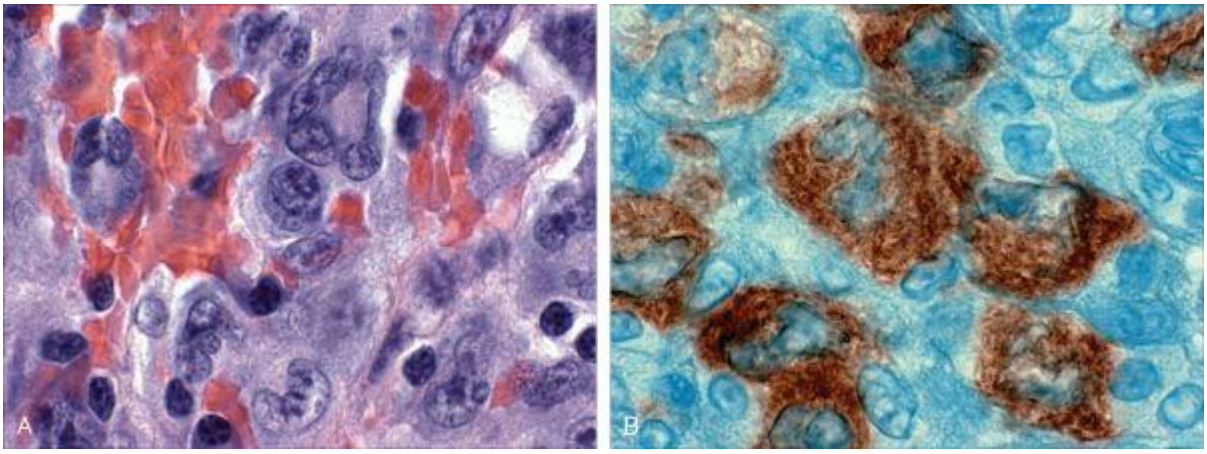

FIGURE 13-23 Anaplastic large-cell lymphoma. **A**, Several "hallmark" cells with horseshoe-like or "embryoid" nuclei and abundant cytoplasm lie near the center of the field. **B**, Immunohistochemical stain demonstrating the presence of ALK fusion protein. *(Courtesy of Dr. Jeffrey Kutok, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

T-cell lymphomas with ALK rearrangements tend to occur in children or young adults, frequently involve soft tissues, and carry a very good prognosis (unlike other aggressive peripheral T-cell neoplasms). The cure rate with chemotherapy is 75% to 80%. Inhibitors of ALK are under development and offer an excellent opportunity for the development of a selective, targeted therapy. Morphologically similar tumors lacking *ALK* rearrangements occur in older adults and have a poor prognosis, similar to that of peripheral T-cell lymphoma, unspecified.

Adult T-Cell Leukemia/Lymphoma

This neoplasm of CD4+ T cells is only observed in adults infected by human T-cell leukemia retrovirus type 1 (HTLV-1), which was discussed in Chapter 7 . It occurs mainly in regions where HTLV-1 is endemic, namely southern Japan, West Africa, and the Caribbean basin. Common findings include skin lesions, generalized lymphadenopathy, hepatosplenomegaly, peripheral blood lymphocytosis, and hypercalcemia. The appearance of the tumor cells varies, but cells with multilobated nuclei ("cloverleaf" or "flower" cells) are frequently observed. *The tumor cells contain clonal HTLV-1 provirus, which is believed to play a critical pathogenic role*. Notably, HTLV-1 encodes a protein called Tax that is a potent activator of NF-κB,[49] which (as we have discussed) enhances lymphocyte growth and survival.

Most patients present with rapidly progressive disease that is fatal within months to 1 year despite aggressive chemotherapy. Less commonly, the tumor involves only the skin and follows a much more indolent course, like that of mycosis fungoides (described below). It should be noted that in addition to

adult T-cell leukemia/lymphoma, HTLV-1 infection sometimes gives rise to a progressive demyelinating disease of the central nervous system and spinal cord (see Chapter 28).

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides and Sézary syndrome are different manifestations of a tumor of CD4+ helper T cells that home to the skin. Clinically, the cutaneous lesions of *mycosis fungoides* typically progress through three somewhat distinct stages, an inflammatory *premycotic phase*, a *plaque phase*, and a *tumor phase* (all discussed in more detail in Chapter 25). Histologically, the epidermis and upper dermis are infiltrated by neoplastic T cells, which often have a cerebriform appearance due to marked infolding of the nuclear membrane. Late disease progression is characterized by extracutaneous spread, most commonly to lymph nodes and bone marrow.

Sézary syndrome is a variant in which skin involvement is manifested as a *generalized exfoliative erythroderma*. In contrast to mycosis fungoides, the skin lesions rarely proceed to tumefaction, and *there is an associated leukemia of "Sézary" cells* with characteristic cerebriform nuclei.

The tumor cells characteristically express the adhesion molecule CLA and the chemokine receptors CCR4 and CCR10, all of which contribute to the homing of normal CD4+ T cells to the skin. Although cutaneous disease dominates the clinical picture, sensitive molecular analyses have shown that the tumor cells circulate through the blood, marrow, and lymph nodes even early in the course. Nevertheless, these are indolent tumors, with a median survival of 8 to 9 years. Transformation to aggressive T-cell lymphoma occurs occasionally as a terminal event.

Large Granular Lymphocytic Leukemia

T-cell and NK-cell variants of this rare neoplasm are recognized, both of which occur mainly in adults. Individuals with T-cell disease usually present with mild to moderate lymphocytosis and splenomegaly. Lymphadenopathy and hepatomegaly are usually absent. NK-cell disease often presents in an even more subtle fashion, with little or no lymphocytosis or splenomegaly.

The tumor cells are large lymphocytes with abundant blue cytoplasm and a few coarse azurophilic granules, best seen in peripheral blood smears. The marrow usually contains sparse interstitial lymphocytic infiltrates, which can be difficult to appreciate without immunohistochemical stains. Infiltrates are also usually present in the spleen and liver. As might be expected, T-cell variants are CD3+, whereas NK-cell large granular lymphocytic leukemias are CD3-, CD56+.

Despite the relative paucity of marrow infiltration, neutropenia and anemia dominate the clinical picture. Neutropenia is often accompanied by a striking decrease in late myeloid forms in the marrow. Rarely, pure red cell aplasia is seen. *There is also an increased incidence of rheumatologic disorders*. Some patients with Felty syndrome, a triad of rheumatoid arthritis, splenomegaly, and neutropenia, have this disorder as an underlying cause. The basis for these varied clinical abnormalities is unknown, but autoimmunity, provoked in some way by the tumor, seems likely.

The course is variable, being largely dependent on the severity of the cytopenias and their responsiveness to low-dose chemotherapy or steroids. In general, tumors of T-cell origin pursue an indolent course, whereas NK-cell tumors behave more aggressively.

Extranodal NK/T-Cell Lymphoma

This neoplasm is rare in the United States and Europe, but constitutes as many as 3% of NHLs in Asia. It presents most commonly as a destructive nasopharygeal mass; less common sites of presentation include the testis and the skin. *The tumor cell infiltrate typically surrounds and invades small vessels*,

leading to extensive ischemic necrosis. The tumor cell size is variable but usually includes a large-cell component. In touch preparations, *large azurophilic granules* are seen in the cytoplasm of the tumor cells that resemble those found in normal NK cells.

This form of lymphoma is highly associated with EBV. Within individual patients, all of the tumor cells contain identical EBV episomes, indicating that the tumor originates from a single EBV-infected cell. How EBV gains entry is uncertain, since the tumor cells fail to express CD21, a surface protein that serves as the B-cell EBV receptor. Most tumors are CD3- and lack T-cell receptor rearrangements and express NK-cell markers, including a restricted set of killer-cell Ig-like receptors, supporting an NK-cell origin. No consistent chromosome aberration has been described, and relatively little is known about the molecular pathogenesis beyond the involvement of EBV.

Most extranodal NK/T-cell lymphomas are highly aggressive neoplasms that respond well to radiation therapy but are resistant to chemotherapy. Thus, the prognosis is poor in patients with advanced disease.

This ends the discussion of the lymphocytic leukemias and the NHLs. We will now turn to the second major category of lymphoid neoplasms, Hodgkin lymphoma.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) encompasses a group of lymphoid neoplasms that differ from NHL in several respects (Table 13-7). While NHLs frequently occur at extranodal sites and spread in an unpredictable fashion, *HL arises in a single node or chain of nodes and spreads first to anatomically contiguous lymphoid tissues*. For this reason, the staging of HL is much more important in guiding therapy than it is in NHL. HL also has distinctive morphologic features. It is characterized by the presence of neoplastic giant cells called *Reed-Sternberg cells*. These cells release factors that induce the accumulation of reactive lymphocytes, macrophages, and granulocytes, which typically make up greater than 90% of the tumor cellularity. In the vast majority of HLs, the neoplastic Reed-Sternberg cells are derived from germinal center or post-germinal center B cells.

TABLE 13-7 -- Differences between Hodgkin and Non-Hodgkin Lymphomas

Hodgkin Lymphoma	Non-Hodgkin Lymphoma
More often localized to a single axial group of nodes (cervical, mediastinal, para-aortic)	More frequent involvement of multiple peripheral nodes
Orderly spread by contiguity	Noncontiguous spread
Mesenteric nodes and Waldeyer ring rarely involved	Waldeyer ring and mesenteric nodes commonly involved
Extra-nodal presentation rare	Extra-nodal presentation common

Hodgkin lymphoma accounts for 0.7% of all new cancers in the United States; there are about 8000 new cases each year. The average age at diagnosis is 32 years. It is one of the most common cancers of young adults and adolescents, but also occurs in the aged. It was the first human cancer to be successfully treated with radiation therapy and chemotherapy, and is curable in most cases.

Classification.

The WHO classification recognizes five subtypes of HL:

1. Nodular sclerosis

2. Mixed cellularity
3. Lymphocyte-rich
4. Lymphocyte depletion
5. Lymphocyte predominance

In the first four subtypes—nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte depletion—the Reed-Sternberg cells have a similar immunophenotype. These subtypes are often lumped together as *classical* forms of HL. In the remaining subtype, lymphocyte predominance, the Reed-Sternberg cells have a distinctive B-cell immunophenotype that differs from that of the "classical" types.

Morphology. Identification of Reed-Sternberg cells and their variants is essential for the diagnosis. **Diagnostic Reed-Sternberg cells are large cells (≥45 μm in diameter) with multiple nuclei or a single nucleus with multiple nuclear lobes, each with a large inclusion-like nucleolus about the size of a small lymphocyte (5–7 μm in diameter)** (Fig. 13-24A). The cytoplasm is abundant. Several Reed-Sternberg cell variants are also recognized. Mononuclear variants contain a single nucleus with a large inclusion-like nucleolus (Fig. 13-24B). Lacunar cells (seen in the nodular sclerosis subtype) have more delicate, folded, or multilobate nuclei and abundant pale cytoplasm that is often disrupted during the cutting of sections, leaving the nucleus sitting in an empty hole (a lacuna) (Fig. 13-24C). In classical forms of HL, Reed-Sternberg cells undergo a peculiar form of cell death in which the cells shrink and become pyknotic, a process described as "mummification." Lymphohistocytic variants (L&H cells) with polypoid nuclei, inconspicuous nucleoli, and moderately abundant cytoplasm are characteristic of the lymphocyte predominance subtype (Fig. 13-24D).

HL must be distinguished from other conditions in which cells resembling Reed-Sternberg cells can be seen, such as infectious mononucleosis, solid-tissue cancers, and large-cell NHLs. The diagnosis of HL depends on the identification of Reed-Sternberg cells in a typical prominent background of non-neoplastic inflammatory cells. The Reed-Sternberg cells of HL also have a characteristic immunohistochemical profile.

With this as background, we turn to the subclasses of HL, pointing out some of the salient morphologic and immunophenotypic features of each (summarized in Table 13-8). The clinical manifestations common to all will be presented later.

***Nodular Sclerosis Type*.** This is the most common form of HL, constituting 65% to 70% of cases. It is characterized by the presence of **lacunar variant** Reed-Sternberg cells and the **deposition of collagen in bands that divide involved lymph nodes into circumscribed nodules** (Fig. 13-25). The fibrosis may be scant or abundant. The Reed-Sternberg cells are found in a polymorphous background of T cells, eosinophils, plasma cells and macrophages. Diagnostic Reed-Sternberg cells are often uncommon. The Reed-Sternberg cells in this and other "classical" HL subtypes have a characteristic immunophenotype; they are positive for PAX5 (a B-cell transcription factor), CD15, and CD30, and negative for other B-cell markers, T-cell markers, and CD45 (leukocyte common antigen). As in other forms of HL, involvement of the spleen, liver, bone marrow, and other organs and tissues can appear in due course in the form of irregular tumor nodules resembling those seen in lymph nodes. This subtype is uncommonly associated with EBV.

The nodular sclerosis type occurs with equal frequency in males and females. It has a propensity to involve the lower cervical, supraclavicular, and mediastinal lymph nodes of adolescents or young adults. The prognosis is excellent.

***Mixed-Cellularity Type*.** This form of HL constitutes about 20% to 25% of cases. Involved lymph nodes are diffusely effaced by a heterogeneous cellular infiltrate, which includes T cells, eosinophils, plasma cells, and benign macrophages admixed with Reed-Sternberg cells (Fig. 13-26). **Diagnostic ReedSternberg cells and mononuclear variants are usually plentiful. The Reed-Sternberg cells are infected with EBV in about 70% of cases**. The immunophenotype is identical to that observed in the nodular sclerosis type.

Mixed-cellularity HL is more common in males. Compared with the lymphocyte predominance and nodular sclerosis subtypes, it is more likely to be associated with older age, systemic symptoms such as night sweats and weight loss, and advanced tumor stage. Nonetheless, the overall prognosis is very good.

***Lymphocyte-Rich Type*.** This is an uncommon form of classical HL in which reactive lymphocytes make up the vast majority of the cellular infiltrate. In most cases, involved lymph nodes are diffusely effaced, but vague nodularity due to the presence of residual B-cell follicles is sometimes seen. This entity is distinguished from the lymphocyte predominance type by the presence of frequent mononuclear variants and diagnostic Reed-Sternberg cells with a "classical" immunophenotypic profile. It is associated with EBV in about 40% of cases and has a very good to excellent prognosis.

***Lymphocyte Depletion Type*.** This is the least common form of HL, amounting to less than 5% of cases. It is characterized by a paucity of lymphocytes and a relative abundance of Reed-Sternberg cells or their pleomorphic variants. The immunophenotype of the Reed-Sternberg cells is identical to that seen in other classical types of HL. Immunophenotyping is essential, since most tumors suspected of being lymphocyte depletion HL actually prove to be large-cell NHLs. The Reed-Sternberg cells are infected with EBV in over 90% of cases.

Lymphocyte depletion HL occurs predominantly in the elderly, in HIV+ individuals of any age, and in nonindustrialized countries. Advanced stage and systemic symptoms are frequent, and the overall outcome is somewhat less favorable than in the other subtypes.

***Lymphocyte Predominance Type*.** This uncommon "nonclassical" variant of HL accounts for about 5% of cases. Involved nodes are effaced by a nodular infiltrate of small lymphocytes admixed with variable numbers of macrophages (Fig. 13-27). "Classical" Reed-Sternberg cells are usually difficult to find. Instead, this tumor contains so-called L&H (lymphocytic and histiocytic) variants, which have a multilobed nucleus resembling a popcorn kernel ("popcorn cell"). Eosinophils and plasma cells are usually scant or absent.

In contrast to the Reed-Sternberg cells found in classical forms of HL, **L&H variants express B-cell markers typical of germinal-center B cells**, such as CD20 and BCL6, and are usually negative for CD15 and CD30. The typical nodular pattern of growth is due to the presence of expanded B-cell follicles, which are populated with L&H variants, numerous reactive B cells, and follicular dendritic cells. The IgH genes of the L&H variants show evidence of ongoing somatic hypermutation, a modification that occurs only in germinal-center B cells. In 3% to 5% of cases, this type transforms into a tumor resembling diffuse large B-cell lymphoma. EBV is not associated with this subtype.

A majority of patients are males, usually younger than 35 years of age, who typically present with cervical or axillary lymphadenopathy. Mediastinal and bone marrow involvement is rare. In some series, this form of HL is more likely to recur than the classical subtypes, but the prognosis is excellent.

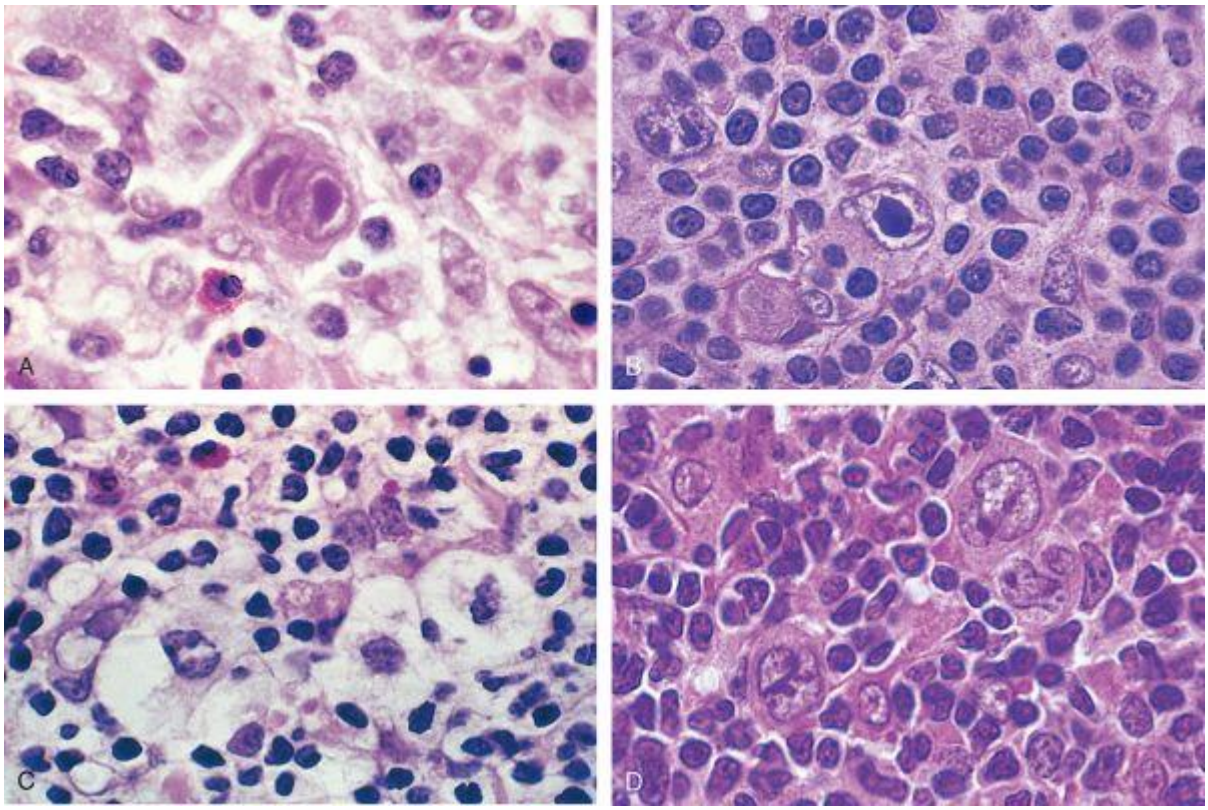

FIGURE 13-24 Reed-Sternberg cells and variants. **A**, Diagnostic Reed-Sternberg cell, with two nuclear lobes, large inclusion-like nucleoli, and abundant cytoplasm, surrounded by lymphocytes, macrophages, and an eosinophil. **B**, Reed-Sternberg cell, mononuclear variant. **C**, Reed-Sternberg cell, lacunar variant. This variant has a folded or multilobated nucleus and lies within a open space, which is an artifact created by disruption of the cytoplasm during tissue sectioning. **D**, Reed-Sternberg cell, lymphohistiocytic variant. Several such variants with multiply infolded nuclear membranes, small nucleoli, fine chromatin, and abundant pale cytoplasm are present. *(**A**, Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

TABLE 13-8 -- Subtypes of Hodgkin Lymphoma

Subtype	Morphology and Immunophenotype	Typical Clinical Features
Nodular sclerosis	Frequent lacunar cells and occasional diagnostic RS cells; background infiltrate composed of T lymphocytes, eosinophils, macrophages, and plasma cells; fibrous bands dividing cellular areas into nodules. RS cells CD15+, CD30+; usually EBV-	Most common subtype; usually stage I or II disease; frequent mediastinal involvement; equal occurrence in males and females (F = M), most patients young adults
Mixed cellularity	Frequent mononuclear and diagnostic RS cells; background infiltrate rich in T lymphocytes, eosinophils, macrophages, plasma cells; RS cells CD15+, CD30+; 70% EBV+	More than 50% present as stage III or IV disease; M greater than F; biphasic incidence, peaking in young adults and again in adults older than 55
Lymphocyte rich	Frequent mononuclear and diagnostic RS cells; background infiltrate rich in T lymphocytes; RS cells CD15+, CD30+; 40% EBV+	Uncommon; M greater than F; tends to be seen in older adults
Lymphocyte depletion	Reticular variant: Frequent diagnostic RS cells and variants and a paucity of background reactive cells; RS cells CD15+, CD30+; most EBV+	Uncommon; more common in older males, HIV-infected individuals, and in developing countries; often presents with advanced disease

Lymphocyte predominance	Frequent L&H (popcorn cell) variants in a background of follicular dendritic cells and reactive B cells; RS cells CD20+, CD15-, C30-; EBV-	Uncommon; young males with cervical or axillary lymphadenopathy; mediastinal

L&H, lymphohistiocytic; RS cell, Reed-Sternberg cell.

Numerous mature-looking lymphocytes surround scattered, large, pale-staining lymphohistiocytic variants ("popcorn" cells). *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Molecular Pathogenesis.

The origin of the neoplastic Reed-Sternberg cells of classical HL has been explained through elegant studies relying on molecular analysis of single isolated Reed-Sternberg cells and variants. In the vast majority of cases, *the Ig genes of Reed-Sternberg cells have undergone both V(D)J recombination and somatic hypermutation, establishing an origin from a germinal center or post-germinal-center B cell*.[50] Despite having the genetic signature of a B cell, the Reed-Sternberg cells of classical HL fail to express most B cell–specific genes, including the Ig genes. The cause of this wholesale reprogramming of gene expression has yet to be fully explained.[51]

Activation of the transcription factor NF-κB is a common event in classical HL. NF-κB is activated either by EBV infection or by some other mechanism and turns on genes that promote lymphocyte survival and proliferation. EBV+ tumor cells express latent membrane protein-1 (LMP-1), a protein encoded by the EBV genome that transmits signals that up-regulate NF-κB. Activation of NF-κB also occurs in EBV^- tumors, in some instances as a result of acquired mutations in IκB,[52] a negative regulator of NF-κB. It is hypothesized that activation of NF-κB by EBV or other mechanisms rescues "crippled" germinal-center B cells that cannot express Igs from apoptosis, setting the stage for the acquisition of other unknown mutations that collaborate to produce ReedSternberg cells. Little is known about the basis for the morphology of Reed-Sternberg cells and variants, but it is intriguing that EBV-infected B cells resembling ReedSternberg cells are found in the lymph nodes of individuals with

infectious mononucleosis, strongly suggesting that EBV-encoded proteins play a part in the remarkable metamorphosis of B cells into Reed-Sternberg cells.

The florid accumulation of reactive cells in tissues involved by classical HL occurs in response to a wide variety of *cytokines* (such as IL-5, IL-10, IL-13, and TGF-β) and *chemokines* (such as TARC, MDC, IP-10, and CCL28) that are secreted by Reed-Sternberg cells.[53] Once attracted, the reactive cells produce factors that support the growth and survival of the tumor cells and further modify the reactive cell response. For example, eosinophils and T cells express ligands that activate the CD30 and CD40 receptors found on Reed-Sternberg cells, producing signals that up-regulate NF-κB. Other examples of "cross-talk" between Reed-Sternberg cells and surrounding reactive cells are provided in Figure 13-28 .

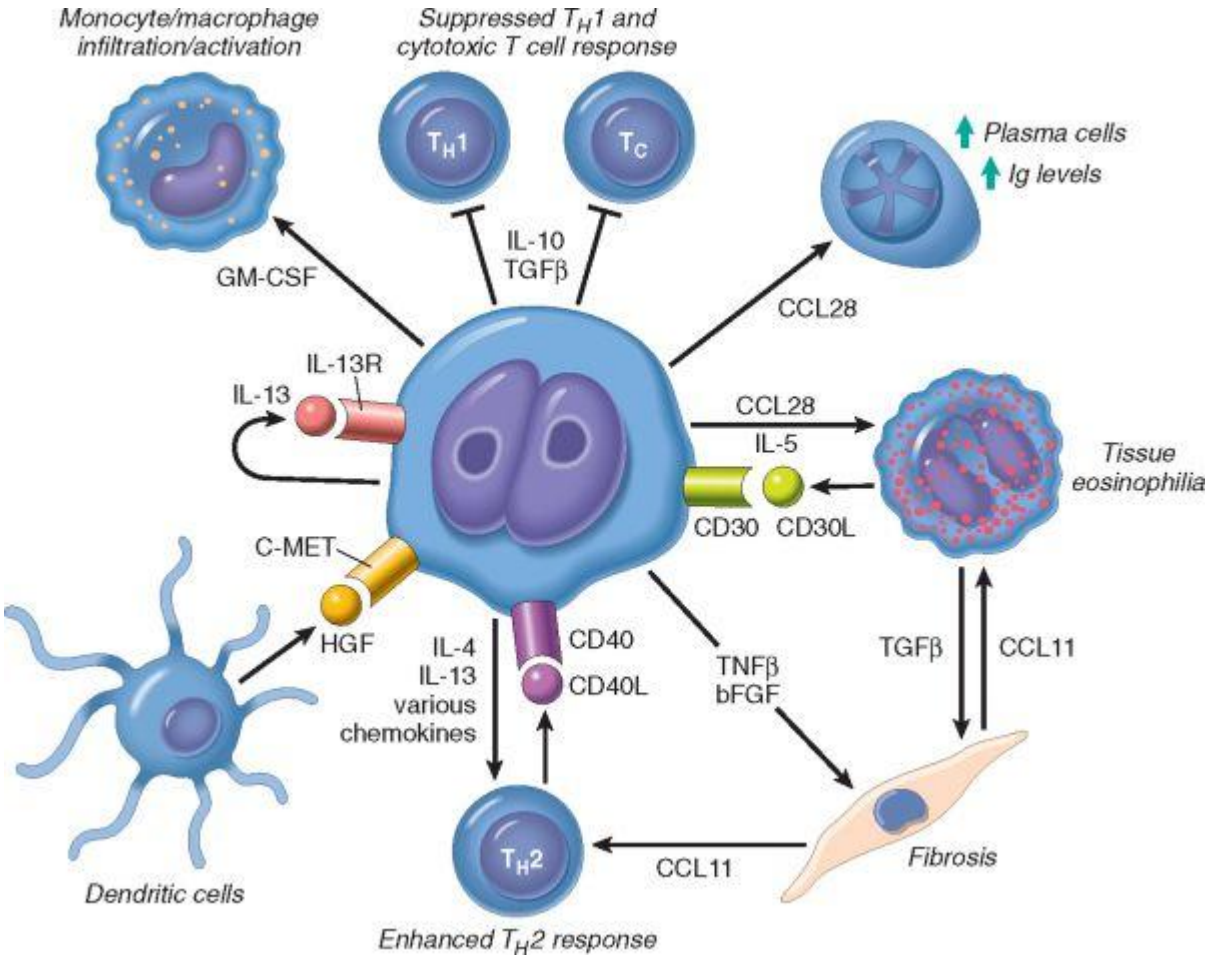

FIGURE 13-28 Proposed signals mediating "cross-talk" between Reed-Sternberg cells and surrounding normal cells in classical forms of Hodgkin lymphoma. CD30L, CD30 ligand; bFGF, basic fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HGF, hepatocyte growth factor (binds to the c-MET receptor); TGFβ, transforming growth factor β; TNFβ, tumor necrosis factor β (lymphotoxin); T_c, CD8+ cytotoxic T cell; T_H1 and T_H2, CD4+ T helper cell subsets.

Reed-Sternberg cells are aneuploid and possess diverse clonal chromosomal aberrations. Copy number gains in the *c-REL* proto-oncogene on chromosome 2p are particularly common and may contribute to increases in NF-κB activity.[54]

Clinical Features.

HL most commonly present as painless lymphadenopathy. Patients with the nodular sclerosis or lymphocyte predominance types tend to present with stage I–II disease and are usually free of systemic manifestations. Patients with disseminated disease (stages III–IV) or the mixed-cellularity or lymphocyte depletion subtypes are more likely to have constitutional symptoms, such as fever, night sweats, and weight loss. Cutaneous anergy resulting from depressed cell-mediated immunity is seen in most cases. The mix of factors released from Reed-Sternberg cells (see Fig. 13-28) suppress T_H1 immune responses and may contribute to immune dysregulation.

The spread of HL is remarkably stereotyped: nodal disease first, then splenic disease, hepatic disease, and finally involvement of the marrow and other tissues. Because of this behavior, radiation therapy can be curative for persons with early-stage disease. Thus, the staging of HL (Table 13-9) not only determines the prognosis, but also guides therapy. Staging involves physical examination, radiologic imaging of the abdomen, pelvis, and chest, and biopsy of the bone marrow. Systemic treatment is preferred whenever the staging is equivocal.

TABLE 13-9 -- Clinical Staging of Hodgkin and Non-Hodgkin Lymphomas (Ann Arbor Classification)

Stage	Distribution of Disease
I	Involvement of a single lymph node region (I) or a single extra-lymphatic organ or site (IE).
II	Involvement of two or more lymph node regions on the same side of the diaphragm alone (II) or localized involvement of an extra-lymphatic organ or site (IIE).
III	Involvement of lymph node regions on both sides of the diaphragm without (III) or with (IIIE) localized involvement of an extra-lymphatic organ or site.
IV	Diffuse involvement of one or more extra-lymphatic organs or sites with or without lymphatic involvement.
All stages are further divided on the basis of the absence (A) or presence (B) of the following symptoms: unexplained fever, drenching night sweats, and/or unexplained weight loss of greater than 10% of normal body weight.	

Data from Carbone PT et al.: Symposium (Ann Arbor): Staging in Hodgkin's disease. Cancer Res 31:1707, 1971.

With current treatment protocols, tumor stage rather than histologic type is the most important prognostic variable. The cure rate of patients with stages I and IIA is close to 90%. Even with advanced disease (stages IVA and IVB), disease-free survival at 5 years is 60% to 70%.

Progress in the treatment of HL has created a new set of problems. Long-term survivors of chemotherapy and radiation therapy have an increased risk of developing second cancers. Myelodysplastic syndromes, AML, and lung cancer head the list, but also included are NHL, breast cancer, gastric cancer, sarcoma, and melanoma. Most of the risk of solid tumors is attributable to radiation therapy, which has also been linked to pulmonary fibrosis and accelerated atherosclerosis. The risk of breast cancer is particularly high in females treated with radiation to the chest during adolescence. Alkylating chemotherapeutic drugs seem to be responsible for the increased risk of AML and myelodysplasia. Fortunately, newer combinations of chemotherapeutic drugs and more judicious use of radiation therapy seem to largely avoid these complications and are equally curative.

MYELOID NEOPLASMS

The common feature of this heterogeneous group of neoplasms is an origin from hematopoietic progenitor cells. These diseases primarily involve the marrow and to a lesser degree the secondary hematopoietic organs (the spleen, liver, and lymph nodes), and usually present with symptoms related to altered hematopoiesis. Three broad categories of myeloid neoplasia exist:

- *Acute myeloid leukemias*, in which an accumulation of immature myeloid forms (blasts) in the bone marrow suppresses normal hematopoiesis
- *Myelodysplastic syndromes*, in which ineffective hematopoiesis leads to cytopenias
- *Myeloproliferative disorders*, in which there is usually increased production of one or more types of blood cells

The pathogenesis of myeloid neoplasms is best understood in the context of normal hematopoiesis, which (you will remember from Fig. 13-1) involves a hierarchy of hematopoietic stem cells, committed progenitors, and more differentiated elements. Normal hematopoiesis is finely tuned by homeostatic feedback mechanisms involving cytokines and growth factors that modulate the production of red cells, white cells, and platelets in the marrow. These mechanisms are deranged in marrows involved by myeloid neoplasms, which "escape" from normal homeostatic controls on growth and survival and suppress the function of residual normal stem cells. The specific manifestations of the different myeloid neoplasms are influenced by

- *The position of the transformed cell within the hierarchy of progenitors* (i.e., a pluripotent hematopoietic stem cell versus a more committed progenitor)
- *The effect of the transforming events on differentiation*, which may be inhibited, skewed, or deranged by particular oncogenic mutations

We will return to these themes as each type of myeloid neoplasm is discussed.

Given that all myeloid neoplasms originate from transformed hematopoietic progenitors, it is not surprising that divisions between these neoplasms are sometimes blurred. Myeloid neoplasms, like other malignancies, tend to evolve over time to more aggressive forms of disease. In particular, both myelodysplastic syndromes and myeloproliferative disorders often "transform" to AML. In one of the most important myeloproliferative disorders, chronic myeloid leukemia, transformation to acute lymphoblastic leukemia is also seen, indicating that it originates from a transformed pluripotent hematopoietic stem cell.

Acute Myeloid Leukemia

Acute myeloid leukemia (AML) is a tumor of hematopoietic progenitors caused by acquired oncogenic mutations that impede differentiation, leading to the accumulation of immature myeloid blasts in the marrow. The arrest in myeloid development leads to marrow failure and complications related to anemia, thrombocytopenia, and neutropenia. AML occurs at all ages, but the incidence rises throughout life, peaking after 60 years of age. There are about 13,000 new cases each year in the United States.

Classification.

AML is quite heterogeneous, reflecting the complexities of myeloid cell differentiation. A new proposed classification from the WHO subdivides AML into four categories (Table 13-10).[11] The first includes forms of AML that are associated with particular genetic aberrations, which are important because they correlate with prognosis and guide therapy. Also included are categories of AML arising after a myelodysplastic disorder (MDS) or with MDS-like features, and therapy-related AML. AMLs in these two categories have distinct genetic features and respond poorly to therapy. A fourth "wastebasket" category includes AMLs lacking any of these features. These are classified according to the earlier French-American-British (FAB) classification, which divide AMLs into subtypes based on the degree of differentiation and the lineage of the leukemic blasts. Although it has limited utility, the FAB classification is still commonly referred to in practice. In recognition of this, Table 13-10 correlates (to the extent possible) the FAB and WHO classifications. Given the increasing role of cytogenetic and

molecular features in directing therapy, a further shift toward genetic classification of AML is both inevitable and desirable.

TABLE 13-10 -- Major Subtypes of AML in the WHO Classification

Class	Prognosis	FAB Subtype	Morphology/Comments
I. AML WITH GENETIC ABERRATIONS			
AML with t(8;21)(q22;q22); *CBF*α/*ETO* fusion gene	Favorable	M2	Full range of myelocytic maturation; Auer rods easily found; abnormal cytoplasmic granules
AML with inv(16)(p13;q22); *CBF*β/*MYH*11 fusion gene	Favorable	M4eo	Myelocytic and monocytic differentiation; abnormal eosinophilic precursors with abnormal basophilic granules
AML with t(15;17)(q22;11-12); *RAR*α/*PML* fusion gene	Intermediate	M3, M3v	Numerous Auer rods, often in bundles within individual progranulocytes; primary granules usually very prominent (M3 subtype), but inconspicuous in microgranular variant (M3v); high incidence of DIC
AML with t(11q23;v); diverse *MLL* fusion genes	Poor	M4, M5	Usually some degree of monocytic differentiation
AML with normal cytogenetics and mutated *NPM*	Favorable	Variable	Detected by immunohistochemical staining for NPM
II. AML WITH MDS-LIKE FEATURES			
With prior MDS	Poor	Variable	Diagnosis based on clinical history
AML with multilineage dysplasia	Poor	Variable	Maturing cells with dysplastic features typical of MDS
AML with MDS-like cytogenetic aberrations	Poor	Variable	Associated with 5q-, 7q-, 20q-aberrations
III. AML, THERAPY-RELATED	Very poor	Variable	If following alkylator therapy or radiation therapy, 2- to 8-year latency period, MDS-like cytogenetic aberrations (e.g., 5q-, 7q-); if following topoisomerase II inhibitor (e.g., etoposide) therapy, 1- to 3-year latency, translocations involving *MLL* (11q23)
IV. AML, NOT OTHERWISE SPECIFIED			
AML, minimally differentiated	Intermediate	M0	Negative for myeloperoxidase; myeloid antigens detected on blasts by flow cytometry
AML without maturation	Intermediate	M1	>3% of blasts positive for myeloperoxidase
AML with myelocytic maturation	Intermediate	M2	Full range of myelocytic maturation
AML with myelomonocytic maturation	Intermediate	M4	Myelocytic and monocytic differentiation
AML with monocytic maturation	Intermediate	M5a, M5b	In M5a subtype, nonspecific esterase-positive monoblasts and pro-monocytes predominate in marrow and blood; in M5b subtype, mature monocytes predominate in the blood
AML with erythroid maturation	Intermediate	M6a, M6b	Erythroid/myeloid subtype (M6a) defined by >50% dysplastic maturing erythroid precursors and >20% myeloblasts; pure erythroid subtype (M6b) defined by >80% erythroid precursors

Class	Prognosis	FAB Subtype	Morphology/Comments
			without myeloblasts
AML with megakaryocytic maturation	Intermediate	M7	Blasts of megakaryocytic lineage predominate; detected with antibodies against megakaryocyte-specific markers (GPIIb/IIIa or vWF); often associated with marrow fibrosis; most common AML in Down syndrome

AML, acute myeloid leukemia; DIC, disseminated intravascular coagulation; MDS, myelodysplasia; NPM, nucleophosmin; vWF, von Willebrand factor.

Morphology. The diagnosis of AML is based on the presence of at least 20% myeloid blasts in the bone marrow. Several types of myeloid blasts are recognized, and individual tumors may have more than one type of blast or blasts with hybrid features. **Myeloblasts** have delicate nuclear chromatin, two to four nucleoli, and more voluminous cytoplasm than lymphoblasts (Fig. 13-29A). The cytoplasm often contains fine, peroxidase-positive azurophilic granules. **Auer rods**, distinctive needle-like azurophilic granules, are present in many cases; they are particularly numerous in AML with the t(15;17) (acute promyelocytic leukemia) (Fig. 13-30A). **Monoblasts** (Fig. 13-30B) have folded or lobulated nuclei, lack Auer rods, and are nonspecific esterase-positive. In some AMLs, blasts show megakaryocytic differentiation, which is often accompanied by marrow fibrosis caused by the release of fibrogenic cytokines. Rarely, the blasts of AML show erythroid differentiation.

The number of leukemic cells in the blood is highly variable. Blasts may be more than 100,000 per mm^3, but are under 10,000 per mm^3 in about 50% of patients. **Occasionally, blasts are entirely absent from the blood** (aleukemic leukemia). For this reason, a bone marrow examination is essential to exclude acute leukemia in pancytopenic patients.

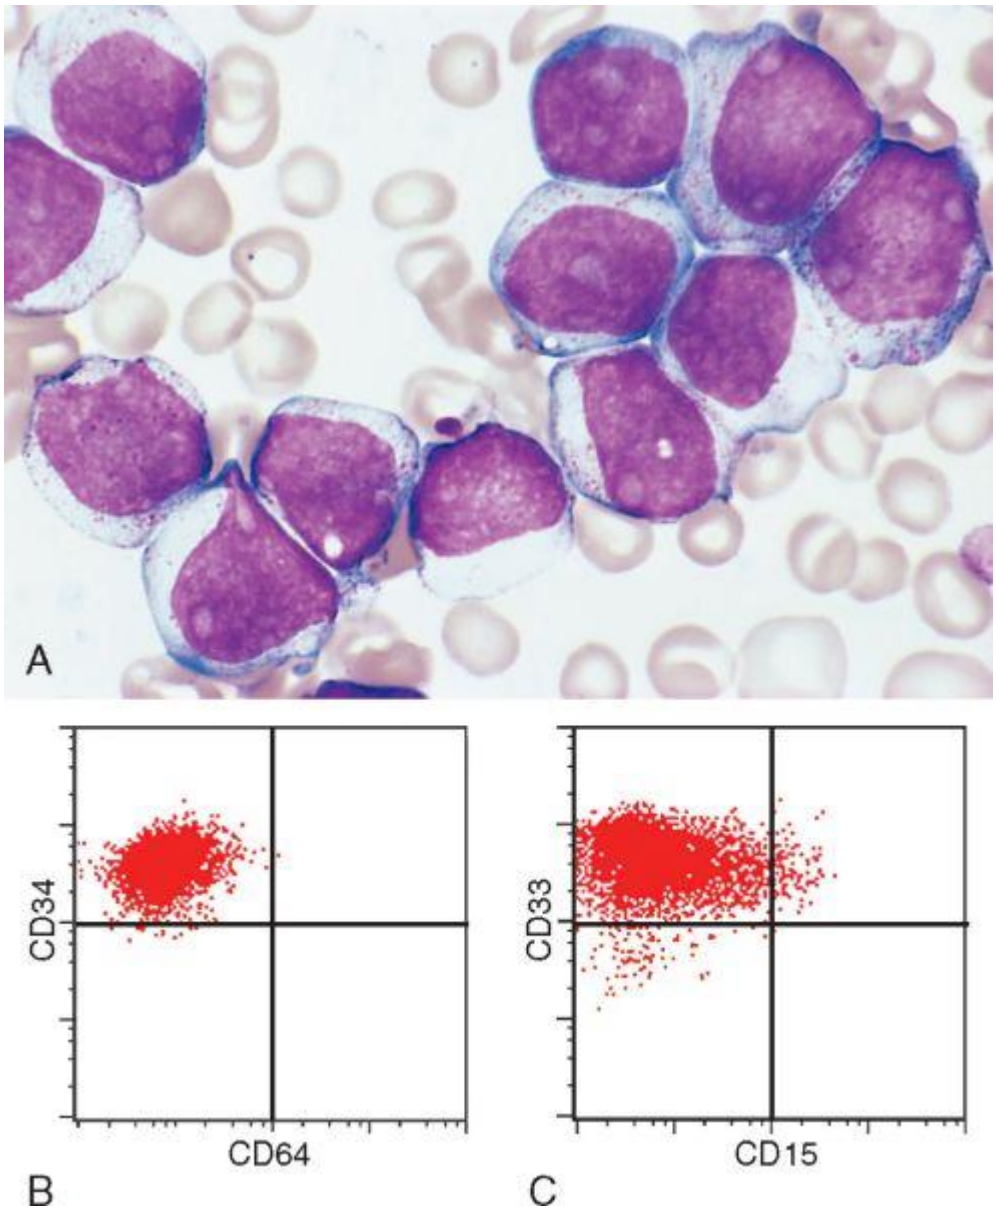

FIGURE 13-29 **A**, Acute myeloid leukemia without maturation (FAB M1 subtype). Myeloblasts have delicate nuclear chromatin, prominent nucleoli, and fine azurophilic granules in the cytoplasm. **B**, In the flow cytometric analysis shown, the myeloid blasts, represented by the red dots, express CD34, a marker of multipotent stem cells, but do not express CD64, a marker of mature myeloid cells. **C**, The same myeloid blasts express CD33, a marker of immature myeloid cells, and a subset express CD15, a marker of more mature myeloid cells. Thus, these blasts are myeloid cells showing limited maturation. *(**A**, Courtesy of Dr. Robert W. McKenna Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX; **B** and **C**, courtesy of Dr. Louis Picker, Oregon Health Science Center, Portland, OR.)*

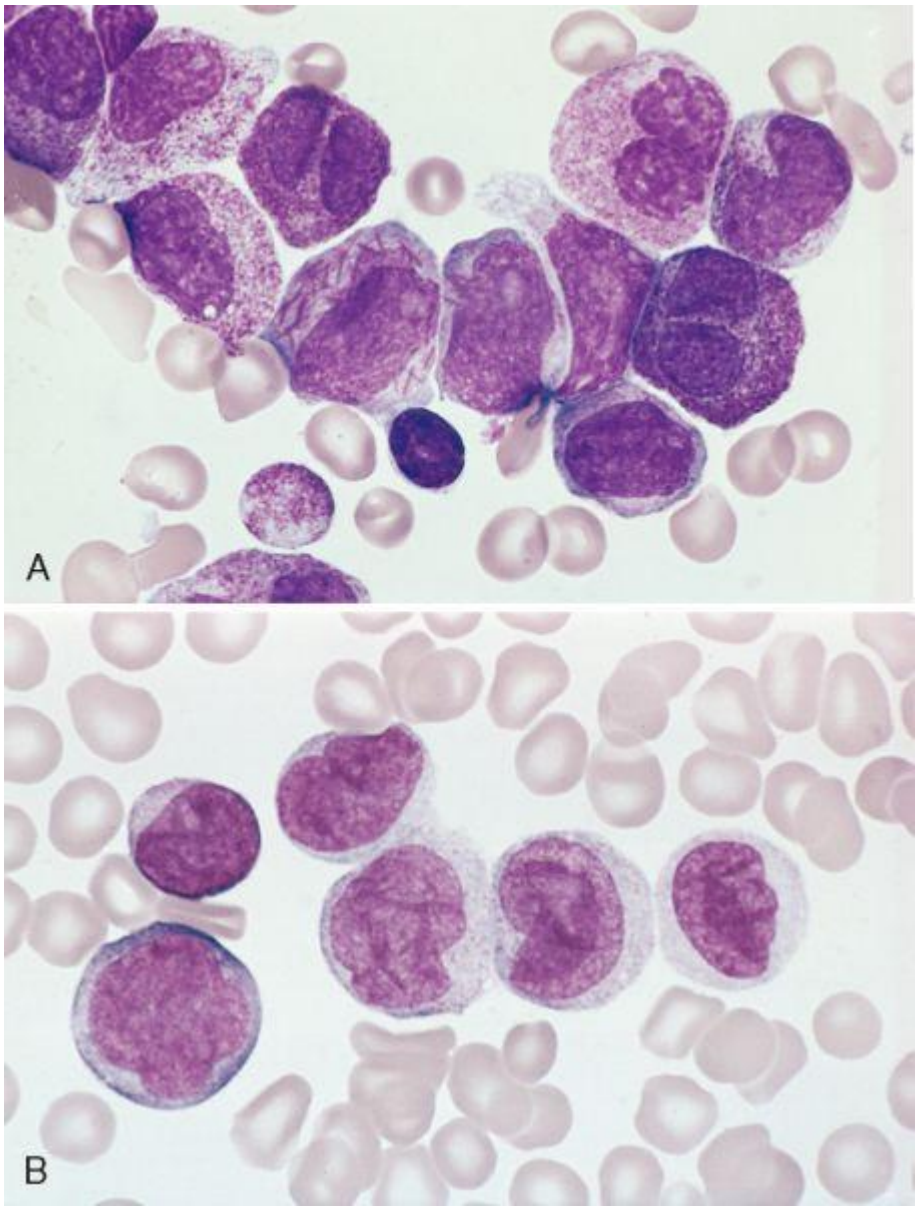

FIGURE 13-30 Acute myeloid leukemia subtypes. **A**, Acute promyelocytic leukemia with the t(15;17) (FAB M3 subtype). Bone marrow aspirate shows neoplastic promyelocytes with abnormally coarse and numerous azurophilic granules. Other characteristic findings include the presence of several cells with bilobed nuclei and a cell in the center of the field that contains multiple needle-like Auer rods. **B**, Acute myeloid leukemia with monocytic differentiation (FAB M5b subtype). Peripheral smear shows one monoblast and five promonocytes with folded nuclear membranes. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Immunophenotype.

Because it can be difficult to distinguish myeloblasts and lymphoblasts morphologically, the diagnosis of AML is confirmed by performing stains for myeloidspecific antigens (see Fig. 13-29B, C).

Cytogenetics.

Cytogenetic analysis has a central role in the classification of AML. Karyotypic aberrations are detected in 50% to 70% of cases with standard techniques and in approximately 90% of cases using special high-resolution banding. Particular chromosomal abnormalities correlate with certain clinical features. AMLs arising de novo in younger adults are commonly associated with balanced chromosomal translocations, particularly t(8;21), inv(16), and t(15;17). In contrast, AMLs following MDS or exposure to DNA-damaging agents (such as chemotherapy or radiation therapy) often have deletions or monosomies involving chromosomes 5 and 7 and usually lack chromosomal translocations. The exception to this rule is AML occurring after treatment with topoisomerase II inhibitors, which is strongly associated with translocations involving the *MLL* gene on chromosome 11q23. AML in the elderly is also more likely to be associated with "bad" aberrations, such as deletions of chromosomes 5q and 7q.

Molecular Pathogenesis.

Many recurrent genetic aberrations seen in AML disrupt genes encoding transcription factors that are required for normal myeloid differentiation. For example, the two most common chromosomal rearrangements, t(8;21) and inv(16), disrupt the *CBF1*α and *CBF1*β genes, respectively. These two genes encode polypeptides that bind one another to form a CBF1α/CBF1β transcription factor that is required for normal hematopoiesis.[55] The t(8;21) and the inv(16) create chimeric genes encoding fusion proteins that interfere with the function of CBF1α/CBF1β and block the maturation of myeloid cells. It should be noted, however, that "knockout" mice lacking either CBF1α or CBF1β and "knock-in" mice expressing the CBF1α or CBF1β fusion proteins succumb to hematopoietic failure, not leukemia. Thus, genetic lesions that merely block the maturation of myeloid progenitors are not by themselves sufficient to cause AML.

In line with this idea, *there is increasing evidence that mutated tyrosine kinases collaborate with transcription factor aberrations to produce AML*. One example is found in AML with the t(15;17), acute promyelocytic leukemia. The t(15;17) creates yet another fusion gene that encodes a part of the retinoic acid receptor-α (RARα) fused to a portion of a protein called PML (after the tumor). In the presence of physiologic amounts of retinoic acid, normal RARα interacts with other transcription factors to activate genes that are needed for granulocytic differentiation. However, the PML-RARα fusion protein interacts instead with transcriptional repressors, which results in an inhibition of granulocytic maturation.[56] AMLs with the t(15;17) also have frequent activating mutations in FLT3, a receptor tyrosine kinase that transmits signals that increase cellular proliferation and survival. The combination of PML-RARα and activated FLT3 is a potent inducer of AML in mice,[57] whereas neither gene alone is sufficient. Identical FLT3 mutations are also found in other forms of AML, particularly those associated with *NPM* (nucleophosmin) mutations,[58] and activating mutations in another tyrosine kinase receptor, c-KIT, are found in about 25% of AMLs associated with the inv(16) or the t(8;21).[59] Thus, aberrant tyrosine kinase activation is a common (and possibly universal) feature of AML.

The t(15;17) not only has pathogenic significance, but also guides therapy, since tumors with this translocation respond to pharmacologic doses of all-*trans* retinoic acid (ATRA). ATRA binds to the PML-RARα fusion protein and antagonizes its inhibitory effect on the transcription of target genes. Remarkably, the resulting activation of transcription overcomes the block in differentiation, and within 1 to 2 days the neoplastic promyelocytes begin to differentiate into neutrophils, which rapidly die. The response to ATRA proves that the major effect of PML-RARα is to block differentiation, and stands as one of the most successful uses of a targeted therapy in a human cancer.

Clinical Features.

Most patients present within weeks or a few months of the onset of symptoms with complaints related to anemia, neutropenia, and thrombocytopenia, most notably fatigue, fever, and spontaneous mucosal and cutaneous bleeding. You will remember that these findings are very similar to those produced by ALL.

Thrombocytopenia results in a bleeding diathesis, which is often prominent. Cutaneous petechiae and ecchymoses, serosal hemorrhages into the linings of the body cavities and viscera, and mucosal hemorrhages into the gingivae and urinary tract are common. Procoagulants and fibrinolytic factors released by leukemic cells, especially in AML with the t(15;17), exacerbate the bleeding tendency. Infections are frequent, particularly in the oral cavity, skin, lungs, kidneys, urinary bladder, and colon, and are often caused by opportunists such as fungi, *Pseudomonas*, and commensals.

Signs and symptoms related to involvement of tissues other than the marrow are usually less striking in AML than in ALL, but tumors with monocytic differentiation often infiltrate the skin (leukemia cutis) and the gingiva; this probably reflects the normal tendency of monocytes to extravasate into tissues. Central nervous system spread is less common than in ALL. AML occasionally presents as a localized soft-tissue mass known variously as a myeloblastoma, granulocytic sarcoma, or chloroma. Without systemic treatment, such tumors inevitably progress to full-blown AML over time.

Prognosis.

AML is a difficult disease to treat. About 60% of patients achieve complete remission with chemotherapy, but only 15% to 30% remain free of disease for 5 years. AMLs with t(8;21) or inv(16) have a relatively good prognosis with conventional chemotherapy, particularly in the absence of c-KIT mutations.[59] In contrast, the prognosis is dismal for AMLs that follow MDS or genotoxic therapy, or that occur in the elderly, possibly because in these contexts the disease arises out of a background of hematopoietic stem cell damage or depletion. These "high-risk" forms of AML (as well as relapsed AML of all types) are treated with bone marrow transplantation when possible.

It is hoped that new approaches based on a better understanding of molecular pathogenesis will improve this situation. The best current example is AML with the t(15;17), which (as we have discussed) is treated with pharmacologic doses of ATRA combined with conventional chemotherapy, or, more recently, with arsenic salts, which appear to cause PML-RARα to be degraded. New therapies that target other molecular lesions in AML (e.g., the activated FLT3 and c-KIT tyrosine kinases) are being evaluated.

Myelodysplastic Syndromes

The term "myelodysplastic syndrome" (MDS) refers to a group of clonal stem cell disorders characterized by maturation defects that are associated with ineffective hematopoiesis and a high risk of transformation to AML. In MDS the bone marrow is partly or wholly replaced by the clonal progeny of a neoplastic multipotent stem cell that retains the capacity to differentiate but does so in an ineffective and disordered fashion. These abnormal cells stay within the bone marrow and hence the patients have peripheral blood cytopenias.

MDS may be either primary (idiopathic) or secondary to previous genotoxic drug or radiation therapy (t-MDS). t-MDS usually appears from 2 to 8 years after the genotoxic exposure. All forms of MDS can transform to AML, but transformation occurs with highest frequency and most rapidly in t-MDS. Although characteristic morphologic changes are typically seen in the marrow and the peripheral blood, the diagnosis frequently requires correlation with other laboratory tests. Cytogenetic analysis is particularly helpful, since certain chromosomal aberrations (discussed below) are often observed.

Molecular Pathogenesis.

The pathogenesis is poorly understood.[60] In MDS, bone marrow progenitors undergo apoptotic cell death at an increased rate, the hallmark of ineffective hematopoiesis. Given this, it is difficult to understand how MDS progenitors gain a selective advantage over any remaining normal marrow

progenitors, suggesting that the tumor may arise out of a background of stem cell damage or depletion. Both primary MDS and t-MDS are associated with similar clonal chromosomal abnormalities, including monosomies 5 and 7, deletions of 5q, 7q, and 20q, and trisomy 8.

Morphology. Although the marrow is usually hypercellular at diagnosis, it is sometimes normocellular or, less commonly, hypocellular. The most characteristic finding is disordered (dysplastic) differentiation affecting the erythroid, granulocytic, monocytic, and megakaryocytic lineages to varying degrees (Fig. 13-31). Within the erythroid series, common abnormalities include **ringed sideroblasts**, erythroblasts with iron-laden mitochondria visible as perinuclear granules in Prussian blue–stained aspirates or biopsies; **megaloblastoid maturation**, resembling that seen in vitamin B_{12} and folate deficiency (Chapter 14); and **nuclear budding abnormalities**, recognized as nuclei with misshapen, often polyploid, outlines. Neutrophils frequently contain decreased numbers of secondary granules, toxic granulations, and/or Döhle bodies. **Pseudo-Pelger-Hüet cells**, neutrophils with only two nuclear lobes, are commonly observed, and neutrophils are seen occasionally that completely lack nuclear segmentation. Megakaryocytes with single nuclear lobes or multiple separate nuclei **(pawn ball megakaryocytes)** are also characteristic. **Myeloid blasts** may be increased but make up less than 20% of the overall marrow cellularity. The blood often contains pseudo-Pelger-Hüet cells, giant platelets, macrocytes, and poikilocytes, accompanied by a relative or absolute monocytosis. Myeloid blasts usually make up less than 10% of the leukocytes in the blood.

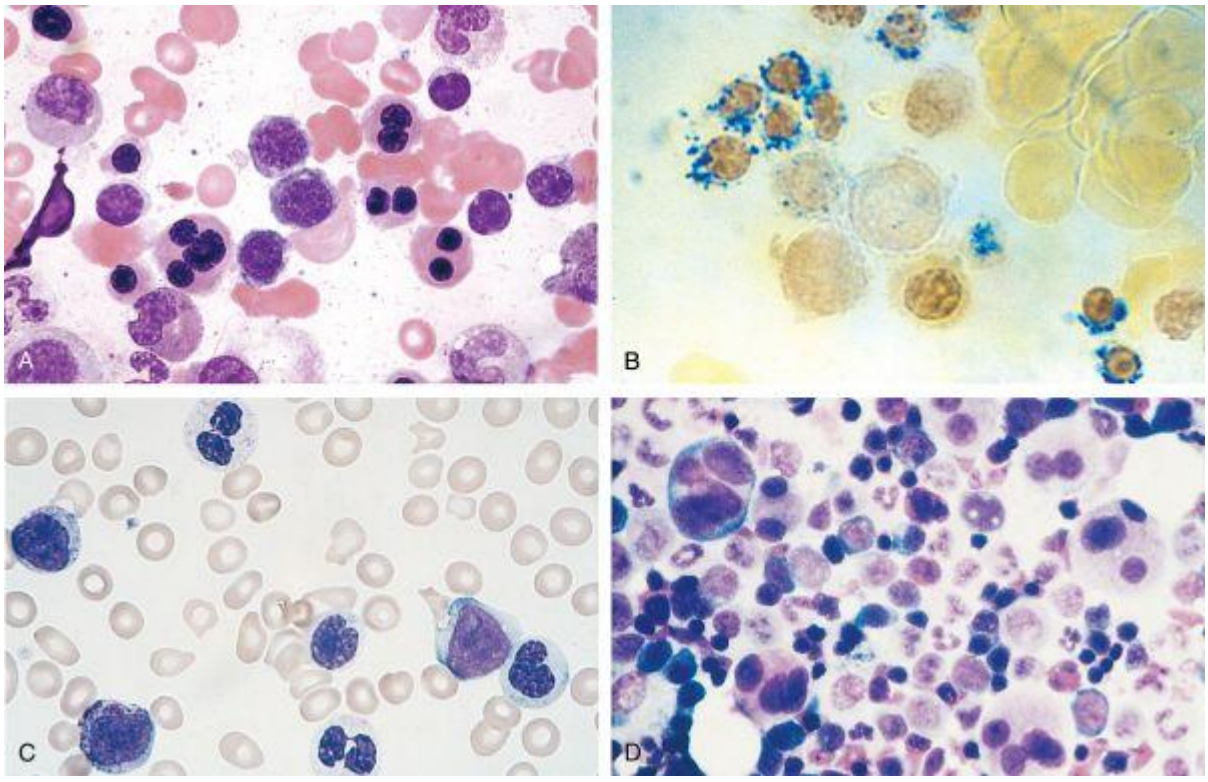

FIGURE 13-31 Myelodysplasia. Characteristic forms of dysplasia are shown. **A**, Nucleated red cell progenitors with multilobated or multiple nuclei. **B**, Ringed sideroblasts, erythroid progenitors with iron-laden mitochondria seen as blue perinuclear granules (Prussian blue stain). **C**, Pseudo-Pelger-Hüet cells, neutrophils with only two nuclear lobes instead of the normal three to four, are observed at the top and bottom of this field. **D**, Megakaryocytes with multiple nuclei instead of the normal single multilobated nucleus. (**A, B, D**, Marrow aspirates; **C**, peripheral blood smear.)

Clinical Course.

Primary MDS is predominantly a disease of the elderly; the mean age of onset is 70 years. In up to half of the cases, it is discovered incidentally on routine blood testing. When symptomatic, it presents with weakness, infections, and hemorrhages, all due to pancytopenia.

Primary MDS is divided into five morphologic categories in the WHO classification,[11] details of which are beyond our scope. Subtypes defined by having a higher proportion of blasts are associated with more severe cytopenias, an increased risk of progression to AML, and a worse prognosis. The presence of multiple clonal chromosomal abnormalities and the severity of peripheral blood cytopenias are independent risk factors also portending a worse outcome.

The median survival in primary MDS varies from 9 to 29 months, but some individuals in good prognostic groups may live for 5 years or more. Overall, progression to AML occurs in 10% to 40% of individuals and is usually accompanied by the appearance of additional cytogenetic abnormalities. Patients often succumb to the complications of thrombocytopenia (bleeding) and neutropenia (infection). The outlook is even grimmer in t-MDS, which has a median survival of only 4 to 8 months. In t-MDS, cytopenias tend to be more severe and progression to AML is often rapid.

Treatment options are fairly limited. In younger patients, allogeneic bone marrow transplantation offers hope for reconstitution of normal hematopoiesis and long-term survival. Older patients with MDS are treated supportively with antibiotics and blood product transfusions. Thalidomide-like drugs (which appear to alter the interaction of MDS progenitors with bone marrow stromal cells) and DNA methylase inhibitors improve the effectiveness of hematopoiesis and the peripheral blood counts in a subset of patients.[60]

Myeloproliferative Disorders

The common pathogenic feature of the myeloproliferative disorders is the presence of mutated, constitutively activated tyrosine kinases.[61,][62] Hematopoietic growth factors act on normal progenitors by binding to surface receptors and activating tyrosine kinases, which turn on pathways that promote growth and survival. *The mutated tyrosine kinases found in the myeloproliferative disorders circumvent normal controls and lead to the growth factor–independent proliferation and survival of marrow progenitors*. Because the tyrosine kinase mutations underlying the various myeloproliferative disorders do not impair differentiation, the most common consequence is an increase in the production of one or more mature blood elements. Most myeloproliferative disorders originate in multipotent myeloid progenitors, whereas others arise in pluripotent stem cells that give rise to both lymphoid and myeloid cells.

There is a considerable degree of clinical and morphologic overlap among the myeloproliferative disorders. The common features include

- *Increased proliferative drive* in the bone marrow
- Homing of the neoplastic stem cells to secondary hematopoietic organs, producing *extramedullary hematopoiesis*
- Variable transformation to a spent phase characterized by marrow fibrosis and peripheral blood *cytopenias*
- Variable transformation to *acute leukemia*

Certain myeloproliferative disorders are strongly associated with activating mutations in specific tyrosine kinases. This insight and the availability of kinase inhibitors have increased the importance of molecular tests for tyrosine kinase mutations, both for purposes of diagnosis and the selection of therapy.

We will confine our discussion to the more common myeloproliferative disorders, which are classified based on clinical, laboratory, and molecular criteria. Systemic mastocytosis, a distinctive myeloproliferative disorder that is associated with mutations in the c-KIT tyrosine kinase, is discussed under disorders of the skin (Chapter 25). The association of various myeloproliferative disorders with specific tyrosine kinase mutations (including several too rare to merit discussion) is summarized in Table 13-11 .

TABLE 13-11 -- Tyrosine Kinase Mutations in Myeloproliferative Disorders

Disorder	Mutation	Frequency[¶]	Consequences[*]
Chronic myeloid leukemia	*BCR-ABL* fusion gene	100%	Constitutive ABL kinase activation[†]
Polycythemia vera	*JAK2* point mutations	>95%	Constitutive JAK2 kinase activation
Essential thrombocythemia	*JAK2* point muations	50% to 60%	Constitutive JAK2 kinase activation
	MPL point mutations	5% to 10%	Constitutive MPL kinase activation
Primary myelofibrosis	*JAK2* point mutations	50% to 60%	Constitutive JAK2 kinase activation
	MPL point mutations	5% to 10%	Constitutive MPL kinase activation
Systemic mastocytosis	*c-KIT* point mutations	>90%	Constitutive c-KIT kinase activation
Chronic eosinophilic leukemia[‖]	*FIP1L1-PDGFR*α fusion gene	Common	Constitutive PDGFRα kinase activation
	*PDE4DIP-PDGFR*β fusion gene	Rare	Constitutive PDGFRβ kinase activation[†]
Stem cell leukemia[‡]	Various *FGFR1* fusion genes	100%	Constitutive FGFR1 kinase activation[§]

[*] All stimulate ligand-independent pro-growth and survival signals.

[†] Responds to imatinib therapy.

[‡] Rare disorder originating in pluripotent hematopoietic stem cells that presents with concomitant myeloproliferative disorder and lymphoblastic leukemia/lymphoma.

[§] Responds to PKC412 therapy.

[¶] Refers to frequency within a diagnostic category.

[‖] Associated with Loefflers endocarditis (Chapter 12).

Chronic Myeloid Leukemia

Chronic myeloid leukemia (CML) is distinguished from other myeloproliferative disorders by the presence of a chimeric BCR-ABL gene derived from portions of the BCR gene on chromosome 22 and the ABL gene on chromosome 9. *BCR-ABL* directs the synthesis of a constitutively active BCR-ABL tyrosine kinase (Fig. 13-32),[63] which in CML is usually 210 kDa in size. In more than 90% of cases, *BCR-ABL* is created by a reciprocal (9;22)(q34;q11) translocation (the so-called Philadelphia chromosome [Ph]). In the remaining cases the *BCR-ABL* fusion gene is formed by cytogenetically complex or cryptic rearrangments and must be detected by other methods, such as fluorescence in situ hybridization or PCR-based tests. The cell of origin is a pluripotent hematopoietic stem cell.

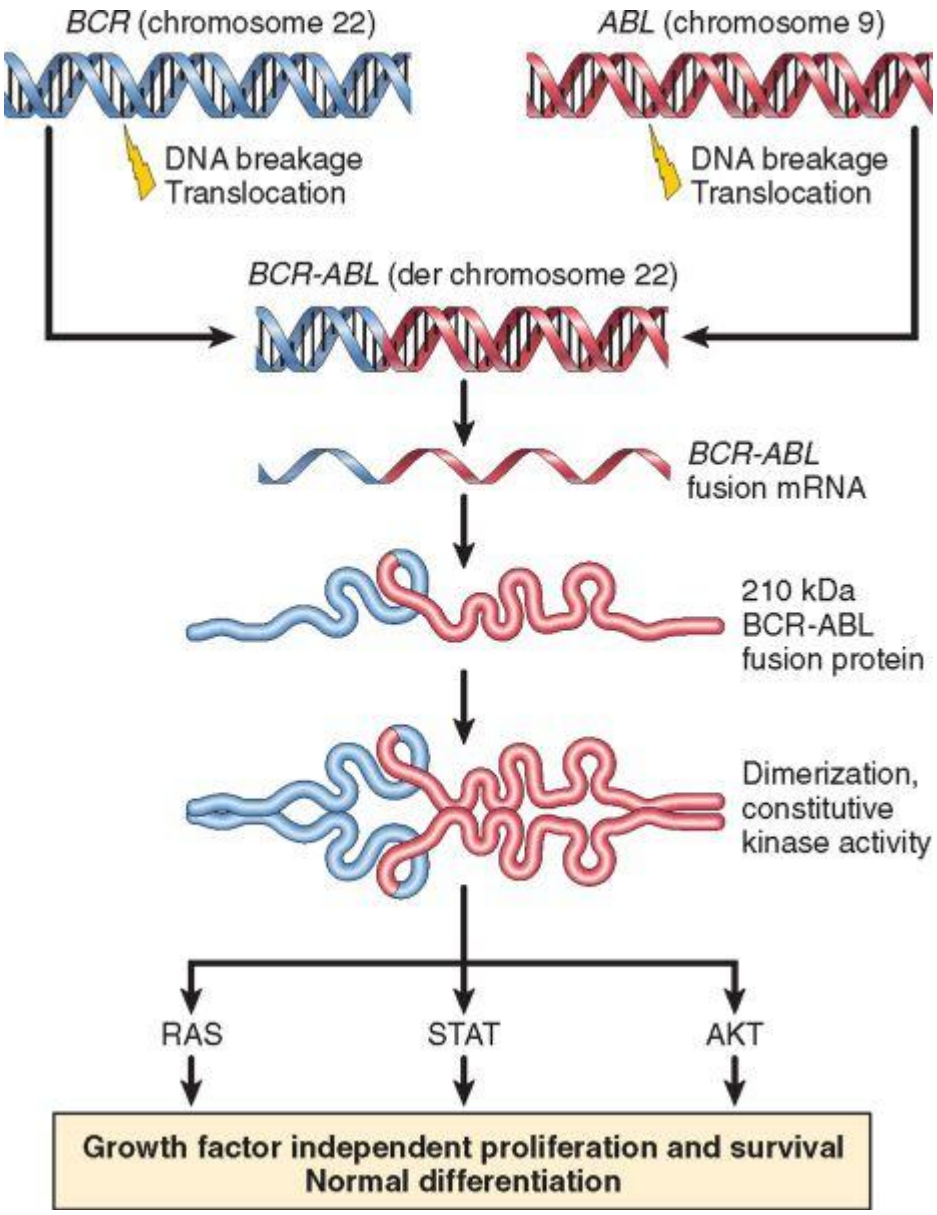

FIGURE 13-32 Molecular pathogenesis of chronic myeloid leukemia. Breakage and joining of *BCR* and *ABL* creates a chimeric *BCR-ABL* fusion gene that encodes a constitutively active BCR-ABL tyrosine kinase. BCR-ABL activates multiple downstream pathways, which drive growth factor–independent proliferation and survival of bone marrow progenitors. Because BCR-ABL does not interfere with differentiation, the net result is an increase in mature elements in the peripheral blood, particularly granulocytes and platelets.

Molecular Pathogenesis.

Tyrosine kinases are normally regulated by ligand-mediated dimerization and autophosphorylation, which creates an activated kinase capable of phosphorylating other protein substrates (discussed in Chapters 3 and 7 . The BCR moiety of BCR-ABL contains a dimerization domain that self-associates, leading to the activation of the ABL tyrosine kinase moiety. The ABL kinase in turn phosphorylates proteins that induce signaling through the same pro-growth and pro-survival pathways that are turned on by hematopoietic growth factors, including the RAS, JAK/STAT, and AKT pathways. For unknown reasons, BCR-ABL preferentially drives the proliferation of granulocytic and megakaryocytic progenitors, and also causes the abnormal release of immature granulocytic forms from the marrow into the blood.

Morphology. The marrow is markedly **hypercellular** because of massively increased numbers of maturing granulocytic precursors, which usually include an elevated proportion of eosinophils and basophils. Megakaryocytes are also increased and usually include small, dysplastic forms. Erythroid progenitors are present in normal or mildly decreased numbers. A characteristic finding is the presence of scattered macrophages with abundant wrinkled, green-blue cytoplasm so-called sea-blue histiocytes. Increased deposition of reticulin is typical, but overt marrow fibrosis is rare early in the course. The blood reveals a **leukocytosis, often exceeding 100,000 cells/mm**^{3} (Fig. 13-33), which consists predominantly of neutrophils, band forms, metamyelocytes, myelocytes, eosinophils, and basophils. Blasts usually make up less than 10% of the circulating cells. Platelets are also usually increased, sometimes markedly. The spleen is often greatly enlarged as a result of extensive extramedullary hematopoiesis (Fig. 13-34) and often contains infarcts of varying age. Extramedullary hematopoiesis can also produce mild hepatomegaly and lymphadenopathy.

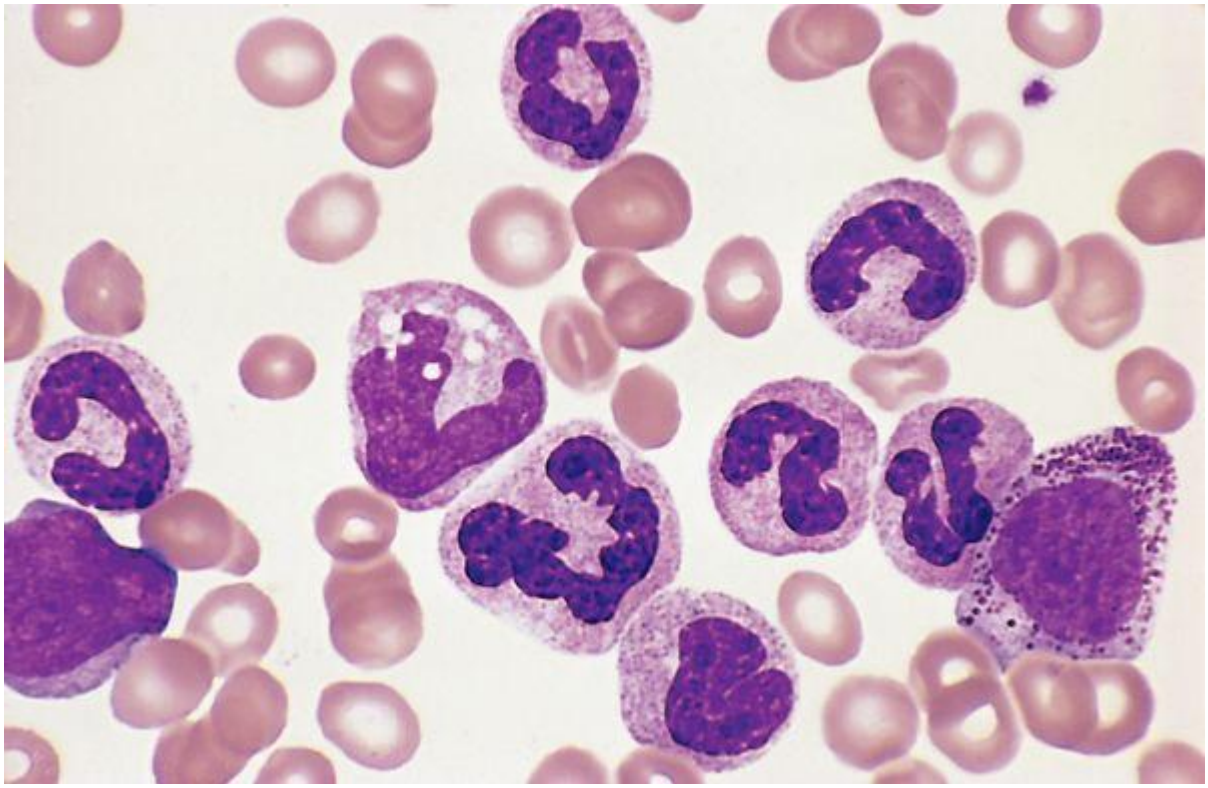

FIGURE 13-33 Chronic myeloid leukemia. Peripheral blood smear shows many mature neutrophils, some metamyelocytes, and a myelocyte. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

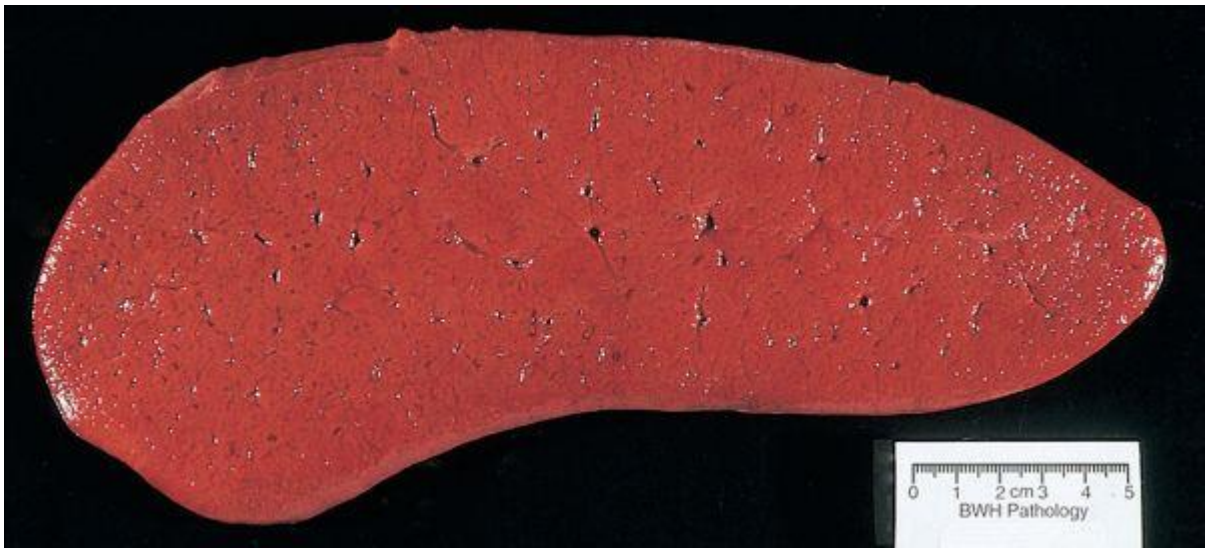

FIGURE 13-34 Chronic myeloid leukemia (spleen). Enlarged spleen (2630 gm; normal: 150–200 gm) with greatly expanded red pulp stemming from neoplastic hematopoiesis. *(Courtesy of Dr. Daniel Jones, Department of Pathology, M.D. Anderson Cancer Center, Houston, TX.)*

Clinical Features.

CML is primarily a disease of adults but also occurs in children and adolescents. The peak incidence is in the fifth to sixth decades of life. There are about 4500 new cases per year in the United States.

The onset is insidious. Mild-to-moderate anemia and hypermetabolism due to increased cell turnover lead to fatigability, weakness, weight loss, and anorexia. Sometimes the first symptom is a dragging sensation in the abdomen caused by splenomegaly, or the acute onset of left upper quadrant pain due to splenic infarction. CML is best differentiated from other myeloproliferative disorders by detection of the *BCR-ABL* fusion gene through either chromosomal analysis or PCR-based tests.

The natural history is one of slow progression; even without treatment, the median survival is about 3 years. After a variable period averaging 3 years, about 50% of patients enter an "accelerated phase" marked by increasing anemia and thrombocytopenia, sometimes accompanied by a rise in the number of basophils in the blood. Additional clonal cytogenetic abnormalities, such as trisomy 8, isochromosome 17q, or duplication of the Ph chromosome, often appear. Within 6 to 12 months, the accelerated phase terminates in a picture resembling acute leukemia (*blast crisis*). In the other 50% of patients, blast crises occur abruptly without an accelerated phase. In 70% of crises, the blasts are of myeloid origin (myeloid blast crisis), whereas in most of the remainder the blasts are of pre–B cell origin (lymphoid blast crisis). This is taken as evidence that CML orginates from a pluripotent stem cell with both myeloid and lymphoid potential. Recently, it has been observed that in greater than 85% of cases CML is associated with the appearance of mutations that interfere with the activity of Ikaros, a transcription factor that regulates the differentiation of hematopoietic progenitors.[64] The same types of Ikaros mutations are also seen in BCR-ABL-positive ALL, suggesting that these two varieties of aggressive leukemia have a similar pathogenic basis.

Understanding of the molecular pathogenesis of CML has led to the use of drugs that target BCR-ABL. Treatment with one BCR-ABL inhibitor, imatinib, results in sustained hematologic remissions in greater

than 90% of patients, with few side effects.[65] Imatinib markedly decreases the number of BCR-ABL-positive cells in the marrow and elsewhere, but does not extinguish the CML "stem cell," a primitive cell that resembles a normal hematopoietic stem cell. As a result, it is not clear if imatinib is ever truly curative. However, imatinib therapy controls blood counts and substantially decreases the risk of transformation to the accelerated phase and blast crisis, which is the greatest threat to the patient. It is thought that by lowering the proliferative drive of the BCR-ABL-positive progenitors, imatinib decreases the rate at which these cells acquire mutations that lead to disease progression.[66] For relatively young patients, allogeneic bone marrow transplantation performed in the stable phase is curative in about 75% of cases and remains the treatment of choice. The outlook is much more dire once the accelerated phase or blast crisis supervenes. Transplantation is not as effective, and (as in BCR-ABLpositive ALL) the disease rapidly becomes resistant to BCR-ABL inhibitors.

Polycythemia Vera

Polycythemia vera (PCV) is characterized by increased marrow production of red cells, granulocytes, and platelets (panmyelosis), but it is the increase in red cells (polycythemia) that is responsible for most of the clinical symptoms. PCV must be differentiated from relative polycythemia resulting from hemoconcentration and other causes of absolute polycythemia (discussed in Chapter 14). *PCV is strongly associated with activating point mutations in the tyrosine kinase JAK2*.[61,][62] JAK2 participates in the JAK/STAT pathway, which lies downstream of multiple hematopoietic growth factor receptors, including the erythropoietin receptor.

Molecular Pathogenesis.

In PCV the progenitor cells have markedly decreased requirements for erythropoietin and other hematopoietic growth factors due to constitutive JAK2 signaling. Accordingly, serum erythropoietin levels in PCV are very low, whereas secondary forms of absolute polycythemia have high erythropoietin levels. The elevated hematocrit leads to increased blood viscosity and sludging. These hemodynamic factors, together with thrombocytosis and abnormal platelet function, make patients with PCV prone to both thrombosis and bleeding.

More than 97% of cases are associated with a mutation in *JAK2* that results in a valine-to-phenylalanine substitution at residue 617; other *JAK2* mutations are found in most (and perhaps all) of the remaining cases. The mutated forms of JAK2 found in PCV render hematopoietic cell lines growth factor–independent, and when expressed in murine bone marrow progenitors cause a PCV-like syndrome that is associated with marrow fibrosis.[61,][62] In 25% to 30% of cases the tumor cells contain two mutated copies of *JAK2*, a homozygous genotype that is associated with higher white cell counts, more significant splenomegaly, symptomatic pruritus, and a greater rate of progression to the spent phase.[67]

The proliferative drive in PCV (and other myeloproliferative disorders associated with JAK2 mutations) is less than in CML, which is associated with more pronounced marrow hypercellularity, leukocytosis, and splenomegaly. Presumably, JAK2 signals are quantitatively weaker or qualitatively different from those produced by BCR-ABL (see Fig. 13-32).

Morphology. The marrow is hypercellular, but some residual fat is usually present. The increase in red cell progenitors is subtle and usually accompanied by an increase in granulocytic precursors and megakaryocytes as well. At diagnosis, a moderate to marked increase in reticulin fibers is seen in about 10% of marrows. Mild organomegaly is common, being caused early in the course largely by congestion; at this stage extramedullary hematopoiesis is minimal. The peripheral blood often contains increased numbers of basophils and abnormally large platelets.

Late in the course, PCV often progresses to a spent phase characterized by extensive marrow fibrosis that displaces hematopoietic cells. This is accompanied by increased extramedullary hematopoiesis in the spleen and liver, often leading to prominent organomegaly (Fig. 13-35). Transformation to AML, with its typical features, occurs in about 1% of patients.

FIGURE 13-35 Polycythemia vera, spent phase. Massive splenomegaly (3020 gm; normal: 150–200 gm) largely due to extramedullary hematopoiesis occurring in the setting of advanced marrow myelofibrosis. *(Courtesy of Dr. Mark Fleming, Department of Pathology, Children's Hospital, Boston, MA.)*

Clinical Features.

PCV is uncommon, having an incidence of 1 to 3 per 100,000 per year. It appears insidiously, usually in adults of late middle age. *Most symptoms are related to the increased red cell mass and hematocrit*. Usually, there is also an increased total blood volume. Together, these factors cause abnormal blood flow, particularly on the low-pressure venous side of the circulation, which becomes greatly distended. Patients are plethoric and cyanotic due to stagnation and deoxygenation of blood in peripheral vessels. Headache, dizziness, hypertension, and gastrointestinal symptoms are common. Intense pruritus and peptic ulceration may occur, both possibly resulting from the release of histamine from basophils. High cell turnover gives rise to hyperuricemia; symptomatic gout is seen in 5% to 10% of cases.

More ominously, the abnormal blood flow and platelet function lead to an increased risk of both major bleeding and thrombotic episodes. About 25% of patients first come to attention due to deep venous thrombosis, myocardial infarction, or stroke. Thromboses sometimes also occur in the hepatic veins (producing Budd-Chiari syndrome) and the portal and mesenteric veins (leading to bowel infarction). It should be remembered that thrombotic complications sometimes precede the appearance of the typical

hematologic findings.[68] Minor hemorrhages (epistaxis, bleeding gums) are common, and life-threatening hemorrhages occur in 5% to 10% of cases.

The hemoglobin concentration ranges from 14 to 28 gm/dL, and the hematocrit is usually 60% or more. Sometimes chronic bleeding leads to iron deficiency, which can suppress erythropoiesis sufficiently to lower the hematocrit into the normal range, an example of two defects counteracting one another to "correct" a laboratory abnormality. The white cell count ranges from 12,000 to 50,000 cells/mm^3, and the platelet count is often greater than 500,000 platelets/mm^3. The platelets usually exhibit morphologic abnormalities such as giant forms and are often defective in functional aggregation studies.

Without treatment, death from bleeding or thrombosis occurs within months of diagnosis. However, simply maintaining the red cell mass at nearly normal levels by phlebotomy extends the median survival to about 10 years. JAK2 inhibitors are in preclinical development and represent a promising form of targeted therapy.

Extended survival with treatment has revealed that *PCV tends to evolve to a "spent phase," during which clinical and anatomic features of primary myelofibrosis develop*. The disease undergoes this transition in about 15% to 20% of patients after an average period of 10 years. It is marked by the appearance of obliterative fibrosis in the bone marrow (myelofibrosis) and extensive extramedullary hematopoiesis, principally in the spleen, which enlarges greatly. The mechanisms underlying the progression to the spent phase are not known.

In about 2% of patients, PCV transforms to AML. Surprisingly, the AML clone often lacks *JAK2* mutations,[69] suggesting that *JAK2* mutations are late secondary events, rather than early initiators of PCV. Unlike CML, transformation to ALL is rarely observed, consistent with the cell of origin being a progenitor committed to myeloid differentiation.

Essential Thrombocytosis

Essential thrombocytosis (ET) is often associated with activating point mutations in JAK2 (50% of cases) or MPL (5–10% of cases), a receptor tyrosine kinase that is normally activated by thrombopoietin.[61] It manifests clinically with elevated platelet counts and is separated from PCV and primary myelofibrosis based on the absence of polycythemia and marrow fibrosis, respectively. In those cases without tyrosine kinase mutations, causes of reactive thrombocytosis, such as inflammatory disorders and iron deficiency, must be excluded before the diagnosis can be established.

Constitutive JAK2 or MPL signaling renders the progenitors thrombopoietin-independent and leads to hyperprolifer-ation. The *JAK2* mutation is the same as that found in almost all cases of PCV. Why some patients with *JAK2* mutations present with PCV and others with ET is not understood. Some cases of "ET" may in fact be PCV disguised by iron deficiency (which is more common in individuals diagnosed with ET), but this is probably true of only a small fraction of patients. Mutations in other tyrosine kinases are being sought in those cases in which *JAK2* and *MPL* are apparently normal.

Bone marrow cellularity is usually only mildly increased, but megakaryocytes are often markedly increased in number and include abnormally large forms. Delicate reticulin fibrils are often seen, but the overt fibrosis of primary myelofibrosis (see below) is absent. *Peripheral smears usually reveal abnormally large platelets* (Fig. 13-36), often accompanied by mild leukocytosis. Modest degrees of extramedullary hematopoiesis may occur, producing mild organomegaly in about 50% of patients. Uncommonly, a spent phase of marrow fibrosis or transformation to AML supervenes.

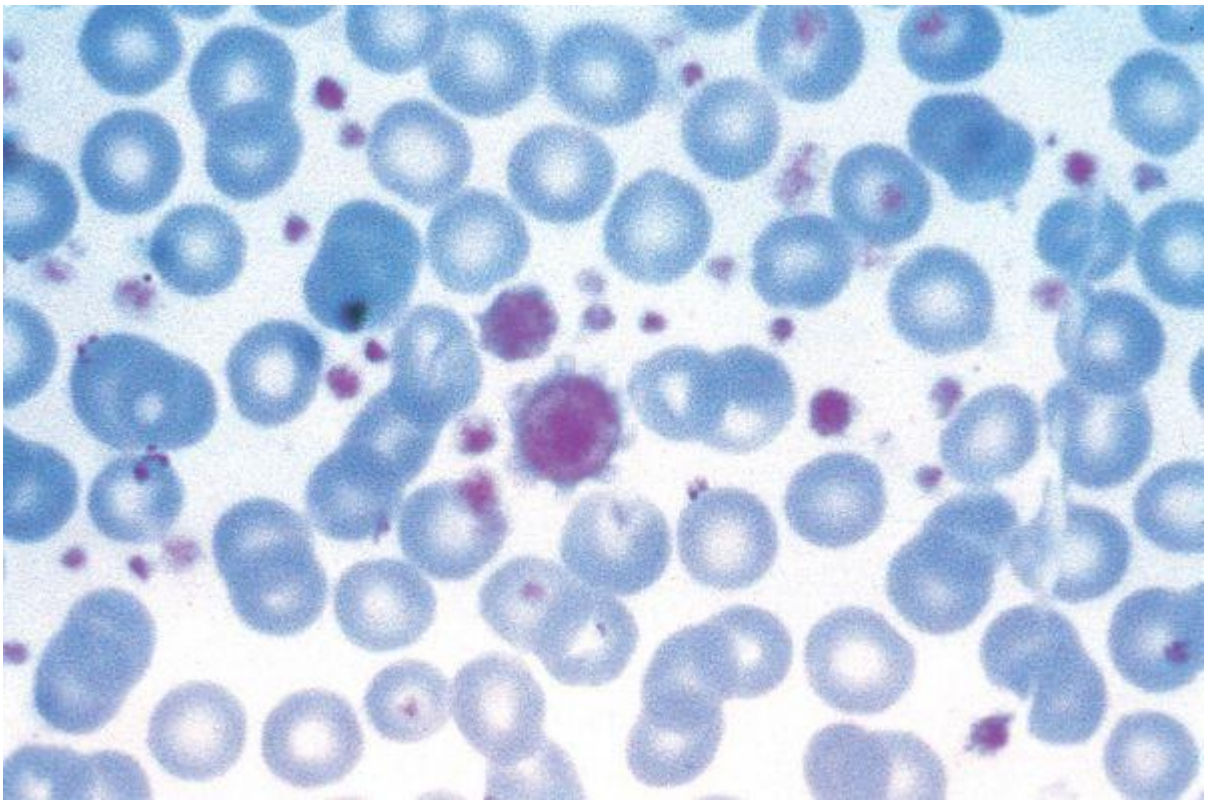

FIGURE 13-36 Essential thrombocytosis. Peripheral blood smear shows marked thrombocytosis, including giant platelets approximating the size of surrounding red cells.

The incidence of ET is 1 to 3 per 100,000 per year. It usually occurs past the age of 60 but may also be seen in young adults. *Dysfunctions of platelets derived from the neoplastic clone can lead to thrombosis and hemorrhage*, the major clinical manifestations. Platelets are not only increased in numbers but also frequently demonstrate qualitative abnormalities in functional tests. The types of thrombotic events resemble those observed in PCV; they include deep venous thrombosis, portal and hepatic vein thrombosis, and myocardial infarction. One characteristic symptom is *erythromelalgia*, a throbbing and burning of hands and feet caused by occlusion of small arterioles by platelet aggregates, which may also be seen in PCV.

ET is an indolent disorder with long asymptomatic periods punctuated by occasional thrombotic or hemorrhagic crises. Median survival times are 12 to 15 years. Thrombotic complications are most likely in patients with very high platelet counts and homozygous *JAK2* mutations.[67] Therapy consists of "gentle" chemotherapeutic agents that suppress thrombopoiesis.

Primary Myelofibrosis

The hallmark of primary myelofibrosis is the development of obliterative marrow fibrosis. The replacement of the marrow by fibrosis suppresses bone marrow hematopoiesis, leading to cytopenias and extensive neoplastic extramedullary hematopoiesis. Histologically, the appearance is identical to the spent phase that occurs occasionally late in the course of other myeloproliferative disorders. This similarity also extends to the underlying molecular pathogenesis.

Molecular Pathogenesis.

Activating JAK2 mutations are present in 50% to 60% of cases and activating MPL mutations in an additional 1% to 5% of cases.[61] The chief pathologic feature is the extensive deposition of collagen in the marrow by non-neoplastic fibroblasts. The fibrosis inexorably displaces hematopoietic elements, including stem cells, from the marrow and eventually leads to marrow failure. It is probably caused by the inappropriate release of fibrogenic factors from neoplastic megakaryocytes. Two factors synthesized by megakaryocytes have been implicated: platelet-derived growth factor and TGF-β. As you recall, platelet-derived growth factor and TGF-β are fibroblast mitogens. In addition, TGF-β promotes collagen deposition and causes angiogenesis, both of which are observed in myelofibrosis. As marrow fibrosis progresses, circulating hematopoietic stem cells take up residence in niches in secondary hematopoietic organs, such as the spleen, the liver, and the lymph nodes, leading to the appearance of extramedullary hematopoiesis. For incompletely understood reasons, blood cell production at extramedullary sites is disordered. This factor and the concomitant suppression of marrow function result in moderate to severe cytopenias. It is not clear whether primary myelofibrosis (particularly when associated with *JAK2* or *MPL* mutations) is truly distinct from PCV and ET, or merely reflects unusually rapid progression of these MPDs to the spent phase.[61]

Morphology. Early in the course, the marrow is often hypercellular due to increases in maturing cells of all lineages, a feature reminiscent of PCV. Morphologically, the erythroid and granulocytic precursors appear normal, but megakaryocytes are large, dysplastic, and abnormally clustered. At this stage fibrosis is minimal, and the blood may show leukocytosis and thrombocytosis. With progression, the marrow becomes more hypocellular and diffusely fibrotic. Clusters of atypical megakaryocytes are seen, and hematopoietic elements are often found within dilated sinusoids, which is a manifestation of severe architectural distortion cause by the fibrosis. Very late in the course, the fibrotic marrow space may be converted into bone, a change called "osteosclerosis." These features are identical to those seen in the spent phase of other myeloproliferative disorders.

Fibrotic obliteration of the marrow space leads to extensive extramedullary hematopoiesis, principally in the spleen, which is usually markedly enlarged, sometimes up to 4000 gm. Grossly, such spleens are firm and diffusely red to gray. As in CML, subcapsular infarcts are common (see Fig. 13-40). Initially, extramedullary hematopoiesis is confined to the sinusoids, but later it expands into the cords. The **liver** may be enlarged moderately by sinusoidal foci of extramedullary hematopoiesis. Hematopoiesis can also appear within lymph nodes, but significant lymphadenopathy is uncommon.

The marrow fibrosis is reflected in several characteristic blood findings (Fig. 13-37). Marrow distortion leads to the premature release of nucleated erythroid and early granulocyte progenitors **(leukoerythroblastosis)**, and immature cells also enter the circulation from sites of extramedullary hematopoiesis. **Teardrop-shaped red cells** (dacryocytes), cells that were probably damaged during the birthing process in the fibrotic marrow, are also often seen. Although characteristic of primary myelofibrosis, leukoerythroblastosis and teardrop red cells are seen in many infiltrative disorders of the marrow, including granulomatous diseases and metastatic tumors. Other common, albeit nonspecific, blood findings include abnormally large platelets and basophilia.

FIGURE 13-40 Splenic infarcts. Multiple well-circumscribed infarcts are present in this spleen, which is massively enlarged (2820 gm; normal: 150–200 gm) by extramedullary hematopoiesis secondary to a myeloproliferative disorder (myelofibrosis). Recent infarcts are hemorrhagic, whereas older, more fibrotic infarcts are a pale yellow-gray color.

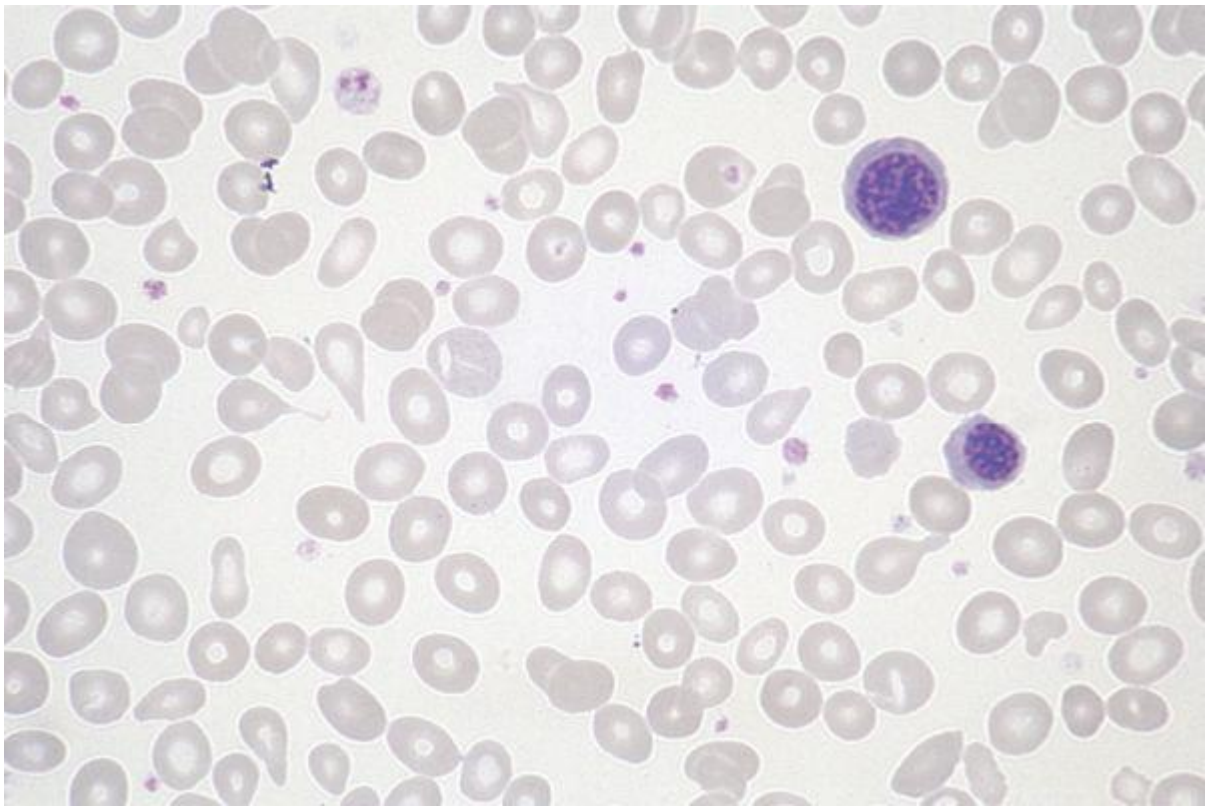

FIGURE 13-37 Primary myelofibrosis (peripheral blood smear). Two nucleated erythroid precursors and several teardrop-shaped red cells (dacryocytes) are evident. Immature myeloid cells were present in other fields. An identical picture can be seen in other diseases producing marrow distortion and fibrosis.

Clinical Features.

Primary myelofibrosis is less common than PCV and ET and usually occurs in individuals older than 60 years of age. Except when preceded by another myeloproliferative disorder, it comes to attention because of progressive anemia and splenomegaly, which produces a sensation of fullness in the left upper quadrant. Nonspecific symptoms such as fatigue, weight loss, and night sweats result from an increase in metabolism associated with the expanding mass of hematopoietic cells. Hyperuricemia and secondary gout due to a high rate of cell turnover can complicate the picture.

Laboratory studies typically show a moderate to severe normochromic normocytic anemia accompanied by leukoerythroblastosis. The white cell count is usually normal or reduced, but can be markedly elevated (80,000–100,000 cells/mm^3) early in the course. The platelet count is usually normal or elevated at the time of diagnosis, but thrombocytopenia supervenes as the disease progresses. These blood findings are not specific; bone marrow biopsy is essential for diagnosis.

Primary myelofibrosis is a much more difficult disease to treat than PCV or ET. The course is variable, but the median survival is in the range of 3 to 5 years. Threats to life include intercurrent infections, thrombotic episodes, bleeding related to platelet abnormalities, and transformation to AML, which occurs in 5% to 20% of cases. When myelofibrosis is extensive, AML sometimes arises at extramedullary sites, including lymph nodes and soft tissues. Bone marrow transplantation is being used in some younger patients, and kinase inhibitors represent a future hope for targeted therapy.

LANGERHANS CELL HISTIOCYTOSIS

The term *histiocytosis* is an "umbrella" designation for a variety of proliferative disorders of dendritic cells or macrophages. Some, such as rare "histiocytic" lymphomas, are clearly malignant, whereas others, such as reactive proliferations of macrophages in lymph nodes, are clearly benign. Lying between these two extremes are the Langerhans cell histiocytoses, a spectrum of proliferations of a special type of immature dendritic cell called the Langerhans cell (see Chapter 6). In most instances, these proliferations are monoclonal and therefore likely to be neoplastic in origin.

Regardless of the clinical picture, the proliferating Langerhans cells have abundant, often vacuolated cytoplasm and vesicular nuclei containing linear grooves or folds (Fig. 13-38A). *The presence of Birbeck granules in the cytoplasm is characteristic*. Birbeck granules are pentalaminar tubules, often with a dilated terminal end producing a tennis racket–like appearance (Fig. 13-38B), which contain the protein langerin. In addition, the tumor cells also typically express HLA-DR, S-100, and CD1a.

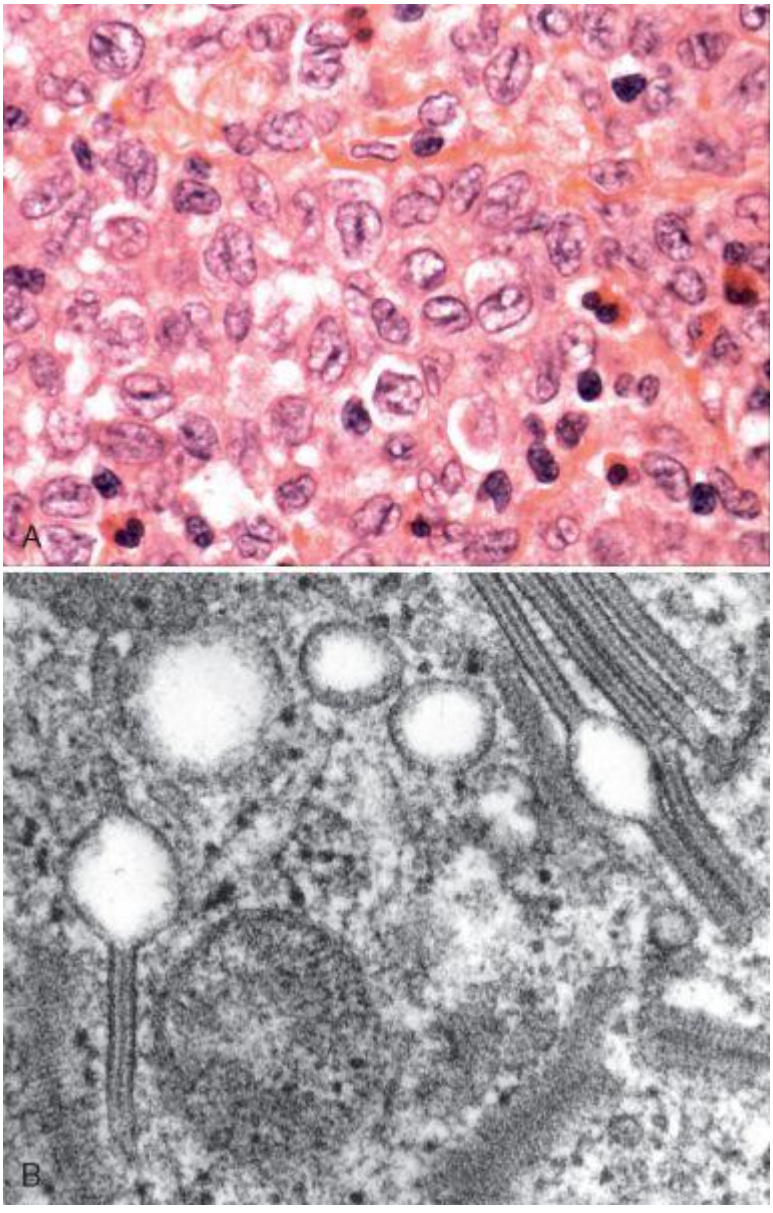

FIGURE 13-38 Langerhans cell histiocytosis. **A**, Langerhans cells with folded or grooved nuclei and moderately abundant pale cytoplasm are mixed with a few eosinophils. **B**, An electron micrograph shows rodlike Birbeck granules with characteristic periodicity and dilated terminal

end. ***(B**, Courtesy of Dr. George Murphy, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

Langerhans cell histiocytosis presents as several clinicopathologic entities:

- *Multifocal multisystem Langerhans cell histiocytosis (Letterer-Siwe disease)* occurs most frequently before 2 years of age but occasionally affects adults. A dominant clinical feature is the development of cutaneous lesions resembling a seborrheic eruption, which is caused by infiltrates of Langerhans cells over the front and back of the trunk and on the scalp. Most of those affected have concurrent hepatosplenomegaly, lymphadenopathy, pulmonary lesions, and (eventually) destructive osteolytic bone lesions. Extensive infiltration of the marrow often leads to anemia, thrombocytopenia, and a predisposition to recurrent infections, such as otitis media and mastoiditis. In some instances the tumor cells are quite anaplastic; such tumors are sometimes referred to as Langerhans cell sarcoma. The course of untreated disease is rapidly fatal. With intensive chemotherapy, 50% of patients survive 5 years.
- *Unifocal and multifocal unisystem Langerhans cell histiocytosis (eosinophilic granuloma)* is characterized by proliferations of Langerhans cells admixed with variable numbers of eosinophils, lymphocytes, plasma cells, and neutrophils. Eosinophils are usually, but not always, a prominent component of the infiltrate. It typically arises within the medullary cavities of bones, most commonly the calvarium, ribs, and femur. Less commonly, unisystem lesions of identical histology arise in the skin, lungs, or stomach. *Unifocal lesions* most commonly affect the skeletal system in older children or adults. Bone lesions can be asymptomatic or cause pain, tenderness, and, in some instances, pathologic fractures. Unifocal disease is indolent and may heal spontaneously or be cured by local excision or irradiation. *Multifocal unisystem disease* usually affects young children, who present with multiple erosive bony masses that sometimes expand into adjacent soft tissue. Involvement of the posterior pituitary stalk of the hypothalamus leads to diabetes insipidus in about 50% of patients. The combination of calvarial bone defects, diabetes insipidus, and exophthalmos is referred to as the *Hand-Schuller-Christian* triad. Many patients experience spontaneous regression; others can be treated successfully with chemotherapy.
- *Pulmonary Langerhans cell histiocytosis* represents a special category of disease, most often seen in adult smokers, which may regress spontaneously upon cessation of smoking. It usually comprises a polyclonal population of Langerhans cells, suggesting that it is a reactive hyperplasia rather than a true neoplasm.

One factor that contributes to the homing of neoplastic Langerhans cells is the aberrant expression of chemokine receptors.[70,][71] For example, while normal epidermal Langerhans cells express CCR6, their neoplastic counterparts express both CCR6 and CCR7. This allows the neoplastic cells to migrate into tissues that express the relevant chemokines—CCL20 (a ligand for CCR6) in skin and bone, and CCL19 and 21 (ligands for CCR7) in lymphoid organs.

3.3.3 Spleen

The spleen is an ingeniously designed filter for the blood and a site of immune responses to blood-borne antigens. Normally in the adult it weighs about 150 gm and is enclosed within a thin, glistening, slate-gray connective tissue capsule. Its cut surface reveals extensive red pulp dotted with gray specks, which are the white pulp follicles. These consist of an artery with an eccentric collar of T lymphocytes, the so-called periarteriolar lymphatic sheath. At intervals this sheath expands to form lymphoid nodules composed mainly of B lymphocytes, which are capable of developing into germinal centers identical to those seen in lymph nodes in response to antigenic stimulation (Fig. 13-39).

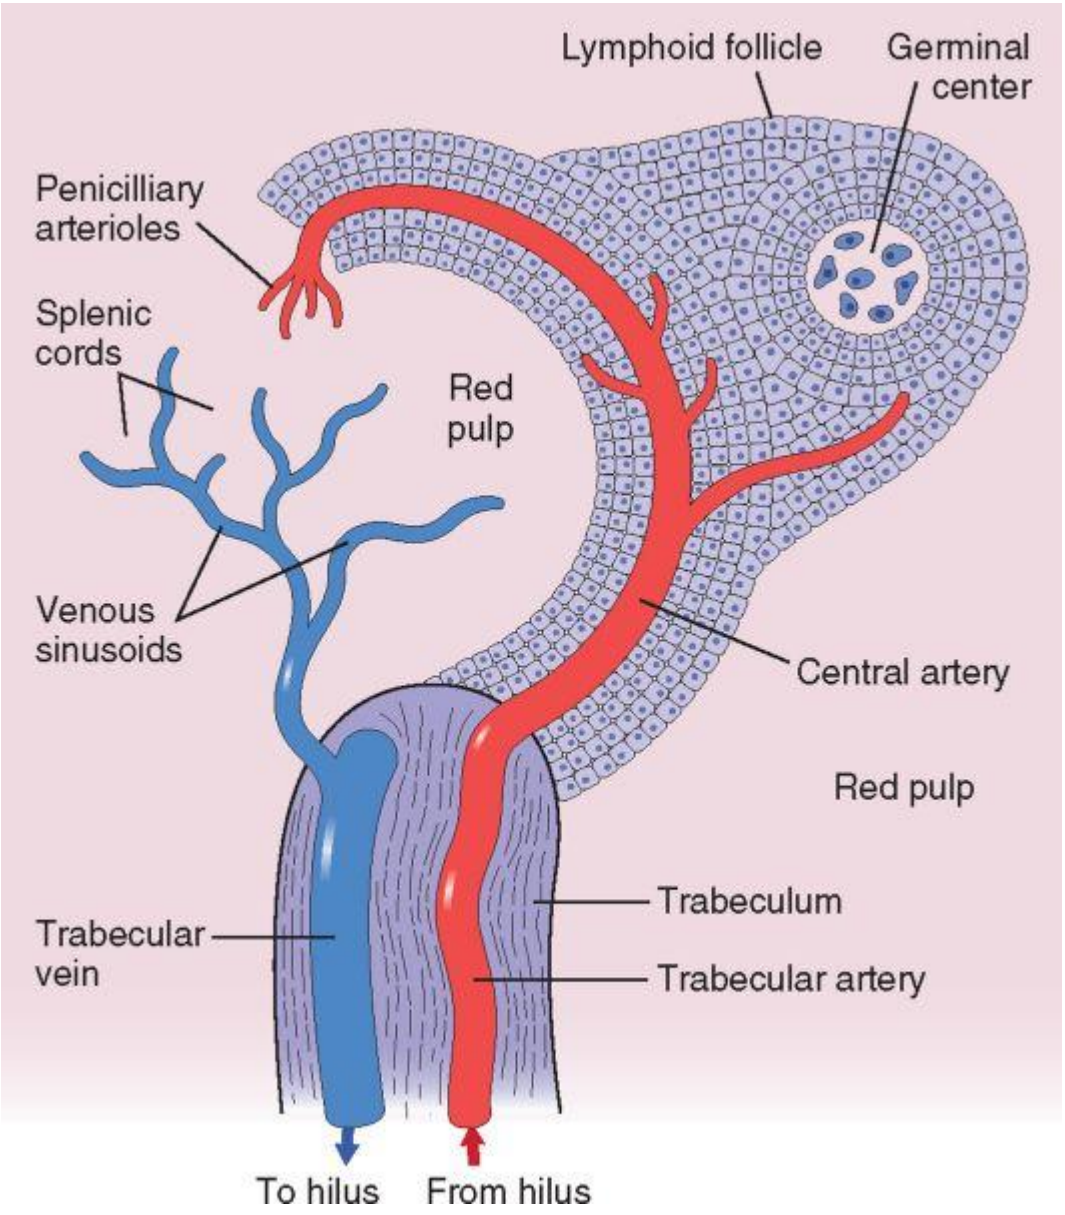

FIGURE 13-39 Normal splenic architecture. *(Modified from Faller DV: Diseases of the spleen. In Wyngaarden JB, Smith LH (eds): Cecil Textbook of Medicine, 18th ed. Philadelphia, WB Saunders, 1988, p. 1036.)*

The red pulp of the spleen is traversed by numerous thin-walled vascular sinusoids, separated by the splenic cords or "cords of Billroth." The endothelial lining of the sinusoid is discontinuous, providing a passage for blood cells between the sinusoids and cords. The cords contain a labyrinth of macrophages loosely connected through long dendritic processes to create both a physical and a functional filter. As it traverses the red pulp, the blood takes two routes to reach the splenic veins. Some flows through capillaries into the cords, from which blood cells squeeze through gaps in the discontinuous basement of the endothelial lining to reach the sinusoids; this is the so-called open circulation or slow compartment. In the other "closed circuit," blood passes rapidly and directly from the capillaries to the splenic veins. Although only a small fraction of the blood pursues the "open" route, during the course of a day the entire blood volume passes through the cords, where it is closely examined by macrophages.

The spleen has four functions that impact disease states:

1. *Phagocytosis of blood cells and particulate matter*. As will be discussed under the hemolytic anemias (Chapter 14), red cells undergo extreme deformation during passage from the cords into the sinusoids. In conditions in which red cell elasticity is decreased, red cells become trapped in the cords and are more readily phagocytosed by macrophages. Splenic macrophages are also responsible for “pitting” of red cells, the process by which inclusions such as Heinz bodies and Howell-Jolly bodies are excised, and for the removal of particles, such as bacteria, from the blood.
2. *Antibody production*. Dendritic cells in the periarterial lymphatic sheath trap antigens and present them to T lymphocytes. T- and B-cell interaction at the edges of white pulp follicles leads to the generation of antibody-secreting plasma cells, which are found mainly within the sinuses of the red pulp. The spleen seems to be an important source of antibodies directed against platelets and red cells in immune thrombocytopenia purpura and immunohemolytic anemias, both discussed in Chapter 14 .
3. *Hematopoiesis*. Splenic hematopoiesis normally ceases before birth, but can be reactivated in severe anemia. As we have seen, the spleen is also a prominent site of extramedullary hematopoiesis in myeloproliferative disorders, such as chronic myeloid leukemia.
4. *Sequestration of formed blood elements*. The normal spleen contains only about 30 to 40 mL of red cells, but this volume increases greatly with splenomegaly. The normal spleen also harbors approximately 30% to 40% of the total platelet mass in the body. *With splenomegaly up to 80% to 90% of the total platelet mass can be sequestered in the interstices of the red pulp, producing thrombocytopenia*. Similarly, the enlarged spleen can trap white cells and thereby induce leukopenia.

As the largest unit of the mononuclear phagocyte system, the spleen is involved in all systemic inflammations, generalized hematopoietic disorders, and many metabolic disturbances. In each, the spleen undergoes enlargement *(splenomegaly)*, which is the major manifestation of disorders of this organ. It is rarely the primary site of disease. *Splenic insufficiency due to splenectomy or autoinfarction (as in sickle-cell disease) has one major clinical manifestation, an increased susceptibility to sepsis cause by encapsulated bacteria such as pneumococcus, meningococcus, and Haemophilus influenzae*. The loss of filtering and antibody production functions both contribute to the increased risk of sepsis, which may be fatal. All asplenic individuals should be vaccinated against these agents to reduce the risk of this tragic complication.

3.3.3.1 Splenomegaly

When sufficiently enlarged, the spleen causes a dragging sensation in the left upper quadrant and, through pressure on the stomach, discomfort after eating. In addition, enlargement can cause a syndrome known as *hypersplenism*, which is characterized by anemia, leukopenia, thrombocytopenia, alone or in combination. The probable cause of the cytopenias is increased sequestration of formed elements and the consequent enhanced phagocytosis by the splenic macrophages.

A list of the major disorders associated with splenomegaly is provided in Table 13-12 . Splenomegaly in virtually all the conditions mentioned has been discussed elsewhere. There remain only a few disorders to consider.

TABLE 13-12 -- Disorders Associated with Splenomegaly

I. INFECTIONS
Nonspecific splenitis of various blood-borne infections (particularly infectious endocarditis)
Infectious mononucleosis
Tuberculosis
Typhoid fever
Brucellosis

Cytomegalovirus
Syphilis
Malaria
Histoplasmosis
Toxoplasmosis
Kala-azar
Trypanosomiasis
Schistosomiasis
Leishmaniasis
Echinococcosis
II. CONGESTIVE STATES RELATED TO PORTAL HYPERTENSION
Cirrhosis of the liver
Portal or splenic vein thrombosis
Cardiac failure
III. LYMPHOHEMATOGENOUS DISORDERS
Hodgkin lymphoma
Non-Hodgkin lymphomas and lymphocytic leukemias
Multiple myeloma
Myeloproliferative disorders
Hemolytic anemias
IV. IMMUNOLOGICAL-INFLAMMATORY CONDITIONS
Rheumatoid arthritis
Systemic lupus erythematosus
V. STORAGE DISEASES
Gaucher disease
Niemann-Pick disease
Mucopolysaccharidoses
VI. MISCELLANEOUS DISORDERS
Amyloidosis
Primary neoplasms and cysts
Secondary neoplasms

NONSPECIFIC ACUTE SPLENITIS

Enlargement of the spleen occurs in any blood-borne infection. The nonspecific splenic reaction in these infections is caused both by the microbiologic agents themselves and by cytokines that are released as part of the immune response.

Morphology. The spleen is enlarged (200–400 gm) and soft. Microscopically, the major feature is acute congestion of the red pulp, which may encroach on and virtually efface the lymphoid follicles. Neutrophils, plasma cells, and occasionally eosinophils are usually present throughout the white and red pulp. At times the white pulp follicles may undergo necrosis, particularly when the causative agent is a hemolytic streptococcus. Rarely, abscess formation occurs.

CONGESTIVE SPLENOMEGALY

Chronic venous outflow obstruction causes a form of splenic enlargement referred to as *congestive splenomegaly*. Venous obstruction may be caused by intrahepatic disorders that retard portal venous drainage, or arise from extrahepatic disorders that directly impinge upon the portal or splenic veins. All of these disorders ultimately lead to portal or splenic vein hypertension. *Systemic, or central, venous congestion* is encountered in cardiac decompensation involving the right side of the heart, as can occur in tricuspid or pulmonic valvular disease, chronic cor pulmonale, or following left-sided heart failure. Systemic congestion is associated with only moderately enlarged spleens that rarely exceed 500 gm in weight.

Cirrhosis of the liver is the main cause of massive congestive splenomegaly. The "pipe-stem" hepatic fibrosis of schistosomiasis causes particularly severe congestive splenomegaly, while the diffuse fibrous scarring of alcoholic cirrhosis and pigment cirrhosis also evokes profound enlargements. Other forms of cirrhosis are less commonly implicated.

Congestive splenomegaly is also caused by obstruction of the extrahepatic portal vein or splenic vein. This can stem from *spontaneous portal vein thrombosis*, which is usually associated with some intrahepatic obstructive disease, or inflammation of the portal vein *(pylephlebitis)*, such as follows intraperitoneal infections. Thrombosis of the splenic vein can be caused by infiltrating tumors arising in neighboring organs, such as carcinomas of the stomach or pancreas.

Morphology. Long-standing splenic congestion produces marked enlargement (1000–5000 gm). The organ is firm, and the capsule is usually thickened and fibrous. Microscopically, the red pulp is congested early in the course but becomes increasingly fibrotic and cellular with time. The elevated portal venous pressure stimulates the deposition of collagen in the basement membrane of the sinusoids, which appear dilated because of the rigidity of their walls. The resultant slowing of blood flow from the cords to the sinusoids prolongs the exposure of the blood cells to macrophages, resulting in excessive destruction (hypersplenism).

SPLENIC INFARCTS

Splenic infarcts are common lesions caused by the occlusion of the major splenic artery or any of its branches. The spleen, along with kidneys and brain, ranks as one of the most frequent sites where emboli lodge. In normal-sized spleens, infarcts are most often caused by emboli that arise from the heart. The infarcts can be small or large, single or multiple, or even involve the entire organ. They are usually bland, except in individuals with infectious endocarditis of the mitral or aortic valves, in whom septic infarcts are common. Infarcts are also common in markedly enlarged spleens, regardless of cause, presumably because the blood supply is tenuous and easily compromised.

Morphology. Bland infarcts are characteristically pale, wedge-shaped, and subcapsular in location. The overlying capsule is often covered with fibrin (Fig. 13-40). In septic infarcts this appearance is

modified by the development of suppurative necrosis. In the course of healing, large depressed scars often develop.

3.3.3.2 Neoplasms

Neoplastic involvement of the spleen is rare except in myeloid and lymphoid tumors, which (as already discussed) often cause splenomegaly. Benign fibromas, osteomas, chondromas, lymphangiomas, and hemangiomas may arise in the spleen. Of these, lymphangiomas and hemangiomas are most common and often cavernous in type.

3.3.3.3 Congenital Anomalies

Complete absence of the spleen is rare and is usually associated with other congenital abnormalities, such as situs inversus and cardiac malformations. *Hypoplasia* is a more common finding.

Accessory spleens (spleniculi) are common, being present singly or multiply in 20% to 35% of postmortem examinations. They are small, spherical structures that are histologically and functionally identical to the normal spleen. They can be found at any place within the abdominal cavity. Accessory spleens are of great clinical importance in some hematologic disorders, such as hereditary spherocytosis and immune thrombocytopenia purpura, where splenectomy is used as a treatment. If an accessory spleen is overlooked, the therapeutic benefit of removal of the definitive spleen may be reduced or lost entirely.

3.3.3.4 Rupture

Splenic rupture is usually precipitated by blunt trauma. Much less often, it occurs in the apparent absence of a physical blow. Such "spontaneous ruptures" never involve truly normal spleens but rather stem from some minor physical insult to a spleen made fragile by an underlying condition. The most common predisposing conditions are infectious mononucleosis, malaria, typhoid fever, and lymphoid neoplasms. They cause the spleen to enlarge rapidly, producing a thin, tense capsule that is susceptible to rupture. This dramatic event often precipitates intraperitoneal hemorrhage, which must be treated by prompt splenectomy to prevent death from blood loss. Chronically enlarged spleens are unlikely to rupture because of the toughening effect of extensive reactive fibrosis.

3.3.4 Thymus

Once an organ buried in obscurity, the thymus has risen to a starring role in cell-mediated immunity (as detailed in Chapter 6). Here, our interest centers on the disorders of the gland itself.

The thymus is embryologically derived from the third and, inconstantly, the fourth pair of pharyngeal pouches. At birth it weighs 10 to 35 gm. It grows until puberty, when it achieves a maximum weight of 20 to 50 gm, and thereafter undergoes progressive involution to little more than 5 to 15 gm in the elderly. The thymus can also involute in children and young adults in response to severe illness and HIV infection.

The fully developed thymus is composed of two fused, well-encapsulated lobes. Fibrous extensions of the capsule divide each lobe into numerous lobules, each with an outer cortical layer enclosing the central medulla. Diverse types of cells populate the thymus, but thymic epithelial cells and immature T lymphocytes predominate. The cortical, peripheral, epithelial cells are polygonal in shape and have an abundant cytoplasm with dendritic extensions that contact adjacent cells. In contrast, the epithelial cells in the medulla are densely packed, often spindle-shaped, and have scant cytoplasm devoid of

interconnecting processes. Whorls of medullary epithelial cells create *Hassall corpuscles*, with their characteristic keratinized cores.

As you know from the earlier consideration of the thymus in relation to immunity, progenitor cells of marrow origin migrate to the thymus and mature into T cells, which are exported to the periphery, but only after they have been educated in the "thymic university" to distinguish between self and non-self antigens. During adulthood the thymic production of T cells slowly declines as the organ atrophies.

Macrophages, dendritic cells, a minor population of B lymphocytes, rare neutrophils and eosinophils, and scattered myoid (muscle-like) cells are also found within the thymus. The myoid cells are of particular interest because of the suspicion that they play some role in the development of myasthenia gravis, a musculoskeletal disorder of immune origin.

Pathologic changes within the thymus are limited and will be described here. The changes associated with myasthenia gravis are considered in Chapter 27 .

3.3.4.1 Developmental Disorders

Thymic hypoplasia or *aplasia* is seen in DiGeorge syndrome, which is marked by severe defects in cell-mediated immunity and variable abnormalities of parathyroid development associated with hypoparathyroidism. As discussed in Chapter 5 , DiGeorge syndrome is often associated with other developmental defects as part of the 22q11 deletion syndrome.

Isolated *thymic cysts* are uncommon lesions that are usually discovered incidentally postmortem or during surgery. They rarely exceed 4 cm in diameter, can be spherical or arborizing, and are lined by stratified to columnar epithelium. The fluid contents can be serous or mucinous and are often modified by hemorrhage.

While isolated cysts are not clinically significant, neoplastic thymic masses (whatever their origin) compress and distort adjacent normal thymus and sometimes cause cysts to form. Therefore, the presence of a cystic thymic lesion in a symptomatic patient should provoke a thorough search for a neoplasm, particularly a lymphoma or a thymoma.

3.3.4.2 Thymic Hyperplasia

The term *thymic hyperplasia* is a bit misleading, since it usually applies to the appearance of B-cell germinal centers within the thymus, a finding that is referred to as *thymic follicular hyperplasia*. Such B-cell follicles are present in only small numbers in the normal thymus. Although follicular hyperplasia can occur in a number of chronic inflammatory and immunological states, it is most frequently encountered in myasthenia gravis, in which it is found in 65% to 75% of cases (see Chapter 27). Similar thymic changes are sometimes encountered in Graves' disease, systemic lupus erythematosus, scleroderma, rheumatoid arthritis, and other autoimmune disorders. In other instances, a morphologically normal thymus is simply large for the age of the patient. As mentioned, the size of the thymus varies widely, and whether this constitutes a true hyperplasia or is merely a variant of normal is unclear. The main significance of this form of thymic "hyperplasia" is that it may be mistaken radiologically for a thymoma, leading to unnecessary surgical procedures.

3.3.4.3 Thymomas

A diversity of neoplasms may arise in the thymus—germ cell tumors, lymphomas, carcinoids, and others—but *the designation "thymoma" is restricted to tumors of thymic epithelial cells*. Such tumors typically also contain benign immature T cells (thymocytes).

The WHO has created a classification system based on histology for thymomas, but its clinical utility remains uncertain. We will instead use a classification that relies on the most important prognostic features, the surgical stage and the presence or absence of overt cytologic features of malignancy. In this simple system there are only three histologic subtypes:

- Tumors that are cytologically benign and noninvasive
- Tumors that are cytologically benign but invasive or metastatic
- Tumors that are cytologically malignant (thymic carcinoma)

In all categories, the tumors usually occur in adults older than 40 years of age; thymomas are rare in children. Males and females are affected equally. Most arise in the anterior superior mediastinum, but sometimes they occur in the neck, thyroid, pulmonary hilus, or elsewhere. They are uncommon in the posterior mediastinum. Thymomas account for 20% to 30% of tumors in the anterosuperior mediastinum, which is also a common location for certain lymphomas.

Morphology. Macroscopically, thymomas are lobulated, firm, gray-white masses of up to 15 to 20 cm in size. They sometimes have areas of cystic necrosis and calcification. Most are encapsulated, but 20% to 25% of the tumors penetrate the capsule and infiltrate perithymic tissues and structures.

Noninvasive thymomas are most often composed of medullary-type epithelial cells or a mixture of medullary- and cortical-type epithelial cells. The medullary-type epithelial cells are elongated or spindle-shaped (Fig. 13-41A). There is usually a sparse infiltrate of thymocytes, which often recapitulate the phenotype of medullary thymocytes. In mixed thymomas there is an admixture of polygonal cortical-type epithelial cells and a denser infiltrate of thymocytes. The medullary and mixed patterns together account for about 50% of all thymomas. Tumors that have a substantial proportion of medullary-type epithelial cells are usually noninvasive.

Invasive thymoma refers to a tumor that is cytologically benign but locally invasive. These tumors are much more likely to metastasize. The epithelial cells are most commonly of the cortical variety, with abundant cytoplasm and rounded vesicular nuclei (Fig. 13-41B), and are usually mixed with numerous thymocytes. In some cases, the neoplastic cells show cytologic atypia, a feature that correlates with a propensity for more aggressive behavior. These tumors account for about 20% to 25% of all thymomas. **By definition, invasive thymomas penetrate through the capsule into surrounding structures**. The extent of invasion has been subdivided into various stages, which are beyond our scope. With minimal invasion, complete excision yields a 5-year survival rate of greater than 90%, whereas extensive invasion is associated with a 5-year survival rate of less than 50%.

Thymic carcinoma represents about 5% of thymomas. Macroscopically, they are usually fleshy, obviously invasive masses, sometimes accompanied by metastases to sites such as the lungs. Microscopically, most are **squamous cell carcinomas**. The next most common variant is **lymphoepithelioma-like carcinoma**, a tumor composed of sheets of cells with indistinct borders that bears a close histologic resemblance to nasopharyngeal carcinoma. About 50% of lymphoepithelioma-like carcinomas contain monoclonal EBV genomes, consistent with a role for EBV in their pathogenesis. A variety of other less common histologic patterns of thymic carcinoma have been described; all exhibit cytologic atypia seen in other carcinomas.

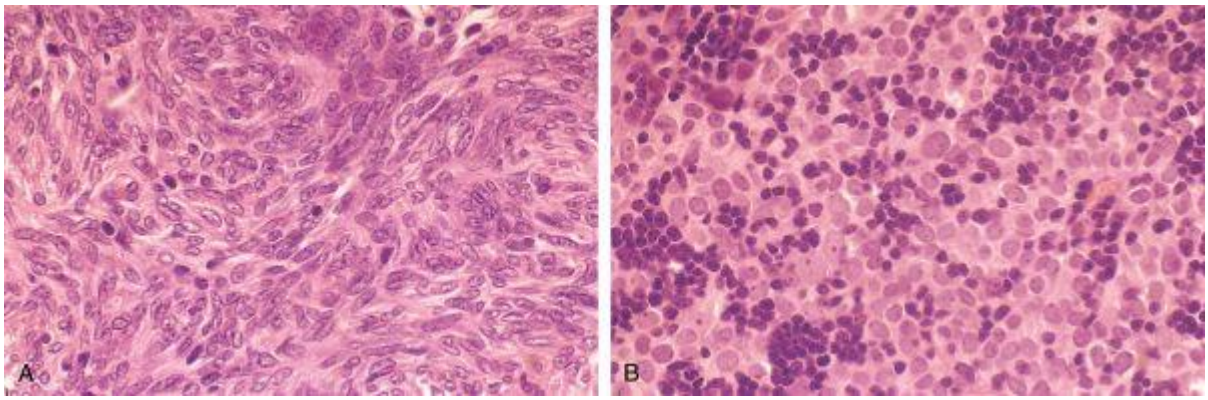

FIGURE 13-41 Thymoma. **A**, Benign thymoma (medullary type). The neoplastic epithelial cells are arranged in a swirling pattern and have bland, oval to elongated nuclei with inconspicuous nucleoli. Only a few small, reactive lymphoid cells are interspersed. **B**, Malignant thymoma, type I. The neoplastic epithelial cells are polygonal and have round to oval, bland nuclei with inconspicuous nucleoli. Numerous small, reactive lymphoid cells are interspersed. The morphologic appearance of this tumor is identical to that of benign thymomas of the cortical type. In this case, however, the tumor was locally aggressive, invading adjacent lung and pericardium.

Clinical Features.

About 40% of thymomas present with symptoms stemming from impingement on mediastinal structures. Another 30% to 45% are detected in the course of evaluating patients with myasthenia gravis. The rest are discovered incidentally during imaging studies or cardiothoracic surgery. In addition to myasthenia gravis, other associated autoimmune disorders include hypogammaglobulinemia, pure red cell aplasia, Graves' disease, pernicious anemia, dermatomyositis-polymyositis, and Cushing syndrome. The basis for these associations is still obscure, but the thymocytes that arise within thymomas give rise to long-lived CD4+ and CD8+ T cells, and cortical thymomas rich in thymocytes are more likely to be associated with autoimmune disease. Hence, it seems likely that abnormalities in the selection or "education" of T cells maturing within the environment of the neoplasm contribute to the development of diverse autoimmune disorders.

3.4 14. Red Blood Cell & Bleeding Disorders

3.4.1 Anemias

In this chapter we will first consider diseases of red cells. Of these, by far the most important are the anemias, red cell deficiency states that most commonly have a non-neoplastic basis. We will then complete our review of blood diseases by discussing the major bleeding disorders.

Anemias

Anemia is defined as a reduction of the total circulating red cell mass below normal limits. Anemia reduces the oxygen-carrying capacity of the blood, leading to tissue hypoxia. In practice, the measurement of red cell mass is not easy, and anemia is usually diagnosed based on a reduction in the

hematocrit (the ratio of packed red cells to total blood volume) and the *hemoglobin concentration* of the blood to levels that are below the normal range. These values correlate with the red cell mass except when there are changes in plasma volume caused by fluid retention or dehydration.

There are many classifications of anemia. We will follow one based on underlying mechanisms that is presented in Table 14-1 . A second clinically useful approach classifies anemia according to alterations in red cell morphology, which often point to particular causes. Morphologic characteristics providing etiologic clues include red cell size (normocytic, microcytic, or macrocytic); degree of hemoglobinization, reflected in the color of red cells (normochromic or hypochromic); and shape. In general, microcytic hypochromic anemias are caused by disorders of hemoglobin synthesis (most often iron deficiency), while macrocytic anemias often stem from abnormalities that impair the maturation of erythroid precursors in the bone marrow. Normochromic, normocytic anemias have diverse etiologies; in some of these anemias, specific abnormalities of red cell shape (best appreciated through visual inspection of peripheral smears) provide an important clue as to the cause. The other indices can also be assessed qualitatively in smears, but precise measurement is carried out in clinical laboratories with special instrumentation. The most useful red cell indices are as follows:

- *Mean cell volume*: the average volume of a red cell expressed in femtoliters (fL)
- *Mean cell hemoglobin*: the average content (mass) of hemoglobin per red cell, expressed in picograms
- *Mean cell hemoglobin concentration*: the average concentration of hemoglobin in a given volume of packed red cells, expressed in grams per deciliter
- *Red cell distribution width*: the coefficient of variation of red cell volume

TABLE 14-1 -- Classification of Anemia According to Underlying Mechanism

Mechanism	Specific Examples
BLOOD LOSS	
Acute blood loss	Trauma
Chronic blood loss	Gastrointestinal tract lesions, gynecologic disturbances[*]
INCREASED RED CELL DESTRUCTION (HEMOLYSIS)	
Inherited genetic defects	
Red cell membrane disorders	Hereditary spherocytosis, hereditary elliptocytosis
Enzyme deficiencies	
Hexose monophosphate shunt enzyme deficiencies	G6PD deficiency, glutathione synthetase deficiency
Glycolytic enzyme deficiencies	Pyruvate kinase deficiency, hexokinase deficiency
Hemoglobin abnormalities	
Deficient globin synthesis	Thalassemia syndromes
Structurally abnormal globins (hemoglobinopathies)	Sickle cell disease, unstable hemoglobins
Acquired genetic defects	
Deficiency of phosphatidylinositol-linked glycoproteins	Paroxysmal nocturnal hemoglobinuria
Antibody-mediated destruction	Hemolytic disease of the newborn (Rh disease), transfusion reactions, drug-induced, autoimmune disorders
Mechanical trauma	
Microangiopathic hemolytic anemias	Hemolytic uremic syndrome, disseminated intravascular coagulation, thrombotic thrombocytopenia purpura

Mechanism	Specific Examples
Cardiac traumatic hemolysis	Defective cardiac valves
Repetitive physical trauma	Bongo drumming, marathon running, karate chopping
Infections of red cells	Malaria, babesiosis
Toxic or chemical injury	Clostridial sepsis, snake venom, lead poisoning
Membrane lipid abnormalities	Abetalipoproteinemia, severe hepatocellular liver disease
Sequestration	Hypersplenism
DECREASED RED CELL PRODUCTION	
Inherited genetic defects	
Defects leading to stem cell depletion	Fanconi anemia, telomerase defects
Defects affecting erythroblast maturation	Thalassemia syndromes
Nutritional deficiencies	
Deficiencies affecting DNA synthesis	B_{12} and folate deficiencies
Deficiencies affecting hemoglobin synthesis	Iron deficiency anemia
Erythropoietin deficiency	Renal failure, anemia of chronic disease
Immune-mediated injury of progenitors	Aplastic anemia, pure red cell aplasia
Inflammation-mediated iron sequestration	Anemia of chronic disease
Primary hematopoietic neoplasms	Acute leukemia, myelodysplasia, myeloproliferative disorders (Chapter 13)
Space-occupying marrow lesions	Metastatic neoplasms, granulomatous disease
Infections of red cell progenitors	Parvovirus B19 infection
Unknown mechanisms	Endocrine disorders, hepatocellular liver disase

G6PD, Glucose-6-phosphate dehydrogenase.

* Most often cause anemia due to iron deficiency, not bleeding per se.

Adult reference ranges for red cell indices are shown in Table 14-2 .

TABLE 14-2 -- Adult Reference Ranges for Red Cells[*]

Measurement (units)	Men	Women
Hemoglobin (gm/dL)	13.6–17.2	12.0–15.0
Hematocrit (%)	39–49	33–43
Red cell count (× 10^6/μL)	4.3–5.9	3.5–5.0
Reticulocyte count (%)	0.5–1.5	
Mean cell volume (fL)	82–96	
Mean cell hemoglobin (pg)	27–33	
Mean cell hemoglobin concentration (gm/dL)	33–37	
Red cell distribution width	11.5–14.5	

* Reference ranges vary among laboratories. The reference ranges for the laboratory providing the result should always be used in interpreting the test result.

Whatever its cause, when sufficiently severe anemia leads to certain clinical features. Patients appear pale. Weakness, malaise, and easy fatigability are common complaints. The lowered oxygen content of the circulating blood leads to dyspnea on mild exertion. Hypoxia can cause fatty change in the liver, myocardium, and kidney. If fatty changes in the myocardium are sufficiently severe, cardiac failure can develop and compound the tissue hypoxia caused by the deficiency of O_2 in the blood. On occasion, the myocardial hypoxia manifests as angina pectoris, particularly when complicated by pre-existing coronary artery disease. With acute blood loss and shock, oliguria and anuria can develop as a result of renal hypoperfusion. Central nervous system hypoxia can cause headache, dimness of vision, and faintness.

ANEMIAS OF BLOOD LOSS

Acute Blood Loss

The effects of acute blood loss are mainly due to the loss of intravascular volume, which if massive can lead to cardiovascular collapse, shock, and death. The clinical features depend on the rate of hemorrhage and whether the bleeding is external or internal. If the patient survives, the blood volume is rapidly restored by the intravascular shift of water from the interstitial fluid compartment. This fluid shift results in hemodilution and a lowering of the hematocrit. The reduction in oxygenation triggers increased secretion of erythropoietin from the kidney, which stimulates the proliferation of committed erythroid progenitors (CFU-E) in the marrow (see Fig. 13-1). It takes about 5 days for the progeny of these CFU-Es to mature and appear as newly released red cells (reticulocytes) in the peripheral blood. The iron in hemoglobin is recaptured if red cells extravasate into tissues, whereas bleeding into the gut or out of the body leads to iron loss and possible iron deficiency, which can hamper the restoration of normal red cell counts.

Significant bleeding results in predictable changes in the blood involving not only red cells, but also white cells and platelets. If the bleeding is sufficiently massive to cause a decrease in blood pressure, the compensatory release of adrenergic hormones mobilizes granulocytes from the intravascular marginal pool and results in *leukocytosis* (see Fig. 13-2). Initially, red cells appear normal in size and color (normocytic, normochromic). However, as marrow production increases there is a striking *increase in the reticulocyte count* (reticulocytosis), which reaches 10% to 15% after 7 days. Reticulocytes are larger in size than normal red cells (macrocytes) and have a blue-red polychromatophilic cytoplasm. Early recovery from blood loss is also often accompanied by *thrombocytosis*, which results from an increase in platelet production.

Chronic Blood Loss

Chronic blood loss induces anemia only when the rate of loss exceeds the regenerative capacity of the marrow or when iron reserves are depleted and iron deficiency anemia appears; this will be discussed later.

HEMOLYTIC ANEMIAS

Hemolytic anemias share the following features:

- Premature destruction of red cells and a shortened red cell life span below the normal 120 days
- Elevated erythropoietin levels and a compensatory increase in erythropoiesis
- Accumulation of hemoglobin degradation products released by red cell breakdown derived from hemoglobin

The physiologic destruction of senescent red cells takes place within mononuclear phagocytes, which are abundant in the spleen, liver, and bone marrow. This process appears to be triggered by age-dependent changes in red cell surface proteins, which lead to their recognition and phagocytosis.[1] *In the great majority of hemolytic anemias the premature destruction of red cells also occurs within phagocytes*, an event that is referred to as *extravascular hemolysis*. If persistent, extravascular hemolysis leads to a hyperplasia of phagocytes manifested by varying degrees of *splenomegaly*.

Extravascular hemolysis is generally caused by alterations that render the red cell less deformable. Extreme changes in shape are required for red cells to navigate the splenic sinusoids successfully. Reduced deformability makes this passage difficult, leading to red cell sequestration and phagocytosis within the cords. *Regardless of the cause, the principal clinical features of extravascular hemolysis are (1) anemia, (2) splenomegaly, and (3) jaundice*. Some hemoglobin inevitably escapes from phagocytes, which leads to variable decreases in plasma haptoglobin, an α_2-globulin that binds free hemoglobin and prevents its excretion in the urine. Because much of the pathologic destruction of red cells occurs in the spleen, individuals with extravascular hemolysis often benefit from splenectomy.

Less commonly, *intravascular hemolysis* predominates. Intravascular hemolysis of red cells may be caused by mechanical injury, complement fixation, intracellular parasites (e.g., falciparum malaria, Chapter 8), or exogenous toxic factors. Causes of mechanical injury include trauma caused by cardiac valves, thrombotic narrowing of the microcirculation, or repetitive physical trauma (e.g., marathon running and bongo drum beating). Complement fixation occurs in a variety of situations in which antibodies recognize and bind red cell antigens. Toxic injury is exemplified by clostridial sepsis, which results in the release of enzymes that digest the red cell membrane.

Whatever the mechanism, *intravascular hemolysis is manifested by (1) anemia, (2) hemoglobinemia, (3) hemoglobinuria, (4) hemosiderinuria, and (5) jaundice*. The large amounts of free hemoglobin released from lysed red cells are promptly bound by haptoglobin, producing a complex that is rapidly cleared by mononuclear phagocytes. As serum haptoglobin is depleted, free hemoglobin oxidizes to methemoglobin, which is brown in color. The renal proximal tubular cells reabsorb and catabolize much of the filtered hemoglobin and methemoglobin, but some passes out in the urine, imparting a red-brown color. Iron released from hemoglobin can accumulate within tubular cells, giving rise to renal hemosiderosis. Concomitantly, heme groups derived from hemoglobinhaptoglobin complexes are catabolized to bilirubin within mononuclear phagocytes, leading to jaundice. Unlike in extravascular hemolysis, splenomegaly is not seen.

In all types of uncomplicated hemolytic anemias, the excess serum bilirubin is unconjugated. The level of hyperbilirubinemia depends on the functional capacity of the liver and the rate of hemolysis. When the liver is normal, jaundice is rarely severe. Excessive bilirubin excreted by the liver into the gastrointestinal tract leads to increased formation and fecal excretion of urobilin (Chapter 18), and often leads to the formation of gallstones derived from heme pigments.

Morphology. Certain changes are seen in hemolytic anemias regardless of cause or type. Anemia and lowered tissue oxygen tension trigger the production of erythropoietin, which stimulates erythroid differentiation and leads to the appearance of **increased numbers of erythroid precursors (normoblasts) in the marrow** (Fig. 14-1). Compensatory increases in erythropoiesis result in a **prominent reticulocytosis in the peripheral blood**. The phagocytosis of red cells leads to hemosiderosis, which is most pronounced in the spleen, liver, and bone marrow. If the anemia is severe, extramedullary hematopoiesis can appear in the liver, spleen, and lymph nodes. With chronic hemolysis, elevated biliary excretion of bilirubin promotes the formation of pigment gallstones

(cholelithiasis).

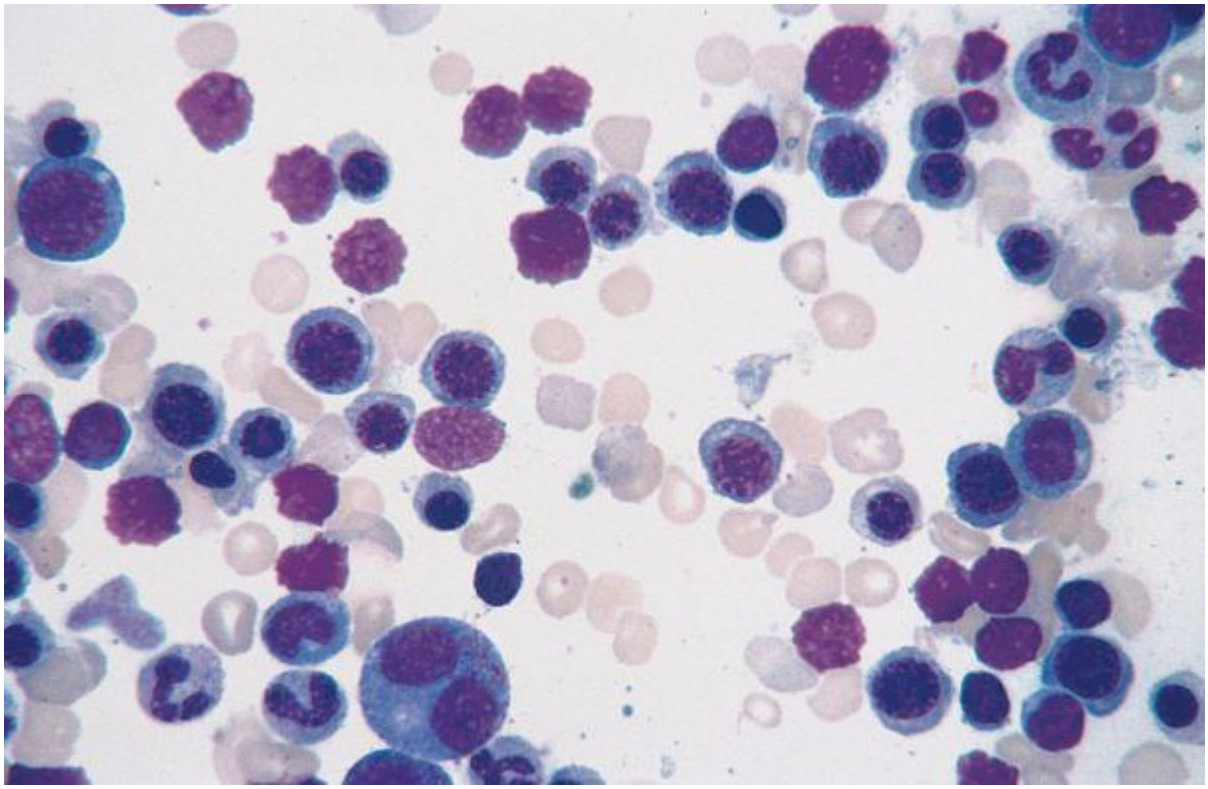

FIGURE 14-1 Marrow smear from a patient with hemolytic anemia. The marrow reveals greatly increased numbers of maturing erythroid progenitors (normoblasts). *(Courtesy of Dr. Steven Kroft, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

The hemolytic anemias can be classified in a variety of ways; here, we classify them according to underlying mechanisms (see Table 14-1). We begin by discussing the major inherited forms of hemolytic anemia, and then move on to the acquired forms that are most common or of particular pathophysiologic interest.

Hereditary Spherocytosis (HS)

This inherited disorder is caused by intrinsic defects in the red cell membrane skeleton that render red cells spheroid, less deformable, and vulnerable to splenic sequestration and destruction.[2] The prevalence of HS is highest in northern Europe, where rates of 1 in 5000 are reported. An autosomal dominant inheritance pattern is seen in about 75% of cases. The remaining patients have a more severe form of the disease that is usually caused by the inheritance of two different defects (a state known as compound heterozygosity).

Pathogenesis.

The remarkable elasticity and durability of the normal red cell are attributable to the physicochemical properties of its specialized membrane skeleton (Fig. 14-2), which lies closely apposed to the internal surface of the plasma membrane. Its chief protein component, spectrin, consists of two polypeptide

chains, α and β, which form intertwined (helical) flexible heterodimers. The "head" regions of spectrin dimers self-associate to form tetramers, while the "tails" associate with actin oligomers. Each actin oligomer can bind multiple spectrin tetramers, thus creating a two-dimensional spectrin-actin skeleton that is connected to the cell membrane by two distinct interactions. The first, involving the proteins ankyrin and band 4.2, binds spectrin to the transmembrane ion transporter, band 3. The second, involving protein 4.1, binds the "tail" of spectrin to another transmembrane protein, glycophorin A.

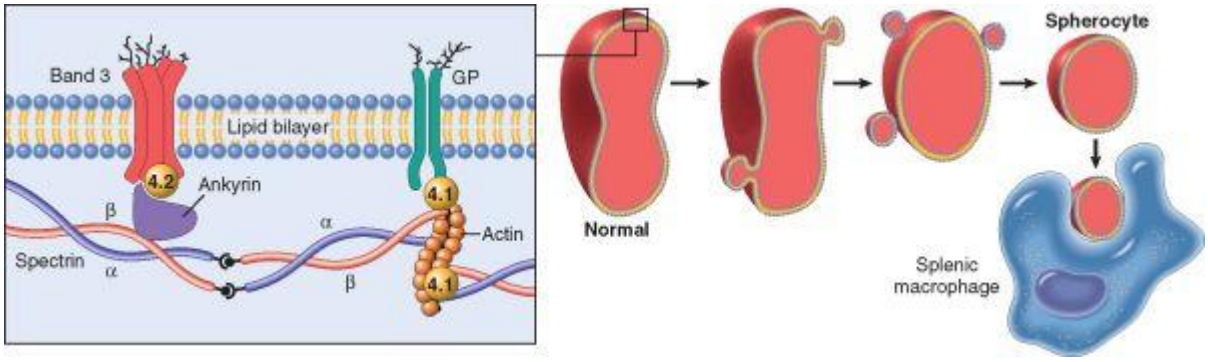

FIGURE 14-2 Role of the red cell membrane skeleton in hereditary spherocytosis. The left panel shows the normal organization of the major red cell membrane skeletal proteins. Various mutations involving α-spectrin, β-spectrin, ankyrin, band 4.2, or band 3 that weaken the interactions between these proteins cause red cells to lose membrane fragments. To accommodate the resultant change in the ratio of surface area to volume these cells adopt a spherical shape. Spherocytic cells are less deformable than normal ones and therefore become trapped in the splenic cords, where they are phagocytosed by macrophages. GP, glycophorin.

HS is caused by diverse mutations that lead to an insufficiency of membrane skeletal components. As a result of these alterations, the life span of the affected red cells is decreased on average to 10 to 20 days from the normal 120 days. The pathogenic mutations most commonly affect ankyrin, band 3, spectrin, or band 4.2, the proteins involved in the first of the two tethering interactions, presumably because this complex is particularly important in stabilizing the lipid bilayer. Most mutations cause shifts in reading frame or introduce premature stop codons, such that the mutated allele fails to produce any protein. The defective synthesis of the affected protein reduces the assembly of the skeleton as a whole and results in a decrease in the density of the membrane skeleton components. Compound heterozygosity for two defective alleles understandably results in a more severe membrane skeleton deficiency. Young HS red cells are normal in shape, but *the deficiency of membrane skeleton reduces the stability of the lipid bilayer, leading to the loss of membrane fragments as red cells age in the circulation*. The loss of membrane relative to cyt oplasm "forces" the cells to assume the smallest possible diameter for a given volume, namely, a sphere.

The invariably beneficial effects of splenectomy prove that the spleen has a cardinal role in the premature demise of spherocytes. The travails of spherocytic red cells are fairly well defined. In the life of the portly inflexible spherocyte, the spleen is the villain. Normal red cells must undergo extreme deformation to leave the cords of Billroth and enter the sinusoids. Because of their spheroidal shape and reduced deformability, the hapless spherocytes are trapped in the splenic cords, where they provide a happy meal for phagocytes. The splenic environment also somehow exacerbates the tendency of HS red cells to lose membrane along with K^+ ions and H_2O; prolonged splenic exposure (erythrostasis), depletion of red cell glucose, and diminished red cell pH have all been suggested to contribute to these abnormalities (Fig. 14-3). After splenectomy the spherocytes persist, but the anemia is corrected.

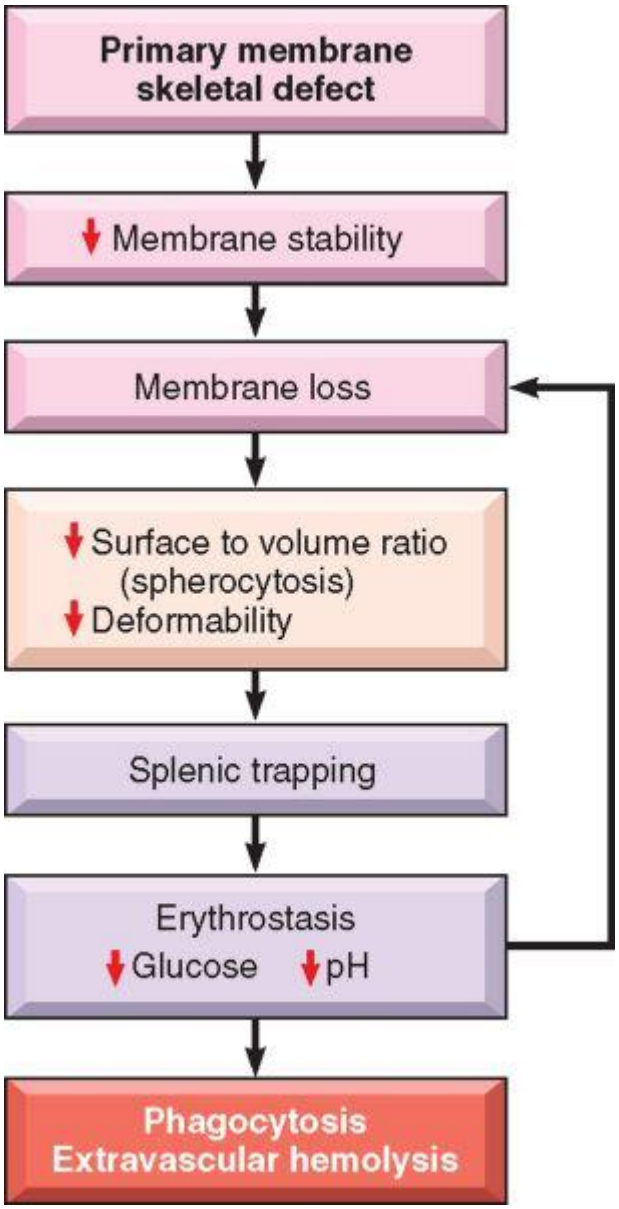

FIGURE 14-3 Pathophysiology of hereditary spherocytosis.

Morphology. The most specific morphologic finding is spherocytosis, apparent on smears as abnormally small, dark-staining (hyperchromic) red cells lacking the central zone of pallor (Fig. 14-4). Spherocytosis is distinctive but not pathognomonic, since other forms of membrane loss, such as in autoimmune hemolytic anemias, also cause the formation of spherocytes. Other features are common to all hemolytic anemias. These include reticulocytosis, marrow erythroid hyperplasia, hemosiderosis, and mild jaundice. Cholelithiasis (pigment stones) occurs in 40% to 50% of affected adults. Moderate splenic enlargement is characteristic (500–1000 gm); in few other hemolytic anemias is the spleen enlarged as much or as consistently. Splenomegaly results from congestion of the cords of Billroth and increased numbers of phagocytes needed to clear the spherocytes.

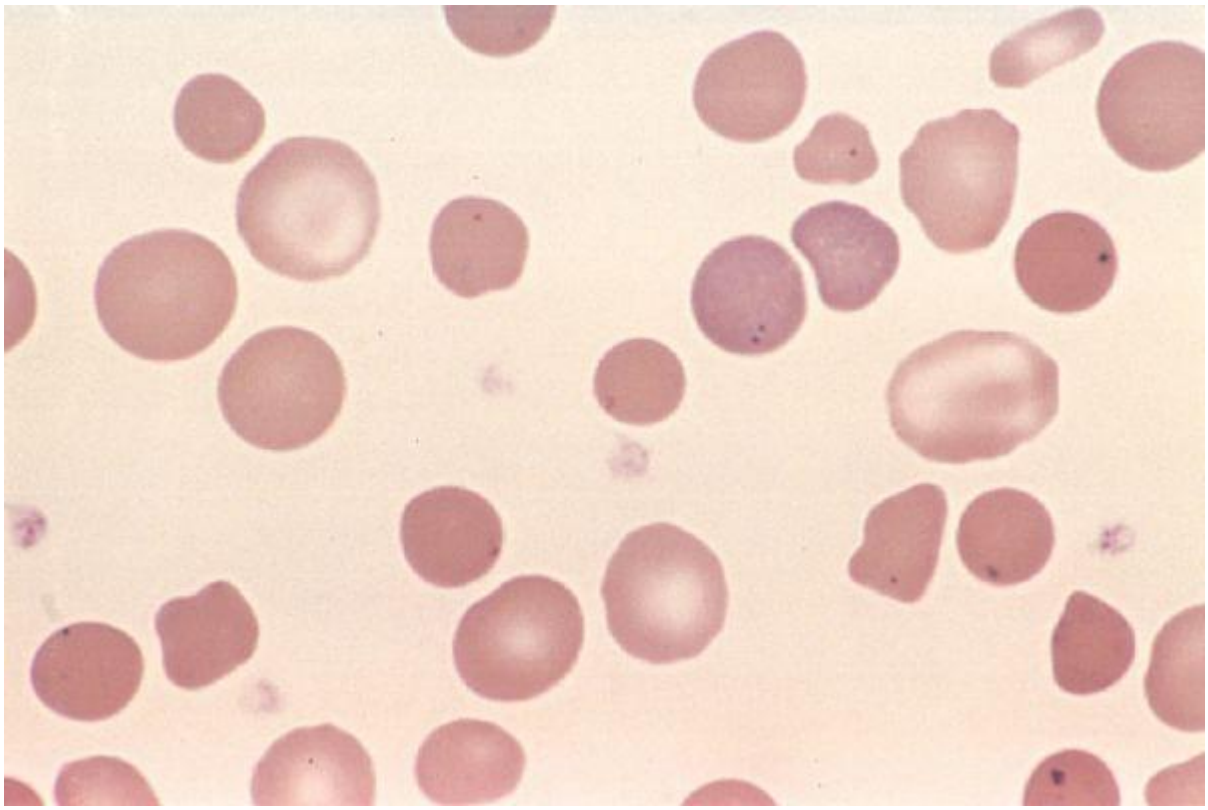

FIGURE 14-4 Hereditary spherocytosis (peripheral smear). Note the anisocytosis and several dark-appearing spherocytes with no central pallor. Howell-Jolly bodies (small dark nuclear remnants) are also present in red cells of this asplenic patient. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Clinical Features.

The diagnosis is based on family history, hematologic findings, and laboratory evidence. In two thirds of the patients the red cells are *abnormally sensitive to osmotic lysis* when incubated in hypotonic salt solutions, which causes the influx of water into spherocytes with little margin for expansion. HS red cells also have an *increased mean cell hemoglobin concentration*, due to dehydration caused by the loss of K^+ and H_2O.

The characteristic clinical features are anemia, splenomegaly, and jaundice. The severity of HS varies greatly. In a small minority (mainly compound heterozygotes) HS presents at birth with marked jaundice and requires exchange transfusions. In 20% to 30% of patients the disease is so mild as to be virtually asymptomatic; here the decreased red cell survival is readily compensated for by increased erythropoiesis. In most, however, the compensatory changes are outpaced, producing a chronic hemolytic anemia of mild to moderate severity. The generally stable clinical course is sometimes punctuated by *aplastic crises*, usually triggered by an acute parvovirus infection. Parvovirus infects and kills red cell progenitors, causing red cell production to cease until an effective immune response commences, generally in 1 to 2 weeks. Because of the reduced life span of HS red cells, cessation of erythropoiesis for even short time periods leads to sudden worsening of the anemia. Transfusions may be necessary to support the patient until the immune response clears the infection. *Hemolytic crises* are produced by intercurrent events leading to increased splenic destruction of red cells (e.g., infectious mononucleosis); these are clinically less significant than aplastic crises. Gallstones, found in many

patients, can also produce symptoms. Splenectomy treats the anemia and its complications, but brings with it the risk of sepsis.

Hemolytic Disease Due to Red Cell Enzyme Defects: Glucose-6-Phosphate Dehydrogenase Deficiency

The red cell is vulnerable to injury by exogenous and endogenous oxidants. *Abnormalities in the hexose monophosphate shunt or glutathione metabolism resulting from deficient or impaired enzyme function reduce the ability of red cells to protect themselves against oxidative injuries and lead to hemolysis*. The most important of these enzyme derangements is the hereditary deficiency of glucose-6-phosphate dehydrogenase (G6PD) activity. G6PD reduces nicotinamide adenine dinucleotide phosphate (NADP) to NADPH while oxidizing glucose-6-phosphate (Fig. 14-5). NADPH then provides reducing equivalents needed for conversion of oxidized glutathione to reduced glutathione, which protects against oxidant injury by catalyzing the breakdown of compounds such as H_2O_2 (Chapter 1).

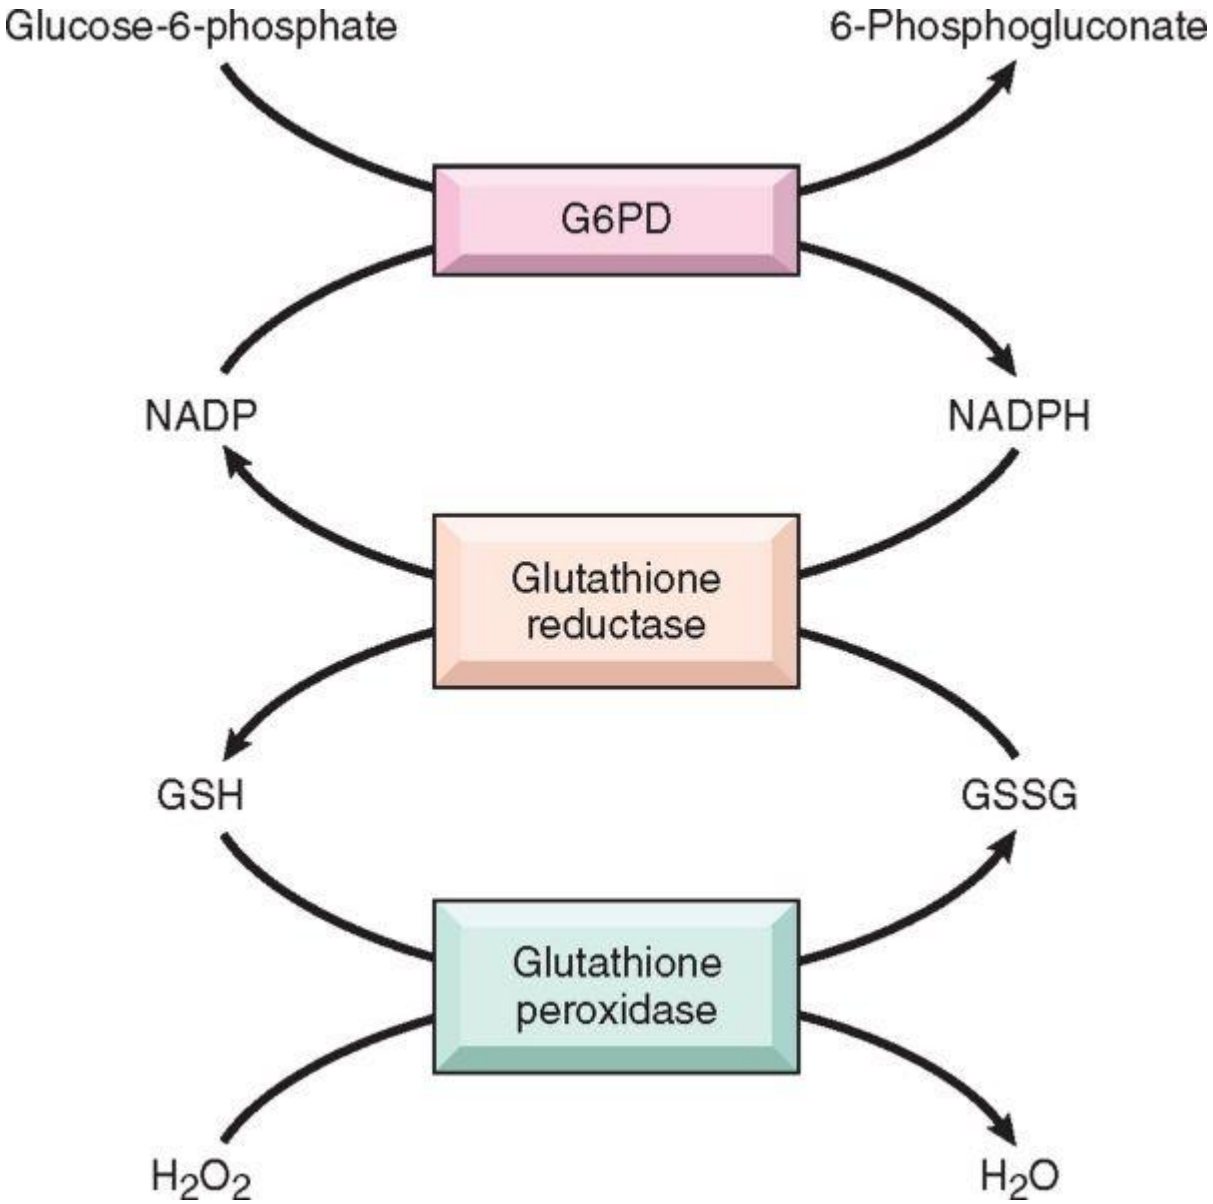

FIGURE 14-5 Role of glucose-6-phosphate dehydrogenase (G6PD) in defense against oxidant injury. The disposal of H_2O_2, a potential oxidant, is dependent on the adequacy of reduced glutathione (GSH), which is generated by the action of the reduced form of nicotinamide

adenine dinucleotide (NADPH). The synthesis of NADPH is dependent on the activity of G6PD. GSSG, oxidized glutathione.

G6PD deficiency is a recessive X-linked trait, placing males at higher risk for symptomatic disease. Several hundred G6PD genetic variants are known, but most are harmless. Only two variants, designated G6PD^{-} and G6PD Mediterranean, cause most of the clinically significant hemolytic anemias. G6PD^{-} is present in about 10% of American blacks; G6PD Mediterranean, as the name implies, is prevalent in the Middle East. The high frequency of these variants in each population is believed to stem from a protective effect against *Plasmodium falciparum* malaria.[3]

G6PD variants associated with hemolysis result in misfolding of the protein, making it more susceptible to proteolytic degradation. Compared with the most common normal variant, G6PD B, the half-life of G6PD^{-} is moderately reduced, whereas that of G6PD Mediterranean is more markedly abnormal. Because mature red cells do not synthesize new proteins, G6PD^{-} or G6PD Mediterranean enzyme activities fall quickly to levels inadequate to protect against oxidant stress as red cells age. Thus, older red cells are much more prone to hemolysis than younger ones.

The episodic hemolysis that is characteristic of G6PD deficiency is caused by exposures that generate oxidant stress. The most common triggers are *infections*, in which oxygen-derived free radicals are produced by activated leukocytes. Many infections can trigger hemolysis; viral hepatitis, pneumonia, and typhoid fever are among those most likely to do so. The other important initiators are *drugs* and certain *foods*. The oxidant drugs implicated are numerous, including antimalarials (e.g., primaquine and chloroquine), sulfonamides, nitrofurantoins, and others. Some drugs cause hemolysis only in individuals with the more severe Mediterranean variant. The most frequently cited food is the fava bean, which generates oxidants when metabolized. “Favism” is endemic in the Mediterranean, Middle East, and parts of Africa where consumption is prevalent. Uncommonly, G6PD deficiency presents as neonatal jaundice or a chronic low-grade hemolytic anemia in the absence of infection or known environmental triggers.

Oxidants cause both intravascular and extravascular hemolysis in G6PD-deficient individuals. Exposure of G6PD-deficient red cells to high levels of oxidants causes the cross-linking of reactive sulfhydryl groups on globin chains, which become denatured and form membrane-bound precipitates known as *Heinz bodies*. These are seen as dark inclusions within red cells stained with crystal violet (Fig. 14-6). Heinz bodies can damage the membrane sufficiently to cause intravascular hemolysis. Less severe membrane damage results in decreased red cell deformability. As inclusion-bearing red cells pass through the splenic cords, macrophages pluck out the Heinz bodies. As a result of membrane damage, some of these partially devoured cells retain an abnormal shape, appearing to have a bite taken out of them (see Fig. 14-6). Other less severely damaged cells revert to a spherocytic shape due to loss of membrane surface area. Both bite cells and spherocytes are trapped in splenic cords and removed rapidly by phagocytes.

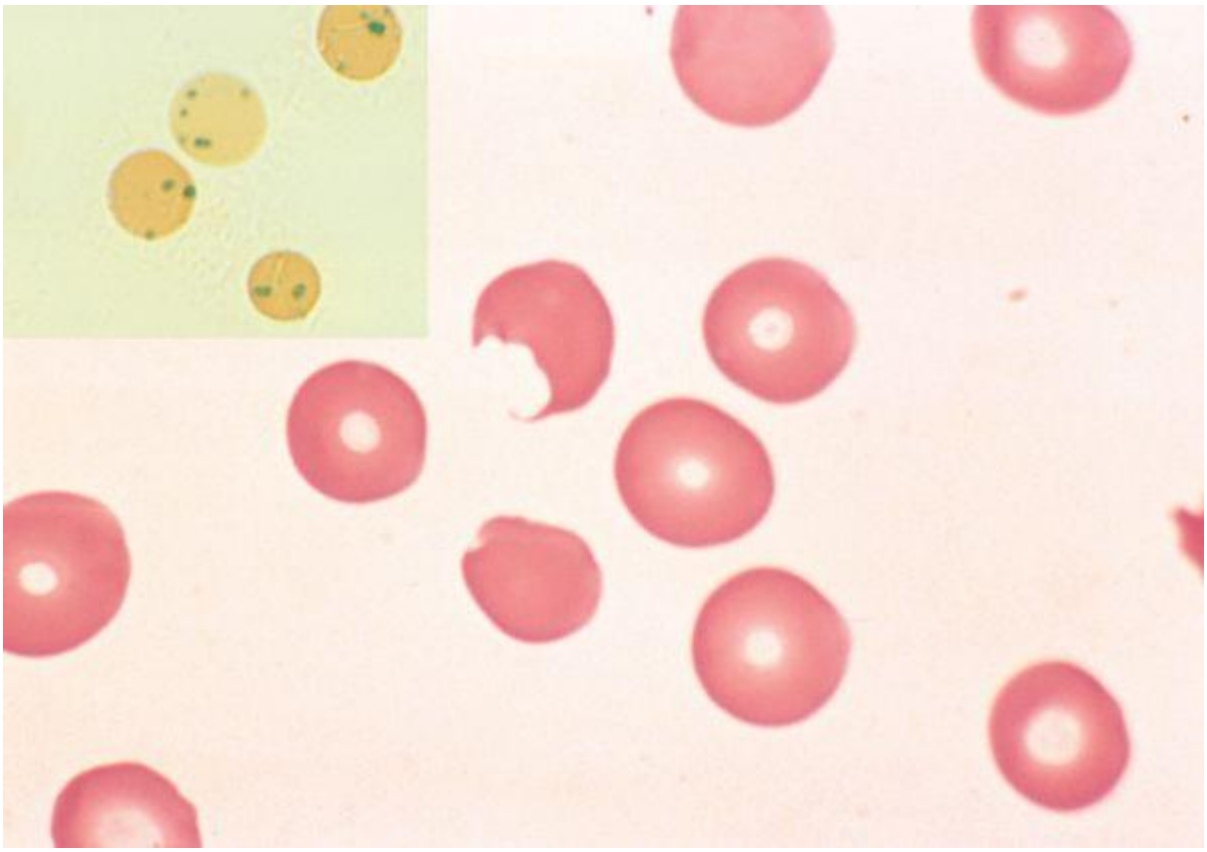

FIGURE 14-6 G6PD deficiency: effects of oxidant drug exposure (peripheral blood smear). *Inset,* Red cells with precipitates of denatured globin (Heinz bodies) revealed by supravital staining. As the splenic macrophages pluck out these inclusions, "bite cells" like the one in this smear are produced. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Acute intravascular hemolysis, marked by anemia, hemoglobinemia, and hemoglobinuria, usually begins 2 to 3 days following exposure of G6PD-deficient individuals to oxidants. The hemolysis tends to be greater in individuals with the highly unstable G6PD Mediterranean variant. Since only older red cells are at risk for lysis, the episode is *self-limited*, since hemolysis ceases when only younger G6PD-replete red cells remain (even if administration of an offending drug continues). The recovery phase is heralded by reticulocytosis. Since hemolytic episodes related to G6PD deficiency occur intermittently, features related to chronic hemolysis (e.g., splenomegaly, cholelithiasis) are absent.

Sickle Cell Disease

Sickle cell disease is a common hereditary hemoglobinopathy that occurs primarily in individuals of African descent. Several hundred different hemoglobinopathies caused by mutations in globin genes are known, but only those associated with sickle cell disease are prevalent enough in the United States to merit discussion. Hemoglobin, as you recall, is a tetrameric protein composed of two pairs of globin chains, each with its own heme group. Normal adult red cells contain mainly HbA ($\alpha_2\beta_2$), along with small amounts of HbA_2 ($\alpha_2\delta_2$) and fetal hemoglobin (HbF; $\alpha_2\gamma_2$). Sickle cell disease is caused by a point mutation in the sixth codon of β-globin that leads to the replacement of a glutamate residue with a valine residue. The abnormal physiochemical properties of the resulting sickle hemoglobin (HbS) are responsible for the disease.

About 8% to 10% of African Americans, or roughly 2 million individuals, are heterozygous for HbS, a largely asymptomatic condition known as sickle cell trait. The offspring of two heterozygotes has a 1 in 4 chance of being homozygous for the sickle mutation, a state that produces symptomatic sickle cell disease. In such individuals, almost all the hemoglobin in the red cell is HbS ($\alpha_2\beta^s_2$). There are about 70,000 individuals with sickle cell disease in the United States. In certain populations in Africa the prevalence of heterozygosity is as high as 30%. This high frequency probably stems from protection afforded by HbS against falciparum malaria.[3]

Pathogenesis.

HbS molecules undergo polymerization when deoxygenated. Initially the red cell cytosol converts from a freely flowing liquid to a viscous gel as HbS aggregates form. With continued deoxygenation aggregated HbS molecules assemble into long needle-like fibers within red cells, producing a distorted sickle or holly-leaf shape.

The presence of HbS underlies the major pathologic manifestations: (1) chronic hemolysis, (2) microvascular occlusions, and (3) tissue damage. Several variables affect the rate and degree of sickling:

- *Interaction of HbS with the other types of hemoglobin in the cell*. In heterozygotes with sickle cell trait, about 40% of the hemoglobin is HbS and the rest is HbA, which interferes with HbS polymerization. As a result, red cells in heterozygous individuals do not sickle except under conditions of profound hypoxia. HbF inhibits the polymerization of HbS even more than HbA; hence, infants do not become symptomatic until they reach 5 or 6 months of age, when the level of HbF normally falls. However, in some individuals HbF expression remains at relatively high levels, a condition known as hereditary persistence of HbF; in these individuals, sickle cell disease is much less severe. Another variant hemoglobin is HbC, in which lysine is substituted for glutamate in the sixth amino acid residue of β-globin. In HbSC cells the percentage of HbS is 50%, as compared with only 40% in HbAS cells. Moreover, HbSC cells tend to lose salt and water and become dehydrated, which increases the intracellular concentration of HbS. Both of these factors increase the tendency for HbS to polymerize. As a result, individuals with HbS and HbC have a symptomatic sickling disorder (termed *HbSC disease*), but it is milder than sickle cell disease. About 2% to 3% of American blacks are asymptomatic HbC heterozygotes, and about 1 in 1250 has HbSC disease.
- *Mean cell hemoglobin concentration* (MCHC). Higher HbS concentrations increase the probability that aggregation and polymerization will occur during any given period of deoxygenation. Thus, intracellular dehydration, which increases the MCHC, facilitates sickling. Conversely, conditions that decrease the MCHC reduce the disease severity. This occurs when the individual is homozygous for HbS but also has coexistent α-thalassemia, which reduces Hb synthesis and leads to milder disease.
- *Intracellular pH*. A decrease in pH reduces the oxygen affinity of hemoglobin, thereby increasing the fraction of deoxygenated HbS at any given oxygen tension and augmenting the tendency for sickling.
- *Transit time of red cells through microvascular beds*. As will be discussed, much of the pathology of sickle cell disease is related to vascular occlusion caused by sickling within microvascular beds. Transit times in most normal microvascular beds are too short for significant aggregation of deoxygenated HbS to occur, and as a result sickling is confined to microvascular beds with slow transit times. Transit times are slow in the normal spleen and bone marrow, which are prominently affected in sickle cell disease, and also in vascular beds that are inflamed. As you will recall from Chapter 2 , the movement of blood through inflamed tissues is slowed because of the adhesion of leukocytes and red cells to activated endothelial cells and the transudation of fluid through leaky vessels. As a result, inflamed vascular beds are prone to sickling and occlusion. Sickle red cells may express elevated levels of several adhesion molecules that have been implicated in binding to endothelial cells. [4] [5] [6] There is also evidence suggesting that sickle red cells induce some degree of endothelial activation,[7] which may be related to the adhesion of red cells and granulocytes, vaso-occlusion–induced hypoxia, and other insults.

Sickling causes cumulative damage to red cells through several mechanisms. As HbS polymers grow, they herniate through the membrane skeleton and project from the cell ensheathed by only the lipid bilayer. This severe derangement in membrane structure causes the influx of $Ca^{[2]+}$ ions, which induce the cross-linking of membrane proteins and activate an ion channel that permits the efflux of K^+ and H_2O.

With repeated episodes of sickling, red cells become increasingly dehydrated, dense, and rigid (Fig. 14-7). Eventually, the most severely damaged cells are converted to end-stage, nondeformable, irreversibly sickled cells, which retain a sickle shape even when fully oxygenated. *The severity of the hemolysis correlates with the percentage of irreversibly sickled cells*, which are rapidly sequestered and removed by mononuclear phagocytes (extravascular hemolysis). Sickled red cells are also mechanically fragile, leading to some intravascular hemolysis as well.

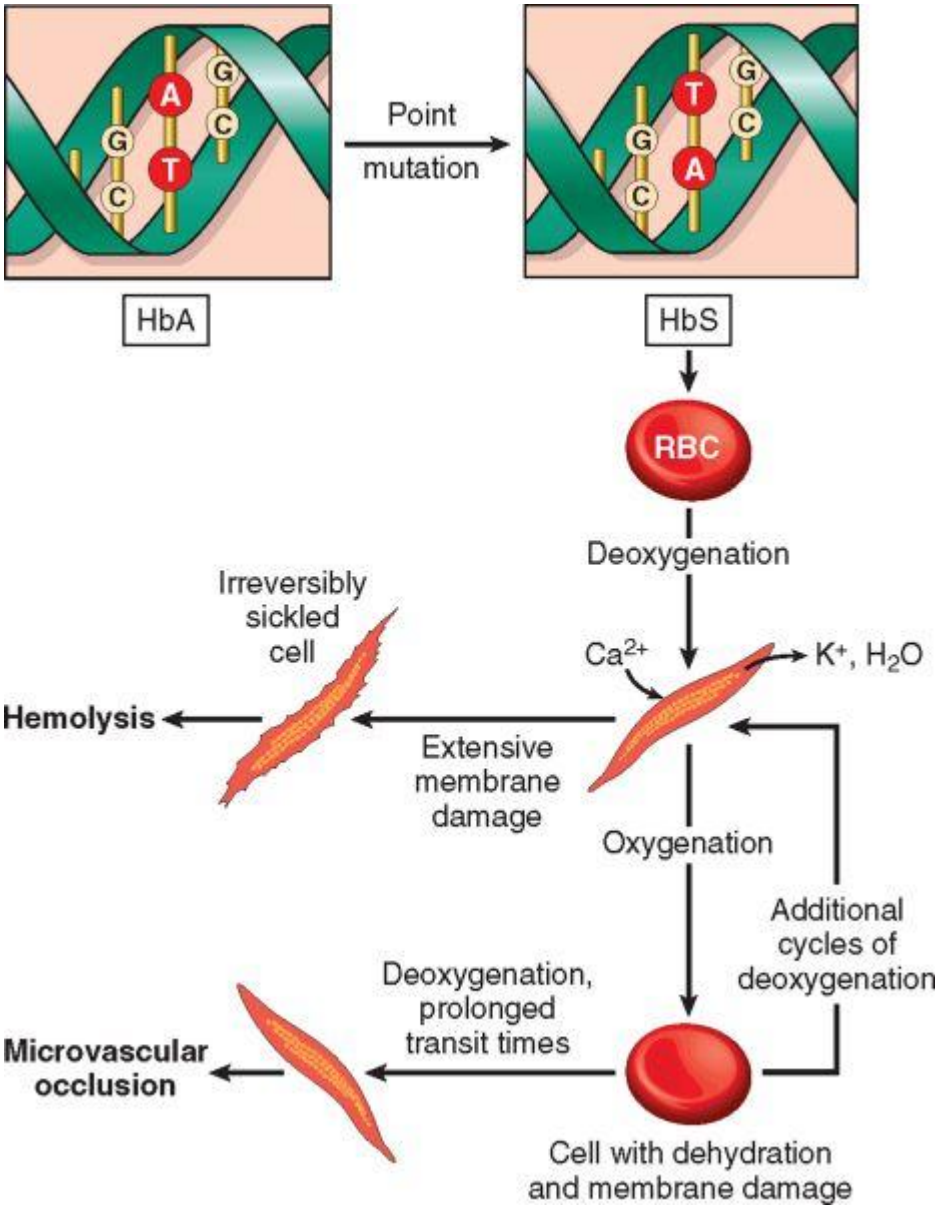

FIGURE 14-7 Pathophysiology of sickle cell disease.

The pathogenesis of the *microvascular occlusions*, which are responsible for the most serious clinical features, is less certain. Microvascular occlusions are not related to the number of irreversibly sickled cells in the blood, but instead may be dependent upon more subtle red cell membrane damage and other factors, such as inflammation, that tend to slow or arrest the movement of red cells through microvascular beds (see Fig. 14-7). As mentioned above, sickle red cells express higher than normal

levels of adhesion molecules and are sticky. Mediators released from granulocytes during inflammatory reactions up-regulate the expression of adhesion molecules on endothelial cells (Chapter 2) and further enhance the tendency for sickle red cells to get arrested during transit throughthe microvasculature. A possible role for inflammatory cells is suggested by observations showing that the leukocyte count correlates with the frequency of pain crises and other measures of tissue damage. The stagnation of red cells within inflamed vascular beds results in extended exposure to low oxygen tension, sickling, and vascular obstruction. Once started, it is easy to envision how a vicious cycle of sickling, obstruction, hypoxia, and more sickling ensues. Depletion of nitric oxide (NO) may also play a part in the vascular occlusions. Free hemoglobin released from lysed sickle red cells can bind and inactivate NO, which is a potent vasodilator and inhibitor of platelet aggregation. Thus, reduced NO increases vascular tone (narrowing vessels) and enhances platelet aggregation, both of which may contribute to red cell stasis, sickling, and (in some instances) thrombosis.

Morphology. In full-blown sickle cell anemia, the peripheral blood demonstrates variable numbers of irreversibly sickled cells, reticulocytosis, and target cells, which result from red cell dehydration (Fig. 14-8). Howell-Jolly bodies (small nuclear remnants) are also present in some red cells due to the asplenia (see below). The bone marrow is hyperplastic as a result of a compensatory erythroid hyperplasia. Expansion of the marrow leads to bone resorption and secondary new bone formation, resulting in prominent cheekbones and changes in the skull that resemble a crew-cut in x-rays. Extramedullary hematopoiesis can also appear. The increased breakdown of hemoglobin can cause pigment gallstones and hyperbilirubinemia.

In early childhood, the spleen is enlarged up to 500 gm by red pulp congestion, which is caused by the trapping of sickled red cells in the cords and sinuses (Fig. 14-9). With time, however, the chronic erythrostasis leads to splenic infarction, fibrosis, and progressive shrinkage, so that by adolescence or early adulthood only a small nubbin of fibrous splenic tissue is left; this process is called **autosplenectomy** (Fig. 14-10). Infarctions caused by vascular occlusions can occur in many other tissues as well, including the bones, brain, kidney, liver, retina, and pulmonary vessels, the latter sometimes producing cor pulmonale. In adult patients, vascular stagnation in subcutaneous tissues often leads to leg ulcers; this complication is rare in children.

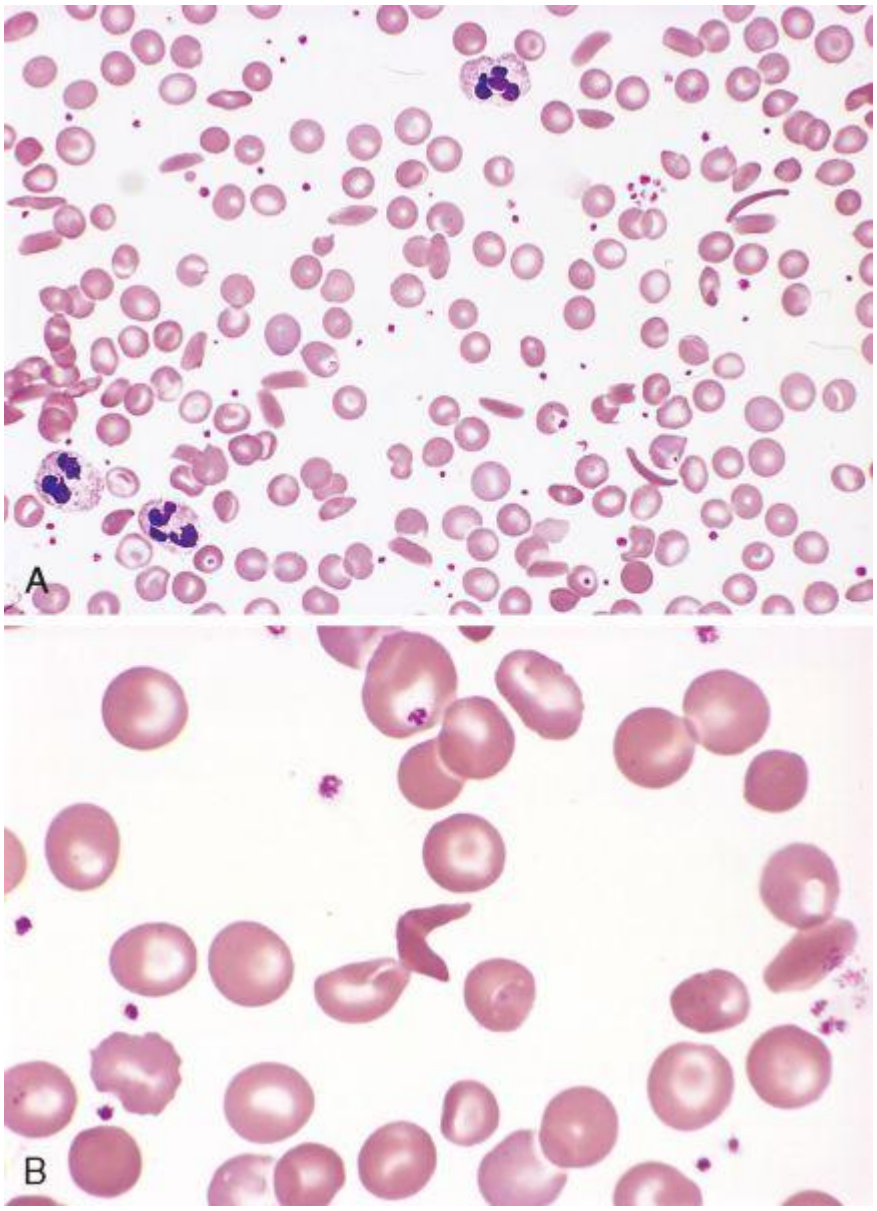

FIGURE 14-8 Sickle cell disease (peripheral blood smear). **A**, Low magnification shows sickle cells, anisocytosis, and poikilocytosis. **B**, Higher magnification shows an irreversibly sickled cell in the center. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Clinical Features.

Sickle cell disease causes a moderately severe hemolytic anemia (hematocrit 18% to 30%) that is associated with reticulocytosis, hyperbilirubinemia, and the presence of irreversibly sickled cells. Its course is punctuatedby a variety of "crises." *Vaso-occlusive crises*, also called *pain crises*, are episodes of hypoxic injury and infarction that cause severe pain in the affected region. Although infection, dehydration, and acidosis (all of which favor sickling) can act as triggers, in most instances no predisposing cause is identified. The most commonly involved sites are the bones, lungs, liver, brain, spleen, and penis. *In children, painful bone crises are extremely common and often difficult to distinguish from acute osteomyelitis*. These frequently manifest as the hand-foot syndrome or dactylitis of the bones of the hands or feet, or both. *Acute chest syndrome* is a particularly dangerous type of vaso-occlusive crisis involving the lungs, which typically presents with fever, cough, chest pain, and pulmonary infiltrates. Pulmonary inflammation (such as may be induced by a simple infection) causes blood flow to become sluggish and "spleenlike," leading to sickling and vaso-occlusion. This compromises pulmonary function, creating a potentially fatal cycle of worsening pulmonary and systemic hypoxemia, sickling, and vaso-occlusion. Other forms of vascular obstruction, particularly stroke, can take a devastating toll. Factors proposed to contribute to stroke include the adhesion of sickle red cells to arterial vascular endothelium and vasoconstriction caused by the depletion of NO by free hemoglobin.[8]

Although occlusive crises are the most common cause of patient morbidity and mortality, several other acute events complicate the course. *Sequestration crises* occur in children with intact spleens. Massive entrapment of sickle red cells leads to rapid splenic enlargement, hypovolemia, and sometimes shock. These complications may be fatal in several cases. Survival from sequestration crises and the acute

chest syndrome requires treatment with exchange transfusions. *Aplastic crises* stem from the infection of red cell progenitors by parvovirus B19, which causes a transient cessation of erythropoiesis and a sudden worsening of the anemia.

In addition to these dramatic crises, chronic tissue hypoxia takes a subtle but important toll. Chronic hypoxia is responsible for a generalized impairment of growth and development, as well as organ damage affecting spleen, heart, kidneys, and lungs. Sickling provoked by hypertonicity in the renal medulla causes damage that eventually leads to hyposthenuria (the inability to concentrate urine), which increases the propensity for dehydration and its attendant risks.

Increased susceptibility to infection with encapsulated organisms is another threat. This is due in large part to altered splenic function, which is severely impaired in children by congestion and poor blood flow, and completely absent in adults because of splenic infarction. Defects of uncertain etiology in the alternative complement pathway also impair the opsonization of bacteria. *Pneumococcus pneumoniae* and *Haemophilus influenzae* septicemia and meningitis, common causes of death, particularly in children, can be reduced by vaccination and prophylactic antibiotics.

It must be emphasized that there is great variation in the clinical manifestations of sickle cell disease. Some individuals are crippled by repeated vaso-occlusive crises, whereas others have only mild symptoms. The basis for this wide range in disease expression is not understood.

The diagnosis is suggested by the clinical findings and the presence of irreversibly sickled red cells and is confirmed by various tests for sickle hemoglobin. In general, these involve mixing a blood sample with an oxygen-consuming reagent, such as metabisulfite, which induces sickling of red cells if HbS is present. Hemoglobin electrophoresis is also used to demonstrate the presence of HbS and exclude other sickle syndromes, such as HbSC disease. Prenatal diagnosis is possible by analysis of fetal DNA obtained by amniocentesis or chorionic biopsy.

The outlook for patients with sickle cell disease has improved considerably over the last 10 to 20 years. About 90% of patients survive to age 20, and close to 50% survive beyond the fifth decade. A mainstay of treatment is an inhibitor of DNA synthesis, hydroxyurea, which has several beneficial effects. These include (1) an increase in red cell HbF levels, which occurs by unknown mechanisms; and (2) an anti-inflammatory effect, which stems from an inhibition of white cell production. These activities (and possibly others[9]) are believed to act in concert to decrease crises related to vascular occlusions in both children and adults.

Thalassemia Syndromes

The thalassemia syndromes are a heterogeneous group of disorders caused by inherited mutations that decrease the synthesis of adult hemoglobin, HbA ($\alpha_2\beta_2$). The two α chains in HbA are encoded by an identical pair of α-globin genes on chromosome 16, while the two β chains are encoded by a single β-globin gene on chromosome 11. β-Thalassemia is caused by deficient synthesis of β chains, whereas α-thalassemia is caused by deficient synthesis of α chains. The hematologic consequences of diminished synthesis of one globin chain stem not only from hemoglobin deficiency but also from a relative excess of the other globin chain, particularly in β-thalassemia. Thalassemia syndromes are endemic in the Mediterranean basin, the Middle East, tropical Africa, the Indian subcontinent, and Asia, and in aggregate are among the most common inherited disorders of humans. As with sickle cell disease and other common inherited red cell disorders, their prevalence seems to be explained by the protection they afford heterozygous carriers against malaria.[3] Although we will discuss the thalassemia syndromes with other inherited forms of anemia associated with hemolysis, *it is important to recognize that the defects in globin synthesis that underlie these disorders also impair red cell production and contribute to the pathogenesis of these disorders*.

β-Thalassemias

The β-thalassemias are caused by mutations that diminish the synthesis of β-globin chains. The clinical severity varies because of heterogeneity in the causative mutations. We will begin our discussion with the molecular lesions in β-thalassemia and then relate the clinical variants to specific underlying molecular defects.

Molecular Pathogenesis.

The causative mutations fall into two categories: (1) β^0 *mutations*, associated with absent β-globin synthesis, and (2) β^+ *mutations*, characterized by reduced (but detectable) β-globin synthesis. Sequencing of β-thalassemia genes has revealed more than 100 different causative mutations, mostly consisting of point mutations. Details of these mutations and their effects are found in specialized texts. Figure 14-11 gives a few illustrative examples.

- *Splicing mutations. These are the most common cause of* β^+*-thalassemia*. Most of these mutations lie within introns, while a few are located within exons. Some of these mutations destroy the normal RNA splice junctions and completely prevent the production of normal β-globin mRNA, resulting in β^0-thalassemia. Others create an "ectopic" splice site within an intron. Because the flanking normal splice sites remain, both normal and abnormal splicing occurs and some normal β-globin mRNA is made, resulting in β^+-thalassemia.
- *Promoter region mutations*. These mutations reduce transcription by 75% to 80%. Some normal β-globin is synthesized; thus, these mutations are associated with β^+-thalassemia.
- *Chain terminator mutations. These are the most common cause of* β^0*-thalassemia*. Two subtypes of mutations fall into this category. The most common type creates a new stop codon within an exon; the second introduces small insertions or deletions that shift the mRNA reading frames (frameshift mutations; see Chapter 5). Both block translation and prevent the synthesis of any functional β-globin.

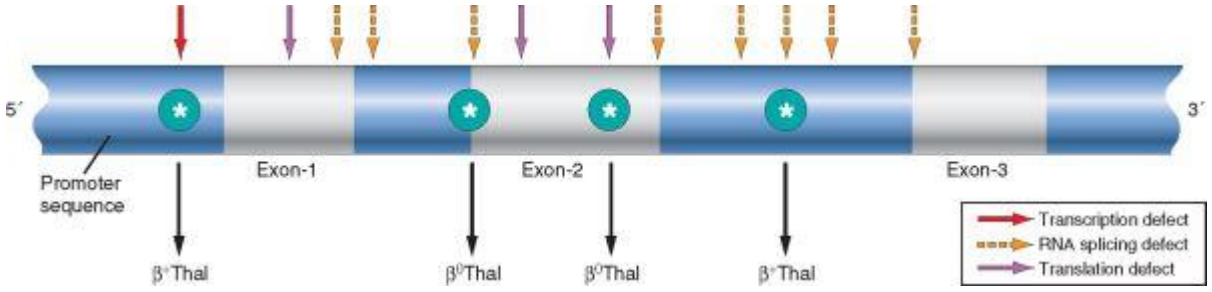

FIGURE 14-11 Distribution of β-globin gene mutations associated with β-thalassemia. Arrows denote sites where point mutations giving rise to β^0 or β^+ thalassemia have been identified.

Impaired β-globin synthesis results in anemia by two mechanisms (Fig. 14-12). The deficit in HbA synthesis produces "underhemoglobinized" hypochromic, microcytic red cells with subnormal oxygen transport capacity. Even more important is the diminished survival of red cells and their precursors, which results from the imbalance in α- and β-globin synthesis. Unpaired α chains precipitate within red cell precursors, forming insoluble inclusions. These inclusions cause a variety of untoward effects, but *membrane damage is the proximal cause of most red cell pathology*. Many red cell precursors succumb to membrane damage and undergo apoptosis. In severe β-thalassemia, it is estimated that 70% to 85% of red cell precursors suffer this fate, which leads to *ineffective erythropoiesis*. Those red cells that are released from the marrow also bear inclusions and membrane damage and are prone to splenic sequestration and *extravascular hemolysis*.

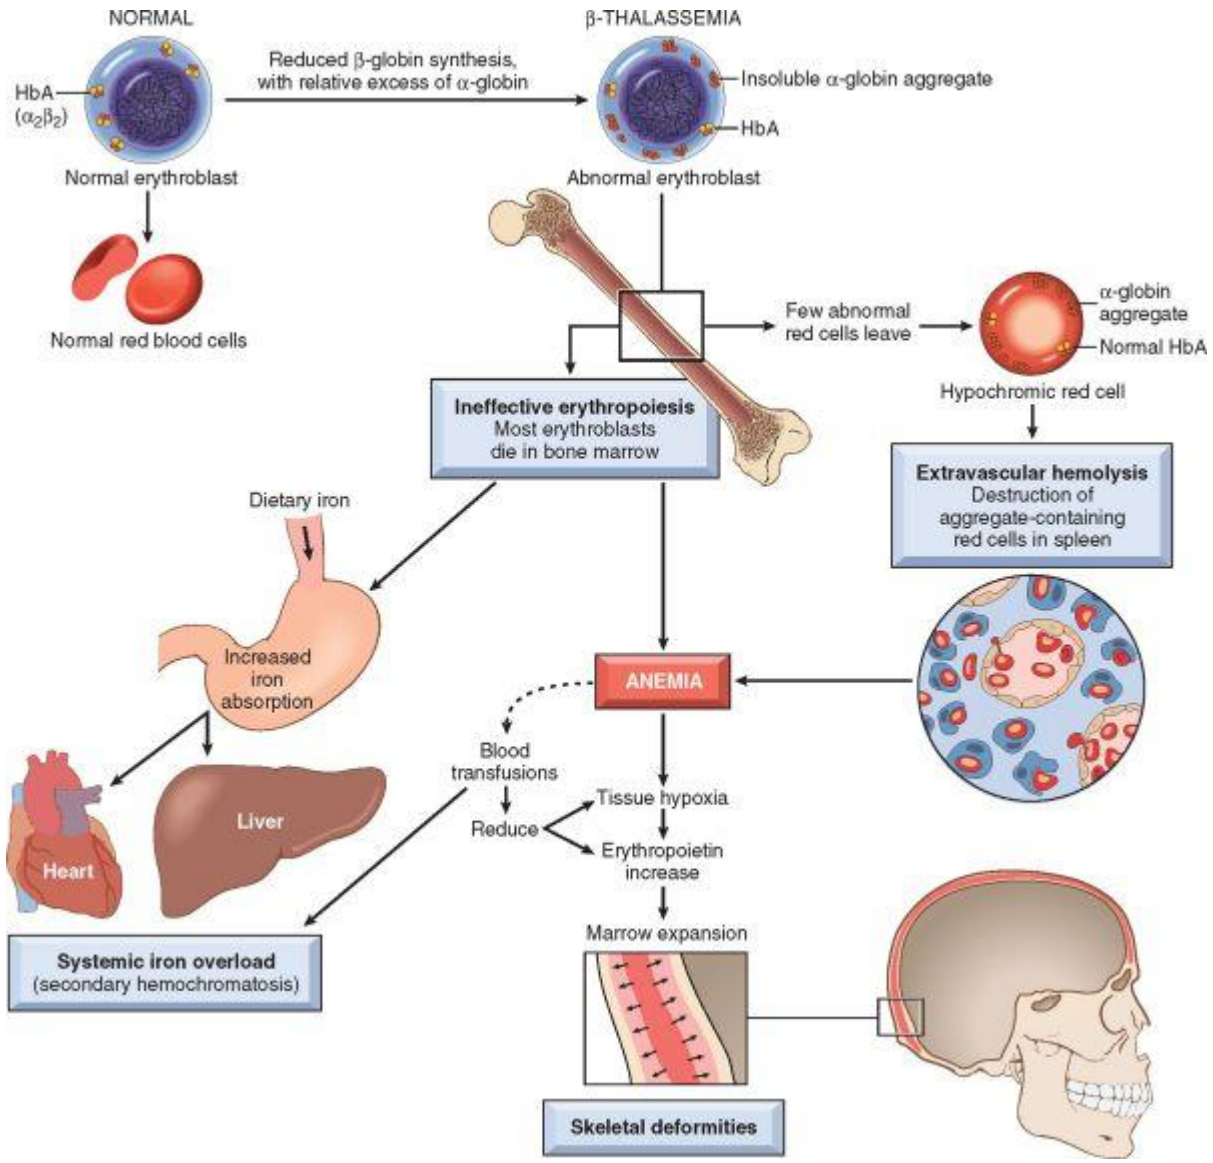

FIGURE 14-12 Pathogenesis of β-thalassemia major. Note that the aggregates of unpaired α-globin chains, a hallmark of the disease, are not visible in routinely stained blood smears. Blood transfusions are a double-edged sword, diminishing the anemia and its attendant complications, but also adding to the systemic iron overload.

In severe β-thalassemia, ineffective erythropoiesis creates several additional problems. Erythropoietic drive in the setting of severe uncompensated anemia leads to massive erythroid hyperplasia in the marrow and extensive extramedullary hematopoiesis. The expanding mass of red cell precursors erodes the bony cortex, impairs bone growth, and produces skeletal abnormalities (described later). Extramedullary hematopoiesis involves the liver, spleen, and lymph nodes, and in extreme cases produces extraosseous masses in the thorax, abdomen, and pelvis. The metabolically active erythroid progenitors steal nutrients from other tissues that are already oxygen-starved, causing severe cachexia in untreated patients.

Another serious complication of ineffective erythropoiesis is the excessive absorption of dietary iron. Ineffective erythropoiesis suppresses the circulating levels of hepcidin, a critical negative regulator of iron absorption (described later under iron deficiency anemia). Low levels of hepcidin and the iron load

of repeated blood transfusions inevitably lead to severe iron overload unless preventive steps are taken. Secondary injury to parenchymal organs, particularly the iron-laden liver, often follows and sometimes induces secondary hemochromatosis (Chapter 18).

Clinical Syndromes.

The relationships of clinical phenotypes to underlying genotypes are summarized in Table 14-3 . Clinical classification of β-thalassemia is based on the severity of the anemia, which in turn depends on the genetic defect (β^+ or β^0) and the gene dosage (homozygous or heterozygous). In general, individuals with two β-thalassemia alleles (β^+/β^+, β^+/β^0, or β^0/β^0) have a severe, transfusion-dependent anemia called β-*thalassemia major*. Heterozygotes with one βthalassemia gene and one normal gene (β^+/β or β^0/β) usually have a mild asymptomatic microcytic anemia. This condition is referred to as β-*thalassemia minor* or β-*thalassemia trait*. A third genetically heterogeneous variant of moderate severity is called β-*thalassemia intermedia*. This category includes milder variants of β^+/β^+ or β^+/β^0-thalassemia and unusual forms of heterozygous β-thalassemia. Some patients with β-thalassemia intermedia have two defective β-globin genes and an α-thalassemia gene defect, which lessens the imbalance in α- and β-chain synthesis. In other rare but informative cases, individuals have a single β-globin defect and one or two extra copies of normal α-globin genes (stemming from a gene duplication event), which worsens the chain imbalance.[10] These unusual forms of the disease serve to emphasize the cardinal role of unpaired α-globin chains in the pathology. The clinical and morphologic features of β-thalassemia intermedia are not described separately but can be surmised from the following discussions of β-thalassemia major and β-thalassemia minor.

TABLE 14-3 -- Clinical and Genetic Classification of Thalassemias

Clinical Syndromes	Genotype	Clinical Features	Molecular Genetics
β-THALASSEMIAS			
β-Thalassemia major	Homozygous β-thalassemia (β^0/β^0, β^+/β^+, β^0/β^+)	Severe; requires blood transfusions	Mainly point mutations that lead to defects in the transcription, splicing, or translation of β-globin mRNA
β-Thalassemia intermedia	Variable (β^0/β^+, β^+/β^+, β^0/β, β^+/β)	Severe but does not require regular blood transfusions	
β-Thalassemia minor	Heterozygous β-thalassemia (β^0/β, β^+/β)	Asymptomatic with mild or absent anemia; red cell abnormalities seen	
α-THALASSEMIAS			
Silent carrier	-/α α/α	Asymptomatic; no red cell abnormality	Mainly gene deletions
α-Thalassemia trait	-/- α/α (Asian)	Asymptomatic, like β-thalassemia minor	
	-/α -/α (black African, Asian)		
HbH disease	-/- -/α	Severe; resembles β-thalassemia intermedia	
Hydrops fetalis	-/- -/-	Lethal in utero without transfusions	

β-Thalassemia Major.

β-thalassemia major is most common in Mediterranean countries, parts of Africa, and Southeast Asia. In the United States the incidence is highest in immigrants from these areas. The anemia manifests 6 to 9 months after birth as hemoglobin synthesis switches from HbF to HbA. In untransfused patients, hemoglobin levels are 3 to 6 gm/dL. The red cells may completely lack HbA (β^0/β^0 genotype) or contain small amounts (β^+/β^+ or β^0/β^+ genotypes). The major red cell hemoglobin is HbF, which is markedly elevated. HbA_2 levels are sometimes high but more often are normal or low.

Morphology. Blood smears show severe red cell abnormalities, including marked variation in size (anisocytosis) and shape (poikilocytosis), microcytosis, and hypochromia. Target cells (so called because hemoglobin collects in the center of the cell), basophilic stippling, and fragmented red cells are also common. Inclusions of aggregated α chains are efficiently removed by the spleen and not easily seen. The reticulocyte count is elevated, but it is lower than expected for the severity of anemia because of the ineffective erythropoiesis. Variable numbers of poorly hemoglobinized nucleated red cell precursors (normoblasts) are seen in the peripheral blood as a result of "stress" erythropoiesis and abnormal release from sites of extramedullary hematopoiesis.

Other major alterations involve the bone marrow and spleen. In the untransfused patient there is a striking expansion of hematopoietically active marrow. In the bones of the face and skull the burgeoning marrow erodes existing cortical bone and induces new bone formation, giving rise to a "crew-cut" appearance on x-ray (Fig. 14-13). Both phagocyte hyperplasia and extramedullary hematopoiesis contribute to enlargement of the spleen, which can weigh as much as 1500 gm. The liver and the lymph nodes can also be enlarged by extramedullary hematopoiesis.

Hemosiderosis and secondary hemochromatosis, the two manifestations of iron overload (Chapter 18), occur in almost all patients. The deposited iron often damages organs, most notably the heart, liver, and pancreas.

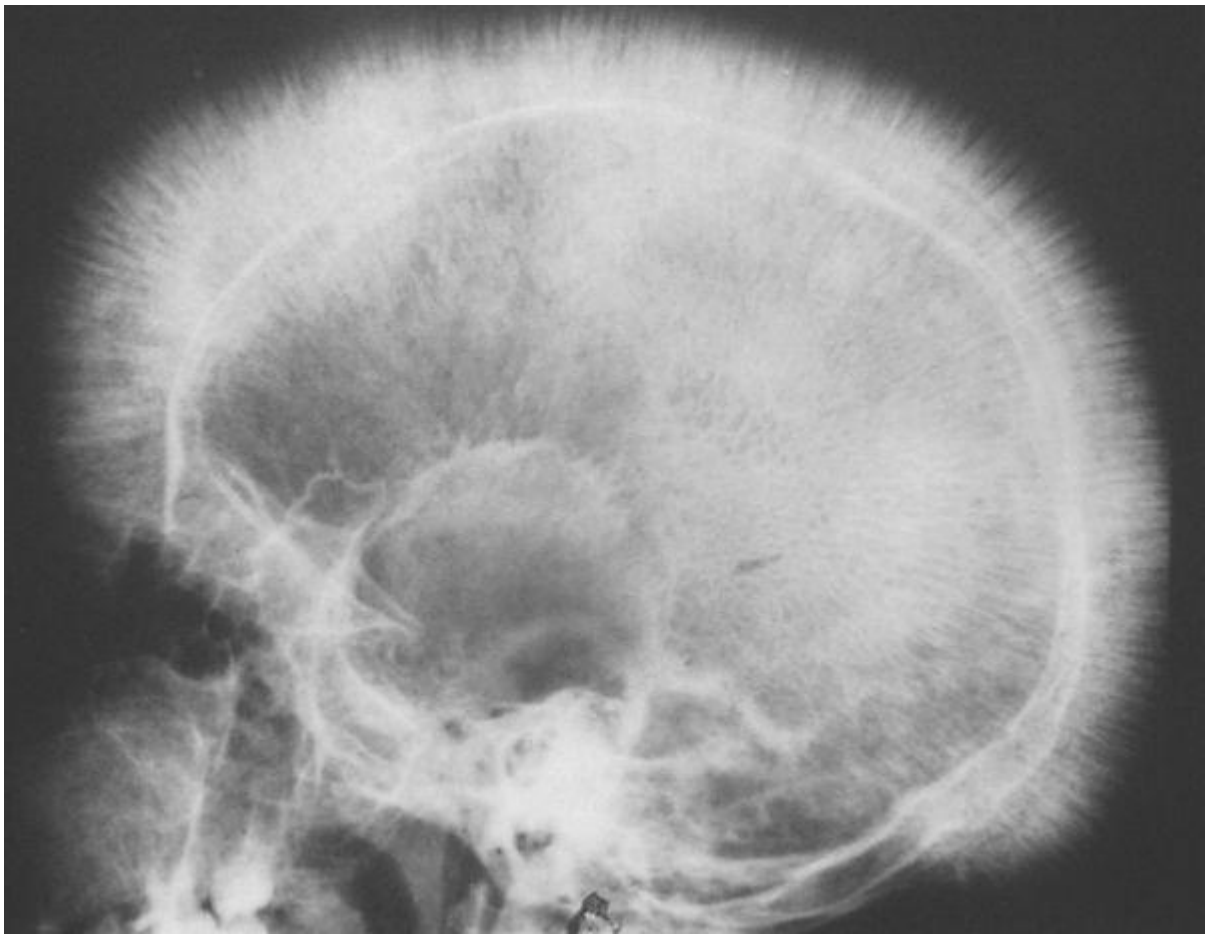

FIGURE 14-13 Thalassemia: x-ray film of the skull showing new bone formation on the outer table, producing perpendicular radiations resembling a crewcut. *(Courtesy of Dr. Jack Reynolds, Department of Radiology, University of Texas Southwestern Medical School, Dallas, TX.)*

The clinical course of β-thalassemia major is brief unless blood transfusions are given. Untreated children suffer from growth retardation and die at an early age from the effects of anemia. In those who survive long enough, the cheekbones and other bony prominences are enlarged and distorted. Hepatosplenomegaly due to extramedullary hematopoiesis is usually present. Although blood transfusions improve the anemia and suppress complications related to excessive erythropoiesis, they lead to complications of their own. Cardiac disease resulting from progressive iron overload and secondary hemochromatosis (Chapter 18) is an important cause of death, particularly in heavily transfused patients, who must be treated with iron chelators to prevent or reduce this complication. With transfusions and iron chelation, survival into the third decade is possible, but the overall outlook remains guarded. Bone marrow transplantation is the only therapy offering a cure and is being used increasingly.[11] Prenatal diagnosis is possible by molecular analysis of DNA.

β-Thalassemia Minor.

β-Thalassemia minor is much more common than β-thalassemia major and understandably affects the same ethnic groups. Most patients are heterozygous carriers of a β^{+} or β^{0} allele. These patients are

usually asymptomatic. Anemia, if present, is mild. The peripheral blood smear typically shows some red cell abnormalities, including hypochromia, microcytosis, basophilic stippling, and target cells. Mild erythroid hyperplasia is seen in the bone marrow. Hemoglobin electrophoresis usually reveals an increase in HbA_2 ($\alpha_2\delta_2$) to 4% to 8% of the total hemoglobin (normal, 2.5% ± 0.3%), which is a reflection of an elevated ratio of δ-chain to β-chain synthesis. HbF levels are generally normal or occasionally slightly increased.

Recognition of β-thalassemia trait is important for two reasons: (1) differentiation from the hypochromic microcytic anemia of iron deficiency and (2) genetic counseling. Iron deficiency can usually be excluded through measurement of serum iron, total iron-binding capacity, and serum ferritin (as described later under iron deficiency anemia). The increase in HbA_2 is diagnostically useful, particularly in individuals (such as women of childbearing age) who are at risk for both β-thalassemia trait and iron deficiency.

α-Thalassemias

The α-thalassemias are caused by inherited deletions that result in reduced or absent synthesis of α-globin chains. Normally, there are four α-globin genes, and the severity of α-thalassemia depends on how many α-globin genes are affected. As in β-thalassemias, the anemia stems both from a lack of adequate hemoglobin and the effects of excess unpaired non-α chains (β, γ, and δ), which vary in type at different ages. In newborns with α-thalassemia, excess unpaired γ-globin chains form γ_4 tetramers known as hemoglobin Barts, whereas in older children and adults excess β-globin chains form β_4 tetramers known as HbH. Since free β and γ chains are more soluble than free α chains and form fairly stable homotetramers, hemolysis and ineffective erythropoiesis are less severe than in β-thalassemias. A variety of molecular lesions give rise to α-thalassemia, but gene deletion is the most common cause of reduced α-chain synthesis.

Clinical Syndromes.

The clinical syndromes are determined and classified by the number of α-globin genes that are deleted. Each of the four α-globin genes normally contributes 25% of the total α-globin chains. α-Thalassemia syndromes stem from combinations of deletions that remove one to four α-globin genes. Not surprisingly, the severity of the clinical syndrome is proportional to the number of α-globin genes that are deleted. The different types of α-thalassemia and their salient clinical features are listed in Table 14-3 .

Silent Carrier State.

This is associated with the deletion of a single α-globin gene, which causes a barely detectable reduction in α-globin chain synthesis. These individuals are completely asymptomatic, but they have slight microcytosis.

α-Thalassemia Trait.

This is caused by the deletion of two α-globin genes from a single chromosome (α/α α/α), or the deletion of one α-globin gene from each of the two chromosomes (α/—α α/—α) (see Table 14-3). The former genotype is more common in Asian populations, the latter in regions of Africa. Both genotypes produce similar quantitative deficiencies of α-globin and are clinically identical, but have different implications for the children of affected individuals, who are at risk of clinically significant α-thalassemia (HbH disease or hydrops fetalis) only when at least one parent has the α/—α haplotype. As a result, symptomatic α-thalassemia is relatively common in Asian populations and rare in black African populations. The clinical picture in α-thalassemia trait is identical to that described for β-thalassemia

minor, that is, small red cells (microcytosis), minimal or no anemia, and no abnormal physical signs. HbA_2 levels are normal or low.

Hemoglobin H Disease.

This is caused by deletion of three α-globin genes. As already discussed, HbH disease is most common in Asian populations. With only one normal α-globin gene, the synthesis of α chains is markedly reduced, and tetramers of β-globin, called HbH, form. HbH has an extremely high affinity for oxygen and therefore is not useful for oxygen delivery, leading to tissue hypoxia disproportionate to the level of hemoglobin. Additionally, HbH is prone to oxidation, which causes it to precipitate out and form intracellular inclusions that promote red cell sequestration and phagocytosis in the spleen. The result is a moderately severe anemia resembling β-thalassemia intermedia.

Hydrops Fetalis

This most severe form of α-thalassemia is caused by deletion of all four α-globin genes. In the fetus, excess γ-globin chains form tetramers (hemoglobin Barts) that have such a high affinity for oxygen that they deliver little to tissues. Survival in early development is due to the expression of ζ chains, an embryonic globin that pairs with γ chains to form a functional $\zeta_2\gamma_2$ Hb tetramer. Signs of fetal distress usually become evident by the third trimester of pregnancy. In the past, severe tissue anoxia led to death in utero or shortly after birth; with intrauterine transfusion many such infants are now saved. The fetus shows severe pallor, generalized edema, and massive hepatosplenomegaly similar to that seen in hemolytic disease of the newborn (Chapter 10). There is a lifelong dependence on blood transfusions for survival, with the associated risk of iron overload. Bone marrow transplantation can be curative.[11]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a disease that results from acquired mutations in the phosphatidylinositol glycan complementation group A gene (PIGA), an enzyme that is essential for the synthesis of certain cell surface proteins. PNH has an incidence of 2 to 5 per million in the United States. Despite its rarity, it has fascinated hematologists because it is the only hemolytic anemia caused by an acquired genetic defect. Recall that proteins are anchored into the lipid bilayer in two ways. Most have a hydrophobic region that spans the cell membrane; these are called transmembrane proteins. The others are attached to the cell membrane through a covalent linkage to a specialized phospholipid called glycosylphosphatidylinositol (GPI). In PNH, these GPI-linked proteins are deficient because of somatic mutations that inactivate PIGA. PIGA is X-linked and subject to lyonization (random inactivation of one X chromosome in cells of females; Chapter 5). As a result, a single acquired mutation in the active *PIGA* gene of any given cell is sufficient to produce a deficiency state. Because the causative mutations occur in a hematopoietic stem cell, all of its clonal progeny (red cells, white cells, and platelets) are deficient in GPI-linked proteins. Typically the mutant clone coexists with the progeny of normal stem cells that are not PIGA deficient.

Remarkably, most normal individuals harbor small numbers of bone marrow cells with *PIGA* mutations identical to those that cause PNH. It is hypothesized that these cells increase in numbers (thus producing clinically evident PNH) only in rare instances where they have a selective advantage, such as in the setting of autoimmune reactions against GPI-linked antigens.[12] Such a scenario might explain the frequent association of PNH and aplastic anemia, a marrow failure syndrome (discussed later) that has an autoimmune basis in many individuals.

PNH blood cells are deficient in three GPI-linked proteins that regulate complement activity: (1) decay–accelerating factor, or CD55; (2) membrane inhibitor of reactive lysis, or CD59; and (3) C8 binding

protein. Of these factors, the most important is CD59, a potent inhibitor of C3 convertase that prevents the spontaneous activation of the alternative complement pathway.

Red cells, platelets, and granulocytes deficient in these GPI-linked factors are abnormally susceptible to lysis or injury by complement. In red cells this manifests as *intravascular hemolysis*, which is caused by the C5b-C9 membrane attack complex. The hemolysis is paroxysmal and nocturnal in only 25% of cases; chronic hemolysis without dramatic hemoglobinuria is more typical. The tendency for red cells to lyse at night is explained by a slight decrease in blood pH during sleep, which increases the activity of complement. The anemia is variable but usually mild to moderate in severity. The loss of heme iron in the urine (hemosiderinuria) eventually leads to iron deficiency, which can exacerbate the anemia if untreated.

Thrombosis is the leading cause of disease-related death in individuals with PNH. About 40% of patients suffer from venous thrombosis, often involving the hepatic, portal, or cerebral veins. Dysfunction of platelets due to the absence of certain GPI-linked proteins contributes to the prothrombotic state, as does the absorption of NO by free hemoglobin (as discussed under sickle cell disease).[13] About 5% to 10% of patients eventually develop acute myeloid leukemia or a myelodysplastic syndrome, possibly because hematopoietic stem cells have suffered some type of genetic damage.

PNH is diagnosed by flow cytometry, which provides a sensitive means for detecting red cells that are deficient in GPI-linked proteins such as CD59 (Fig. 14-14). Several therapeutic approaches are available, none of which is entirely satisfactory. Infusion of a monoclonal antibody inhibitor of C5a greatly reduces the hemolysis but exposes patients to an increased risk of serious or fatal meningococcal infections (as is true of individuals with inherited complement defects). Immunosuppressive drugs are sometimes beneficial for those with evidence of marrow aplasia. The only cure is bone marrow transplantation.

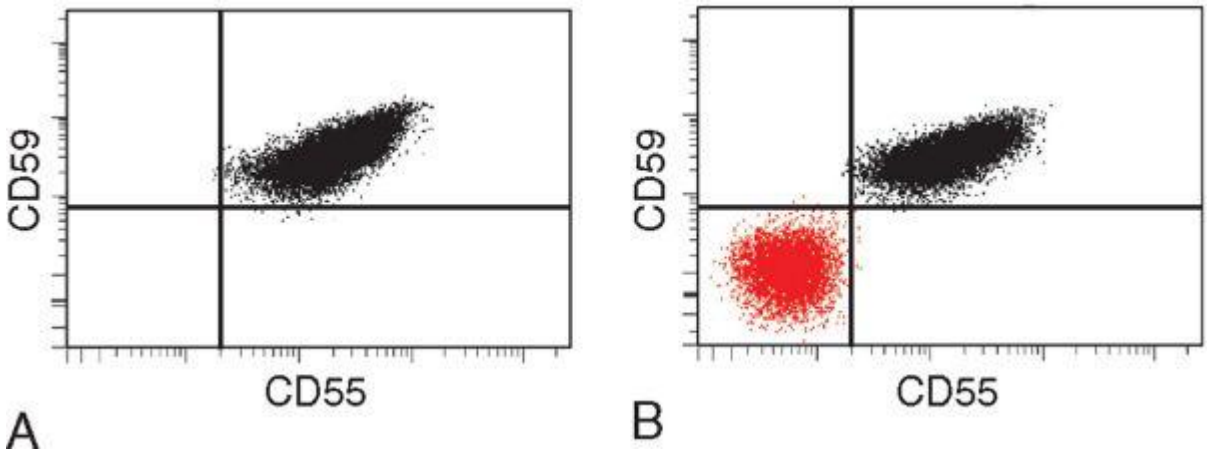

FIGURE 14-14 Paroxysmal nocturnal hemoglobinuria (PNH). **A**, Flow cytogram of blood from a normal individual shows that the red cells express two phosphatidylinositol glycan (PIG)–linked membrane proteins, CD55 and CD59, on their surfaces. **B**, Flow cytogram of blood from a patient with PNH shows a population of red cells that is deficient in both CD55 and CD59. As is typical of PNH, a second population of CD55+/CD59+ red cells that is derived from residual normal hematopoietic stem cells is also present. *(Courtesy of Dr. Scott Rodig, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

Hemolytic anemias in this category are caused by antibodies that bind to red cells, leading to their premature destruction. Although these disorders are commonly referred to as autoimmune hemolytic anemias, the designation immunohemolytic anemia is preferred because in some instances the immune reaction is initiated by an ingested drug. Immunohemolytic anemia can be classified based on the characteristics of the responsible antibody (Table 14-4).

TABLE 14-4 -- Classification of Immunohemolytic Anemias

WARM ANTIBODY TYPE (IgG ANTIBODIES ACTIVE AT 37°C)
Primary (idiopathic)
Secondary
Autoimmune disorders (particularly systemic lupus erythematosus)
Drugs
Lymphoid neoplasms
COLD AGGLUTININ TYPE (IgM ANTIBODIES ACTIVE BELOW 37°C)
Acute (mycoplasmal infection, infectious mononucleosis)
Chronic
Idiopathic
Lymphoid neoplasms
COLD HEMOLYSIN TYPE (IgG ANTIBODIES ACTIVE BELOW 37°C)
Rare; occurs mainly in children following viral infections

The diagnosis of immunohemolytic anemia requires the detection of antibodies and/or complement on red cells from the patient. This is done using the *direct Coombs antiglobulin test*, in which the patient's red cells are mixed with sera containingantibodies that are specific for human immunoglobulin or complement. If either immunoglobulin or complement is present on the surface of the red cells, the multivalent antibodies cause agglutination, which is easily appreciated visually as clumping. In the *indirect Coombs antiglobulin test*, the patient's serum is tested for its ability to agglutinate commercially available red cells bearing particular defined antigens. This test is used to characterize the antigen target and temperature dependence of the responsible antibody. Quantitative immunological tests to measure such antibodies directly are also available.

Warm Antibody Type.

This is the most common form of immunohemolytic anemia. About 50% of cases are idiopathic (primary); the others are related to a predisposing condition (see Table 14-4) or exposure to a drug. Most causative antibodies are of the IgG class; less commonly, IgA antibodies are culpable. The red cell hemolysis is mostly extravascular. IgG-coated red cells bind to Fc receptors on phagocytes, which remove red cell membrane during “partial” phagocytosis. As in hereditary spherocytosis, the loss of membrane converts the red cells to spherocytes, which are sequestered and removed in the spleen. Moderate splenomegaly due to hyperplasia of splenic phagocytes is usually seen.

As with other autoimmune disorders, the cause of primary immunohemolytic anemia is unknown. In many cases, the antibodies are directed against the Rh blood group antigens. The mechanisms of drug-

induced immunohemolytic anemia are better understood. Two different mechanisms have been described.

- *Antigenic drugs*. In this setting hemolysis usually follows large, intravenous doses of the offending drug and occurs 1 to 2 weeks after therapy is initiated. These drugs, exemplified by penicillin and cephalosporins, bind to the red cell membrane and are recognized by anti-drug antibodies. Sometimes the antibodies bind only to the drug, as in penicillin-induced hemolysis. In other cases, such as in quinidine-induced hemolysis, the antibodies recognize a complex of the drug and a membrane protein. The responsible antibodies sometimes fix complement and cause intravascular hemolysis, but more often they act as opsonins that promote extravascular hemolysis within phagocytes.
- *Tolerance-breaking drugs*. These drugs, of which the antihypertensive agent α-methyldopa is the prototype, induce in some unknown manner the production of antibodies against red cell antigens, particularly the Rh blood group antigens. About 10% of patients taking α-methyldopa develop autoantibodies, as assessed by the direct Coombs test, and roughly 1% develop clinically significant hemolysis.

Cold Agglutinin Type.

This form of immunohemolytic anemia is caused by IgM antibodies that bind red cells avidly at low temperatures (0°–4°C).[14] It is less common than warm antibody immunohemolytic anemia, accounting for 15% to 30% of cases. Cold agglutinin antibodies sometimes appear transiently following certain infections, such as with *Mycoplasma pneumoniae*, Epstein-Barr virus, cytomegalovirus, influenza virus, and human immunodeficiency virus (HIV). In these settings the disorder is self-limited and the antibodies rarely induce clinically important hemolysis. Chronic cold agglutinin immunohemolytic anemia occurs in association with certain B-cell neoplasms or as an idiopathic condition.

Clinical symptoms result from binding of IgM to red cells in vascular beds where the temperature may fall below 30°C, such as in exposed fingers, toes, and ears. IgM binding agglutinates red cells and fixes complement rapidly. As the blood recirculates and warms, IgM is released, usually before complement-mediated hemolysis can occur. However, the transient interaction with IgM is sufficient to deposit sublytic quantities of C3b, an excellent opsonin, which leads to the removal of affected red cells by phagocytes in the spleen, liver, and bone marrow. The hemolysis is of variable severity. Vascular obstruction caused by agglutinated red cells results in pallor, cyanosis, and Raynaud phenomenon (Chapter 11) in body parts exposed to cold temperature.

Cold Hemolysin Type.

Cold hemolysins are autoantibodies responsible for an unusual entity known as *paroxysmal cold hemoglobinuria*. This rare disorder causes substantial, sometimes fatal, intravascular hemolysis and hemoglobinuria. The autoantibodies are IgGs that bind to the P blood group antigen on the red cell surface[14] in cool, peripheral regions of the body. Complement-mediated lysis occurs when the cells recirculate to warm central regions, since the complement cascade functions more efficiently at 37°C. Most cases are seen in children following viral infections; in this setting the disorder is transient, and most of those affected recover within 1 month.

Treatment of warm antibody immunohemolytic anemia centers on the removal of initiating factors (i.e., drugs); when this is not feasible, immunosuppressive drugs and splenectomy are the mainstays.[15] Chronic cold agglutinin immunohemolytic anemia caused by IgM antibodies is more difficult to treat.[14]

Hemolytic Anemia Resulting from Trauma to Red Cells

The most significant hemolysis caused by trauma to red cells is seen in individuals with cardiac valve prostheses and microangiopathic disorders. Artificial mechanical cardiac valves are more frequently implicated than are bioprosthetic porcine valves. The hemolysis stems from shear forces produced by turbulent blood flow and pressure gradients across damaged valves. Microangiopathic hemolytic anemia

is most commonly seen with disseminated intravascular coagulation, but it also occurs in thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), malignant hypertension, systemic lupus erythematosus, and disseminated cancer. The common pathogenic feature in these disorders is a microvascular lesion that results in luminal narrowing, often due to the deposition of fibrin and platelets. These vascular changes produce shear stresses that mechanically injure passing red cells. Regardless of the cause, traumatic damage leads to the appearance of red cell fragments (schistocytes), "burr cells," "helmet cells," and "triangle cells" in blood smears (Fig. 14-15).

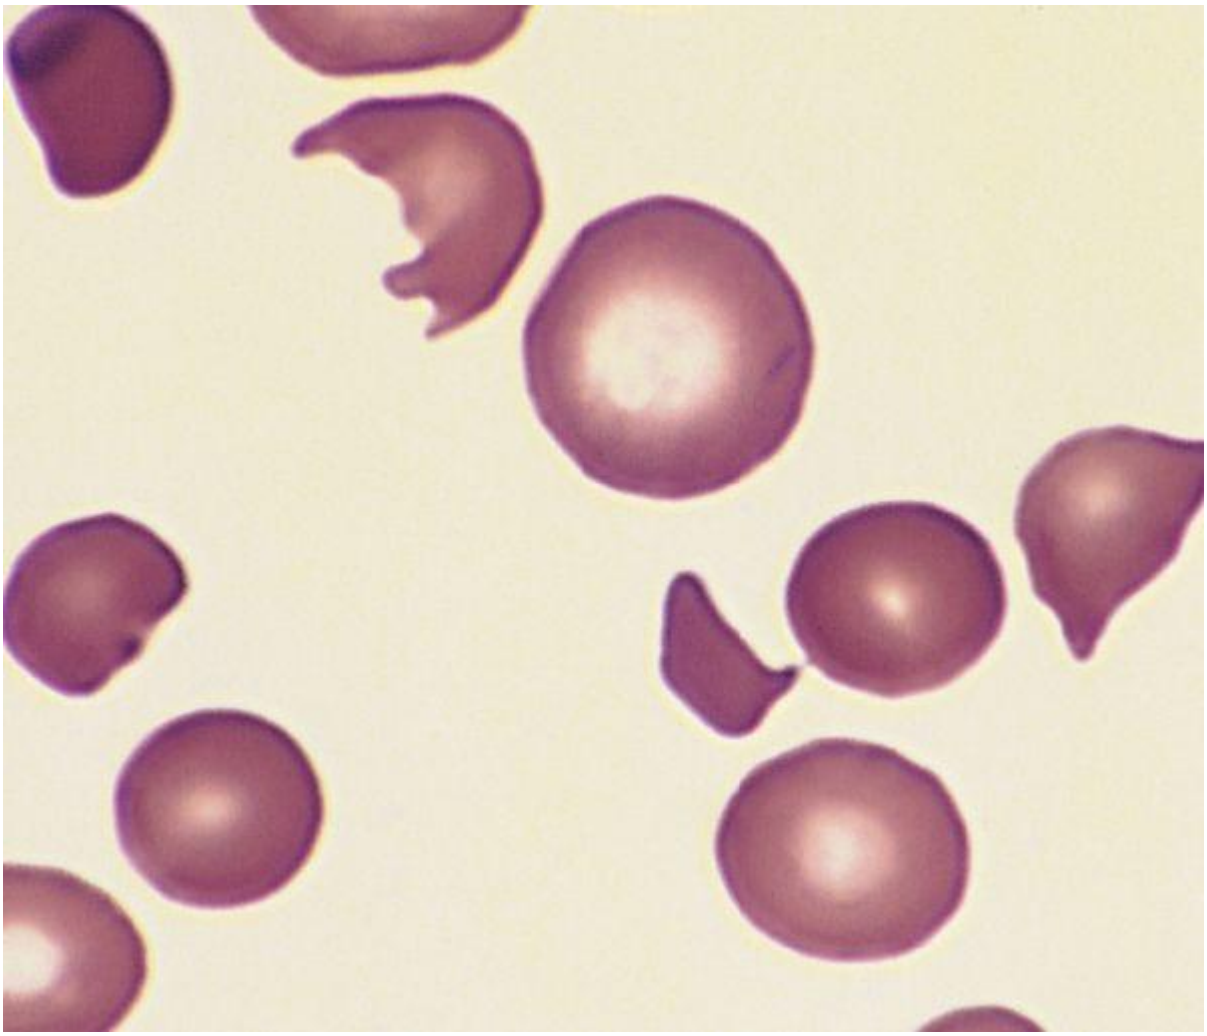

FIGURE 14-15 Microangiopathic hemolytic anemia. A peripheral blood smear from a person with hemolytic-uremic syndrome shows several fragmented red cells. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

ANEMIAS OF DIMINISHED ERYTHROPOIESIS

Although the anemias that stem from the inadequate production of red cells are heterogeneous, they can be classified into several major categories based on pathophysiology (see Table 14-1). The most common and important anemias associated with red cell underproduction are those caused by nutritional deficiencies, followed by those that arise secondary to renal failure and chronic inflammation. Also included are less common disorders that lead to generalized bone marrow failure, such as aplastic

anemia, primary hematopoietic neoplasms (discussed in Chapter 13), and infiltrative disorders that lead to marrow replacement (such as metastatic cancer and disseminated granulomatous disease). We will first discuss the extrinsic causes of diminished erythropoiesis, which are more common and clinically important, and then move to the non-neoplastic intrinsic causes.

Megaloblastic Anemias

The common theme among the various causes of megaloblastic anemia (Table 14-5 *) is an impairment of DNA synthesis that leads to distinctive morphologic changes, including abnormally large erythroid precursors and red cells*. The following discussion first describes the common features and then turns to the two principal types: pernicious anemia (the major form of vitamin B_{12} deficiency anemia) and folate deficiency anemia.

TABLE 14-5 -- Causes of Megaloblastic Anemia

VITAMIN B_{12} DEFICIENCY
Decreased Intake
Inadequate diet, vegetarianism
Impaired Absorption
Intrinsic factor deficiency Pernicious anemia Gastrectomy Malabsorption states Diffuse intestinal disease (e.g., lymphoma, systemic sclerosis) Ileal resection, ileitis Competitive parasitic uptake Fish tapeworm infestation Bacterial overgrowth in blind loops and diverticula of bowel
FOLIC ACID DEFICIENCY
Decreased Intake
Inadequate diet, alcoholism, infancy
Impaired Absorption
Malabsorption states Intrinsic intestinal disease Anticonvulsants, oral contraceptives
Increased Loss
Hemodialysis
Increased Requirement
Pregnancy, infancy, disseminated cancer, markedly increased hematopoiesis
Impaired Utilization
Folic acid antagonists
UNRESPONSIVE TO VITAMIN B_{12} OR FOLIC ACID THERAPY

Metabolic inhibitors of DNA synthesis and/or folate metabolism (e.g., methotrexate)

Modified from Beck WS: Megaloblastic anemias. In Wyngaarden JB, Smith LH (eds): Cecil Textbook of Medicine, 18th ed. Philadelphia, WB Saunders, 1988, p. 900.

Some of the metabolic roles of vitamin B_{12} and folate are considered later. For now it suffices that vitamin B_{12} and folic acid are coenzymes required for the synthesis of thymidine, one of the four bases found in DNA. A deficiency of these vitamins or impairment in their metabolism results in defective nuclear maturation due to deranged or inadequate DNA synthesis, with an attendant delay or block in cell division.

Morphology. Certain peripheral blood findings are shared by all megaloblastic anemias. **The presence of red cells that are macrocytic and oval (macro-ovalocytes) is highly characteristic**. Because they are larger than normal and contain ample hemoglobin, most macrocytes lack the central pallor of normal red cells and even appear "hyperchromic," but the MCHC is not elevated. There is marked variation in the size (anisocytosis) and shape (poikilocytosis) of red cells. The reticulocyte count is low. Nucleated red cell progenitors occasionally appear in the circulating blood when anemia is severe. **Neutrophils are also larger than normal (macropolymorphonuclear) and hypersegmented, having five or more nuclear lobules instead of the normal three to four** (Fig. 14-16).

The marrow is usually markedly hypercellular as a result of increased hematopoietic precursors, which often completely replace the fatty marrow. **Megaloblastic changes are detected at all stages of erythroid development**. The most primitive cells (promegaloblasts) are large, with a deeply basophilic cytoplasm, prominent nucleoli, and a distinctive, fine nuclear chromatin pattern (Fig. 14-17 , cell A). As these cells differentiate and begin to accumulate hemoglobin, the nucleus retains its finely distributed chromatin and fails to develop the clumped pyknotic chromatin typical of normoblasts. While nuclear maturation is delayed, cytoplasmic maturation and hemoglobin accumulation proceed at a normal pace, leading to nuclear-to-cytoplasmic asynchrony. Because DNA synthesis is impaired in all proliferating cells, granulocytic precursors also display dysmaturation in the form of **giant metamyelocytes and band forms**. Megakaryocytes, too, can be abnormally large and have bizarre, multilobate nuclei.

The marrow hyperplasia is a response to increased levels of growth factors, such as erythropoietin. However, the derangement in DNA synthesis causes most precursors to undergo apoptosis in the marrow (an example of ineffective hematopoiesis) and leads to pancytopenia. The anemia is further exacerbated by a mild degree of red cell hemolysis of uncertain etiology.

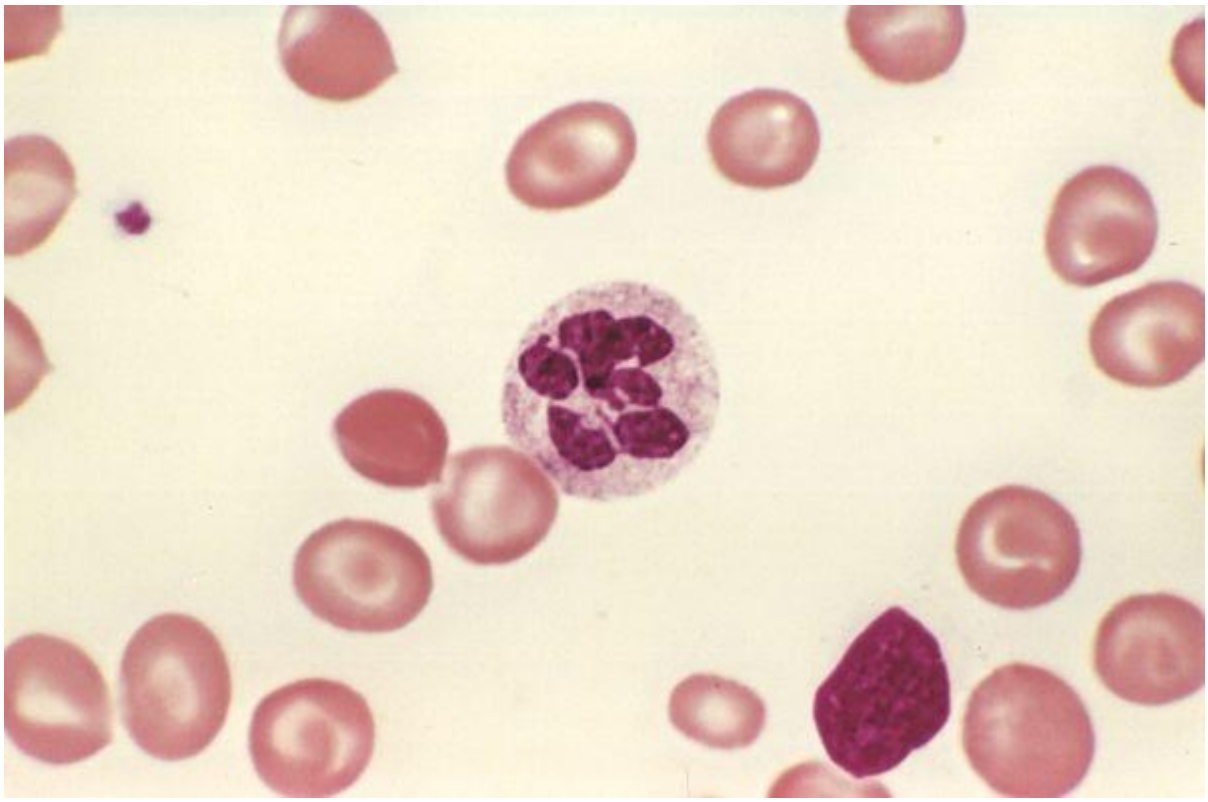

FIGURE 14-16 Megaloblastic anemia. A peripheral blood smear shows a hypersegmented neutrophil with a six-lobed nucleus. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

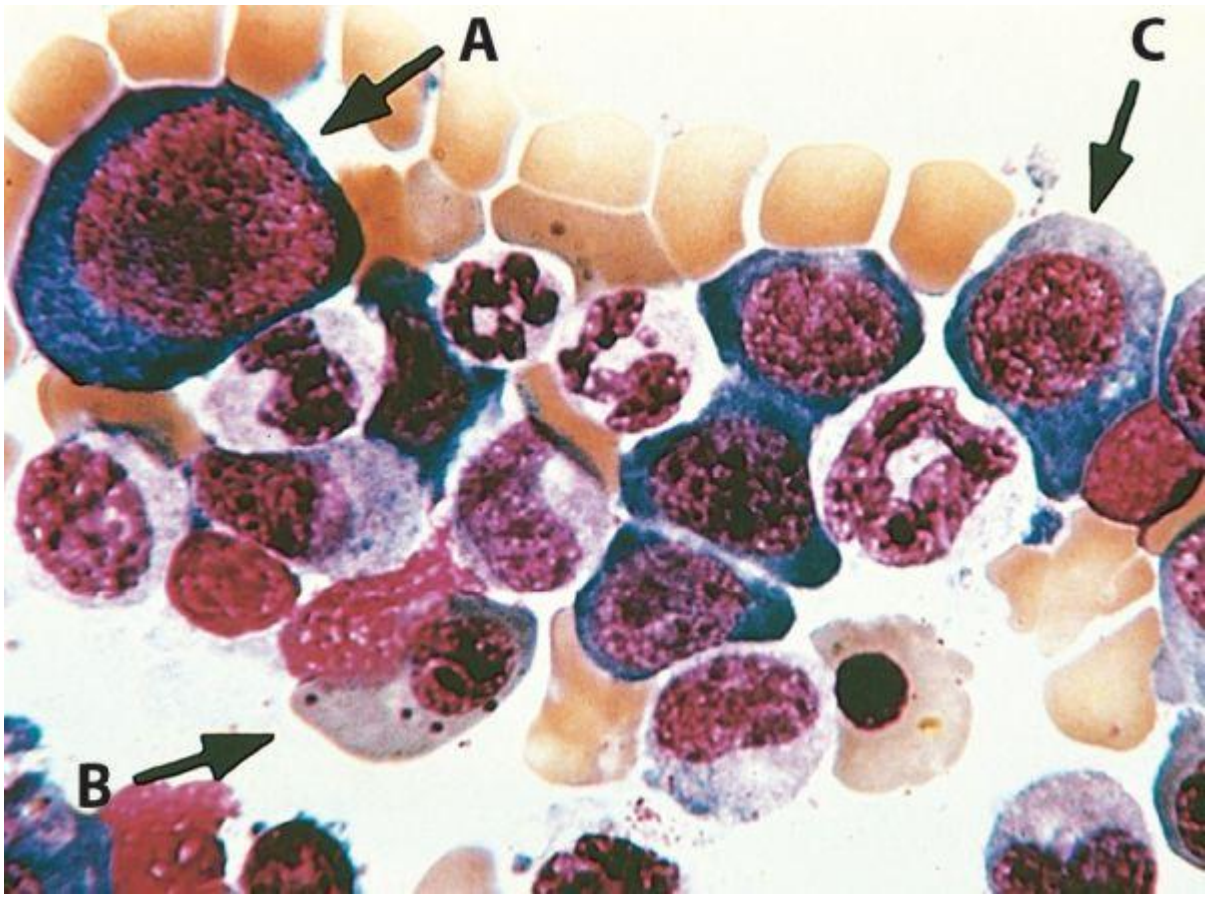

FIGURE 14-17 Megaloblastic anemia (bone marrow aspirate). **A** to **C**, Megaloblasts in various stages of differentiation. Note that the orthochromatic megaloblast (**B**) is hemoglobinized (as revealed by cytoplasmic color), but in contrast to normal orthochromatic normoblasts, the nucleus is not pyknotic. The early erythroid precursors (**A,C**) and the granulocytic precursors are also large and have abnormally immature chromatin. *(Courtesy of Dr. Jose Hernandez, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Anemias of Vitamin B_{12} Deficiency: Pernicious Anemia

Pernicious anemia is a specific form of megaloblastic anemia caused by autoimmune gastritis and an attendant failure of intrinsic factor production, which leads to vitamin B_{12} deficiency. We first review vitamin B_{12} metabolism, since this helps to place pernicious anemia in perspective relative to the other causes of vitamin B_{12} deficiency anemia.

Normal Vitamin B_{12} Metabolism.

Vitamin B_{12} is a complex organometallic compound known as cobalamin. Under normal circumstances humans are totally dependent on dietary vitamin B_{12}. Microorganisms are the ultimate origin of cobalamin in the food chain. Plants and vegetables contain little cobalamin, save that contributed by microbial contamination, and strictly vegetarian or macrobiotic diets do not provide adequate amounts of this essential nutrient. The daily requirement is 2 to 3 μg. A diet that includes animal products contains significantly larger amounts and normally results in the accumulation of intrahepatic stores of vitamin B_{12} that are sufficient to last for several years.

Absorption of vitamin B_{12} requires intrinsic factor, which is secreted by the parietal cells of the fundic mucosa (Fig. 14-18). Vitamin B_{12} is freed from binding proteins in food through the action of pepsin in the stomach and binds to salivary proteins called cobalophilins, or R-binders. In the duodenum, bound vitamin B_{12} is released by the action of pancreatic proteases. It then associates with intrinsic factor. This complex is transported to the ileum, where it is endocytosed by ileal enterocytes that express intrinsic factor receptors on their surfaces. Within ileal cells, vitamin B_{12} associates with a major carrier protein, transcobalamin II, and is secreted into the plasma. Transcobalamin II delivers vitamin B_{12} to the liver and other cells of the body, including rapidly proliferating cells in the bone marrow and the gastrointestinal tract. In addition to this major pathway, there is also a poorly understood alternative uptake mechanism that is not dependent on intrinsic factor or an intact terminal ileum. Up to 1% of a large oral dose can be absorbed by this pathway, making it feasible to treat pernicious anemia with high doses of oral vitamin B_{12}.

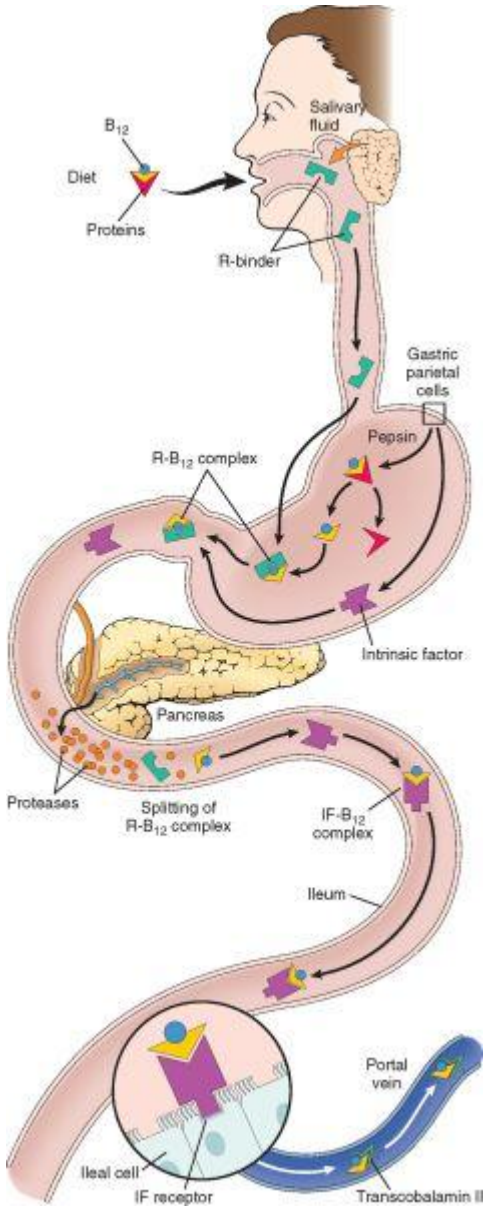

FIGURE 14-18 Schematic illustration of vitamin B_{12} absorption. IF, intrinsic factor; R-binders, cobalophilins (see text).

Biochemical Functions of Vitamin B_2.

Only two reactions in humans are known to require vitamin B_{12}. In one, methylcobalamin serves as an essential cofactor in the conversion of homocysteine to methionine by methionine synthase (Fig. 14-19). In the process, methylcobalamin yields a methyl group that is recovered from N^5-methyltetrahydrofolic acid (N^5-methyl FH_4), the principal form of folic acid in plasma. In the same reaction, N^5-methyl FH_4 is converted to tetrahydrofolic acid (FH_4). FH_4 is crucial, since it is required (through its derivative $N^{5,10}$-methylene FH_4) for the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), an immediate precursor of DNA. *It is postulated that the fundamental cause of the impaired DNA synthesis in vitamin B_{12} deficiency is the reduced availability of FH_4*, most of which is "trapped" as N^5-methyl FH_4. The FH_4 deficit may be further exacerbated by an "internal" folate deficiency caused by a failure to synthesize metabolically active polyglutamylated forms. This stems from the requirement for vitamin B_{12} in the synthesis of methionine, which contributes a carbon group needed in the metabolic reactions that create folate polyglutamates (Fig. 14-20). Whatever the mechanism, *lack of folate is the proximate cause of anemia in vitamin B_{12} deficiency*, since the anemia improves with administration of folic acid.

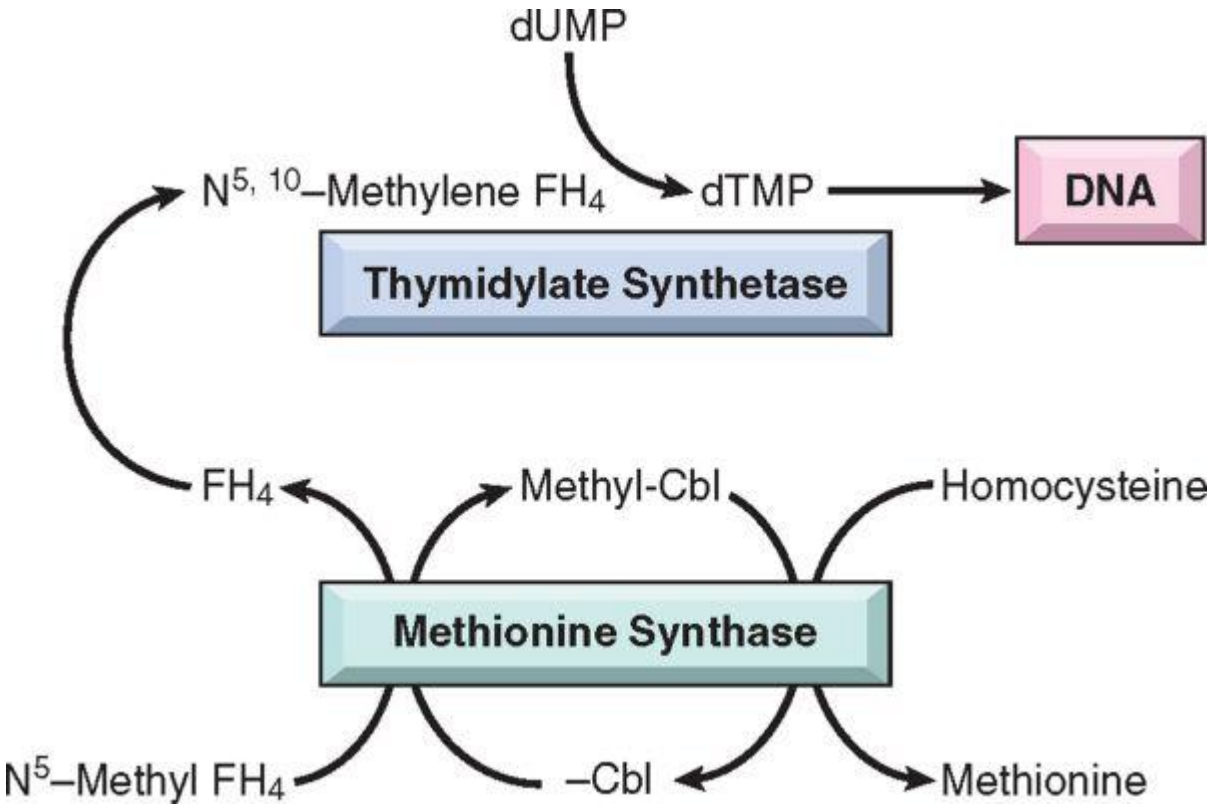

FIGURE 14-19 Relationship of N^5-methyl FH_4, methionine synthase, and thymidylate synthetase. In cobalamin (Cbl) deficiency, folate is sequestered as N^5-methyl FH_4. This ultimately deprives thymidylate synthetase of its folate coenzyme ($N^{5,10}$-methylene FH_4), thereby impairing DNA synthesis. FH_4, tetrahydrofolic acid.

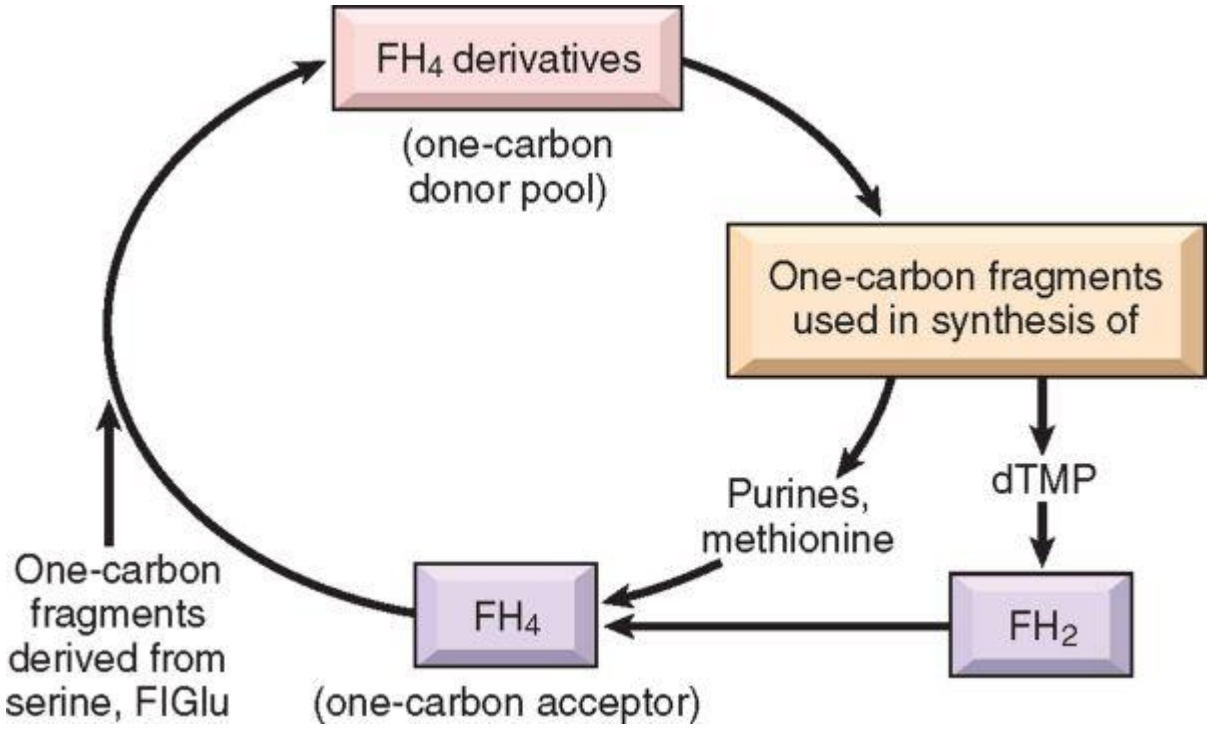

FIGURE 14-20 Role of folate derivatives in the transfer of one-carbon fragments for synthesis of biologic macromolecules. FH_4, tetrahydrofolic acid; FH_2, dihydrofolic acid; FIGlu, formiminoglutamate; dTMP, deoxythymidine monophosphate.

The neurologic complications associated with vitamin B_{12} deficiency are more enigmatic, since they are not improved by folate administration. The other known reaction that depends on vitamin B_{12} is the isomerization of methylmalonyl coenzyme A to succinyl coenzyme A, which requires adenosylcobalamin as a prosthetic group on the enzyme methylmalonyl–coenzyme A mutase. A deficiency of vitamin B_{12} thus leads to increased plasma and urine levels of methylmalonic acid. Interruption of this reaction and the consequent buildup of methylmalonate and propionate (a precursor) could lead to the formation and incorporation of abnormal fatty acids into neuronal lipids. It has been suggested that this biochemical abnormality predisposes to myelin breakdown and thereby produces the neurologic complications of vitamin B_{12} deficiency (Chapter 28). However, rare individuals with hereditary deficiencies of methylmalonyl–coenzyme A mutase, while having complications related to methylmalonyl acidemia, do not suffer from the neurologic abnormalities seen in vitamin B_{12} deficiency, casting doubt on this explanation.

Having completed our overview of vitamin B_{12} metabolism, we can now turn to pernicious anemia.

Incidence.

Although somewhat more prevalent in Scandinavian and other Caucasian populations, pernicious anemia occurs in all racial groups, including blacks and Hispanics. It is a disease of older adults; the median age at diagnosis is 60 years, and it is rare in people younger than 30. A genetic predisposition is strongly suspected, but no definable genetic pattern of transmission has been discerned. As described below, many affected individuals have a tendency to form antibodies against multiple self-antigens.

Pathogenesis.

Pernicious anemia is believed to result from an autoimmune attack on the gastric mucosa. Histologically, there is a *chronic atrophic gastritis* marked by a loss of parietal cells, a prominent infiltrate of lymphocytes and plasma cells, and megaloblastic changes in mucosal cells similar to those found in erythroid precursors. *Three types of autoantibodies are present in many, but not all, patients*. About 75% of patients have a type I antibody that blocks the binding of vitamin B_{12} to intrinsic factor. Type I antibodies are found in both plasma and gastric juice. Type II antibodies prevent binding of the intrinsic factor–vitamin B_{12} complex to its ileal receptor. These antibodies are also found in a large proportion of patients with pernicious anemia. Type III antibodies, present in 85% to 90% of patients, recognize the α and β subunits of the gastric proton pump, which is normally localized to the microvilli of the canalicular system of the gastric parietal cell. These antibodies are not specific for pernicious anemia or other autoimmune diseases, since they are found in as many as 50% of elderly persons with idiopathic chronic gastritis not associated with pernicious anemia.

Autoantibodies are of diagnostic utility, but they are not thought to be the primary cause of the gastric pathology. Rather, it seems that an autoreactive T-cell response initiates gastric mucosal injury and triggers the formation of autoantibodies, which may exacerbate the epithelial injury. When the mass of intrinsic factor–secreting cells falls below a threshold (and reserves of stored vitamin B_{12} are depleted), anemia develops. In an animal model of autoimmune gastritis mediated by CD4+ T cells, a pattern of autoantibodies resembling that seen in pernicious anemia develops, thus supporting the primacy of T-cell autoimmunity. The common association of pernicious anemia with other autoimmune disorders, particularly autoimmune thyroiditis and adrenalitis, is also consistent with an underlying immune basis. The tendency to develop multiple autoimmune disorders, including pernicious anemia, is linked to specific sequence variants of NALP1,[16] an innate immune receptor that maps to chromosome 17p13.

Vitamin B_{12} deficiency is associated with disorders other than pernicious anemia. Most of these impair absorption of the vitamin at one of the steps outlined earlier (see Table 14-5). With achlorhydria and loss of pepsin secretion (which occurs in some elderly individuals), vitamin B_{12} is not readily released from proteins in food. With gastrectomy, intrinsic factor is not available for uptake in the ileum. With loss of exocrine pancreatic function, vitamin B_{12} cannot be released from R-binder–vitamin B_{12} complexes. Ileal resection or diffuse ileal disease can remove or damage the site of intrinsic factor–vitamin B_{12} complex absorption. Tapeworms compete with the host for B_{12} and can induce a deficiency state. In some settings, such as pregnancy, hyperthyroidism, disseminated cancer, and chronic infection, an increased demand for vitamin B_{12} can produce a relative deficiency, even with normal absorption.

Morphology. The findings in the **bone marrow and blood** in pernicious anemia are similar to those described earlier for all megaloblastic anemias. The stomach typically shows diffuse chronic gastritis (Chapter 17). **The most characteristic alteration is atrophy of the fundic glands**, affecting both chief cells and parietal cells, the latter being virtually absent. The glandular lining epithelium is replaced by mucus-secreting goblet cells that resemble those lining the large intestine, a form of metaplasia referred to as **intestinalization**. Some of the cells as well as their nuclei may increase to double the normal size, a form of "megaloblastic" change exactly analogous to that seen in the marrow. With time, the tongue may become shiny, glazed, and "beefy" **(atrophic glossitis)**. The gastric atrophy and metaplastic changes are due to autoimmunity and not vitamin B_{12} deficiency; hence, parenteral administration of vitamin B_{12} corrects the megaloblastic changes in the marrow and the epithelial cells of the alimentary tract, but gastric atrophy and achlorhydria persist.

Central nervous system lesions are found in about three fourths of all cases of florid pernicious anemia but can also be seen in the absence of overt hematologic findings. **The principal alterations involve the spinal cord, where there is demyelination of the dorsal and lateral tracts**, sometimes followed by loss of axons. These changes give rise to spastic paraparesis, sensory ataxia, and severe

paresthesias in the lower limbs. Less frequently, degenerative changes occur in the ganglia of the posterior roots and in peripheral nerves (Chapter 28).

Clinical Features.

Pernicious anemia is insidious in onset, so the anemia is often quite severe by the time the affected person seeks medical attention. The course is progressive unless halted by therapy.

The diagnosis is based on (1) a moderate to severe megaloblastic anemia, (2) leukopenia with hypersegmented granulocytes, (3) low serum vitamin B_{12}, and (4) elevated levels of homocysteine and methylmalonic acid in the serum. The diagnosis is confirmed by a striking increase in reticulocytes and an improvement in hematocrit levels beginning about 5 days after parenteral administration of vitamin B_{12}. Serum antibodies to intrinsic factor are highly specific for pernicious anemia. Their presence attests to the cause rather than the presence or absence of vitamin B_{12} deficiency.

Persons with atrophic and metaplastic changes in the gastric mucosa associated with pernicious anemia are at increased risk of developing gastric carcinoma (Chapter 17). As mentioned, serum homocysteine levels are raised in individuals with vitamin B_{12} deficiency. Elevated homocysteine levels are a risk factor for atherosclerosis and thrombosis, and it is suspected that vitamin B_{12} deficiency may increase the incidence of vascular disease. With parenteral or high-dose oral vitamin B_{12}, the anemia can be cured and the peripheral neurologic changes reversed or at least halted in their progression, but the changes in the gastric mucosa and the risk of carcinoma are unaffected.

Anemia of Folate Deficiency

A deficiency of folic acid (more properly, pteroylmonoglutamic acid) results in a megaloblastic anemia having the same characteristics as that caused by vitamin B_{12} deficiency. FH_4 derivatives act as intermediates in the transfer of one-carbon units such as formyl and methyl groups to various compounds (see Fig. 14-20). FH_4 serves as an acceptor of one-carbon fragments from compounds such as serine and formiminoglutamic acid. The FH_4 derivatives so generated in turn donate the acquired one-carbon fragments in reactions synthesizing various metabolites. FH_4, then, can be viewed as the biologic “middleman” in a series of swaps involving one-carbon moieties. The most important metabolic processes depending on such transfers are (1) purine synthesis; (2) the conversion of homocysteine to methionine, a reaction also requiring vitamin B_{12}; and (3) deoxythymidylate monophosphate synthesis. In the first two reactions, FH_4 is regenerated from its one-carbon carrier derivatives and is available to accept another one-carbon moiety and reenter the donor pool. In the synthesis of dTMP, a dihydrofolate is produced that must be reduced by dihydrofolate reductase for reentry into the FH_4 pool. The reductase step is significant, since this enzyme is susceptible to inhibition by various drugs. Among the molecules whose synthesis is dependent on folates, dTMP is perhaps the most important biologically, since it is required for DNA synthesis. It should be apparent from this discussion that suppressed synthesis of DNA, the common denominator of folic acid and vitamin B_{12} deficiency, is the immediate cause of megaloblastosis.

Etiology.

The three major causes of folic acid deficiency are (1) decreased intake, (2) increased requirements, and (3) impaired utilization (see Table 14-5). Humans are entirely dependent on dietary sources for their folic acid requirement, which is 50 to 200 μg daily. Most normal diets contain ample amounts. The richest sources are green vegetables such as lettuce, spinach, asparagus, and broccoli. Certain fruits (e.g., lemons, bananas, melons) and animal sources (e.g., liver) contain lesser amounts. The folic acid in these foods is largely in the form of folylpolyglutamates. Despite their abundance in raw foods, polyglutamates are sensitive to heat; *boiling, steaming, or frying of foods for 5 to 10 minutes destroys*

up to 95% of the folate content. Intestinal conjugases split the polyglutamates into monoglutamates that are readily absorbed in the proximal jejunum. During intestinal absorption they are modified to 5-methyltetrahydrofolate, the normal transport form of folate. The body's reserves of folate are relatively modest, and a deficiency can arise within weeks to months if intake is inadequate.

Decreased intake can result from either a nutritionally inadequate diet or impairment of intestinal absorption. A normal diet contains folate in excess of the minimal daily adult requirement. Inadequate dietary intakes are almost invariably associated with grossly deficient diets. *Such dietary inadequacies are most frequently encountered in chronic alcoholics, the indigent, and the very elderly*. In alcoholics with cirrhosis, other mechanisms of folate deficiency such as trapping of folate within the liver, excessive urinary loss, and disordered folate metabolism have also been implicated. Under these circumstances, the megaloblastic anemia is often accompanied by general malnutrition and manifestations of other avitaminoses, including cheilosis, glossitis, and dermatitis. Malabsorption syndromes, such as sprue, can lead to inadequate absorption of this nutrient, as can diffuse infiltrative diseases of the small intestine (e.g., lymphoma). In addition, certain drugs, particularly the anticonvulsant phenytoin and oral contraceptives, interfere with absorption.

Despite normal intake of folic acid, a *relative deficiency* can be encountered when requirements are increased. Conditions in which this is seen include pregnancy, infancy, hematologic derangements associated with hyperactive hematopoiesis (hemolytic anemias), and disseminated cancer. In all these circumstances the demands of increased DNA synthesis render normal intake inadequate.

Folic acid antagonists, such as methotrexate, inhibit dihydrofolate reductase and lead to a deficiency of FH_4. With inhibition of folate metabolism, all rapidly growing cells are affected, but particularly the cells of the bone marrow and the gastrointestinal tract. Many chemotherapeutic drugs used in the treatment of cancer damage DNA or inhibit DNA synthesis through other mechanisms; these can also cause megaloblastic changes in rapidly dividing cells.

As mentioned at the outset, the megaloblastic anemia that results from a deficiency of folic acid is identical to that encountered in vitamin B_{12} deficiency. Thus, the diagnosis of folate deficiency can be made only by demonstration of decreased folate levels in the serum or red cells. As in vitamin B_{12} deficiency, serum homocysteine levels are increased, but methylmalonate concentrations are normal. However, neurologic changes do not occur.

Although prompt hematologic response heralded by reticulocytosis follows the administration of folic acid, it should be remembered that the hematologic symptoms of vitamin B_{12} deficiency anemia also respond to folate therapy. However, *folate does not prevent (and may even exacerbate) the neurologic deficits typical of the vitamin B_{12} deficiency states*. It is thus essential to exclude vitamin B_{12} deficiency in megaloblastic anemia before initiating therapy with folate.

Iron Deficiency Anemia

Deficiency of iron is the most common nutritional disorder in the world. Although the prevalence of iron deficiency anemia is higher in developing countries, this form of anemia is also common in the United States, particularly in toddlers, adolescent girls, and women of childbearing age. The factors underlying the iron deficiency differ somewhat in various population groups and can be best considered in the context of normal iron metabolism.[17]

Iron Metabolism.

The normal daily Western diet contains about 10 to 20 mg of iron, most in the form of heme contained in animal products, with the remainder being inorganic iron in vegetables. About 20% of heme iron (in

contrast to 1% to 2% of nonheme iron) is absorbable, so the average Western diet contains sufficient iron to balance fixed daily losses. The total body iron content is normally about 2 gm in women and as high as 6 gm in men, and can be divided into functional and storage compartments (Table 14-6). About 80% of the functional iron is found in hemoglobin; myoglobin and iron-containing enzymes such as catalase and the cytochromes contain the rest. The storage pool represented by hemosiderin and ferritin contains about 15% to 20% of total body iron. Healthy young females have smaller stores of iron than do males, primarily because of blood loss during menstruation, and often develop iron deficiency due to excessive losses or increased demands associated with menstruation and pregnancy, respectively.

TABLE 14-6 -- Iron Distribution in Healthy Young Adults (mg)

Pool	Men	Women
Total	3450	2450
Functional		
Hemoglobin	2100	1750
Myoglobin	300	250
Enzymes	50	50
Storage		
Ferritin, hemosiderin	1000	400

Iron in the body is recycled extensively between the functional and storage pools (Fig. 14-21). It is transported in plasma by an iron-binding glycoprotein called *transferrin*, which is synthesized in the liver. In normal individuals, transferrin is about one third saturated with iron, yielding serum iron levels that average 120 μg/dL in men and 100 μg/dL in women. The major function of plasma transferrin is to deliver iron to cells, including erythroid precursors, which require iron to synthesize hemoglobin. Erythroid precursors possess high-affinity receptors for transferrin, which mediate iron import through receptor-mediated endocytosis.

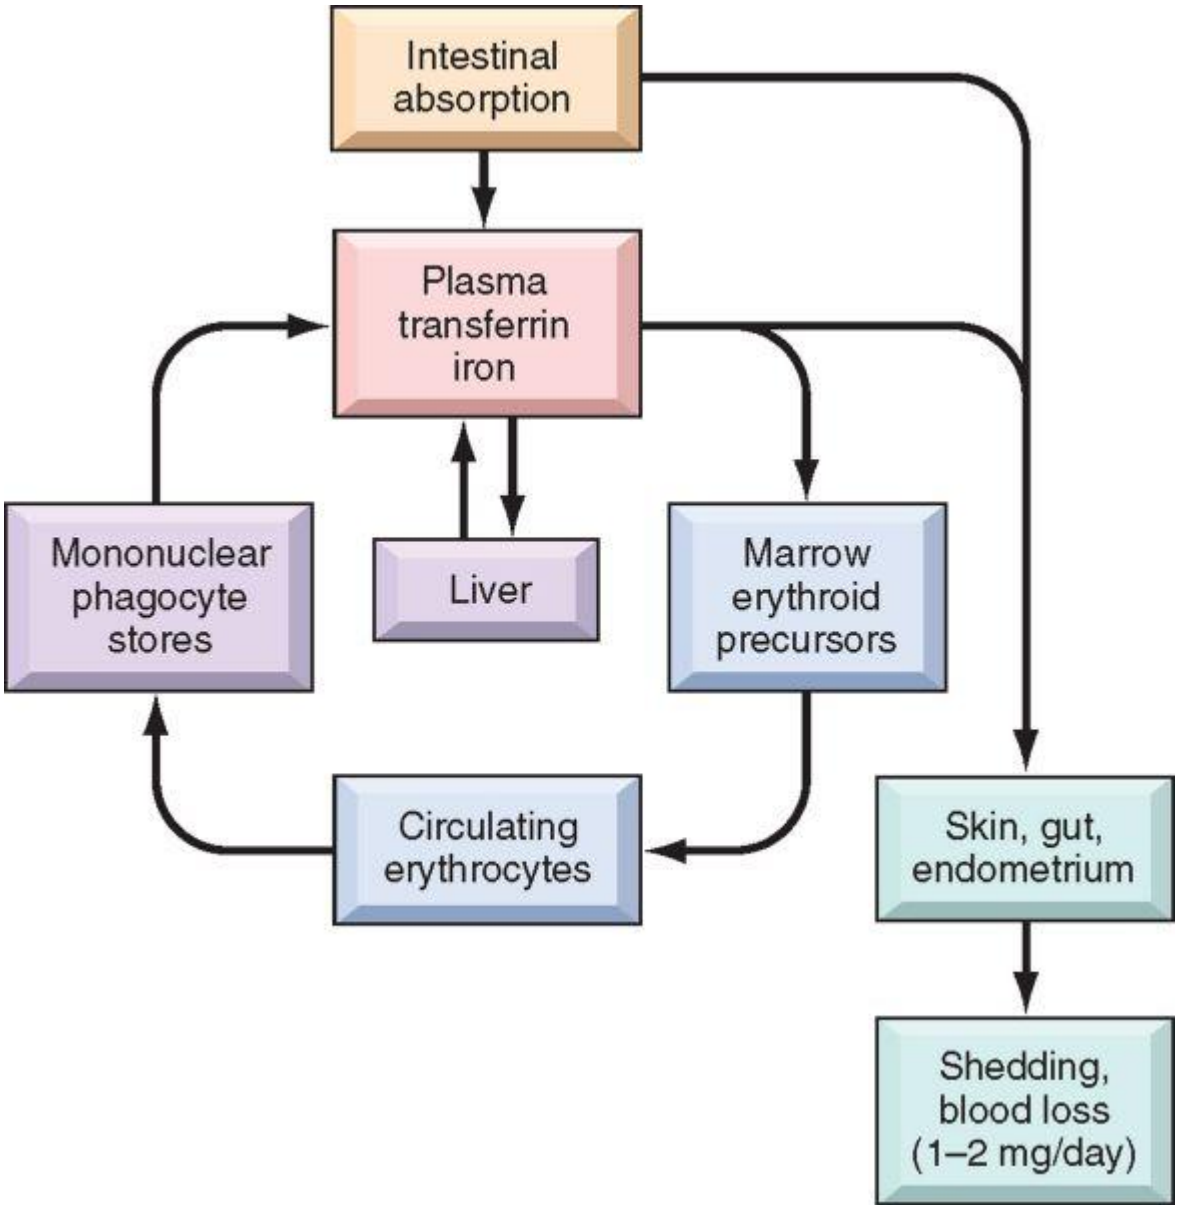

FIGURE 14-21 Iron metabolism. Iron absorbed from the gut is bound to plasma transferrin and transported to the marrow, where it is delivered to developing red cells and incorporated into hemoglobin. Mature red cells are released into the circulation and, after 120 days, are ingested by macrophages, primarily in the spleen, liver, and bone marrow. Here iron is extracted from hemoglobin and recycled to plasma transferrin. At equilibrium, iron absorbed from the gut is balanced by losses in shed keratinocytes, enterocytes, and (in women) endometrium.

Free iron is highly toxic (as described in Chapter 18), and it is therefore important that storage iron be sequestered. This is achieved by binding iron in the storage pool tightly to either ferritin or hemosiderin. *Ferritin is a ubiquitous protein-iron complex* that is found at highest levels in the liver, spleen, bone marrow, and skeletal muscles. In the liver, most ferritin is stored within the parenchymal cells; in other tissues, such as the spleen and the bone marrow, it is found mainly in macrophages. Hepatocyte iron is derived from plasma transferrin, whereas storage iron in macrophages is derived from the breakdown of red cells. Intracellular ferritin is located in the cytosol and in lysosomes, in which partially degraded protein shells of ferritin aggregate into *hemosiderin* granules. Iron in hemosiderin is chemically reactive and turns blue-black when exposed to potassium ferrocyanide, which is the basis for the Prussian blue

stain. With normal iron stores, only trace amounts of hemosiderin are found in the body, principally in macrophages in the bone marrow, spleen, and liver. In iron-overloaded cells, most iron is stored in hemosiderin.

Since plasma ferritin is derived largely from the storage pool of body iron, its levels correlate well with body iron stores. In iron deficiency, serum ferritin is always below 12 μg/L, whereas in iron overload values approaching 5000 μg/L can be seen. Of physiologic importance, the storage iron pool can be readily mobilized if iron requirements increase, as may occur after loss of blood.

Iron balance is maintained largely by regulating the absorption of dietary iron in the proximal duodenum. Iron is both essential for cellular metabolism and highly toxic in excess, and total body iron stores must therefore be regulated meticulously. There is no regulated pathway for iron excretion, which is limited to the 1 to 2 mg lost each day through the shedding of mucosal and skin epithelial cells. In contrast, as body iron stores rise, absorption falls, and vice versa. The pathways responsible for the absorption of iron are now understood in reasonable detail (Fig. 14-22), and differ partially for nonheme and heme iron.[17] Luminal nonheme iron is mostly in the $Fe^{[3]+}$ (ferric) state and must first be reduced to $Fe^{[2]+}$ (ferrous) iron by ferrireductases, such as b cytochromes and STEAP3. $Fe^{[2]+}$ iron is then transported across the apical membrane by divalent metal transporter 1 (DMT1). The absorption of nonheme iron is variable and often inefficient, being inhibited by substances in the diet that bind and stabilize $Fe^{[3]+}$ iron and enhanced by substances that stabilize $Fe^{[2]+}$ iron (described below). Frequently, less than 5% of dietary nonheme iron is absorbed. In contrast, about 25% of the heme iron derived from hemoglobin, myoglobin, and other animal proteins is absorbed. Heme iron is moved across the apical membrane into the cytoplasm through transporters that are incompletely characterized. Here, it is metabolized to release $Fe^{[2]+}$ iron, which enters a common pool with nonheme $Fe^{[2]+}$ iron. Iron that enters the duodenal cells can follow one of two pathways: transport to the blood or storage as mucosal iron. This distribution is influenced by body iron stores, as we shall discuss below. $Fe^{[2]+}$ iron destined for the circulation, is transported from the cytoplasm across the basolateral enterocyte membrane by ferriportin. This process is coupled to the oxidation of $Fe^{[2]+}$ iron to $Fe^{[3]+}$ iron, which is carried out by the iron oxidases hephaestin and ceruloplasmin. Newly absorbed $Fe^{[3]+}$ iron binds rapidly to the plasma protein transferrin, which delivers iron to red cell progenitors in the marrow (see Fig. 14-21). Both DMT1 and ferriportin are widely distributed in the body and are involved in iron transport in other tissues as well. For example, DMT1 also mediates the uptake of “functional” iron (derived from endocytosed transferrin) across lysosomal membranes into the cytosol of red cell precursors in the bone marrow, and ferriportin plays an important role in the release of storage iron from macrophages.

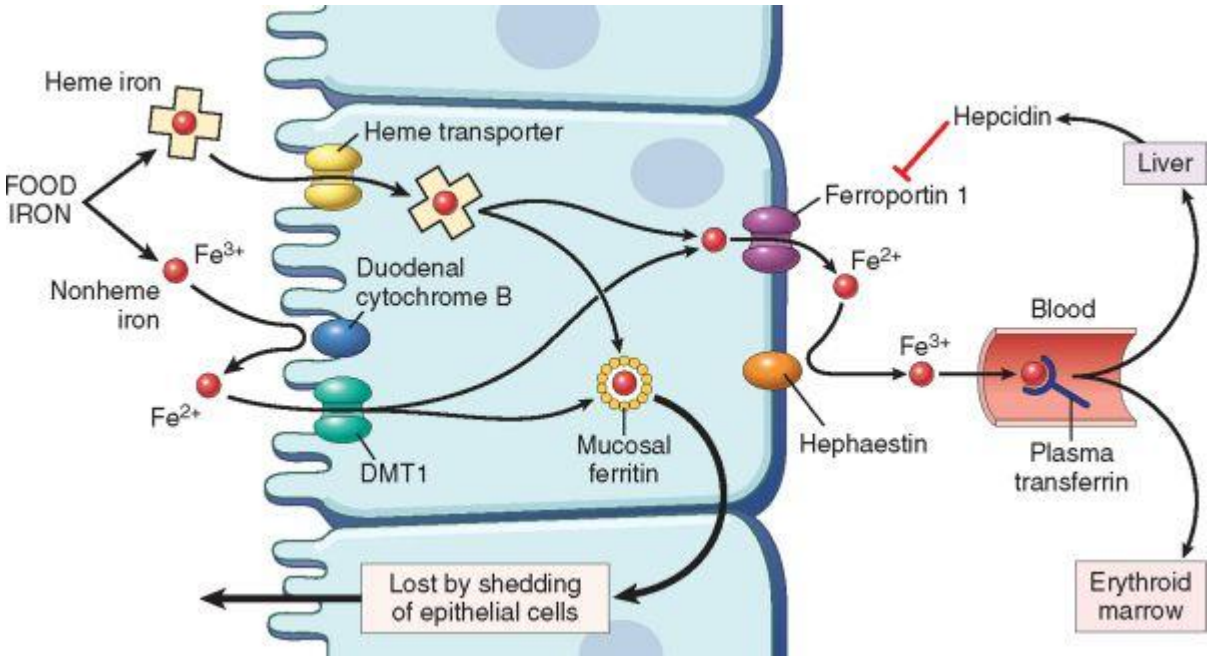

FIGURE 14-22 Regulation of iron absorption. Duodenal epithelial cell uptake of heme and nonheme iron is depicted. When the storage sites of the body are replete with iron and erythropoietic activity is normal, plasma hepcidin levels are high. This leads to downregulation of ferriportin and trapping of most of the absorbed iron, which is lost when duodenal epithelial cells are shed into the gut. Conversely, when body iron stores decrease or when erythropoiesis is stimulated, hepcidin levels fall and ferriportin activity increases, allowing a greater fraction of the absorbed iron to be transferred to plasma transferrin. DMT1, divalent metal transporter 1.

Iron absorption is regulated by hepcidin, a small circulating peptide that is synthesized and released from the liver in response to increases in intrahepatic iron levels.[17] Hepcidin inhibits iron transfer from the enterocyte to plasma by binding to ferriportin and causing it to be endocytosed and degraded. As a result, as hepcidin levels rise, iron becomes trapped within duodenal cells in the form of mucosal ferritin and is lost as these cells are sloughed. Thus, when the body is replete with iron, high hepcidin levels inhibit its absorption into the blood. Conversely, with low body stores of iron, hepcidin synthesis falls and this in turn facilitates iron absorption. By inhibiting ferriportin, hepcidin not only reduces iron uptake from enetrocytes but also suppresses iron release from macrophages, which are an important source of the iron that is used by erythroid precursors to make hemoglobin. This, as we shall see, is important in the pathogenesis of anemia of chronic diseases.

Alterations in hepcidin have a central role in diseases involving disturbances of iron metabolism. As will be described subsequently, the *anemia of chronic disease* is caused in part by inflammatory mediators that increase hepatic hepcidin production.[18] A rare form of microcytic anemia is caused by mutations that disable TMPRSS6, a hepatic transmembrane serine protease that normally suppresses hepcidin production when iron stores are low. Affected patients have high hepcidin levels, resulting in reduced iron absorption and failure to respond to iron therapy. Conversely, hepcidin activity is inappropriately low in both primary and secondary *hemochromatosis*, a syndrome caused by systemic iron overload. Secondary hemochromatosis can occur in diseases associated with *ineffective erythropoiesis*, such as β-thalassemia major and myelodysplastic syndromes (Chapter 13). Through incompletely understood mechanisms, ineffective erythropoiesis suppresses hepatic hepcidin production, even when iron stores are high. As discussed in Chapter 18 , the various inherited forms of primary hematochromatosis are associated with mutations in hepcidin or the genes that regulate hepcidin expression.

Etiology.

Iron deficiency can result from (1) dietary lack, (2) impaired absorption, (3) increased requirement, or (most importantly) (4) chronic blood loss. To maintain a normal iron balance, about 1 mg of iron must be absorbed from the diet every day. Because only 10% to 15% of ingested iron is absorbed, the daily iron requirement is 7 to 10 mg for adult men and 7 to 20 mg for adult women. Since the average daily dietary intake of iron in the Western world is about 15 to 20 mg, most men ingest more than adequate iron, whereas many women consume marginally adequate amounts of iron. The bioavailability of dietary iron is as important as the overall content. Heme iron is much more absorbable than inorganic iron, the absorption of which is influenced by other dietary contents. Absorption of inorganic iron is enhanced by ascorbic acid, citric acid, amino acids, and sugars in the diet, and inhibited by tannates (found in tea), carbonates, oxalates, and phosphates.

Dietary lack is rare in developed countries, where on average about two thirds of the dietary iron is in the readily absorbed heme form provided by meat. The situation is different in developing countries, where food is less abundant and most iron in the diet is found in plants in the poorly absorbable inorganic form. Dietary iron inadequacy occurs in even privileged societies in the following groups:

- *Infants*, who are at high risk due to the very small amounts of iron in milk. Human breast milk provides only about 0.3 mg/L of iron. Cow's milk contains about twice as much iron, but its bioavailability is poor.
- *The impoverished*, who can have suboptimal diets for socioeconomic reasons at any age.
- *The elderly*, who often have restricted diets with little meat because of limited income or poor dentition.
- *Teenagers* who subsist on “junk” food.

Impaired absorption is found in sprue, other causes of fat malabsorption (steatorrhea), and chronic diarrhea. Gastrectomy impairs iron absorption by decreasing hydrochloric acid and transit time through the duodenum. Specific items in the diet, as is evident from the preceding discussion, can also affect absorption.

Increased requirement is an important cause of iron deficiency in growing infants, children, and adolescents, as well as premenopausal women, particularly during pregnancy. Economically deprived women having multiple, closely spaced pregnancies are at exceptionally high risk.

Chronic blood loss is the most common cause of iron deficiency in the Western world. External hemorrhage or bleeding into the gastrointestinal, urinary, or genital tracts depletes iron reserves. *Iron deficiency in adult men and postmenopausal women in the Western world must be attributed to gastrointestinal blood loss until proven otherwise*. To prematurely ascribe iron deficiency in such individuals to any other cause is to run the risk of missing an occult gastrointestinal cancer or other bleeding lesion. An alert clinician investigating unexplained iron deficiency anemia occasionally discovers an occult bleed or cancer and thereby saves a life.

Pathogenesis.

Whatever its basis, iron deficiency produces a hypochromic microcytic anemia. At the outset of chronic blood loss or other states of negative iron balance, reserves in the form of ferritin and hemosiderin may be adequate to maintain normal hemoglobin and hematocrit levels as well as normal serum iron and transferrin saturation. Progressive depletion of these reserves first lowers serum iron and transferrin saturation levels without producing anemia. In this early stage there is increased erythroid activity in the bone marrow. Anemia appears only when iron stores are completely depleted and is accompanied by low serum iron, ferritin, and transferrin saturation levels.

Morphology. The bone marrow reveals a mild to moderate increase in erythroid progenitors. A diagnostically significant finding is the **disappearance of stainable iron from macrophages in the bone marrow**, which is best assessed by performing Prussian blue stains on smears of aspirated marrow. In peripheral blood smears, the red cells are small **(microcytic)** and pale **(hypochromic)**. Normal red cells with sufficient hemoglobin have a zone of central pallor measuring about one third of the cell diameter. In established iron deficiency the zone of pallor is enlarged; hemoglobin may be seen only in a narrow peripheral rim (Fig. 14-23). Poikilocytosis in the form of small, elongated red cells (pencil cells) is also characteristically seen.

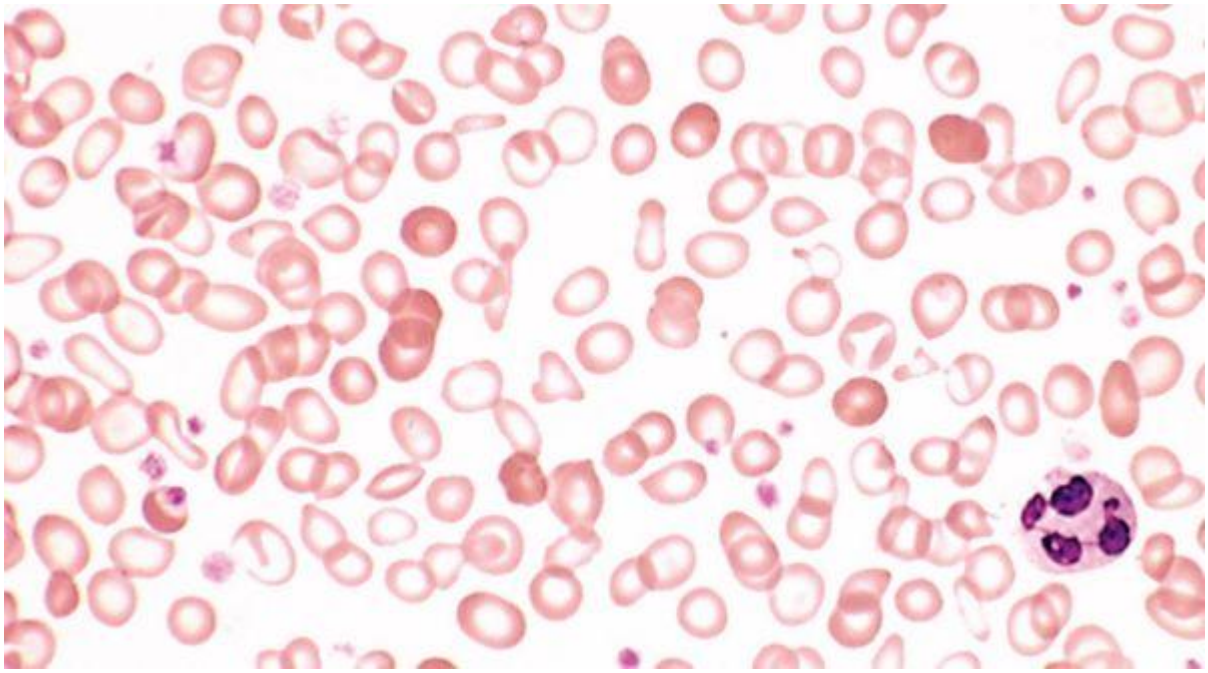

FIGURE 14-23 Hypochromic microcytic anemia of iron deficiency (peripheral blood smear). Note the small red cells containing a narrow rim of peripheral hemoglobin. Scattered fully hemoglobinized cells, present due to recent blood transfusion, stand in contrast. *(Courtesy of Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Clinical Features.

The clinical manifestations of the anemia are nonspecific and were detailed earlier. The dominating signs and symptoms frequently relate to the underlying cause of the anemia, for example, gastrointestinal or gynecologic disease, malnutrition, pregnancy, and malabsorption. In severe and long-standing iron deficiency, depletion of iron-containing enzymes in cells throughout the body also causes other changes, including koilonychia, alopecia, atrophic changes in the tongue and gastric mucosa, and intestinal malabsorption. Depletion of iron from the central nervous system may lead to the appearance of pica, in which affected individuals consume non-foodstuffs such as clay or food ingredients such as flour, and periodically move their limbs during sleep. Esophageal webs appear together with microcytic hypochromic anemia and atrophic glossitis to complete the triad of major findings in the rare *Plummer-Vinson syndrome* (Chapter 17).

The diagnosis of iron deficiency anemia ultimately rests on laboratory studies. Both the hemoglobin and hematocrit are depressed, usually to a moderate degree, in association with hypochromia, microcytosis,

and modest poikilocytosis. *The serum iron and ferritin are low, and the total plasma iron-binding capacity (reflecting elevated transferrin levels) is high. Low serum iron with increased iron-binding capacity results in a reduction of transferrin saturation to below 15%*. Reduced iron stores inhibit hepcidin synthesis, and its serum levels fall. In uncomplicated iron deficiency, oral iron supplementation produces an increase in reticulocytes in about 5 to 7 days that is followed by a steady increase in blood counts and the normalization of red cell indices.

Anemia of Chronic Disease

Impaired red cell production associated with chronic diseases is perhaps the most common cause of anemia among hospitalized patients in the United States. It is associated with a reduction in the proliferation of erythroid progenitors and impaired iron utilization. The chronic illnesses associated with this form of anemia can be grouped into three categories:

1. Chronic microbial infections, such as osteomyelitis, bacterial endocarditis, and lung abscess
2. Chronic immune disorders, such as rheumatoid arthritis and regional enteritis
3. Neoplasms, such as carcinomas of the lung and breast, and Hodgkin lymphoma

The anemia of chronic disease occurs in the setting of persistent systemic inflammation and is associated with low serum iron, reduced total iron-binding capacity, and abundant stored iron in tissue macrophages. Several effects of inflammation contribute to the observed abnormalities. *Most notably, certain inflammatory mediators, particularly interleukin-6 (IL-6), stimulate an increase in the hepatic production of hepcidin*.[17,][18] As was discussed under the anemia of iron deficiency, hepcidin inhibits ferriportin function in macrophages and reduces the transfer of iron from the storage pool to developing erythroid precursors in the bone marrow. As a result, the erythroid precursors are starved for iron in the midst of plenty. In addition, these progenitors do not proliferate adequately because erythropoietin levels are inappropriately low for the degree of anemia. The precise mechanism underlying this alteration is uncertain, but transgenic mice expressing high levels of hepcidin develop a microcytic anemia associated with low erythropoietin levels,[19] suggesting that hepcidin directly or indirectly suppresses erythropoietin production.

What might be the reason for iron sequestration in the setting of inflammation? The best guess is that it serves to enhance the body's ability to fend off certain types of infection, particularly those caused by bacteria (such as *H. influenzae*) that require iron for pathogenicity. In this regard it is interesting to consider that hepcidin is structurally related to defensins, a family of peptides that have intrinsic antibacterial activity. This connection further highlights the uncertain but intriguing interrelationship between inflammation, innate immunity, and iron metabolism.

The anemia is usually mild, and the dominant symptoms are those of the underlying disease. The red cells can be normocytic and normochromic, or hypochromic and microcytic, as in anemia of iron deficiency. *The presence of increased storage iron in marrow macrophages, a high serum ferritin level, and a reduced total iron-binding capacity readily rule out iron deficiency as the cause of anemia*. Only successful treatment of the underlying condition reliably corrects the anemia. However, some patients, particularly those with cancer, benefit from administration of erythropoietin.

Aplastic Anemia

Aplastic anemia refers to a syndrome of chronic primary hematopoietic failure and attendant pancytopenia (anemia, neutropenia, and thrombocytopenia). In the majority of patients autoimmune mechanisms are suspected,[20] but inherited or acquired abnormalities of hematopoietic stem cells also seem to contribute in at least a subset of patients.

Etiology.

The most common circumstances associated with aplastic anemia are listed in Table 14-7 . *Most cases of "known" etiology follow exposure to chemicals and drugs*. Certain drugs and agents (including many cancer chemotherapy drugs and the organic solvent benzene) cause marrow suppression that is dose related and reversible. In other instances, aplastic anemia arises in an unpredictable, idiosyncratic fashion following exposure to drugs that normally cause little or no marrow suppression. The implicated drugs include chloramphenicol and gold salts.

TABLE 14-7 -- Major Causes of Aplastic Anemia

ACQUIRED
Idiopathic
Acquired stem cell defects
Immune mediated
Chemical Agents
Dose related

Carbamazapine
Penicillamine
Gold salts
Physical Agents
Whole-body irradiation
Viral Infections
Hepatitis (unknown virus)
Cytomegalovirus infections
Epstein-Barr virus infections
Herpes zoster (Varicella zoster)
INHERITED
Fanconi anemia
Telomerase defects

Persistent marrow aplasia can also appear after a variety of viral infections, most commonly viral hepatitis of the non-A, non-B, non-C, non-G type, which is associated with 5% to 10% of cases. Why aplastic anemia develops in certain individuals is not understood.

Whole-body *irradiation* can destroy hematopoietic stem cells in a dose-dependent fashion. Persons who receive therapeutic irradiation or are exposed to radiation in nuclear accidents (e.g., Chernobyl) are at risk for marrow aplasia.

Inherited defects underlie some forms of aplastic aplasia. *Fanconi anemia* is a rare autosomal recessive disorder caused by defects in a multiprotein complex that is required for DNA repair (Chapter 7).[21] Marrow hypofunction becomes evident early in life and is often accompanied by multiple congenital anomalies, such as hypoplasia of the kidney and spleen and bone anomalies, which most commonly involve the thumbs or radii. *Inherited defects in telomerase* are found in 5% to 10% of adult-onset aplastic anemia.[22] You will recall from Chapters 1 and 7 that telomerase is required for cellular immortality and limitless replication. It might be anticipated, therefore, that partial deficits in telomerase activity could result in premature hematopoietic stem cell exhaustion and marrow aplasia. Even more common than telomerase mutations are abnormally short telomeres, which are found in the marrow cells of as many as half of those affected with aplastic anemia. It is unknown whether this shortening is due to other unappreciated telomerase defects or is a consequence of excessive stem cell replication.

In most instances, however, no initiating factor can be identified; about 65% of cases fall into this *idiopathic* category.

Pathogenesis.

The pathogenesis of aplastic anemia is not fully understood. Indeed, it is unlikely that a single mechanism underlies all cases. However, two major etiologies have been invoked: an extrinsic, immune-mediated suppression of marrow progenitors; and an intrinsic abnormality of stem cells (Fig. 14-24).

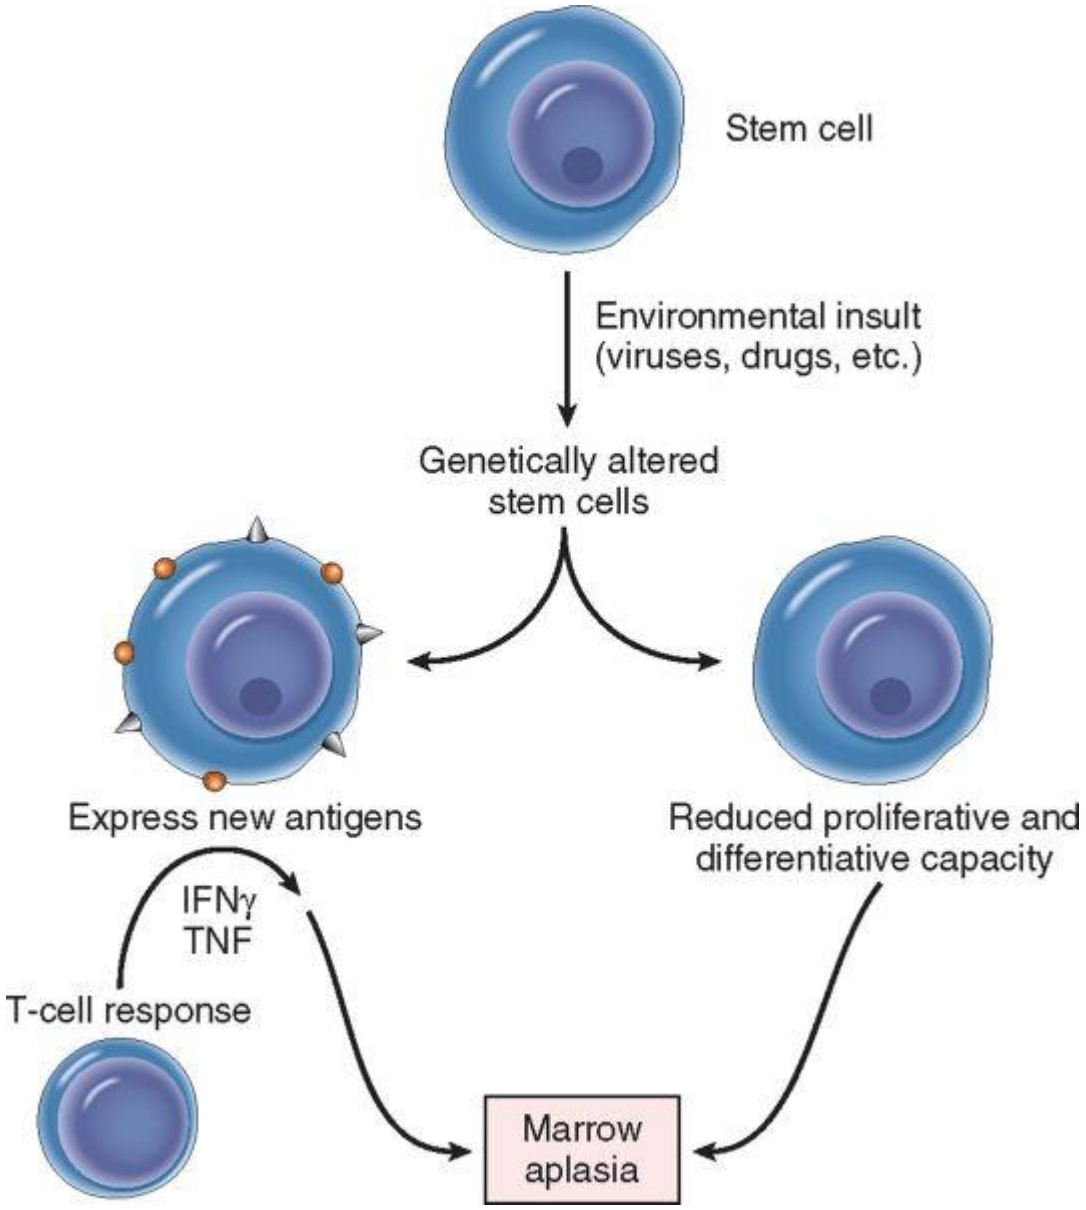

FIGURE 14-24 Pathophysiology of aplastic anemia. Damaged stem cells can produce progeny expressing neoantigens that evoke an autoimmune reaction, or give rise to a clonal population with reduced proliferative capacity. Either pathway could lead to marrow aplasia. See text for abbreviations.

Experimental studies have increasingly focused on a model in which activated T cells suppress hematopoietic stem cells. Stem cells may first be antigenically altered by exposure to drugs, infectious agents, or other unidentified environmental insults. This provokes a cellular immune response, during which activated T_H1 cells produce cytokines such as interferon-γ (IFNγ) and TNF that suppress and kill hematopoietic progenitors. This scenario is supported by several observations. Expression analysis of the few remaining marrow stem cells from aplastic anemia marrows has revealed that genes involved in apoptosis and death pathways are up-regulated; of note, the same genes are up-regulated in normal stem cells exposed to interferon-γ. Even more compelling (and clinically relevant) evidence comes from experience with immunosuppressive therapy. Antithymocyte globulin and other immunosuppressive drugs such as cyclosporine produce responses in 60% to 70% of patients. It is proposed that these

therapies work by suppressing or killing autoreactive T-cell clones. The antigens recognized by the autoreactive T cells are not well defined. In some instances GPI-linked proteins may be the targets, possibly explaining the previously noted association of aplastic anemia and PNH.

Alternatively, the notion that aplastic anemia results from a fundamental stem cell abnormality is supported by the presence of karyotypic aberrations in many cases; the occasional transformation of aplasias into myeloid neoplasms, typically myelodysplasia or acute myeloid leukemia; and the association with abnormally short telomeres. Some marrow insult (or a predisposition to DNA damage) presumably results in sufficient injury to limit the proliferative and differentiative capacity of stem cells. If the damage is extensive enough, aplastic anemia results. These two mechanisms are not mutually exclusive, since genetically altered stem cells might also express "neoantigens" that could serve as targets for a T-cell attack.

Morphology. The markedly hypocellular bone marrow is largely devoid of hematopoietic cells; often only fat cells, fibrous stroma, and scattered lymphocytes and plasma cells remain. Marrow aspirates often yield little material (a "dry tap"); hence, aplasia is best appreciated in marrow biopsies (Fig. 14-25). Other nonspecific pathologic changes are related to granulocytopenia and thrombocytopenia, such as mucocutaneous bacterial infections and abnormal bleeding, respectively. If the anemia necessitates multiple transfusions, systemic hemosiderosis can appear.

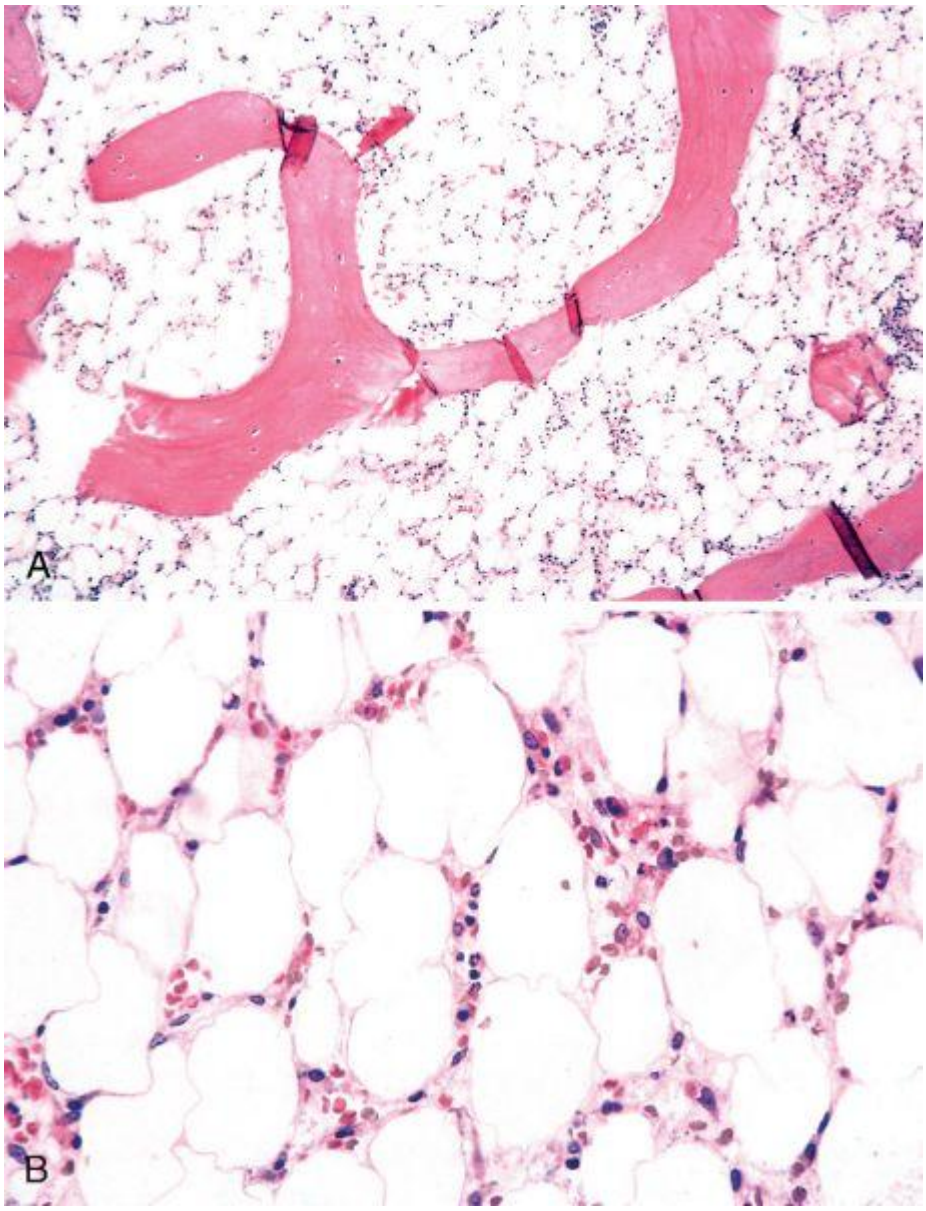

FIGURE 14-25 Aplastic anemia (bone marrow biopsy). Markedly hypocellular marrow contains mainly fat cells. **A**, Low power; **B**, high power. *(Courtesy of Dr. Steven Kroft, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Clinical Features.

Aplastic anemia can occur at any age and in either sex. The onset is usually insidious. Initial manifestations vary somewhat, depending on which cell line is predominantly affected, but pancytopenia ultimately appears, with the expected consequences. Anemia can cause progressive weakness, pallor, and dyspnea; thrombocytopenia is heralded by petechiae and ecchymoses; and neutropenia manifests as frequent and persistent minor infections or the sudden onset of chills, fever, and prostration. *Splenomegaly is characteristically absent; if it is present, the diagnosis of aplastic anemia should be seriously questioned*. The red cells are usually slightly macrocytic and normochromic. *Reticulocytopenia is the rule*.

The diagnosis rests on examination of a bone marrow biopsy. It is important to distinguish aplastic anemia from other causes of pancytopenia, such as “aleukemic” leukemia and myelodysplastic syndromes (Chapter 13), which can have identical clinical manifestations. In aplastic anemia, the marrow is hypocellular (and usually markedly so), whereas myeloid neoplasms are associated with hypercellular marrows filled with neoplastic progenitors.

The prognosis is variable.[20] Bone marrow transplantation is the treatment of choice in those with a suitable donor and provides a 5-year survival of over 75%. Older patients or those without suitable donors often respond well to immunosuppressive therapy.

Pure Red Cell Aplasia

As the name implies, pure red cell aplasia is a primary marrow disorder in which only erythroid progenitors are suppressed. In severe cases, red cell progenitors are completely absent from the marrow. It may occur in association with neoplasms, particularly thymoma and large granular lymphocytic leukemia (Chapter 13), drug exposures, autoimmune disorders, and parvovirus infection (a circumstance that is discussed below). With the exception of those with parvovirus infection, it is likely that most cases have an autoimmune basis. When a thymoma is present, resection leads to hematologic improvement in about half of the patients, possibly because the tumor is a source of marrow suppressive cells. In patients without thymoma, immunosuppressive therapy is often beneficial. Plasmapheresis may also be helpful in unusual patients with pathogenic autoantibodies, such as neutralizing antibodies to erythropoietin that appear de novo or following the administration of recombinant erythropoietin.

A special form of red cell aplasia occurs in individuals infected with parvovirus B19, which preferentially infects and destroys red cell progenitors. Normal individuals clear parvovirus infections within 1 to 2 weeks; as a result, the aplasia is transient and clinically unimportant. However, in persons with moderate to severe hemolytic anemias, even a brief cessation of erythropoiesis results in rapid worsening of the anemia, producing an aplastic crisis. In those who are severely immunosuppressed (such as persons with advanced HIV infection), an ineffective immune response sometimes permits the infection to persist, leading to chronic red cell aplasia and a moderate to severe anemia.

Other Forms of Marrow Failure

Myelophthisic anemia describes a form of marrow failure in which space-occupying lesions replace normal marrow elements. The commonest cause is metastatic cancer, most often carcinomas arising in the breast, lung, and prostate. However, any infiltrative process (e.g., granulomatous disease) involving the marrow can produce identical findings. It should be remembered that myelophthisic anemia is also a feature of the spent phase of myeloproliferative disorders (Chapter 13). All of the responsible diseases cause marrow distortion and fibrosis, which act to displace normal marrow elements and disturb mechanisms that regulate the egress of red cells and granulocytes from the marrow. The latter effect causes the abnormal release of nucleated erythroid precursors and immature granulocytic forms *(leukoerythroblastosis)* into peripheral smears, and the appearance of *teardrop-shaped red cells*, which are believed to be deformed during their tortuous escape from the fibrotic marrow.

Chronic renal failure, whatever its cause, is almost invariably associated with an anemia that tends to be roughly proportional to the severity of the uremia. The basis of anemia in renal failure is multifactorial, but *the dominant cause is the diminished synthesis of erythropoietin by the damaged kidneys*, which leads to inadequate red cell production. Other contributors are an extracorpuscular defect that reduces red cell life span, and iron deficiency due to platelet dysfunction and increased bleeding, which is often encountered in uremia. Administration of recombinant erythropoietin results in a significant improvement of the anemia, although an optimal response may require concomitant iron replacement therapy. *Hepatocellular liver disease*, whether toxic, infectious, or cirrhotic, is associated with anemia

attributed to decreased marrow function. Folate and iron deficiencies caused by poor nutrition and excessive bleeding often exacerbate anemia in this setting. Erythroid progenitors are preferentially affected; depression of the white cell count and platelets is less common but also occurs. The anemia is often slightly macrocytic due to lipid abnormalities associated with liver failure, which cause red cell membranes to acquire phospholipid and cholesterol as they circulate in the peripheral blood. *Endocrine disorders*, particularly hypothyroidism, may also be associated with a mild normochromic, normocytic anemia.

3.4.2 Polycythemia

Polycythemia denotes an abnormally high red cell count, usually with a corresponding increase in the hemoglobin level. The increase in red cell count is *relative* when there is hemoconcentration due to decreased plasma volume, or *absolute* when there is an increase in the total red cell mass. *Relative polycythemia* results from dehydration, such as occurs with deprivation of water, prolonged vomiting or diarrhea, or excessive use of diuretics. It is also associated with an obscure condition of unknown etiology called stress polycythemia, or Gaisböck syndrome. Affected individuals are usually hypertensive, obese, and anxious ("stressed"). *Absolute polycythemia* is *primary* when it results from an intrinsic abnormality of hematopoietic precursors and *secondary* when the red cell progenitors are responding to increased levels of erythropoietin. A pathophysiologic classification of polycythemia divided along these lines is given in Table 14-8 .

TABLE 14-8 -- Pathophysiologic Classification of Polycythemia

RELATIVE
Reduced plasma volume (hemoconcentration)
ABSOLUTE
Primary (Low Erythropoietin)
Polycythemia vera Inherited erythropoietin receptor mutations (rare)
Secondary (High Erythropoietin)
Compensatory Lung disease High-altitude living Cyanotic heart disease Paraneoplastic Erythropoietin-secreting tumors (e.g., renal cell carcinoma, hepatocellular carcinoma, cerebellar hemangioblastoma) Hemoglobin mutants with high O_2 affinity Inherited defects that stabilize HIF-1α Chuvash polycythemia (homozygous *VHL* mutations) Prolyl hydroxylase mutations

HIF-1α, hypoxia-induced factor 1α.

The most common cause of primary polycythemia is *polycythemia vera*, a myeloproliferative disorder associated with mutations that lead to erythropoietin-independent growth of red cell progenitors (considered in Chapter 13). Another much less common form of primary polycythemia results from

familial mutations in the erythropoietin receptor that induce erythropoietin-independent receptor activation. One such individual has won Olympic gold medals in cross-country skiing, having benefited from this natural form of blood doping! Secondary polycythemias are caused by compensatory or pathologic increases in erythropoietin secretion. Causes of the latter include erythropoietin-secreting tumors and rare, but illustrative, inherited defects that lead to the stabilization of HIF-1α, a hypoxia-induced factor that stimulates the transcription of the erythropoietin gene.[23]

3.4.3 Bleeding Disorders: Hemorrhagic Diatheses

Excessive bleeding can result from (1) increased fragility of vessels, (2) platelet deficiency or dysfunction, and (3) derangement of coagulation, alone or in combination. Before discussing specific bleeding disorders, it is helpful to review the common laboratory tests used in the evaluation of a bleeding diathesis. It should be recalled from the discussion in Chapter 4 that the normal hemostatic response involves the blood vessel wall, the platelets, and the clotting cascade. Tests used to evaluate different aspects of hemostasis are the following:

- *Prothrombin time (PT)*. This test assesses the extrinsic and common coagulation pathways. The clotting of plasma after addition of an exogenous source of tissue thromboplastin (e.g., brain extract) and $Ca^{[2]+}$ ions is measured in seconds. A prolonged PT can result from deficiency or dysfunction of factor V, factor VII, factor X, prothrombin, or fibrinogen.
- *Partial thromboplastin time (PTT)*. This test assesses the intrinsic and common clotting pathways. The clotting of plasma after addition of kaolin, cephalin, and $Ca^{[2]+}$ ions is measured in seconds. Kaolin activates the contactdependent factor XII, and cephalin substitutes for platelet phospholipids. Prolongation of the PTT can be due to deficiency or dysfunction of factors V, VIII, IX, X, XI, or XII, prothrombin, or fibrinogen, or to interfering antibodies to phospholipid (described in Chapter 4).
- *Platelet counts*. These are obtained on anticoagulated blood using an electronic particle counter. The reference range is 150×10^3 to 300×10^3 platelets/μL. Counts well outside this range should be confirmed by a visual inspection of a peripheral blood smear, since clumping of platelets can cause spurious "thrombocytopenia" during automated counting, and high counts may be indicative of a myeloproliferative disorder, such as essential thrombocythemia (Chapter 13).
- *Tests of platelet function*. At present, no single test provides an adequate assessment of the complex functions of platelets. One older test, the bleeding time, which measures the time taken for a standardized skin puncture to stop bleeding, has some value but is time-consuming, difficult to perform well, and not a good predictor of bleeding during hemostatic stresses such as surgery. As a result of these limitations, the use of the bleeding time has declined considerably in recent years. Newer instrument-based assays designed to measure platelet function under conditions of high shear stress show promise but at present are also less than ideal screening tests. Other specialized tests that can be useful in particular clinical settings include tests of platelet aggregation, which measure the ability of platelets to aggregate in response to agonists like thrombin; and quantitative and qualitative tests of von Willebrand factor, which (as you will remember from Chapter 4) play an important role in platelet adhesion to the extracellular matrix.

More specialized tests are available to measure the levels of specific clotting factors, fibrinogen, fibrin split products, and the presence of circulating anticoagulants.

BLEEDING DISORDERS CAUSED BY VESSEL WALL ABNORMALITIES

Disorders within this category, sometimes called *nonthrombocytopenic purpuras*, are relatively common but do not usually cause serious bleeding problems. Most often, they induce small hemorrhages (petechiae and purpura) in the skin or mucous membranes, particularly the gingivae. On occasion, however, more significant hemorrhages can occur into joints, muscles, and subperiosteal locations, or take the form of menorrhagia, nosebleeds, gastrointestinal bleeding, or hematuria. *The platelet count, the bleeding time, and tests of coagulation (PT, PTT) usually yield normal results*.

The varied clinical conditions in which abnormalities in the vessel wall cause bleeding include the following:

- Many *infections* induce petechial and purpuric hemorrhages, particularly meningococcemia, other forms of septicemia, infective endocarditis, and several of the rickettsioses. The involved mechanisms include microbial damage to the microvasculature (vasculitis) and disseminated intravascular coagulation (DIC). Failure to recognize meningococcemia as a cause of petechiae and purpura can be catastrophic for the patient.
- *Drug reactions* sometimes induce cutaneous petechiae and purpura without causing thrombocytopenia. In many instances the vascular injury is mediated by the deposition of drug-induced immune complexes in vessel walls, which leads to hypersensitivity (leukocytoclastic) vasculitis (Chapter 11).
- *Scurvy and the Ehlers-Danlos syndrome* are associated with microvascular bleeding, which results from defects in collagen that weakens vessel walls. The same mechanism may account for the spontaneous purpura that are commonly seen in the elderly and the skin hemorrhages that are seen with *Cushing syndrome*, in which the protein-wasting effects of excessive corticosteroid production cause loss of perivascular supporting tissue.
- *Henoch-Schönlein purpura* is a systemic hypersensitivity disease of unknown cause that is characterized by a purpuric rash, colicky abdominal pain, polyarthralgia, and acute glomerulonephritis (Chapter 20). All these changes result from the deposition of circulating immune complexes within vessels throughout the body and within the glomerular mesangial regions.
- *Hereditary hemorrhagic telangiectasia* (also known as Weber-Osler-Rendu syndrome) is an autosomal dominant disorder characterized by dilated, tortuous blood vessels with thin walls that bleed readily. Bleeding can occur anywhere, but it is most common under the mucous membranes of the nose (epistaxis), tongue, mouth, and eyes, and throughout the gastrointestinal tract.
- *Perivascular amyloidosis* can weaken blood vessel walls and cause bleeding. This complication is most common with amyloid light-chain (AL) amyloidosis (Chapter 6) and often manifests as mucocutaneous petechiae.

Among these conditions, serious bleeding is most often associated with hereditary telangiectasia. The bleeding in each is nonspecific, and the diagnosis of these entities is based on the recognition of other more specific associated findings.

BLEEDING RELATED TO REDUCED PLATELET NUMBER: THROMBOCYTOPENIA

Reduction in platelet number constitutes an important cause of generalized bleeding. A count below 100,000 platelets/μL is generally considered to constitute thrombocytopenia. However, spontaneous bleeding does not become evident until platelet counts fall below 20,000 platelets/μL. Platelet counts in the range of 20,000 to 50,000 platelets/μL can aggravate post-traumatic bleeding. Bleeding resulting from thrombocytopenia is associated with a normal PT and PTT.

It hardly needs reiteration that platelets are critical for hemostasis, since they form temporary plugs that stop bleeding and promote key reactions in the coagulation cascade (as discussed in Chapter 4). Spontaneous bleeding associated with thrombocytopenia most often involves small vessels. Common sites for such hemorrhages are the skin and the mucous membranes of the gastrointestinal and genitourinary tracts. *Most feared, however, is intracranial bleeding, which is a threat to any patient with a markedly depressed platelet count*.

The many causes of thrombocytopenia can be classified into four major categories (Table 14-9).

- *Decreased platelet production*. This can result from conditions that depress marrow output generally (such as aplastic anemia and leukemia) or affect megakaryocytes somewhat selectively. Examples of the latter include certain drugs and alcohol, which may suppress platelet production through uncertain mechanisms when taken in large amounts; HIV, which may infect megakaryocytes and inhibit platelet production; and

myelodysplastic syndromes (Chapter 13), which may occasionally present with isolated thrombocytopenia.

- *Decreased platelet survival*. This important mechanism of thrombocytopenia can have an immunological or nonimmunological basis. *In immune thrombocytopenia platelet destruction is caused by antibodies to platelets* or, less often, immune complexes that deposit on platelets. Antibodies to platelets can recognize self-antigens (autoantibodies) or non-self antigens (alloantibodies). Autoimmune thrombocytopenia is discussed in the following section. Alloantibodies can arise when platelets are transfused or cross the placenta from the fetus into the pregnant mother. In the latter case, IgG antibodies made in the mother can cause clinically significant thrombocytopenia in the fetus. This is reminiscent of hemolytic disease of the newborn, in which red cells are the target (Chapter 10). *The most important nonimmunological causes are disseminated intravascular coagulation (DIC) and the thrombotic microangiopathies*, in which unbridled, often systemic, platelet activation reduces platelet life span. Nonimmunological destruction of platelets may also be caused by *mechanical injury*, such as in individuals with prosthetic heart valves.
- *Sequestration*. The spleen normally sequesters 30% to 35% of the body's platelets, but this can rise to 80% to 90% when the spleen is enlarged, producing moderate degrees of thrombocytopenia.
- *Dilution*. Massive transfusions can produce a dilutional thrombocytopenia. With prolonged blood storage the number of viable platelets decreases; thus, plasma volume and red cell mass are reconstituted by transfusion, but the number of circulating platelets is relatively reduced.

TABLE 14-9 -- Causes of Thrombocytopenia

DECREASED PRODUCTION OF PLATELETS
Selective impairment of platelet production
Drug-induced: alcohol, thiazides, cytotoxic drugs
Infections: measles, human immunodeficiency virus (HIV)
Nutritional deficiencies
B_{12}, folate deficiency (megaloblastic leukemia)
Bone marrow failure
Aplastic anemia (see Table 14-7)
Bone marrow replacement
Leukemia, disseminated cancer, granulomatous disease
Ineffective hematopoiesis
Myelodysplastic syndromes (Chapter 13)
DECREASED PLATELET SURVIVAL
Immunologic destruction
Primary autoimmune
Chromic immune thrombocytopenic purpura
Acute immune thrombocytopenic purpura
Secondary autoimmune
Systemic lupus erythematosus, B-cell lymphoid neoplasms
Alloimmune: post-transfusion and neonatal
Drug-associated: quinidine, heparin, sulfa compounds
Infections: HIV, infectious mononucleosis (transient, mild), dengue fever
Nonimmunologic destruction
Disseminated intravascular coagulation

Thrombotic microangiopathies Giant hemangiomas
SEQUESTRATION
Hypersplenism
DILUTION
Transfusions

Chronic Immune Thrombocytopenic Purpura (ITP)

Chronic ITP is caused by autoantibodies to platelets. It can occur in the setting of a variety of predisposing conditions and exposures (secondary) or in the absence of any known risk factors (primary or idiopathic). The contexts in which chronic ITP occurs secondarily are numerous and include individuals with systemic lupus erythematosus (Chapter 6), HIV infection, and B-cell neoplasms such as chronic lymphocytic leukemia (Chapter 13). The diagnosis of primary chronic ITP is made only after secondary causes are excluded.

Pathogenesis.

The autoantibodies, most often directed against platelet membrane glycoproteins IIb-IIIa or Ib-IX, can be demonstrated in the plasma and bound to the platelet surface in about 80% of patients. In the overwhelming majority of cases, the antiplatelet antibodies are of the IgG class.

As in autoimmune hemolytic anemias, antiplatelet antibodies act as opsonins that are recognized by IgG Fc receptors expressed on phagocytes (Chapter 6), leading to increased platelet destruction. The thrombocytopenia is usually markedly improved by splenectomy, indicating that the spleen is the major site of removal of opsonized platelets. The splenic red pulp is also rich in plasma cells, and part of the benefit of splenectomy (a common treatment for chronic ITP) may stem from the removal of a source of autoantibodies. In some instances the autoantibodies may also bind to and damage megakaryocytes, leading to decreases in platelet production that further exacerbate the thrombocytopenia.

Morphology. The principal changes of thrombocytopenic purpura are found in the spleen, bone marrow, and blood, but they are not specific. Secondary changes related to the bleeding diathesis may be found in any tissue or structure in the body.

The **spleen** is of normal size. Typically, there is congestion of the sinusoids and enlargement of the splenic follicles, often associated with prominent reactive germinal centers. In many instances scattered megakaryocytes are found within the sinuses. This may represent a very mild form of extramedullary hematopoiesis that is driven by elevated levels of thrombopoietin. The **marrow** reveals a modestly increased number of megakaryocytes. Some are apparently immature, with large, nonlobulated, single nuclei. These findings are not specific for ITP but merely reflect accelerated thrombopoiesis, being found in most forms of thrombocytopenia resulting from increased platelet destruction. The importance of bone marrow examination is to rule out thrombocytopenias resulting from bone marrow failure or other primary bone marrow disorders. The secondary changes relate to the hemorrhages that are dispersed throughout the body. The **peripheral blood** often reveals abnormally large platelets (megathrombocytes), which are a sign of accelerated thrombopoiesis.

Clinical Features.

Chronic ITP occurs most commonly in adult women typically under 40 years of age. The female-to-male ratio is 3 : 1. It is often insidious in onset and is characterized by bleeding into the skin and mucosal surfaces. Cutaneous bleeding is seen in the form of *pinpoint hemorrhages* (petechiae), which are especially prominent in the dependent areas where the capillary pressure is higher. Petechiae can become confluent, giving rise to *ecchymoses*. Often there is a history of easy bruising, nosebleeds, bleeding from the gums, and hemorrhages into soft tissues from relatively minor trauma. The disease may manifest first with melena, hematuria, or excessive menstrual flow. Subarachnoid hemorrhage and intracerebral hemorrhage are serious and sometimes fatal complications, but fortunately they are rare in treated patients. Splenomegaly and lymphadenopathy are uncommon in primary disease, and their presence should lead one to consider other diagnoses, such as ITP secondary to a B-cell neoplasm.

The clinical signs and symptoms are not specific but rather reflective of the thrombocytopenia. The findings of a low platelet count, normal or increased megakaryocytes in the bone marrow, and large platelets in the peripheral blood are taken as presumptive evidence of accelerated platelet destruction. The PT and PTT are normal. Tests for platelet autoantibodies are not widely available. *Therefore, the diagnosis is one of exclusion and can be made only after other causes of thrombocytopenia, such as those listed in* Table 14-9 *, have been ruled out*.

Almost all patients respond to glucocorticoids (which inhibit phagocyte function), but many eventually relapse. In such individuals, splenectomy normalizes the platelet count in about two thirds of patients, but with the attendant in-creased risk of bacterial sepsis. Immunomodulatory agents such as intravenous immunoglobulin or anti-CD20 antibody (rituximab) are often effective in patients who relapse after splenectomy or for whom splenectomy is contraindicated.

Acute Immune Thrombocytopenic Purpura

Like chronic ITP, this condition is caused by autoantibodies to platelets, but its clinical features and course are distinct. Acute ITP is mainly a disease of childhood occurring with equal frequency in both sexes. Symptoms appear abruptly and usually follow a viral illness, which typically occurs about 2 weeks before the onset of the thrombocytopenia. Unlike chronic ITP, acute ITP is self-limited, usually resolving spontaneously within 6 months. Glucocorticoids are given only if the thrombocytopenia is severe. In about 20% of children, usually those without a viral prodrome, thrombocytopenia persists; these less fortunate children have a childhood form of chronic ITP that follows a course similar to the adult disease.

Drug-Induced Thrombocytopenia

Drugs can induce thrombocytopenia through direct effects on platelets and secondary to immunologically mediated platelet destruction. The drugs most commonly implicated are quinine, quinidine, and vancomycin, all of which bind platelet glycoproteins and in one way or another create antigenic determinants that are recognized by antibodies.[24] Much more rarely, drugs such as gold salts induce true autoantibodies through unknown mechanisms. Thrombocytopenia, which may be severe, is also a common consequence of platelet inhibitory drugs that bind glycoprotein IIb/IIIa; it is hypothesized that these drugs induce conformational changes in glycoprotein IIb/IIIa and create an immunogenic epitope.

Heparin-induced thrombocytopenia (HIT) has a distinctive pathogenesis and is of particular importance because of its potential for severe clinical consequences.[25] Thrombocytopenia occurs in about 5% of persons receiving heparin. Most develop so-called type I thrombocytopenia, which occurs rapidly after the onset of therapy and is of little clinical importance, sometimes resolving despite the continuation of therapy. It most likely results from a direct platelet-aggregating effect of heparin. Type II thrombocytopenia is less common but of much greater clinical significance. It occurs 5 to 14 days

after therapy begins (or sooner if the person has been sensitized to heparin) and, paradoxically, often leads to life-threatening venous and arterial thrombosis. This severe form of HIT is caused by antibodies that recognize complexes of heparin and platelet factor 4, which is a normal component of platelet granules. *Binding of antibody to these complexes activates platelets and promotes thrombosis, even in the setting of thrombocytopenia*. Unless therapy is immediately discontinued and an alternative nonheparin anticoagulant instituted, clots within large arteries may lead to vascular insufficiency and limb loss, and emboli from deep venous thrombosis can cause fatal pulmonary thromboembolism. The risk of severe HIT is lowered, but not completely eliminated, by the use of low-molecular-weight heparin preparations. Unfortunately, once severe HIT develops even low-molecular-weight heparins exacerbate the thrombotic tendency and must be avoided.

HIV-Associated Thrombocytopenia

Thrombocytopenia is one of the most common hematologic manifestation of HIV infection. Both impaired platelet production and increased destruction contribute. CD4 and CXCR4, the receptor and coreceptor, respectively, for HIV, are found on megakaryocytes, allowing these cells to be infected. HIV-infected megakaryocytes are prone to apoptosis and their ability to produce platelets is impaired. HIV infection also causes B-cell hyperplasia and dysregulation, which predisposes to the development of autoantibodies. In some instances the antibodies are directed against platelet membrane glycoprotein IIb-III complexes. As in other immune cytopenias, the autoantibodies opsoninize platelets, promoting their destruction by mononuclear phagocytes in the spleen and elsewhere. The deposition of immune complexes on platelets may also contribute to the accelerated loss of platelets in some patients who are HIV infected.

Thrombotic Microangiopathies: Thrombotic Thrombocytopenic Purpura (TTP) and Hemolytic-Uremic Syndrome (HUS)

The term *thrombotic microangiopathy* encompasses a spectrum of clinical syndromes that includes TTP and HUS. According to its original description, TTP was defined as the pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, transient neurologic deficits, and renal failure. HUS is also associated with microangiopathic hemolytic anemia and thrombocytopenia but is distinguished by the absence of neurologic symptoms, the prominence of acute renal failure, and its frequent occurrence in children. With time, experience, and increased mechanistic insight, however, these distinctions have blurred. Many adult patients with "TTP" lack one or more of the five criteria, and some patients with "HUS" have fever and neurologic dysfunction. *It is now appreciated that HUS and TTP are both caused by insults that lead to the excessive activation of platelets, which deposit as thrombi in microcirculatory beds*. These intravascular thrombi cause a *microangiopathic hemolytic anemia* and widespread *organ dysfunction*, and the attendant consumption of platelets leads to *thrombocytopenia*. It is believed that the varied clinical manifestations of TTP and HUS are related to differing proclivities for thrombus formation in tissues.

Although certain features of the various thrombotic microangiopathies overlap, the triggers for the pathogenic platelet activation are distinctive and provide a more satisfying and clinically relevant way of thinking about these disorders; these are summarized in Table 14-10 . *TTP is usually associated with a deficiency in a plasma enzyme called ADAMTS13*, also designated "vWF metalloprotease." ADAMTS13 normally degrades very high-molecular-weight multimers of von Willebrand factor (vWF). In its absence, these multimers accumulate in plasma and tend to promote platelet activation and aggregation. Superimposition of endothelial cell injury (caused by some other condition) may further promote the formation of platelet microaggregates, thus initiating or exacerbating clinically evident TTP.

TABLE 14-10 -- Thrombotic Microangiopathies: Causes and Associations

THROMBOTIC THROMBOCYTOPENIC PURPURA
Deficiency of ADAMTS13
Inherited
Acquired (autoantibodies)
HEMOLYTIC UREMIC SYNDROME
Epidemic: Escherichia coli strain O157 : H7 infection
Endothelial damage by Shiga-like toxin
Nonepidemic: alternative complement pathway inhibitor deficiencies (complement factor H, membrane cofactor protein (CD46), or factor I)
Inherited
Acquired (autoantibodies)
Miscellaneous associations
Drugs (cyclosporine, chemotherapeutic agents)
Radiation, bone marrow transplantation
Other infections (HIV, pneumococcal sepsis)
Conditions associated with autoimmunity (systemic lupus erythematosus, HIV infection, lymphoid neoplasms)

HIV, human immunodeficiency virus.

The deficiency of ADAMTS13 can be inherited or acquired. In the acquired form, an autoantibody that inhibits the metalloprotease activity of ADAMTS13 is present.[26] Less commonly, patients inherit an inactivating mutation in *ADAMTS13*.[27] In those with hereditary ADAMTS13 deficiency, the onset is often delayed until adolescence and the symptoms are episodic. Thus, factors other than ADAMTS13 (e.g., some superimposed vascular injury or prothrombotic state) must be involved in triggering full-blown TTP.

TTP is an important diagnosis to consider in any patient presenting with thrombocytopenia and microangiopathic hemolytic anemia, since delays in diagnosis can be fatal. With plasma exchange, which removes autoantibodies and provides functional ADAMTS13, TTP (which once was uniformly fatal) can be treated successfully in more than 80% of patients.

In contrast, HUS is associated with normal levels of ADAMTS13 and is initiated by several other distinct defects.[28] *Epidemic, "typical" HUS is strongly associated with infectious gastroenteritis caused by Escherichia coli strain O157:H7, which elaborates a Shiga-like toxin*. This toxin is absorbed from the inflamed gastrointestinal mucosa into the circulation, where it alters endothelial cell function in some manner that results in platelet activation and aggregation. Children and the elderly are at highest risk. Those affected present with bloody diarrhea, and a few days later HUS makes its appearance. With appropriate supportive care complete recovery is possible, but irreversible renal damage and death can occur in more severe cases.

Nonepidemic, "atypical" HUS is often associated with defects in complement factor H, membrane cofactor protein (CD46), or factor I, three proteins that normally act to prevent excessive activation of the alternative complement pathway. Deficiencies of these proteins can be caused by inherited defects

or acquired inhibitory autoantibodies and are associated with a remitting, relapsing course. Unlike TTP, the basis for the platelet activation in HUS is unclear; presumably, both Shiga-like toxin produced by pathogenic *E. coli* and defects in complement-regulatory proteins alter endothelial cell function in some way that promotes platelet activation.

Thrombotic microangiopathies resembling HUS can also be seen following exposures to other agents that damage endothelial cells (e.g., certain drugs and radiation therapy). The prognosis in these settings is guarded, because the HUS is often complicated by chronic, life-threatening conditions.

While DIC (discussed later) and thrombotic microangiopathies share features such as microvascular occlusion and microangiopathic hemolytic anemia, they are pathogenically distinct. In TTP and HUS (unlike in DIC), activation of the coagulation cascade is not of primary importance, and hence laboratory tests of coagulation, such as the PT and PTT, are usually normal.

BLEEDING DISORDERS RELATED TO DEFECTIVE PLATELET FUNCTIONS

Qualitative defects of platelet function can be inherited or acquired. Several inherited disorders characterized by abnormal platelet function and normal platelet count have been described. A brief discussion of these rare diseases is warranted because they provide excellent models for investigating the molecular mechanisms of platelet function.

Inherited disorders of platelet function can be classified into three pathogenically distinct groups: (1) *defects of adhesion*, (2) *defects of aggregation*, and (3) *disorders of platelet secretion (release reaction)*.

- Bleeding resulting from defective adhesion of platelets to subendothelial matrix is best illustrated by the autosomal recessive disorder *Bernard-Soulier syndrome*, which is caused by an inherited deficiency of the platelet membrane glycoprotein complex Ib-IX. This glycoprotein is a receptor for vWF and is essential for normal platelet adhesion to the subendothelial extracellular matrix (Chapter 4).
- Bleeding due to *defective platelet aggregation* is exemplified by *Glanzmann thrombasthenia*, which is also transmitted as an autosomal recessive trait. Thrombasthenic platelets fail to aggregate in response to adenosine diphosphate (ADP), collagen, epinephrine, or thrombin because of deficiency or dysfunction of glycoprotein IIb-IIIa, an integrin that participates in “bridge formation” between platelets by binding fibrinogen.
- *Disorders of platelet secretion* are characterized by the defective release of certain mediators of platelet activation, such as thromboxanes and granule-bound ADP. The biochemical defects underlying these so-called *storage pool disorders* are varied, complex, and beyond the scope of our discussion.

Among the *acquired defects* of platelet function, two are clinically significant. The first is caused by *ingestion of aspirin and other nonsteroidal anti-inflammatory drugs*. Aspirin is a potent, irreversible inhibitor of the enzyme cyclooxygenase, which is required for the synthesis of thromboxane A_2 and prostaglandins (Chapter 2). These mediators play important roles in platelet aggregation and subsequent release reactions (Chapter 4). The antiplatelet effects of aspirin form the basis for its use in the prophylaxis of coronary thrombosis (Chapter 12). *Uremia* (Chapter 20) is the second condition exemplifying an acquired defect in platelet function. The pathogenesis of platelet dysfunction in uremia is complex and involves defects in adhesion, granule secretion, and aggregation.[29]

HEMORRHAGIC DIATHESES RELATED TO ABNORMALITIES IN CLOTTING FACTORS

Inherited or acquired deficiencies of virtually every coagulation factor have been reported as causes of bleeding diatheses. Unlike the petechial bleeding seen with thrombocytopenia, *bleeding due to isolated coagulation factor deficiencies most commonly manifests as large post-traumatic ecchymoses or hematomas, or prolonged bleeding after a laceration or any form of surgical procedure*. Bleeding into the gastrointestinal and urinary tracts, and particularly into weight-bearing joints (hemarthrosis), is

common. Typical stories include the patient who oozes blood for days after a tooth extraction or who develops a hemarthrosis after minor stress on a knee joint.

Hereditary deficiencies typically affect a single clotting factor. The most common and important inherited deficiencies of coagulation factors affect factor VIII (hemophilia A), and factor IX (hemophilia B). Deficiencies of vWF (von Willebrand disease) are also discussed here, as this factor influences both coagulation and platelet function. Rare inherited deficiencies of each of the other coagulation factors have also been described. All cause bleeding except for factor XII deficiency; presumably, in vivo the extrinsic pathway and thrombin-mediated activation of factors XI and IX compensate for the absence of factor XII.

Acquired deficiencies usually involve multiple coagulation factors simultaneously and can be based on decreased protein synthesis or a shortened half-life. Vitamin K deficiency (Chapter 9) results in the impaired synthesis of factors II, VII, IX, and X and protein C. Many of these factors are made in the liver and are therefore deficient in severe parenchymal liver disease. Alternatively, in DIC, multiple coagulation factors are consumed and are therefore deficient. Acquired deficiencies of single factors occur, but they are rare. These are usually caused by inhibitory autoantibodies.

The Factor VIII-vWF Complex

The two most common inherited disorders of bleeding, hemophilia A and von Willebrand disease, are caused by qualitative or quantitative defects involving factor VIII and vWF, respectively. Before we discuss these disorders it will be helpful to review the structure and function of these two proteins, which exist together in the plasma as part of a single large complex.

Factor VIII and vWF are encoded by separate genes and are synthesized in different cells. Factor VIII is an essential cofactor of factor IX, which converts factor X to factor Xa (Fig. 14-26 ; also see Chapter 4). It is made in several tissues; sinusoidal endothelial cells and Kupffer cells in the liver, and tubular epithelial cells in the kidney, seem to be particularly important sources. Once factor VIII reaches the circulation, it binds to vWF, which is produced by endothelial cells and, to a lesser degree, by megakaryocytes, which are the source of the vWF that is found in platelet α-granules. vWF stabilizes factor VIII, which has a half-life of about 2.4 hours when free and 12 hours when bound to vWF in the circulation.

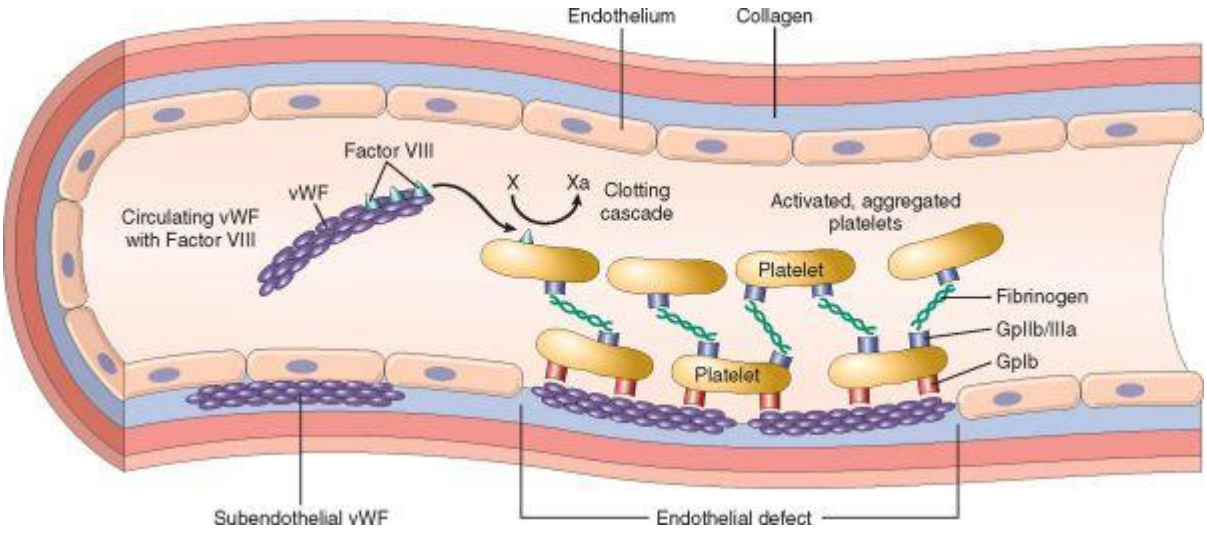

FIGURE 14-26 Structure and function of factor VIII–von Willebrand factor (vWF) complex. Factor VIII is synthesized in the liver and kidney, and vWF is made in endothelial cells and megakaryocytes. The two associate to form a complex in the circulation. vWF is also present

in the subendothelial matrix of normal blood vessels and the α-granules of platelets. Following endothelial injury, exposure of subendothelial vWF causes adhesion of platelets, primarily via the glycoprotein lb (GpIb) platelet receptor. Circulating vWF and vWF released from the α-granules of activated platelets can bind exposed subendothelial matrix, further contributing to platelet adhesion and activation. Activated platelets form hemostatic aggregates; fibrinogen (and possibly vWF) participates in aggregation through bridging interactions with the glycoprotein IIb/IIIa (GpIIb/IIIa) platelet receptor. Factor VIII takes part in the coagulation cascade as a cofactor in the activation of factor X on the surface of activated platelets.

Circulating vWF exists as multimers containing as many as 100 subunits that can exceed 20×10^6 daltons in molecular mass. In addition to factor VIII, these multimers interact with several other proteins involved in hemostasis, including collagen, heparin, and possibly platelet membrane glycoproteins. The most important function of vWF is to promote the adhesion of platelets to the subendothelial matrix. This occurs through bridging interactions between platelet glycoprotein Ib-IX, vWF, and matrix components such as collagen. Some vWF is secreted from endothelial cells directly into the subendothelial matrix, where it lies ready to promote platelet adhesion if the endothelial lining is disrupted (see Fig. 14-26). Endothelial cells and platelets also release vWF into the circulation. Upon vascular injury, this second pool of vWF binds collagen in the subendothelial matrix to further augment platelet adhesion. vWF multimers may also promote platelet aggregation by binding to activated GpIIb/IIIa integrins; this activity may be of particular importance under conditions of high shear stress (such as occurs in small vessels).

Factor VIII and vWF protein levels are measured by immunological techniques. Factor VIII function is assessed by conducting coagulation assays with mixtures of patient plasma and factor VIII-deficient plasma. vWF function is assessed using the ristocetin agglutination test. This assay is performed by mixing the patient's plasma with formalin-fixed platelets and ristocetin, a small molecule that binds and "activates" vWF. Ristocetin induces multivalent vWF multimers to bind platelet glycoprotein Ib-IX and form interplatelet "bridges." The resulting clumping (agglutination) of platelets is measured in a device called an aggregometer. Thus, the degree to which patient plasma promotes ristocetin-dependent platelet agglutination is a measure of vWF activity.

Von Willebrand Disease

Von Willebrand disease is the most common inherited bleeding disorder of humans, affecting about 1% of adults in the United States. In most of those affected, the bleeding tendency is mild and often goes unnoticed until some hemostatic stress, such as surgery or a dental procedure, reveals its presence. The most common symptoms are spontaneous bleeding from mucous membranes (e.g., epistaxis); excessive bleeding from wounds; menorrhagia; and a prolonged bleeding time in the presence of a normal platelet count. It is usually transmitted as an autosomal dominant disorder, but rare autosomal recessive variants have been described.

Von Willebrand disease is molecularly heterogeneous.[30] More than 20 variants have been described, which can be grouped into two major categories:

Type 1 and type 3 von Willebrand disease are associated with a reduced quantity of circulating vWF. Type 1, an autosomal dominant disorder characterized by a mild to moderate quantitative vWF deficiency, accounts for about 70% of all cases. Incomplete penetrance and variable expressivity are commonly observed, but it generally is associated with mild disease. Type 3 (an autosomal recessive disorder) is associated with extremely low levels of functional vWF and correspondingly severe clinical manifestations. Because a severe deficiency of vWF has a marked effect on the stability of factor VIII, some of the bleeding characteristics resemble those seen in hemophilia. The nature of the mutations in

the majority of individuals with type 1 disease is poorly defined. In some cases missense mutations have been found. Type 3 disease is usually caused by deletions or frameshift mutations involving both alleles.

Type 2 von Willebrand disease is characterized by qualitative defects in vWF; there are several subtypes, of which type 2A is the most common. It is inherited as an autosomal dominant disorder. vWF is expressed in normal amounts, but missense mutations are present that lead to defective multimer assembly. Large and intermediate multimers, representing the most active forms of vWF, are missing from plasma. Type 2 von Willebrand disease accounts for 25% of all cases and is associated with mild to moderate bleeding.

Patients with von Willebrand disease have *defects in platelet function* despite a *normal platelet count*. The plasma level of active vWF, measured as the ristocetin cofactor activity, is reduced. Because vWF stabilizes factor VIII, a deficiency of vWF gives rise to a secondary decrease in factor VIII levels. This may be reflected by a prolongation of the PTT in von Willebrand disease types 1 and 3. However, except in rare type 3 patients, adverse complications typical of severe factor VIII deficiency, such as bleeding into the joints, are not seen.

To summarize, in von Willebrand disease inherited defects in vWF lead to secondary abnormalities in platelet adhesion and clot formation. Even within families in which a single defective vWF allele is segregating, a wide variability in clinical expression is common. This is due in part to additional genetic factors that influence circulating levels of vWF, which vary greatly in normal populations. Persons facing hemostatic challenges (dental work, surgery) can be treated with desmopressin, which stimulates vWF release, or infusions of plasma concentrates containing factor VIII and vWF.

Hemophilia A (Factor VIII Deficiency)

Hemophilia A is the most common hereditary disease associated with life-threatening bleeding.[31] It is caused by mutations in factor VIII, which is an essential cofactor for factor IX in the coagulation cascade (Chapter 4). Hemophilia A is inherited as an X-linked recessive trait and thus affects mainly males and homozygous females. Rarely, excessive bleeding occurs in heterozygous females, presumably as a result of inactivation of the X chromosome bearing the normal factor VIII allele by chance in most cells (unfavorable lyonization). About 30% of patients have no family history; their disease is caused by new mutations.

Hemophilia A exhibits a wide range of clinical severity that correlates well with the level of factor VIII activity. Those with less than 1% of normal levels have severe disease; those with 2% to 5% of normal levels have moderately severe disease; and those with 6% to 50% of normal levels have mild disease. The varying degrees of factor VIII deficiency are largely explained by heterogeneity in the causative mutations. As with β-thalassemia, the genetic lesions include deletions, nonsense mutations that create stop codons, and mutations that cause errors in mRNA splicing. The most severe deficiencies result from an inversion involving the X chromosome that completely abolishes the synthesis of factor VIII. Less commonly, severe hemophilia A is associated with point mutations in factor VIII that impair the function of the protein. In such cases factor VIII levels seem normal by immunoassay. Mutations permitting some active factor VIII to be synthesized are associated with mild to moderate disease. The disease in such patients may be modified by other genetic factors that influence factor VIII expression levels, which vary widely in normal individuals.

In all symptomatic cases there is a tendency toward easy bruising and massive hemorrhage after trauma or operative procedures. In addition, “spontaneous” hemorrhages frequently occur in regions of the body normally subject to trauma, particularly the joints, where they are known as *hemarthroses*. Recurrent bleeding into the joints leads to progressive deformities that can be crippling. *Petechiae are characteristically absent.*

Patients with hemophilia A typically have a prolonged PTT and a normal PT. These tests point to an abnormality of the intrinsic coagulation pathway. Factor VIII–specific assays are required for diagnosis.

Given that one arm of the coagulation cascade, the extrinsic pathway, is intact in hemophilia A, it is reasonable to ask: Why do patients bleed? Obviously, test tube assays of coagulation are imperfect surrogates for what occurs in vivo, and it must be that in the face of factor VIII deficiency, fibrin deposition is inadequate to achieve hemostasis. It is beyond our scope to discuss this issue in detail; it seems that the chief role of the extrinsic pathway in hemostasis is to initiate a limited burst of thrombin activation upon tissue injury. This initial procoagulant stimulus is reinforced and amplified by a critical feedback loop in which thrombin activates factors XI and IX of the intrinsic pathway (Chapter 4). In the absence of factor VIII, this feedback loop is inactive and insufficient thrombin (and fibrin) is generated to create a stable clot. In addition, high levels of thrombin are required to activate TAFI (thrombin-activated fibrinolysis inhibitor), a factor that inhibits fibrinolysis. Thus, both inadequate coagulation (fibrinogenesis) and inappropriate clot removal (fibrinolysis) contribute to the bleeding diathesis in hemophilia. The precise explanation for the tendency of hemophiliacs to bleed at particular sites (joints, muscles, and the central nervous system) remains uncertain.

Hemophilia A is treated with infusions of recombinant factor VIII. About 15% of patients with severe hemophilia A develop antibodies that bind and inhibit factor VIII, probably because the protein is perceived as foreign, having never been “seen” by the immune system. These antibody inhibitors can be a very difficult therapeutic challenge. Before the development of recombinant factor VIII therapy, thousands of hemophiliacs received plasma-derived factor VIII concentrates containing HIV, and many developed AIDS (Chapter 6). The risk of HIV transmission has been eliminated but tragically too late for an entire generation of hemophiliacs. Efforts to develop somatic gene therapy for hemophilia are continuing.

Hemophilia B (Christmas Disease, Factor IX Deficiency)

Severe factor IX deficiency produces a disorder clinically indistinguishable from factor VIII deficiency (hemophilia A). This should not be surprising, given that factors VIII and IX function together to activate factor X. A wide spectrum of mutations involving the gene that encodes factor IX is found in hemophilia B. Like hemophilia A it is inherited as an X-linked recessive trait and shows variable clinical severity. In about 15% of these patients, factor IX is present but nonfunctional. As with hemophilia A, the PTT is prolonged and the PT is normal. Diagnosis of Christmas disease (named after the first patient identified with this condition, and not the holiday) is possible only by assay of the factor levels. The disease is treated with infusions of recombinant factor IX.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

DIC is an acute, subacute, or chronic thrombohemorrhagic disorder characterized by the excessive activation of coagulation, which leads to the formation of thrombi in the microvasculature of the body. It occurs as a secondary complication of many different disorders. Sometimes the coagulopathy is localized to a specific organ or tissue. As a consequence of the thrombotic diathesis there is consumption of platelets, fibrin, and coagulation factors and, secondarily, activation of fibrinolysis. DIC can present with signs and symptoms relating to the tissue hypoxia and infarction caused by the myriad microthrombi; with hemorrhage caused by the depletion of factors required for hemostasis and the activation of fibrinolytic mechanisms; or both.

Etiology and Pathogenesis.

At the outset, it must be emphasized that DIC is not a primary disease. It is a coagulopathy that occurs in the course of a variety of clinical conditions. In discussing the general mechanisms underlying DIC, it

is useful to briefly review the normal process of blood coagulation and clot removal (see Chapter 4 for more details).

Clotting can be initiated by either of two pathways: (1) the *extrinsic pathway*, which is triggered by the release of tissue factor ("tissue thromboplastin"); and (2) the *intrinsic pathway*, which involves the activation of factor XII by surface contact with collagen or other negatively charged substances. Both pathways, through a series of intermediate steps, result in the generation of thrombin, which in turn converts fibrinogen to fibrin. At the site of injury, thrombin further augments local fibrin deposition by directly activating the intrinsic pathway and factors that inhibit fibrinolysis.

Once clotting is initiated, it is critically important that it be limited to the site of injury. Remarkably, as thrombin is swept away in the bloodstream and encounters normal vessels, it is converted to an anticoagulant through binding to *thrombomodulin*, a protein found on the surface of endothelial cells. The thrombin-thrombomodulin complex activates protein C, which is an important inhibitor of two procoagulants, factor V and factor VIII. Other activated coagulation factors are removed from the circulation by the liver, and as you will recall, the blood also contains several potent fibrinolytic factors, such as plasmin. These and additional checks and balances normally ensure that just enough clotting occurs at the right place and time.

From this brief review it should be clear that DIC could result from pathologic activation of the extrinsic and/or intrinsic pathways of coagulation or the impairment of clot-inhibiting mechanisms. Since the latter rarely constitute primary mechanisms of DIC, we will focus on the abnormal initiation of clotting.

Two major mechanisms trigger DIC: (1) release of tissue factor or thromboplastic substances into the circulation, and (2) widespread injury to the endothelial cells. Thromboplastic substances can be derived from a variety of sources, such as the placenta in obstetric complications and the cytoplasmic granules of acute promyelocytic leukemia cells (Chapter 13). Mucus released from certain adenocarcinomas can directly activate factor X, independent of factor VII.

Endothelial injury can initiate DIC in several ways. Injuries that cause endothelial cell necrosis expose the subendothelial matrix, leading to the activation of platelets and both arms of the coagulation pathway. However, even subtle endothelial injuries can unleash procoagulant activity. One mediator of such effects is TNF, which is implicated in DIC occurring with sepsis. TNF induces endothelial cells to express tissue factor on their cell surfaces and to decrease the expression of thrombomodulin, shifting the checks and balances that govern hemostasis towards coagulation. In addition, TNF upregulates the expression of adhesion molecules on endothelial cells, thereby promoting the adhesion of leukocytes, which can damage endothelial cells by releasing reactive oxygen species and preformed proteases. Widespread endothelial injury may also be produced by deposition of antigen-antibody complexes (e.g., systemic lupus erythematosus), temperature extremes (e.g., heat stroke, burns), or microorganisms (e.g., meningococci, rickettsiae). Even subtle endothelial injury can unleash procoagulant activity by enhancing membrane expression of tissue factor.

DIC is most likely to be associated with *obstetric complications, malignant neoplasms, sepsis, and major trauma*. The triggers in these conditions are often multiple and interrelated. For example, in bacterial infections *endotoxins* can injure endothelial cells and inhibit the expression of thrombomodulin directly or through production of TNF; stimulate the release of thromboplastins from inflammatory cells; and activate factor XII. Antigen-antibody complexes formed in response to the infection can activate the classical complement pathway, giving rise to complement fragments that secondarily activate both platelets and granulocytes. In *massive trauma, extensive surgery*, and *severe burns*, the major trigger is the release of tissue thromboplastins. In *obstetric conditions*, thromboplastins derived from the placenta,

dead retained fetus, or amniotic fluid may enter the circulation. *Hypoxia, acidosis, and shock,* which often coexist in very ill patients, can also cause widespread endothelial injury, and supervening infections can complicate the problems further. *Among cancers, acute promyelocytic leukemia and adenocarcinomas* of the lung, pancreas, colon, and stomach are most frequently associated with DIC.

The possible consequences of DIC are twofold (Fig. 14-27). Firstly, there is *widespread deposition of fibrin* within the microcirculation. This leads to *ischemia* of the more severely affected or more vulnerable organs and a *microangiopathic hemolytic anemia*, which results from the fragmentation of red cells as they squeeze through the narrowed microvasculature. Secondly, the consumption of platelets and clotting factors and the activation of plasminogen leads to a *hemorrhagic diathesis*. Plasmin not only cleaves fibrin, but it also digests factors V and VIII, thereby reducing their concentration further. In addition, fibrin degradation products resulting from fibrinolysis inhibit platelet aggregation, fibrin polymerization, and thrombin. All of these derangements contribute to the hemostatic failure seen in DIC.

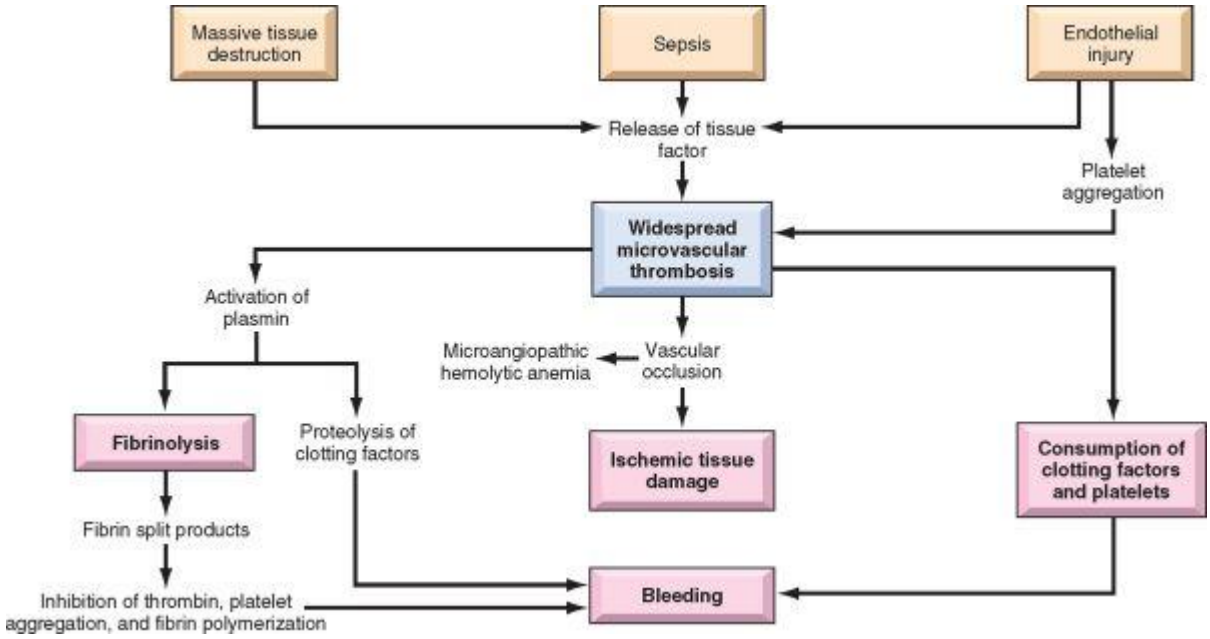

FIGURE 14-27 Pathophysiology of disseminated intravascular coagulation.

Morphology. Thrombi are most often found in the brain, heart, lungs, kidneys, adrenals, spleen, and liver, in decreasing order of frequency, but any tissue can be affected. Affected kidneys may have small thrombi in the glomeruli that evoke only reactive swelling of endothelial cells or, in severe cases, microinfarcts or even bilateral renal cortical necrosis. Numerous fibrin thrombi may be found in alveolar capillaries, sometimes associated with pulmonary edema and fibrin exudation, creating "hyaline membranes" reminiscent of acute respiratory distress syndrome (Chapter 15). In the central nervous system, fibrin thrombi can cause microinfarcts, occasionally complicated by simultaneous hemorrhage, which can sometimes lead to variable neurologic signs and symptoms. The manifestations in the endocrine glands are of considerable interest. In meningococcemia, fibrin thrombi within the microcirculation of the adrenal cortex are the probable basis for the massive adrenal hemorrhages seen in **Waterhouse-Friderichsen syndrome** (Chapter 24). Similarly, **Sheehan postpartum pituitary necrosis** (Chapter 24) is a form of DIC complicating labor and

delivery. In toxemia of pregnancy (Chapter 22) the placenta exhibits widespread microthrombi, providing a plausible explanation for the premature atrophy of the cytotrophoblast and syncytiotrophoblast that is encountered in this condition. An unusual form of DIC occurs in association with giant hemangiomas, in which thrombi form within the neoplasm because of stasis and recurrent trauma to fragile blood vessels.

Clinical Features.

The onset can be fulminant, as in endotoxic shock or amniotic fluid embolism, or insidious and chronic, as in cases of carcinomatosis or retention of a dead fetus. Overall, about 50% of the affected are obstetric patients having complications of pregnancy. In this setting the disorder tends to be reversible with delivery of the fetus. About 33% of the affected patients have carcinomatosis. The remaining cases are associated with the various entities previously listed.

It is almost impossible to detail all the potential clinical presentations, but a few common patterns are worthy of description. These include microangiopathic hemolytic anemia; dyspnea, cyanosis, and respiratory failure; convulsions and coma; oliguria and acute renal failure; and sudden or progressive circulatory failure and shock. In general, *acute DIC, associated with obstetric complications or major trauma, for example, is dominated by a bleeding diathesis, whereas chronic DIC, such as occurs in cancer patients, tends to present with thrombotic complications*. The diagnosis is based on clinical observation and laboratory studies, including measurement of fibrinogen levels, platelets, the PT and PTT, and fibrin degradation products.

The prognosis is highly variable and largely depends on the underlying disorder. *The only definitive treatment is to remove or treat the inciting cause*. The management requires meticulous maneuvering between the Scylla of thrombosis and the Charybdis of bleeding diathesis. Administration of anticoagulants or procoagulants has been advocated in specific settings, but not without controversy.

3.5 15. The Lung

3.5.1 Congenital Anomalies

ALIYA N. HUSAIN

The lungs are ingeniously constructed to carry out their cardinal function: the exchange of gases between inspired air and blood. Developmentally, the respiratory system is an outgrowth from the ventral wall of the foregut. The midline trachea develops two lateral outpocketings, the lung buds. The right lung bud eventually divides into three branches—the lobar bronchi—and the left into two lobar bronchi, thus giving rise to three lobes on the right and two on the left. The right main stem bronchus is more vertical and more directly in line with the trachea. Consequently, aspirated foreign materials, such as vomitus, blood, and foreign bodies, tend to enter the right lung more than the left. The lobar right and left bronchi branch dichotomously, giving rise to progressively smaller airways. Accompanying the branching airways is the double arterial supply to the lungs, that is, the pulmonary and bronchial arteries.

Progressive branching of the bronchi forms *bronchioles*, which are distinguished from bronchi by the lack of cartilage and submucosal glands within their walls. Further branching of bronchioles leads to the *terminal bronchioles*, which are less than 2 mm in diameter. The part of the lung distal to the terminal bronchiole is called the *acinus*; it is roughly spherical, with a diameter of about 7 mm. An acinus is composed of *respiratory bronchioles* (which give off several alveoli from their sides), *alveolar ducts*, and *alveolar sacs*, the blind ends of the respiratory passages, whose walls are formed entirely of alveoli, which are the site of gas exchange. A cluster of three to five terminal bronchioles, each with its appended acinus, is referred to as the pulmonary *lobule*. This lobular architecture assumes importance in distinguishing the major forms of emphysema.

Except for the vocal cords, which are covered by stratified squamous epithelium, the entire respiratory tree, including the larynx, trachea, and bronchioles, is lined by pseudostratified, tall, columnar, ciliated epithelial cells. The bronchial mucosa also contains a population of neuroendocrine cells that have neurosecretory-type granules and can release a variety of factors, including serotonin, calcitonin, and gastrin-releasing peptide (bombesin). Numerous mucus-secreting goblet cells and submucosal glands are dispersed throughout the walls of the trachea and bronchi (but not the bronchioles).

The microscopic structure of the alveolar walls (or alveolar septa) consists, from blood to air, of the following (Fig. 15-1):

- *Capillary endothelium* lining the intertwining network of anastomosing capillaries.
- *Basement membrane and surrounding interstitial tissue* separating the endothelial cells from the alveolar lining epithelial cells. In thin portions of the alveolar septum, the basement membranes of epithelium and endothelium are fused, whereas in thicker portions they are separated by an interstitial space *(pulmonary interstitium)* containing fine elastic fibers, small bundles of collagen, a few fibroblast-like interstitial cells, smooth muscle cells, mast cells, and rarely lymphocytes and monocytes.
- *Alveolar epithelium*, a continuous layer of two cell types: flattened, platelike *type I pneumocytes* covering 95% of the alveolar surface and rounded *type II pneumocytes*. Type II cells synthesize *surfactant*, contained in osmiophilic *lamellar bodies* seen with electron microscopy, and are involved in the repair of alveolar epithelium through their ability to give rise to type I cells.
- *Alveolar macrophages*, loosely attached to the epithelial cells or lying free within the alveolar spaces, are derived from blood monocytes and belong to the mononuclear phagocyte system. Often, they are filled with carbon particles and other phagocytosed materials.

The alveolar walls are perforated by numerous *pores of Kohn*, which permit the passage of bacteria and exudate between adjacent alveoli (see Fig. 15-34B). Adjacent to the alveolar cell membrane is the pulmonary surfactant layer.

Primary respiratory infections, such as bronchitis and pneumonia, are commonplace in clinical and pathologic practice. With cigarette smoking, air pollution, and other environmental inhalants, chronic bronchitis and emphysema have become rampant. In men, malignancy of the lungs had been rising steadily but has now plateaued and is expected to decline in the future. Unfortunately, as more and more women are smoking, lung cancer has become the most common malignancy in women, surpassing even breast cancer and is now the most common lethal visceral malignancy in men and women. Although the lungs are secondarily involved in almost all forms of terminal disease, primary pulmonary diseases are emphasized in this chapter.

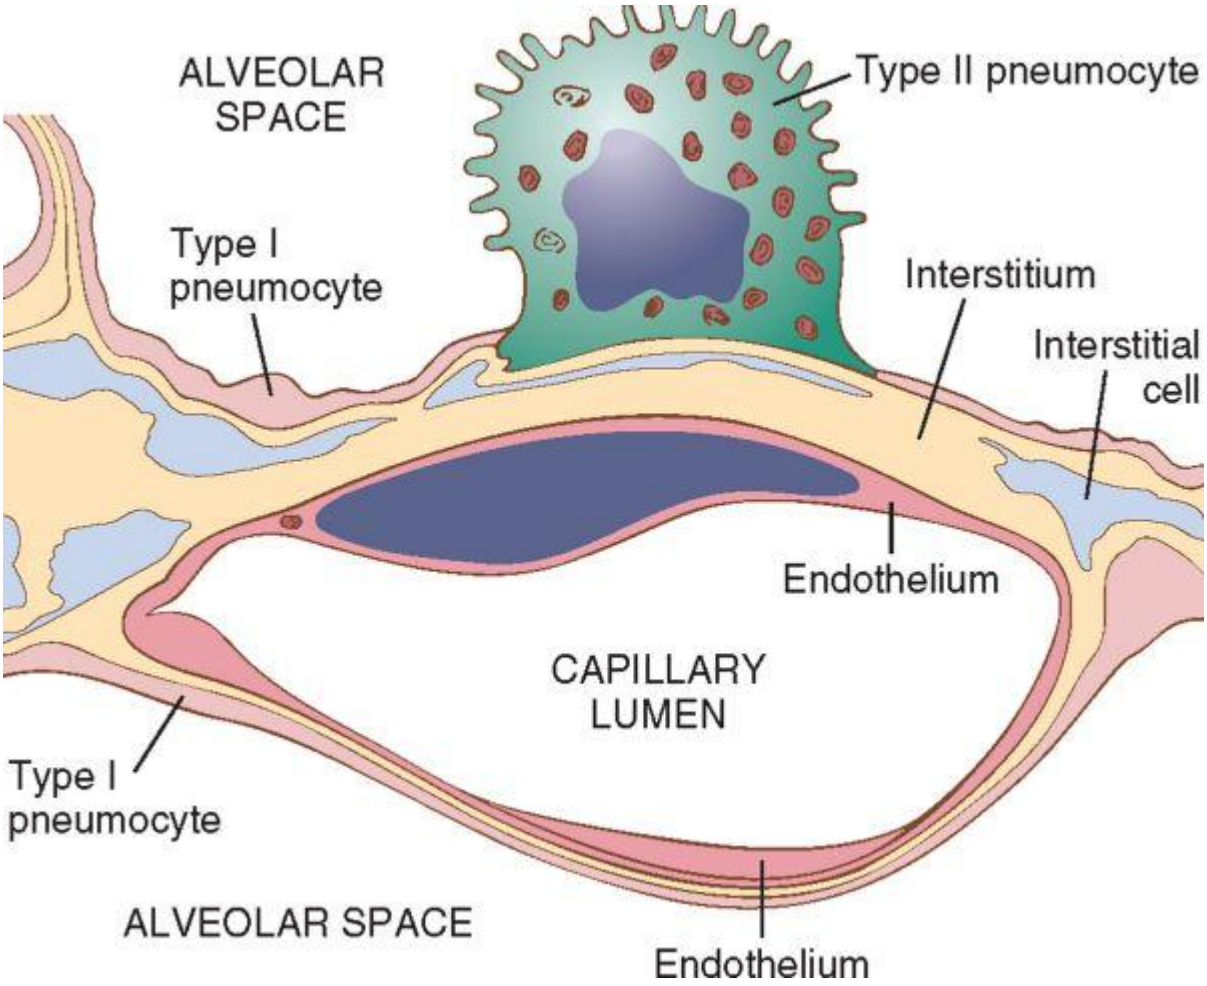

FIGURE 15-1 Microscopic structure of the alveolar wall. Note that the basement membrane *(yellow)* is thin on one side and widened where it is continuous with the interstitial space. Portions of interstitial cells are shown.

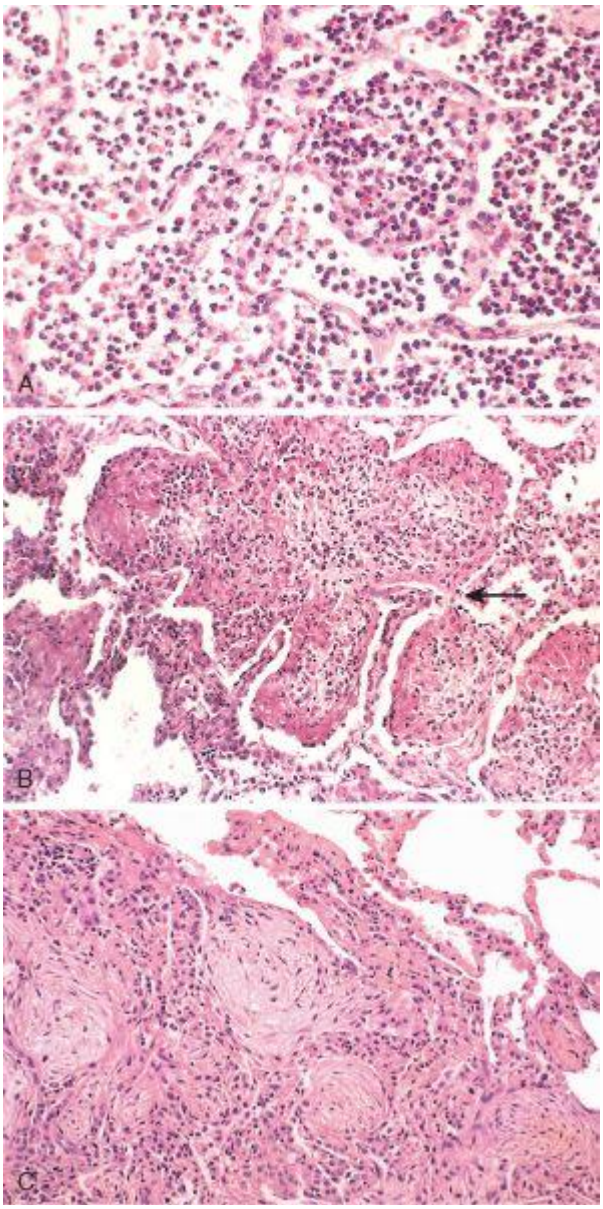

FIGURE 15-34 Stages of bacterial pneumonia. **A**, Acute pneumonia. The congested septal capillaries and extensive neutrophil exudation into alveoli corresponds to early red hepatization. Fibrin nets have not yet formed. **B**, Early organization of intra-alveolar exudate, seen in areas to be streaming through the pores of Kohn *(arrow)*. **C**, Advanced organizing pneumonia featuring transformation of exudates to fibromyxoid masses richly infiltrated by macrophages and fibroblasts.

Congenital Anomalies

Developmental defects of the lung include the following[1]:

- Agenesis or hypoplasia of both lungs, one lung, or single lobes
- Tracheal and bronchial anomalies (atresia, stenosis, tracheoesophageal fistula)
- Vascular anomalies
- Congenital lobar overinflation (emphysema)
- Foregut cysts

- Congenital pulmonary airway malformation
- Pulmonary sequestrations

Only the more common anomalies are discussed here. *Pulmonary hypoplasia* is the defective development of both lungs (one may be more affected than the other) resulting in decreased weight, volume, and acini disproportional to the body weight and gestational age. It is caused by a variety of abnormalities that compress the lung(s) or impede normal lung expansion in utero such as congenital diaphragmatic hernia and oligohydramnions.

Foregut cysts arise from an abnormal detachment of primitive foregut and are most often located in the hilum or middle mediastinum. Depending on the wall structure, these cysts are classified as bronchogenic (most common), esophageal, or enteric. A bronchogenic cyst is rarely connected to the tracheobronchial tree. Microscopically, the cyst is lined by ciliated pseudostratified columnar epithelium with squamous metaplasia occurring in areas of inflammation. The wall contains bronchial glands, cartilage, and smooth muscle. Surgical resection is curative.

Pulmonary sequestration refers to the presence of a discrete mass of lung tissue *without normal connection to the airway system*. Blood supply to the sequestered area arises not from the pulmonary arteries but from the aorta or its branches. *Extralobar sequestrations* are external to the lung and may be located anywhere in the thorax or mediastinum. They most commonly come to attention in infants as abnormal mass lesions, and may be associated with other congenital anomalies. *Intralobar sequestrations* occur within the lung substance usually in older children and are often associated with recurrent localized infection or bronchiectasis.

3.5.2 Atelectasis (Collapse)

Atelectasis refers either to incomplete expansion of the lungs (neonatal atelectasis) or to the collapse of previously inflated lung, producing areas of relatively airless pulmonary parenchyma. Acquired atelectasis, encountered principally in adults, may be divided into *resorption* (or *obstruction*), *compression*, and *contraction atelectasis* (Fig. 15-2).

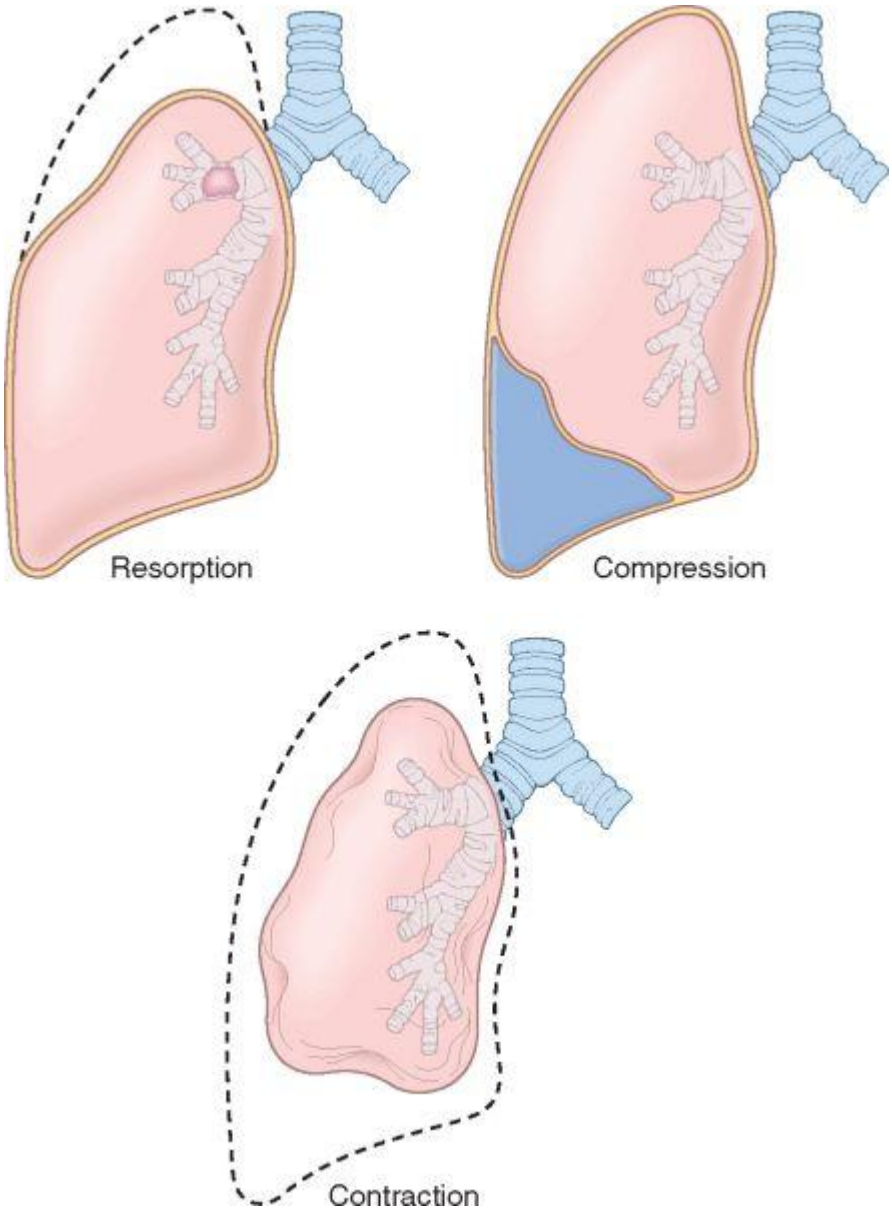

FIGURE 15-2 Various forms of acquired atelectasis. Dashed lines indicate normal lung volume.

Resorption atelectasis is the consequence of complete obstruction of an airway, which in time leads to resorption of the oxygen trapped in the dependent alveoli, without impairment of blood flow through the affected alveolar walls. Since lung volume is diminished, the mediastinum shifts *toward* the atelectatic lung. Resorption atelectasis is caused principally by excessive secretions (e.g., mucus plugs) or exudates within smaller bronchi and is therefore most often found in bronchial asthma, chronic bronchitis, bronchiectasis, postoperative states, aspiration of foreign bodies and, rarely, bronchial neoplasms. *Compression atelectasis* results whenever the pleural cavity is partially or completely filled by fluid exudate, tumor, blood, or air (the last-mentioned constituting *pneumothorax*) or, with *tension pneumothorax*, when air pressure impinges on and threatens the function of the lung and mediastinum, especially the major vessels. With compressive atelectasis, the mediastinum shifts *away* from the affected lung. *Contraction atelectasis* occurs when local or generalized fibrotic changes in the lung or pleura prevent full expansion.

Significant atelectasis reduces oxygenation and predisposes to infection. Because the collapsed lung parenchyma can be re-expanded, *atelectasis is a reversible disorder* (except that caused by contraction).

3.5.3 Pulmonary Edema

A general consideration of edema is in Chapter 4 , and pulmonary congestion and edema are described briefly in the context of congestive heart failure (Chapter 12). Pulmonary edema can result from *hemodynamic* disturbances *(hemodynamic* or *cardiogenic pulmonary edema)* or from direct *increases in capillary permeability*, as a result of microvascular injury (Table 15-1). Therapy and outcome depend on the underlying etiology.

TABLE 15-1 -- Classification and Causes of Pulmonary Edema

HEMODYNAMIC EDEMA
Increased hydrostatic pressure (increased pulmonary venous pressure)
Left-sided heart failure (common)
Volume overload
Pulmonary vein obstruction
Decreased oncotic pressure (less common)
Hypoalbuminemia
Nephrotic syndrome
Liver disease
Protein-losing enteropathies
Lymphatic obstruction (rare)
EDEMA DUE TO MICROVASCULAR INJURY (ALVEOLAR INJURY)
Infections: pneumonia, septicemia
Inhaled gases: oxygen, smoke
Liquid aspiration: gastric contents, near-drowning
Drugs and chemicals: chemotherapeutic agents (bleomycin), other medications (amphotericin B), heroin, kerosene, paraquat
Shock, trauma
Radiation
Transfusion related
EDEMA OF UNDETERMINED ORIGIN
High altitude
Neurogenic (central nervous system trauma)

Hemodynamic Pulmonary Edema

The most common *hemodynamic* cause of pulmonary edema is *increased hydrostatic pressure*, as occurs in left-sided congestive heart failure. Whatever the clinical setting, pulmonary congestion and edema are characterized by heavy, wet lungs. Fluid accumulates initially in the basal regions of the lower lobes because hydrostatic pressure is greater in these sites (dependent edema). Histologically, the

alveolar capillaries are engorged, and an intra-alveolar granular pink precipitate is seen. Alveolar microhemorrhages and *hemosiderin-laden macrophages ("heart failure" cells)* may be present. In long-standing cases of pulmonary congestion, such as those seen in mitral stenosis, hemosiderin-laden macrophages are abundant, and fibrosis and thickening of the alveolar walls cause the soggy lungs to become firm and brown *(brown induration)*. These changes not only impair normal respiratory function but also predispose to infection.

Edema Caused by Microvascular Injury

The second mechanism leading to pulmonary edema is *injury to the capillaries of the alveolar septa*. Here the pulmonary capillary hydrostatic pressure is usually not elevated, and hemodynamic factors play a secondary role. The edema results from primary injury to the vascular endothelium or damage to alveolar epithelial cells (with secondary microvascular injury). This results in leakage of fluids and proteins first into the interstitial space and, in more severe cases, into the alveoli. In most forms of pneumonia the edema remains localized and is overshadowed by the manifestations of infection. When diffuse, however, alveolar edema is an important contributor to a serious and often fatal condition, *acute respiratory distress syndrome*, discussed in the following section.

3.5.4 Acute Lung Injury & Acute Respiratory Distress Syndrome (Diffuse Alveolar Damage)

Acute lung injury (ALI) (also called noncardiogenic pulmonary edema) is characterized by the abrupt onset of significant hypoxemia and diffuse pulmonary infiltrates in the absence of cardiac failure.[2] Acute respiratory distress syndrome (ARDS) refers to severe ALI. ARDS and ALI both have inflammation-associated increase in pulmonary vascular permeability, and epithelial and endothelial cell death. The histologic manifestation of these diseases is *diffuse alveolar damage* (DAD). Most cases of ALI are associated with an underlying etiology such as sepsis. In the absence of any etiologic association, such cases are called acute interstitial pneumonia (AIP).

ALI is a well-recognized complication of diverse conditions, including both direct injuries to the lungs and systemic disorders (Table 15-2). In many cases, a combination of predisposing conditions is responsible (e.g., shock, oxygen therapy, and sepsis). Nonpulmonary organ dysfunction may also be present in severe cases.

* More than 50% of cases of acute respiratory distress syndrome are associated with these four conditions.

Morphology. In the acute stage, the lungs are heavy, firm, red, and boggy. They exhibit congestion, interstitial and intra-alveolar edema, inflammation, fibrin deposition, and **diffuse alveolar damage**. The alveolar walls become lined with waxy **hyaline membranes** (Fig. 15-3) that are morphologically similar to those seen in hyaline membrane disease of neonates (Chapter 10). Alveolar hyaline membranes consist of fibrin-rich edema fluid mixed with the cytoplasmic and lipid remnants of necrotic epithelial cells. In the organizing stage, type II pneumocytes undergo proliferation, and there is a granulation tissue response in the alveolar walls and in the alveolar spaces. In most cases the granulation tissue resolves, leaving minimal functional impairment. Sometimes, however, fibrotic thickening of the alveolar septa ensues, caused by proliferation of interstitial cells and deposition of collagen. Fatal cases often have superimposed bronchopneumonia.

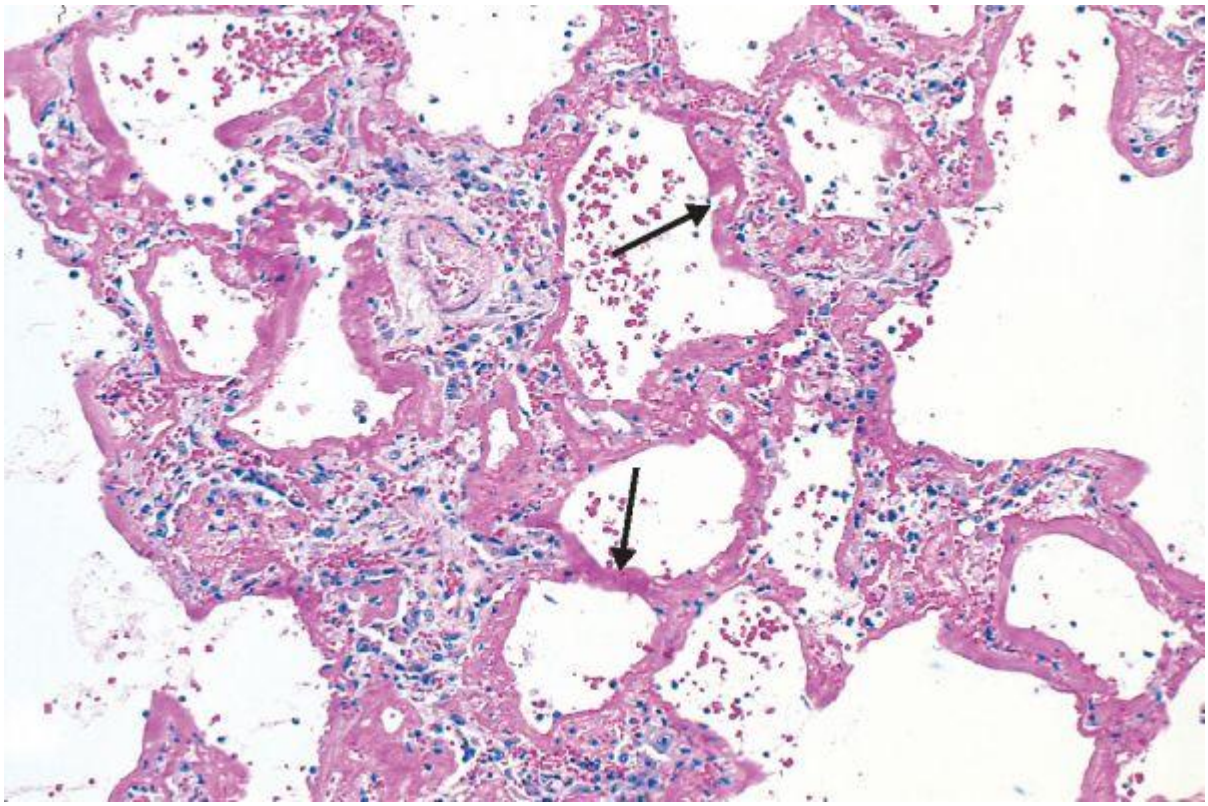

FIGURE 15-3 Diffuse alveolar damage (acute respiratory distress syndrome). Some of the alveoli are collapsed; others are distended, and many are lined by hyaline membranes *(arrows).*

Pathogenesis.

The alveolar capillary membrane is formed by two separate barriers: the microvascular endothelium and the alveolar epithelium. *In ARDS the integrity of this barrier is compromised by either endothelial or epithelial injury or, more commonly, both*.[3] Markers of endothelial injury and activation such as endothelin and von Willebrand factor can be detected at high levels in the serum of patients with ARDS. Evidence of epithelial injury in the form of swelling, vacuolization, bleb formation, and frank necrosis is also noted early in the course of acute lung injury. The acute consequences of damage to the alveolar capillary membrane include increased vascular permeability and alveolar flooding, loss of diffusion capacity, and widespread surfactant abnormalities caused by damage to type II pneumocytes. Endothelial injury also triggers the formation of microthrombi that add the insult of ischemic injury (Fig. 15-4). Hyaline membranes so characteristic of ALI/ARDS result from inspissation of protein rich edema fluid that entraps debris of dead alveolar epithelial cells.

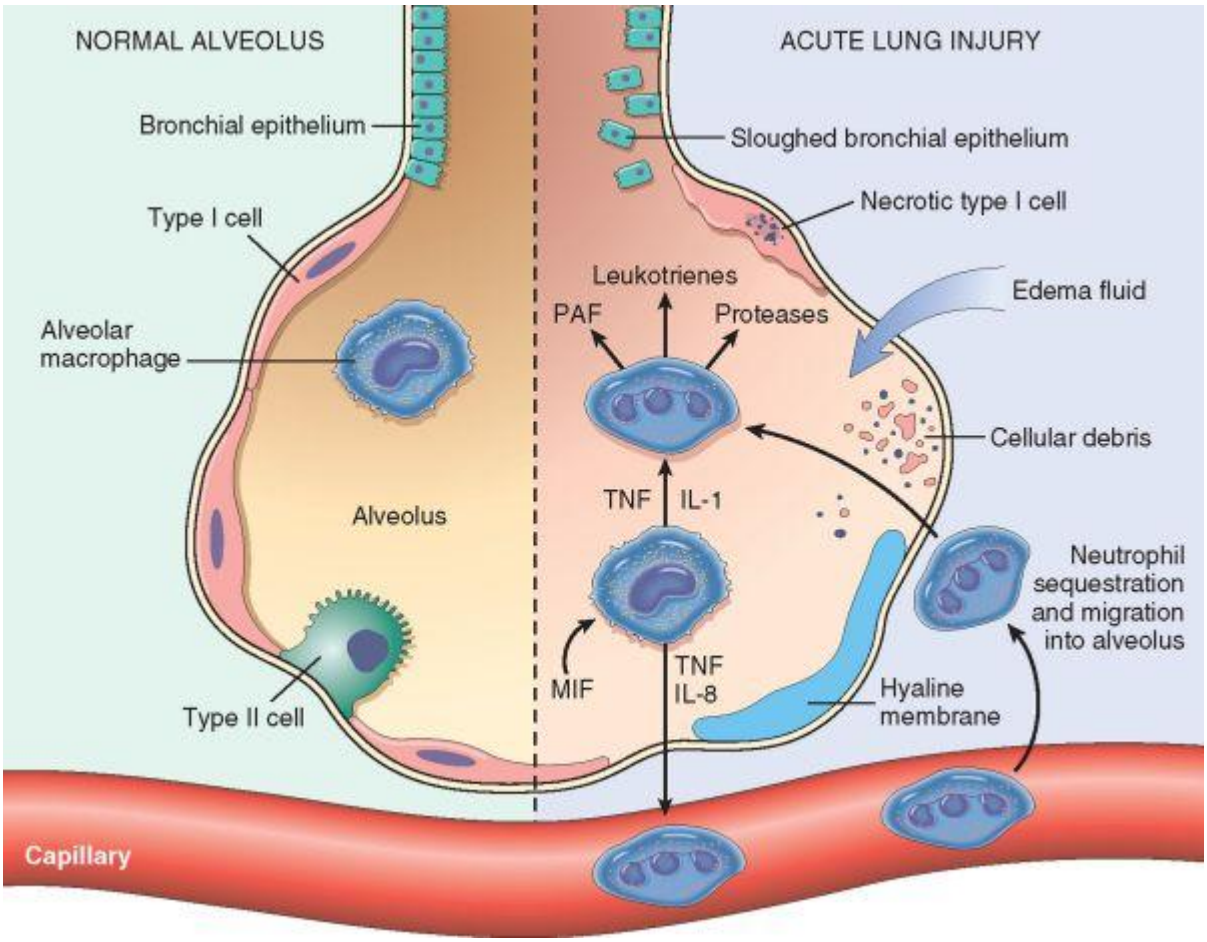

FIGURE 15-4 The normal alveolus *(left side)* compared with the injured alveolus in the early phase of acute lung injury and acute respiratory distress syndrome. Pro-inflammatory cytokines such as interleukin 8 (IL-8), interleukin 1 (IL-1), and tumor necrosis factor (TNF) (released by macrophages), cause neutrophils to adhere to pulmonary capillaries and extravasate into the alveolar space, where they undergo activation. Activated neutrophils release a variety of factors, such as leukotrienes, oxidants, proteases, and platelet-activating factor (PAF), which contribute to local tissue damage, accumulation of edema fluid in the airspaces, surfactant inactivation, and hyaline membrane formation. Macrophage migration inhibitory factor (MIF) released into the local milieu sustains the ongoing pro-inflammatory response. Subsequently, the release of macrophage-derived fibrogenic cytokines such as transforming growth factor β (TGF-β) and platelet-derived growth factor (PDGF) stimulate fibroblast growth and collagen deposition associated with the healing phase of injury. *(Modified with permission from Ware LB, Matthay MA: The acute respiratory distress syndrome. N Engl J Med 342:1334, 2000.)*

Although the cellular and molecular basis of acute lung injury and ARDS remains an area of active investigation, it appears that in ARDS, *lung injury is caused by an imbalance of pro-inflammatory and anti-inflammatory mediators*.[4] The most proximate signals leading to uncontrolled activation of the acute inflammatory response are not yet understood. However, *nuclear factor κB* (NF-κB), a transcription factor whose activation itself is tightly regulated under normal conditions, has emerged as a likely candidate shifting the balance in favor of a pro-inflammatory state. As early as 30 minutes after an acute insult, there is increased synthesis of interleukin-8 (IL-8), a potent neutrophil chemotactic and activating agent, by pulmonary macrophages. Release of this and similar compounds, such as IL-1 and tumor necrosis factor (TNF), leads to endothelial activation, and pulmonary microvascular sequestration and activation of neutrophils. *Neutrophils are thought to have an important role in the pathogenesis of ARDS*. Histologic examination of lungs early in the disease process shows increased numbers of neutrophils within the vascular space, the interstitium, and the alveoli. How neutrophils are sequestered

in the lung is not entirely clear. There are two possible mechanisms. Firstly, neutrophils that are activated by cytokines like IL-8 and TNF upregulate the expression of adhesion molecules that allow them to bind to their ligands on activated endothelial cells. Secondly, activated neutrophils become "stiff" and less deformable and thus get trapped in the narrow capillary beds of the lung. Activated neutrophils release a variety of products (e.g., oxidants, proteases, platelet-activating factor, and leukotrienes) that cause damage to the alveolar epithelium and fuel the inflammatory cascade. Combined assault on the endothelium and epithelium perpetuate vascular leakiness and loss of surfactant that render the alveolar unit unable to expand. It should be noted that the destructive forces unleashed by neutrophils can be counteracted by an array of endogenous antiproteases, antioxidants, and anti-inflammatory cytokines (e.g., IL-10) that are upregulated by pro-inflammatory cytokines. Dysregulation of the coagulation system is also a feature of ARDS. Levels of tissue factor are increased and those of the anticoagulant, protein C, are decreased in the plasma and bronchoalveolar lavage fluid. The coagulation pathway itself is a powerful pro-inflammatory signal. Thrombin, for example, promotes adhesion of neutrophils to endothelium. In the end, it is the balance between the destructive and protective factors that determines the degree of tissue injury and clinical severity of ALI/ARDS.

Resolution of ARDS requires resorption of the exudate, removal of dead cells, and their replacement by new endothelium and alveolar epithelial cells. Removal of exudates and tissue debris is accomplished by macrophages as in any other form of tissue injury. Epithelial cells are recovered by an initial proliferation of surviving type II pneumocytes that line the denuded basement membrane. The recently discovered bronchoalveolar stem cells may also participate. Type II cells then give rise to type I cells that constitute the majority of alveolar epithelium. Endothelial restoration occurs both by migration from uninjured capillaries and marrow-derived endothelial progenitor cells (Chapter 3); the latter can be detected in the circulation during recovery from ARDS.

Clinical Course.

Individuals who develop ALI are usually hospitalized for one of the predisposing conditions listed earlier. Profound *dyspnea and tachypnea* herald ALI, followed by increasing *cyanosis and hypoxemia*, *respiratory failure*, and the appearance of *diffuse bilateral infiltrates* on radiographic examination. Hypoxemia can then become unresponsive to oxygen therapy, due to ventilation perfusion mismatching as described below, and respiratory acidosis can develop. Early in the course of the disease, lungs become stiff due to loss of functional surfactant. In a minority of patients, the exudate and diffuse tissue destruction that occur with ALI-ARDS do not resolve and result in scarring. The interstitial fibrosis in such cases produces stiff lungs and chronic pulmonary disease.

The functional abnormalities in ALI are not evenly distributed throughout the lungs. The lungs can be divided into areas that are infiltrated, consolidated, or collapsed (and thus poorly aerated and poorly compliant) and regions that have nearly normal levels of compliance and ventilation. Poorly aerated regions continue to be perfused, producing *ventilationperfusion mismatch* and hypoxemia. Due to improvements in therapy for sepsis, mechanical ventilation, and supportive care, the mortality rate among the 190,000 ALI cases seen yearly in the United States has decreased from 60% to about 40%.[5] The majority of deaths are attributable to sepsis or multi-organ failure and, in some cases, direct lung injury.[6]

ACUTE INTERSTITIAL PNEUMONIA

Acute interstitial pneumonia is a clinicopathologic term that is used to describe widespread ALI associated with a rapidly progressive clinical course that is of unknownetiology (sometimes referred to as idiopathic ALI-DAD). It is an uncommon disease occurring at a mean age of 50 years with no sex predilection. Patients present with acute respiratory failure often following an illness of less than 3 weeks' duration that resembles an upper respiratory tract infection. The radiographic and pathologic

features are identical to those of the organizing stage of ALI. The mortality rate varies from 33% to 74%, with most deaths occurring within 1 to 2 months.[7] In the surviving patients, recurrences and chronic interstitial disease may develop. [8] [9] [10]

3.5.5 Obstructive versus Restrictive Pulmonary Diseases

Based on pulmonary function tests, chronic noninfectious diffuse pulmonary diseases can be classified in one of two categories: (1) *obstructive diseases* (or *airway diseases*), characterized by an increase in resistance to airflow due to partial or complete obstruction at any level, from the trachea and larger bronchi to the terminal and respiratory bronchioles, and (2) *restrictive diseases*, characterized by reduced expansion of lung parenchyma and decreased total lung capacity. In individuals with diffuse obstructive disorders, pulmonary function tests show decreased maximal airflow rates during forced expiration, usually measured by forced expiratory volume at 1 second. Expiratory airflow obstruction may be caused by a variety of conditions listed in Table 15-3 . They are distinguished by distinct anatomic lesions and hence different mechanisms for airflow obstruction. As discussed below, such neat distinctions are not always possible. In contrast, restrictive diseases are identified by a reduced total lung capacity, and an expiratory flow rate that is normal or reduced proportionately. Restrictive defects occur in two general conditions: (1) *chest wall disorders* (e.g., neuromuscular diseases such as poliomyelitis, severe obesity, pleural diseases, and kyphoscoliosis) and (2) *chronic interstitial and infiltrative diseases*, such as pneumoconioses and interstitial fibrosis of unknown etiology.

TABLE 15-3 -- Disorders Associated with Airflow Obstruction: The Spectrum of Chronic Obstructive Pulmonary Disease

Clinical Term	Anatomic Site	Major Pathologic Changes	Etiology	Signs/Symptoms
Chronic bronchitis	Bronchus	Mucous gland hyperplasia, hypersecretion	Tobacco smoke, air pollutants	Cough, sputum production
Bronchiectasis	Bronchus	Airway dilation and scarring	Persistent or severe infections	Cough, purulent sputum, fever
Asthma	Bronchus	Smooth muscle hyperplasia, excess mucus, inflammation	Immunological or undefined causes	Episodic wheezing, cough, dyspnea
Emphysema	Acinus	Airspace enlargement; wall destruction	Tobacco smoke	Dyspnea
Small-airway disease, bronchiolitis	Bronchiole	Inflammatory scarring/obliteration	Tobacco smoke, air pollutants, miscellaneous	Cough, dyspnea

3.5.6 Obstructive Pulmonary Diseases

In their prototypical forms, these individual disorders—emphysema, chronic bronchitis, asthma, and bronchiectasis—have distinct anatomic and clinical characteristics (Table 15-3). Emphysema and chronic bronchitis are often clinically grouped together and referred to as *chronic obstructive pulmonary disease* (COPD), since many patients have overlapping features of damage at both the acinar level (emphysema) and bronchial level (bronchitis), almost certainly because one extrinsic trigger—cigarette smoking—is common to both. In addition, small-airway disease, a variant of chronic bronchiolitis, is now known to contribute to obstruction both in emphysema and chronic bronchitis.[11] While asthma is distinguished from chronic bronchitis and emphysema by the presence of reversible bronchospasm, some patients with otherwise typical asthma also develop an irreversible component (Fig. 15-5). Conversely, some patients with otherwise typical COPD have a reversible component. It is clinically common to label such patients as having COPD/asthma. In a recent study the overlap between these three disorders was found to be substantial.[12]

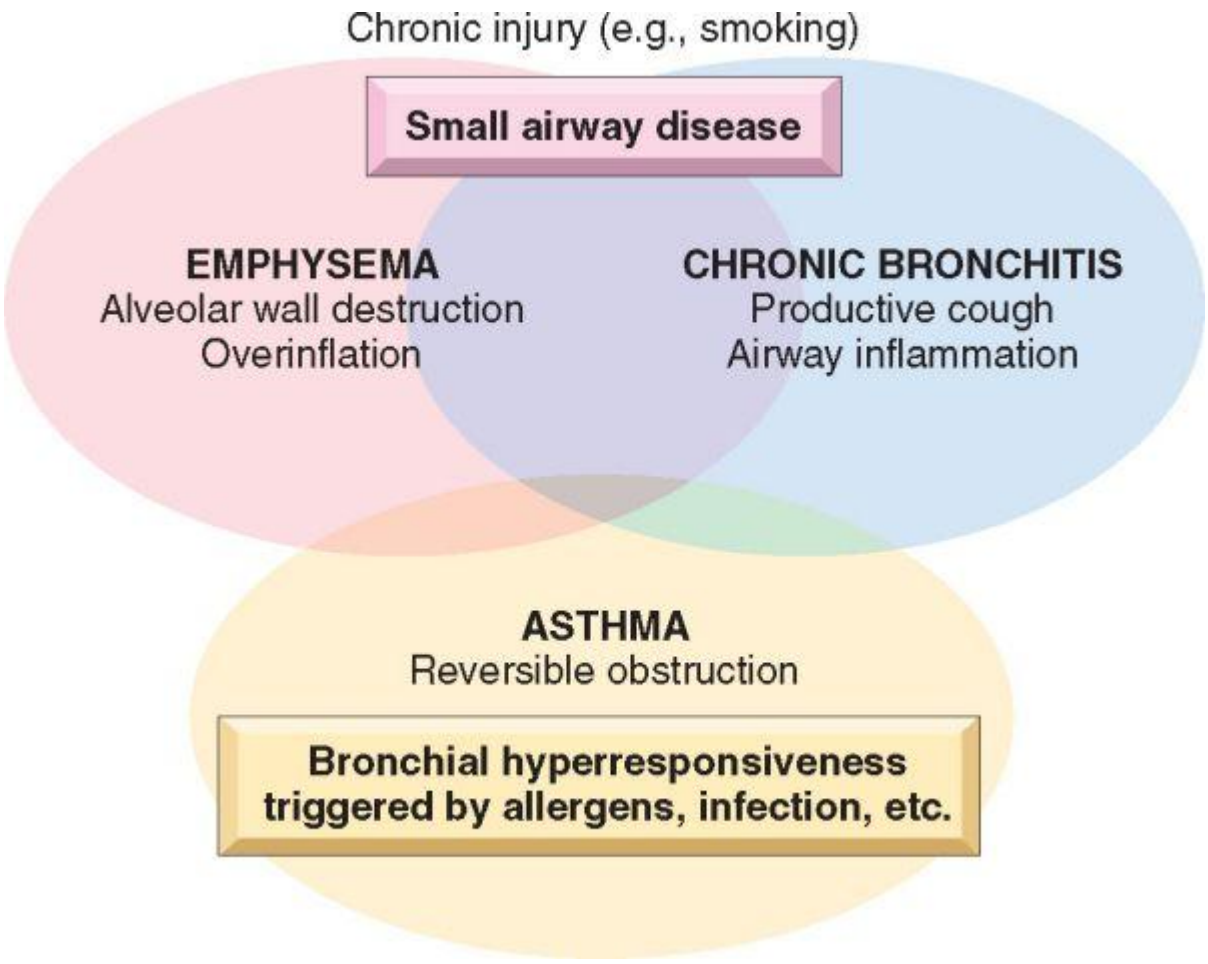

FIGURE 15-5 Schematic representation of overlap between chronic obstructive lung diseases.

In most patients, COPD is the result of long-term heavy cigarette smoking; about 10% of patients are nonsmokers.[13,][14] However, only a minority of smokers develop COPD, the reason for which is still unknown. Because of the increase in smoking (smoking is decreasing in the United States but is increasing worldwide), environmental pollutants, and other noxious exposures, the incidence of COPD has increased markedly in the last few decades and now ranks fourth in the United States as a cause of morbidity and mortality.

Recognizing the overlap between various forms of COPD, each of the components and the features that characterize them in pure forms are discussed next, because it is essential to understand the pathophysiologic basis of different causes of airflow obstruction. While currently they are treated on the basis of symptoms, an understanding of pathogenesis may lead to therapies that target the mechanisms.

EMPHYSEMA

Emphysema is a condition of the lung characterized by *irreversible enlargement of the airspaces distal to the terminal bronchiole*, accompanied by destruction of their walls without obvious fibrosis.[15]

Incidence.

COPD is a major public health problem. It is the fourth leading cause of morbidity and mortality in the United States[16] and is projected to rank fifth by 2020 as a worldwide burden of disease.[17] In one study there was a 50% combined incidence of panacinar and centriacinar emphysema at autopsy, and the pulmonary disease was considered to be responsible for death in 6.5% of these patients.[18] *There is a clear-cut association between heavy cigarette smoking and emphysema*, and women and African Americans are more susceptible than other groups.[19]

Types of Emphysema.

Emphysema is classified according to its *anatomic distribution* within the lobule. Recall that the lobule is a cluster of acini, the terminal respiratory units. Although the term *emphysema* is sometimes loosely applied to diverse conditions, there are four major types: (1) *centriacinar*, (2) *panacinar*, (3) *paraseptal*, and (4) *irregular*. Of these, only the first two cause clinically significant airflow obstruction (Fig. 15-6). Centriacinar emphysema is far more common than the panacinar form, constituting more than 95% of cases.

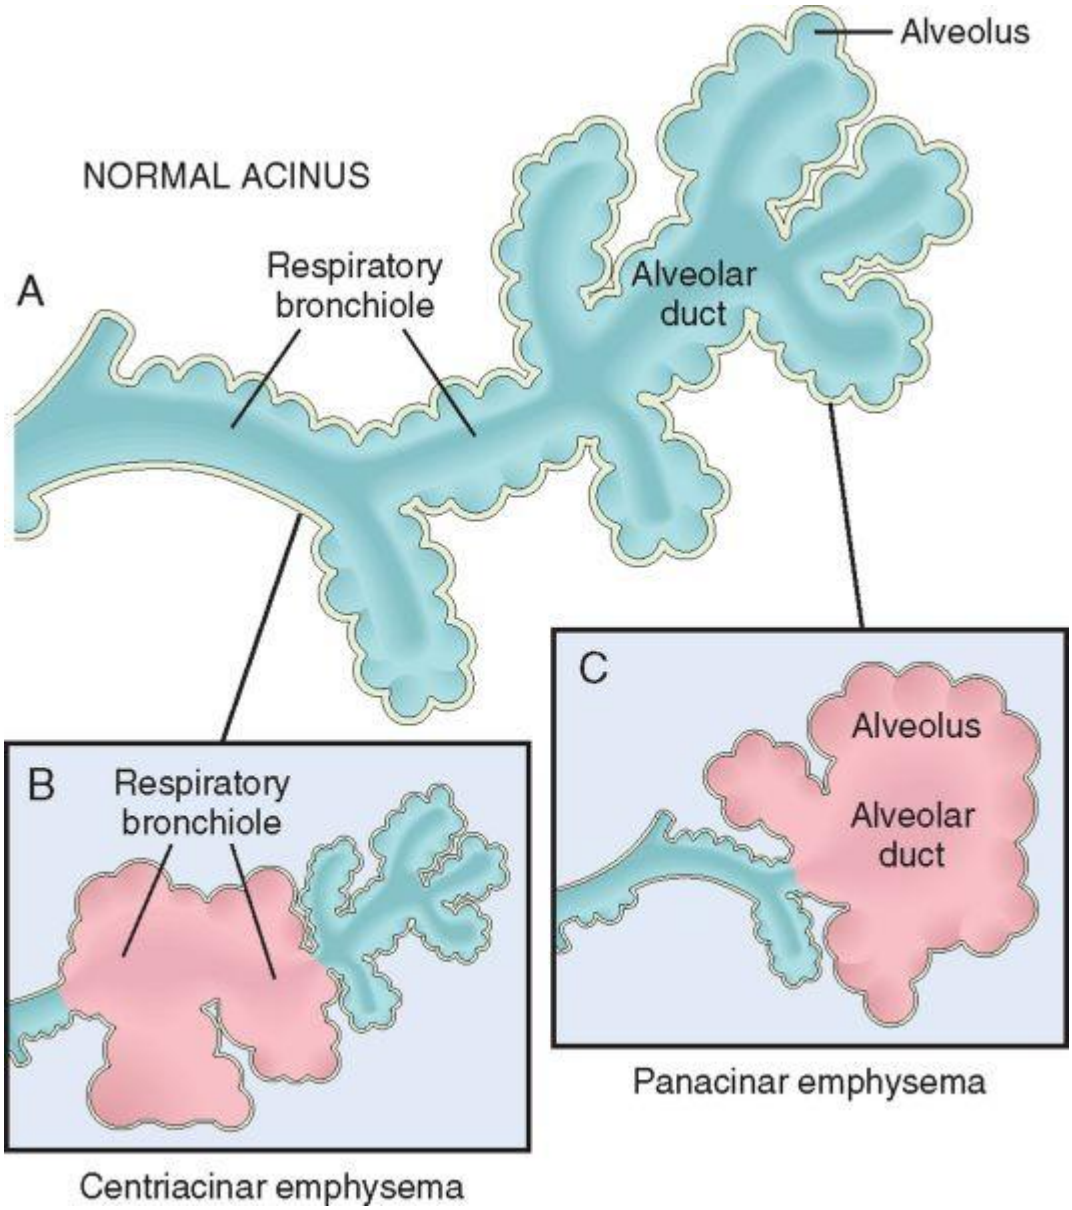

FIGURE 15-6 Major patterns of emphysema. **A**, Normal structure within the acinus. **B**, Centriacinar emphysema with dilation that initially affects the respiratory bronchioles. **C**, Panacinar emphysema with initial distention of the alveolus and alveolar duct.

Centriacinar (Centrilobular) Emphysema.

In this type of emphysema *the central or proximal parts of the acini, formed by respiratory bronchioles, are affected, whereas distal alveoli are spared* (Figs. 15-6B and 15-7A). Thus, both emphysematous and normal airspaces exist within the same acinus and lobule. The lesions are more common and usually more severe in the upper lobes, particularly in the apical segments. The walls of the emphysematous spaces often contain large amounts of black pigment. Inflammation around bronchi and bronchioles is common. In severe centriacinar emphysema, the distal acinus may also be involved, and differentiation from panacinar emphysema becomes difficult. Centriacinar emphysema occurs predominantly in heavy smokers, often in association with chronic bronchitis.

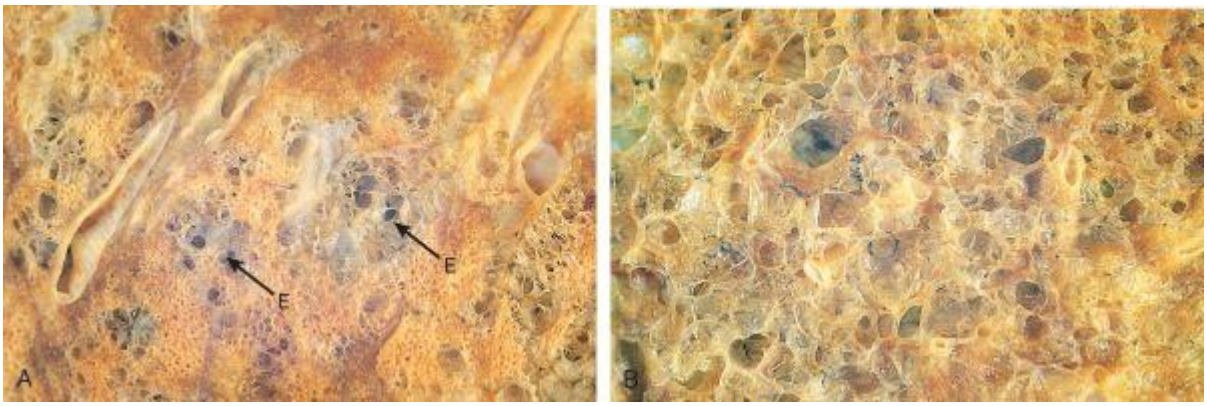

FIGURE 15-7 **A**, Centriacinar emphysema. Central areas show marked emphysematous damage (E), surrounded by relatively spared alveolar spaces. **B**, Panacinar emphysema involving the entire pulmonary lobule.

Panacinar (Panlobular) Emphysema.

In this type, the *acini are uniformly enlarged from the level of the respiratory bronchiole to the terminal blind alveoli* (Figs. 15-6*C* and 15-7B). The prefix "pan" refers to the entire acinus but not to the entire lung. In contrast to centriacinar emphysema, panacinar emphysema tends to occur more commonly in the lower zones and in the anterior margins of the lung, and it is usually most severe at the bases. This type of emphysemais associated with α_1-*antitrypsin* (α_1-*AT) deficiency* (Chapter 18).

Distal Acinar (Paraseptal) Emphysema.

In this type, the *proximal portion of the acinus is normal, and the distal part is predominantly involved*. The emphysema is more striking adjacent to the pleura, along the lobular connective tissue septa, and at the margins of the lobules. It occurs adjacent to areas of fibrosis, scarring, or atelectasis and is usually more severe in the upper half of the lungs. The characteristic findings are of multiple, continuous, enlarged airspaces from less than 0.5 cm to more than 2.0 cm in diameter, sometimes forming cystlike structures. This type of emphysema probably underlies many of the cases of spontaneous pneumothorax in young adults.

Airspace Enlargement with Fibrosis (Irregular Emphysema).

Irregular emphysema, so named because the acinus is irregularly involved, is almost invariably associated with scarring. Thus, it may be the most common form of emphysema, because careful search of most lungs at autopsy shows one or more scars from a healed inflammatory process. In most instances, these foci of irregular emphysema are asymptomatic and clinically insignificant.

Pathogenesis.

COPD is characterized by mild chronic inflammation throughout the airways, parenchyma, and pulmonary vasculature. Macrophages, CD8+ and CD4+ T lymphocytes, and neutrophils are increased in various parts of the lung. Activated inflammatory cells release a variety of mediators, including leukotriene B_4, IL-8, TNF, and others, that are capable of damaging lung structures or sustaining neutrophilic inflammation.[20] Although details of the genesis of the two common forms of emphysema—centriacinar and panacinar—remain unsettled, *the most plausible hypothesis to account for the destruction of alveolar walls is the proteaseantiprotease mechanism, aided and abetted by imbalance of oxidants and antioxidants*.

The *protease-antiprotease imbalance* hypothesis is based on the observation that patients with a genetic deficiency of the antiprotease α1-antitrypsin have a markedly enhanced tendency to develop pulmonary emphysema, which is compounded by smoking (Fig. 15-8). About 1% of all patients with emphysema have this defect. α1-antitrypsin, normally present in serum, tissue fluids, and macrophages, is a major inhibitor of proteases (particularly elastase) secreted by neutrophils during inflammation. α1-antitrypsin is encoded by codominantly expressed genes on the proteinase inhibitor *(Pi)* locus on chromosome 14. The *Pi* locus is extremely polymorphic, with many different alleles. Most common is the normal *(M)* allele and the corresponding phenotype. Approximately 0.012% of the US population is homozygous for the *Z* allele, associated with markedly decreased serum levels of α1antitrypsin. More than 80% of these individuals develop symptomatic panacinar emphysema, which occurs at an earlier age and with greater severity if the individual smokes. The following sequence is postulated:

1. Neutrophils (the principal source of cellular proteases) are normally sequestered in peripheral capillaries, including those in the lung, and a few gain access to the alveolar spaces.
2. Any stimulus that increases either the number of leukocytes (neutrophils and macrophages) in the lung or the release of their protease-containing granules increases proteolytic activity.
3. With low levels of serum α1-antitrypsin, elastic tissue destruction is unchecked and emphysema results.

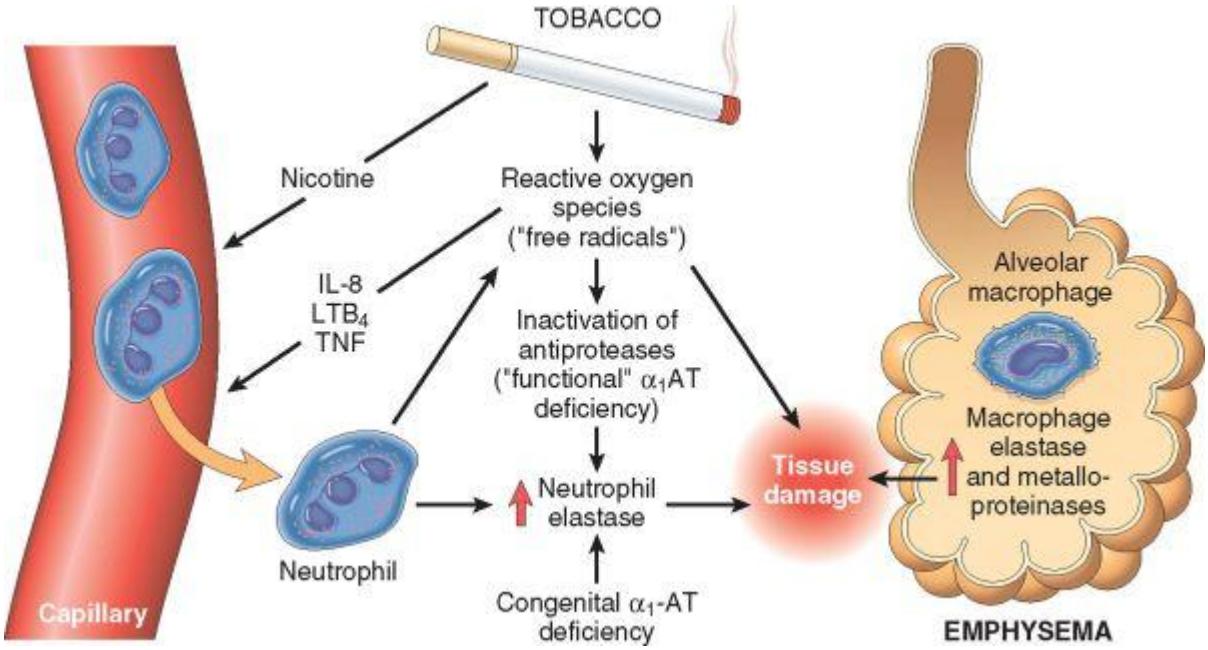

FIGURE 15-8 Pathogenesis of emphysema. Excessive protease activity and reactive oxygen species are additive in their effects and contribute to tissue damage. α_1-antitrypsin (α_1-AT) deficiency can be either congenital or "functional" as a result of oxidative inactivation. See text for details. IL-8, interleukin 8; LTB_4, leukotriene B_4; TNF, tumor necrosis factor.

Thus, *emphysema is seen to result from the destructive effect of high protease activity in subjects with low antiprotease activity*. The protease-antiprotease imbalance hypothesis also helps explain the effect of cigarette smoking in the development of emphysema, particularly the centriacinar form in subjects with normal amounts of α1-antitrypsin:

- *In smokers, neutrophils and macrophages accumulate in alveoli*. The mechanism of inflammation is not entirely clear, but possibly involves the direct chemoattractant effects of nicotine as well as the effects of reactive oxygen species contained in smoke. These activate the transcription factor NF-κB, which switches on genes that encode TNF and chemokines, including IL-8. These, in turn, attract and activate neutrophils.
- Accumulated neutrophils are activated and release their granules, rich in a variety of cellular proteases (neutrophil elastase, proteinase 3, and cathepsin G), resulting in tissue damage.
- Smoking also enhances elastase activity in macrophages; macrophage elastase is not inhibited by α1-antitrypsin) and, indeed, can proteolytically digest this antiprotease. There is increasing evidence that in addition to elastase, matrix metalloproteinases derived from macrophages and neutrophils have a role in tissue destruction.

In addition, smoking has a seminal role in perpetuating the *oxidant-antioxidant imbalance* in the pathogenesis of emphysema. Normally, the lung contains a healthy complement of antioxidants (superoxide dismutase, glutathione) that keep oxidative damage to a minimum. Tobacco smoke contains abundant reactive oxygen species (free radicals), which deplete these antioxidant mechanisms, thereby inciting tissue damage (Chapter 1). Activated neutrophils also add to the pool of reactive oxygen species in the alveoli. A secondary consequence of oxidative injury is inactivation of native antiproteases, resulting in "functional" α1-antitrypsin deficiency even in patients without enzyme deficiency.

Since small airways are normally tethered by the elastic recoil of the lung parenchyma, the loss of elastic tissue in the walls of alveoli that surround respiratory bronchioles reduces radial traction and thus causes the respiratory bronchioles to collapse during expiration. This leads to functional airflow obstruction despite the absence of mechanical obstruction.

Until recently loss of elastic recoil was considered to be the sole mechanism of airflow obstruction in emphysema. However, careful studies in young smokers who died in accidents have revealed that inflammation of small airways, defined as bronchioles less than 2 mm in diameter, occurs early in the evolution of COPD. Several changes are seen:

1. goblet cell metaplasia with mucus plugging of the lumen
2. inflammatory infiltration of the walls with neutrophils, macrophages, B cells (sometimes forming follicles), CD4 and CD8+ T cells
3. thickening of the bronchiolar wall due to smooth muscle hypertrophy and peribronchial fibrosis.

Together these changes narrow the bronchiolar lumen and contribute to airway obstruction.[21,][25]

One of the perplexing features of COPD is that smoldering inflammation and slow progressive destruction of the lung parenchyma often continue for decades after cessation of smoking.[22] While there are no clear answers, there is emerging evidence that the initial insult in the form of tobacco smoke, or other irritants, triggers a maladaptive, self-perpetuating immune response in which both innate and adaptive components play a role. Fingers are pointing to pathogenic CD4+T_H17 cells similar to those that are involved in other immunemediated inflammatory diseases such as Crohn disease, but much remains to be known.

Morphology. Advanced emphysema produces voluminous lungs, often overlapping the heart and hiding it when the anterior chest wall is removed. Generally, the upper two thirds of the lungs are more severely affected. Large apical blebs or bullae are more characteristic of irregular emphysema secondary to scarring and of distal acinar emphysema. Large alveoli can easily be seen on the cut surface of formalin-inflated fixed lung (see Fig. 15-7).

Microscopically, there are abnormally large alveoli separated by thin septa with only focal centriacinar fibrosis. There is loss of attachments of the alveoli to the outer wall of small airways. The pores of Kohn are so large that septa appear to be floating or protrude blindly into alveolar spaces with a club-shaped end. As alveolar walls are destroyed, there is decrease in the capillary bed. With advanced disease, there are even larger abnormal airspaces and possibly blebs or bullae, which often deform and compress the respiratory bronchioles and vasculature of the lung. Inflammatory changes in small airways were described earlier.

Clinical Course.

The clinical manifestations of emphysema do not appear until at least one third of the functioning pulmonary parenchyma is damaged. *Dyspnea* is usually the first symptom; it begins insidiously but is steadily progressive. In some patients, cough or wheezing is the chief complaint, easily confused with asthma. Cough and expectoration are extremely variable and depend on the extent of the associated bronchitis. *Weight loss* is common and can be so severe as to suggest a hidden malignant tumor. Classically, the patient is barrel-chested and dyspneic, with obviously prolonged expiration, sits forward in a hunched-over position, and breathes through pursed lips. *Expiratory airflow limitation, best measured through spirometry, is the key to diagnosis*.

In individuals with severe emphysema, cough is often slight, overdistention is severe, diffusion capacity is low, and blood gas values are relatively normal at rest. Such patients may overventilate and remain well oxygenated, and therefore are somewhat ingloriously designated *pink puffers* (see Table 15-4). Development of cor pulmonale and eventually congestive heart failure, related to secondary pulmonary vascular hypertension, is associated with a poor prognosis. Death in most patients with emphysema is due to (1) respiratory acidosis and coma, (2) right-sided heart failure, and (3) massive collapse of the lungs secondary to pneumothorax. Treatment options include bronchodilators, steroids, bullectomy, and, in selected patients, lung volume reduction surgery and lung transplantation. Substitution therapy with α_1-AT is being evaluated.[23]

TABLE 15-4 -- Emphysema and Chronic Bronchitis

	Predominant Bronchitis	Predominant Emphysema
Age (yr)	40–45	50–75
Dyspnea	Mild; late	Severe; early
Cough	Early; copious sputum	Late; scanty sputum

	Predominant Bronchitis	Predominant Emphysema
Infections	Common	Occasional
Respiratory insufficiency	Repeated	Terminal
Cor pulmonale	Common	Rare; terminal
Airway resistance	Increased	Normal or slightly increased
Elastic recoil	Normal	Low
Chest radiograph	Prominent vessels; large heart	Hyperinflation; small heart
Appearance	*Blue bloater*	*Pink puffer*

Other Forms of Emphysema.

Now we come to some conditions in which the term *emphysema* is applied less stringently and to some closely related conditions.

Compensatory Hyperinflation (Emphysema).

This term is sometimes used to designate dilation of alveoli but not destruction of septal walls in response to loss of lung substance elsewhere. It is best exemplified by the hyperexpansion of the residual lung parenchyma that follows surgical removal of a diseased lung or lobe.

Obstructive Overinflation.

In this condition the lung expands because air is trapped within it. A common cause is subtotal obstruction by a tumor or foreign object. Another example is *congenital lobar overinflation* in infants, probably resulting from hypoplasia of bronchial cartilage and sometimes associated with other congenital cardiac and lung abnormalities. Overinflation in obstructive lesions occurs either (1) because of a ball-valve action of the obstructive agent, so that air enters on inspiration but cannot leave on expiration, or (2) because the bronchus may be totally obstructed but ventilation through *collaterals* may bring in air from behind the obstruction. These collaterals are the *pores of Kohn* and other direct accessory *bronchioloalveolar connections* (the canals of Lambert). Obstructive overinflation can be a life-threatening emergency, because the affected portion distends sufficiently to compress the remaining normal lung.

Bullous Emphysema.

This is a descriptive term for large subpleural blebs or bullae (spaces more than 1 cm in diameter in the distended state) that can occur in any form of emphysema (Fig. 15-9). They represent localized accentuations of emphysema and occur near the apex, sometimes in relation to old tuberculous scarring. On occasion, rupture of the bullae may give rise to pneumothorax.

FIGURE 15-9 Bullous emphysema with large subpleural bullae *(upper left)*.

Interstitial Emphysema.

The entrance of air into the connective tissue stroma of the lung, mediastinum, or subcutaneous tissue is called interstitial emphysema. In most instances, alveolar tears in pulmonary emphysema provide the avenue of entrance of air into the stroma of the lung, but rarely, a wound of the chest that allows air to be sucked in or a fractured rib that punctures the lung substance may underlie this disorder. Alveolar tears usually occur when there is a combination of coughing plus some bronchiolar obstruction, producing sharply increased pressures within the alveolar sacs. Children with whooping cough and bronchitis, patients with obstruction to the airways (by blood clots, tissue, or foreign bodies) or who are being artificially ventilated, and individuals who suddenly inhale irritant gases are at risk.

CHRONIC BRONCHITIS

Chronic bronchitis is defined clinically as persistent cough with sputum production for at least 3 months in at least 2 consecutive years, in the absence of any other identifiable cause. Chronic bronchitis, so common among habitual smokers and inhabitants of smog-laden cities, is not nearly as trivial as was once thought. When persistent for years, it may (1) progress to COPD, (2) lead to cor pulmonale and heart failure, or (3) cause atypical metaplasia and dysplasia of the respiratory epithelium, providing a rich soil for cancerous transformation.

Pathogenesis.

The primary or initiating factor in the genesis of chronic bronchitis seems to be long-standing irritation by inhaled substances such as *tobacco smoke* (90% of patients are smokers), and dust from grain, cotton, and silica. The earliest feature of chronic bronchitis is *hypersecretion of mucus* in the large airways, associated with hypertrophy of the submucosal glands in the trachea and bronchi.[24] Proteases released from neutrophils, such as neutrophil elastase and cathepsin, and matrix metalloproteinases, stimulate this mucus hypersecretion. As chronic bronchitis persists, there is also *a marked increase in goblet cells of small airways—small bronchi and bronchioles*—leading to excessive mucus production that contributes to airway obstruction. It is thought that both the submucosal gland hypertrophy and the increase in goblet cells are protective metaplastic reactions against tobacco smoke or other pollutants (e.g., sulfur dioxide and nitrogen dioxide).

Although mucus hypersecretion in large airways is the cause of sputum overproduction, it is now thought that accompanying *alterations in the small airways of the lung* (small bronchi and bronchioles, less than 2 to 3 mm in diameter) *can result in physiologically important and early manifestations of chronic airway obstruction*.[25,][26] This feature is similar to that described earlier in emphysema and seems to be a common denominator in COPD.

The role of *infection* seems to be secondary. It is not responsible for the initiation of chronic bronchitis but is probably significant in maintaining it and may be critical in producing acute exacerbations. Cigarette smoke predisposes to infection in more than one way. It interferes with ciliary action of the respiratory epithelium, it may cause direct damage to airway epithelium, and it inhibits the ability of bronchial and alveolar leukocytes to clear bacteria. Viral infections can also cause exacerbations of chronic bronchitis.

Morphology. Grossly, there is hyperemia, swelling, and edema of the mucous membranes, frequently accompanied by excessive mucinous or mucopurulent secretions. Sometimes, heavy casts of secretions and pus fill the bronchi and bronchioles. The characteristic histologic features are chronic inflammation of the airways (predominantly lymphocytes) and enlargement of the mucus-secreting glands of the trachea and bronchi. Although the numbers of goblet cells increase slightly, the **major change is in the size of the mucous gland (hyperplasia)**. This increase can be assessed by the ratio of the thickness of the mucous gland layer to the thickness of the wall between the epithelium and the cartilage (**Reid index**). The Reid index (normally 0.4) is increased in chronic bronchitis, usually in proportion to the severity and duration of the disease. The bronchial epithelium may exhibit squamous metaplasia and dysplasia. There is marked narrowing of bronchioles caused by mucus plugging, inflammation, and fibrosis. In the most severe cases, there may be obliteration of lumen due to fibrosis (**bronchiolitis obliterans**).

Clinical Features.

The cardinal symptom of chronic bronchitis is a persistent cough productive of sputum. For many years no other respiratory functional impairment is present, but eventually dyspnea on exertion develops.

With the passage of time, and usually with continued smoking, other elements of COPD may appear, including hypercapnia, hypoxemia, and mild cyanosis *("blue bloaters")*. Differentiation of pure chronic bronchitis from that associated with emphysema can be made in the classic case (see Table 15-4), but, as has been mentioned, many patients with COPD have both conditions. Longstanding severe chronic bronchitis commonly leads to cor pulmonale with cardiac failure. Death may also result from further impairment of respiratory function due to superimposed acute infections.

ASTHMA

Asthma is a chronic inflammatory disorder of the airways that causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and/or in the early morning. These symptoms are usually associated with widespread but variable bronchoconstriction and airflow limitation that is at least partly reversible, either spontaneously or with treatment. The hallmarks of the disease are: increased airway responsiveness to a variety of stimuli, resulting in episodic bronchoconstriction; inflammation of the bronchial walls; and increased mucus secretion. Some of the stimuli that trigger attacks in patients would have little or no effect in subjects with normal airways. Many cells play a role in the inflammatory response, in particular lymphocytes, eosinophils, mast cells, macrophages, neutrophils, and epithelial cells.[27]

Individuals with asthma experience attacks of varying severity of dyspnea, coughing, and wheezing due to sudden episodes of bronchospasm. Rarely, a state of unremitting attacks, called *status asthmaticus*, proves fatal; usually, such patients have had a long history of asthma. Between the attacks, patients may be virtually asymptomatic. *There has been a significant increase in the incidence of asthma in the Western world in the past four decades*.

Asthma may be categorized into *atopic* (evidence of allergen sensitization, often in a patient with a history of allergic rhinitis, eczema) and *non-atopic* (without evidence of allergen sensitization). In either type, episodes of bronchospasm can be triggered by diverse mechanisms, such as respiratory infections (especially viral infections), environmental exposure to irritants (e.g., smoke, fumes), cold air, stress, and exercise. Recent studies have suggested that the recognition of subphenotypes of asthma based on the pattern of airway inflammation may also be useful. There is emerging evidence for differing patterns of airway inflammation: eosinophilic, neutrophilic, mixed inflammatory, and pauci-granulocytic asthma. These subgroups may differ in their etiology, immunopathology, and response to treatment.[28] Asthma may also be classified according to the agents or events that trigger bronchoconstriction. These include seasonal, exercise-induced, drug-induced (e.g., aspirin), and occupational asthma, and asthmatic bronchitis in smokers.

Atopic Asthma.

This most common type of asthma is a *classic example of type I IgE-mediated hypersensitivity reaction*, discussed in detail in Chapter 6 . The disease usually begins in childhood and is triggered by environmental allergens, such as dusts, pollens, roach or animal dander, and foods. A positive family history of asthma is common, and a skin test with the offending antigen in these patients results in an immediate wheal-and-flare reaction. Atopic asthma may also be diagnosed based on evidence of allergen sensitization by serum radioallergosorbent tests (called RAST), which identify the presence of IgE specific for a panel of allergens.

Non-Atopic Asthma.

The second group of individuals with asthma does not have evidence of allergen sensitization, and skin test results are usually negative. A positive family history of asthma is less common in these patients. Respiratory infections due to viruses (e.g., rhinovirus, parainfluenza virus) are common triggers in non-

atopic asthma.[29] In these patients hyperirritability of the bronchial tree probably underlies their asthma. *It is thought that virus-induced inflammation of the respiratory mucosa lowers the threshold of the subepithelial vagal receptors to irritants*. Inhaled air pollutants, such as sulfur dioxide, ozone, and nitrogen dioxide, may also contribute to the chronic airway inflammation and hyperreactivity that are present in some cases.

Drug-Induced Asthma.

Several pharmacologic agents provoke asthma. *Aspirin-sensitive asthma* is an uncommon yet fascinating type, occurring in individuals with recurrent rhinitis and nasal polyps. These individuals are exquisitely sensitive to small doses of aspirin as well as other nonsteroidal anti-inflammatory medications, and they experience not only asthmatic attacks but also urticaria. It is probable that aspirin triggers asthma in these patients by inhibiting the cyclooxygenase pathway of arachidonic acid metabolism without affecting the lipoxygenase route, thus tipping the balance toward elaboration of the bronchoconstrictor leukotrienes.

Occupational Asthma.

This form of asthma is stimulated by fumes (epoxy resins, plastics), organic and chemical dusts (wood, cotton, platinum), gases (toluene), and other chemicals (formaldehyde, penicillin products). Minute quantities of chemicals are required to induce the attack, which usually occurs after repeated exposure. The underlying mechanisms vary according to stimulus and include type I reactions, direct liberation of bronchoconstrictor substances, and hypersensitivity responses of unknown origin.

Pathogenesis.

The major etiologic factors in atopic asthma are a genetic predisposition to type I hypersensitivity (“atopy”) and exposure to environmental triggers that remain poorly defined.[30] It is postulated that inheritance of susceptibility genes makes individuals prone to develop strong T_H2 reactions against environmental antigens (allergens) that are ignored or elicit harmless responses in most individuals. In the airways the scene for the reaction is set by initial sensitization to inhaled allergens, which stimulate induction of *T_H2 cells* (Fig. 15-10). T_H2 cells secrete cytokines that promote allergic inflammation and stimulate B cells to produce IgE and other antibodies. These cytokines include IL-4, which stimulates the production of IgE; IL-5, which activates locally recruited eosinophils; and IL-13, which stimulates mucus secretion from bronchial submucosal glands and also promotes IgE production by B cells. As in other allergic reactions (Chapter 6), IgE coats submucosal mast cells, and repeat exposure to the allergen triggers the mast cells to release granule contents and produce cytokines and other mediators, which collectively induce the *early-phase (immediate hypersensitivity) reaction and the late-phase reaction*. The early reaction is dominated by bronchoconstriction, increased mucus production, and variable degrees of vasodilation with increased vascular permeability. Bronchoconstriction is triggered by direct stimulation of subepithelial vagal (parasympathetic) receptors through both central and local reflexes (including those mediated by unmyelinated sensory C fibers).

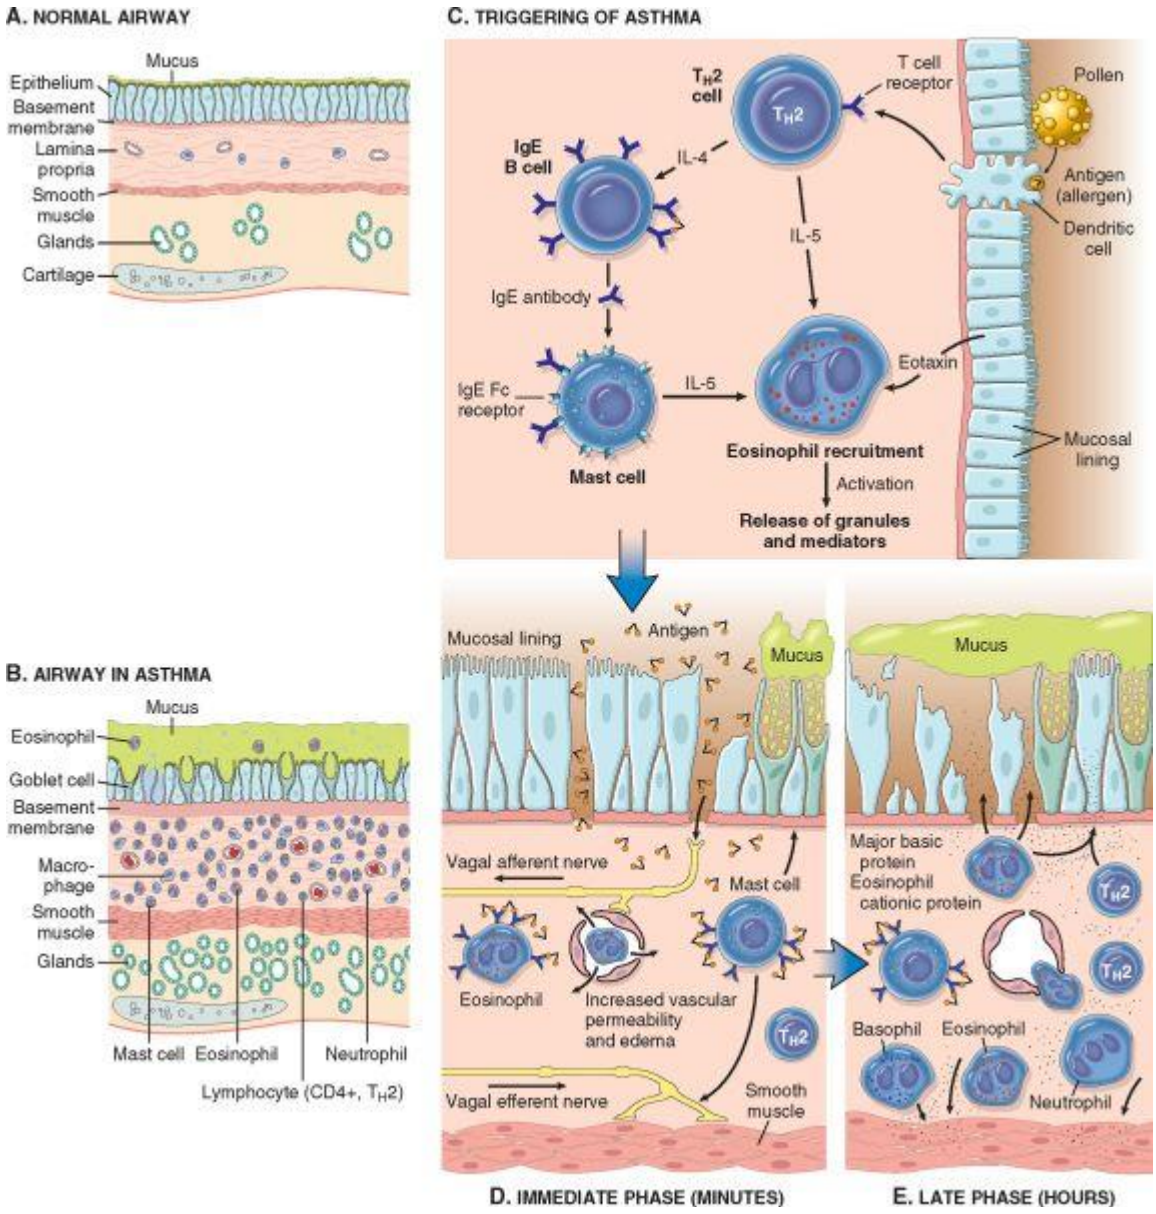

FIGURE 15-10 **A** and **B**, Comparison of a normal bronchus with that in a person with asthma. Note the accumulation of mucus in the bronchial lumen resulting from an increase in the number of mucus-secreting goblet cells in the mucosa and hypertrophy of submucosal glands. In addition, there is intense chronic inflammation due to recruitment of eosinophils, macrophages, and other inflammatory cells. Basement membrane underlying the mucosal epithelium is thickened, and there is hypertrophy and hyperplasia of smooth muscle cells. **C**, Inhaled allergens (antigen) elicit a T_H2-dominated response favoring IgE production and eosinophil recruitment (priming or sensitization). **D**, On re-exposure to antigen (Ag), the immediate reaction is triggered by Ag-induced cross-linking of IgE bound to IgE receptors on mast cells. These cells release preformed mediators. Collectively, either directly or via neuronal reflexes, the mediators induce bronchospasm, increased vascular permeability, and mucus production, and recruit additional mediator-releasing cells from the blood. **E**, The arrival of recruited leukocytes (neutrophils, eosinophils, and basophils; lymphocytes and monocytes) signals the initiation of the late phase of asthma and a fresh round of mediator release from leukocytes, endothelium, and epithelial cells. Factors, particularly from eosinophils (e.g., major basic protein, eosinophil cationic protein), also cause damage to the epithelium. GM-CSF, granulocyte-macrophage colony-stimulating factor.

The late-phase reaction consists largely of inflammation with recruitment of leukocytes, notably eosinophils, neutrophils, and more T cells. Leukocyte recruitment is stimulated by chemokines produced by mast cells, epithelial cells and T cells, and by other cytokines (Chapter 2). Epithelial cells are known to produce a large variety of cytokines in response to infectious agents, drugs, and gases as

well as to inflammatory mediators.[31] This second wave of mediators stimulates the late reaction. For example, *eotaxin*, produced by airway epithelial cells, is a potent chemoattractant and activator of eosinophils.[32] *The major basic protein of eosinophils, in turn*, causes *epithelial damage*[31] and more *airway constriction*.[33] Many mediators have been implicated in the asthmatic response, but the relative importance of each putative mediator in actual human asthma has been difficult to establish. The long list of "suspects" in acute asthma can be subclassified by the clinical efficacy of pharmacologic intervention with inhibitors or antagonists of the mediators.

- The first (disappointingly small) group includes putative mediators whose role in bronchospasm is clearly supported by efficacy of pharmacologic intervention: (1) *leukotrienes* C_4, D_4, and E_4, extremely potent mediators that cause prolonged bronchoconstriction as well as increased vascular permeability and increased mucus secretion, and (2) *acetylcholine*, released from intrapulmonary motor nerves, which can cause airway smooth muscle constriction by directly stimulating muscarinic receptors.
- A second group includes agents present at the *scene of the crime* and with potent asthma-like effects but whose actual role in acute allergic asthma seems relatively minor on the basis of lack of efficacy of potent antagonists or synthesis inhibitors: (1) *histamine*, a potent bronchoconstrictor; (2) *prostaglandin* D_2, which elicits bronchoconstriction and vasodilatation; and (3) *platelet-activating factor*, which causes aggregation of platelets and release of histamine and serotonin from their granules. These mediators might yet prove important in other types of chronic or nonallergic asthma.
- Finally, a large third group comprises the *suspects* for whom specific antagonists or inhibitors are not available or have been insufficiently studied as yet. These include numerous cytokines, such as IL-1, TNF, and IL-6 (some of which exist in a preformed state within the mast cell granules),[34] chemokines (e.g., eotaxin), neuropeptides, nitric oxide, bradykinin, and endothelins.

It is thus clear that multiple mediators contribute to the acute asthmatic response. Moreover, the composition of this mediator soup might differ among different individuals or types of asthma. The appreciation of the importance of inflammatory cells and mediators in asthma has led to greater emphasis on anti-inflammatory drugs, such as corticosteroids, in the treatment of asthma.

Over time, repeated bouts of allergen exposure and immune reactions result in structural changes in the bronchial wall, referred to as "*airway remodeling*." These changes, described later in greater detail, include hypertrophy and hyperplasia of bronchial smooth muscle, epithelial injury, increased airway vascularity, increased subepithelial mucus gland hypertrophy/hyperplasia, and deposition of subepithelial collagen. The complex interactions between the immune system, airway epithelium, and mesenchymal tissues in the airways are poorly understood. Infections with common respiratory pathogens, such as respiratory syncytial virus and influenza, can exacerbate the chronic changes and cause serious worsening of the clinical manifestations of the disease.

Although infections are often triggers for asthma, paradoxically, some infections may be protective. Epidemiologic studies first suggested that the incidence of asthma was greater in populations not exposed to microbes than in those living in an environment with abundant microbes, and this relationship may explain the increasing incidence of asthma in developed countries.[35] These findings have led to the "hygiene hypothesis," which states that eradication of infections may promote allergic and other harmful immune responses. Despite a fascination with this idea, there is no plausible explanation for the inverse relationship between infections and asthma.

Genetics of Asthma.

Asthma is a complex genetic trait in which multiple susceptibility genes interact with environmental factors to initiate the pathologic reaction. As in other complex traits (Chapter 5), there is considerable variability in the expression of these genes and in the combinations of polymorphisms present in individual patients, and even in the significance and reproducibility of reported polymorphisms. Of the more than 100 genes that have been reported to be associated with the disease, relatively few have been

replicated in multiple patient populations. Many of these affect the immune response or tissue remodeling. Some genes may influence the development of asthma, while others modify asthma severity or the patient's response to therapy.[36] A few of these are discussed below:

- One of the most replicated susceptibility loci for asthma is on chromosome 5q, near the gene cluster encoding the cytokines IL-3, IL-4, IL-5, IL-9, and IL-13 and the IL-4 receptor. The receptor for LPS (CD14), and another candidate gene, the β_2-adrenergic receptor, also map here. This region is of great interest because of the connection between several of the genes located here and the mechanisms of IgE regulation and mast cell and eosinophil growth and differentiation. Among the genes in this cluster, polymorphisms in the *IL13* gene have the strongest and most consistent associations with asthma or allergic disease.
  The association between asthma and other forms of atopy with a polymorphism in the gene encoding the monocyte receptor for endotoxin, *CD14*, is worthy of additional comments since it is paradigmatic for studies of gene-environment interactions. In some studies, the TT genotype of *CD14* has been associated with reduced levels of IgE and reduced risk for asthma and atopy. Other studies have revealed the opposite, i.e., an *increased* risk for atopy. Further analysis has revealed that the TT genotype is protective against asthma or allergic sensitization in individuals exposed to low (household) endotoxin levels, whereas the same genotype is associated with an increased risk for asthma or allergic sensitization in individuals exposed to high endotoxin levels (as may occur in those living on farms). These differences may relate to the influence of endotoxin levels on the regulation of T_H1 vs. T_H2 responses. In individuals with the TT genotype high endotoxin levels skew the response towards T_H2 type, thus favoring more brisk IgE production and a predisposition to allergy. These studies indicate that the relationship between genotype and phenotype is context dependent, and help explain some of the discrepant results of association studies in different populations.[37,][38]
- The tendency to produce IgE antibodies against some but not all antigens, such as ragweed pollen, may be linked to particular class II HLA alleles.
- ADAM-33: ADAM-33 belongs to a subfamily of metalloproteinases related to the MMPs such as collagenases (Chapter 3). Although the precise function of ADAM-33 remains to be elucidated, it is known to be expressed by lung fibroblasts and bronchial smooth muscle cells. It is speculated that *ADAM-33 polymorphisms accelerate proliferation of bronchial smooth muscle cells and fibroblasts*, thus contributing to bronchial hyperreactivity and subepithelial fibrosis.[39] ADAM-33 is also associated with decline in lung functions.
- β_2-adrenergic receptor gene: This also maps to 5q and variations in this gene are associated with differential in vivo airway hyper-responsiveness and in vitro response to β-agonist stimulation. Thus, knowledge of the genotype can be of value in predicting response to treatment.[40]
- IL-4 receptor gene: Mutliple polymorphic variants in the gene encoding the alpha-chain of the IL-4 receptor are associated with atopy, elevated total serum IgE, and asthma.
- Mammalian chitinase family: *Chitinases* are enzymes that cleave chitin, a polysaccharide contained in many human parasites and the cell walls of fungi. In humans the chitinase family includes members with and without enzymic activity. One member with activity, acidic mammalian chitinase, is up-regulated in and contributes to T_H2 inflammation. Another chitinase family member with no enzymatic activity, YKL-40, is associated with asthma. Serum levels of YKL-40 correlate with the severity of asthma.[41]

Morphology. In patients dying of status asthmaticus the lungs are overdistended because of overinflation, with small areas of atelectasis. The most striking macroscopic finding is occlusion of bronchi and bronchioles by thick, tenacious mucus plugs. Histologically, the mucus plugs contain whorls of shed epithelium, which give rise to the well-known spiral shaped mucus plugs called **Curschmann spirals** (these result either from mucus plugging in subepithelial mucous gland ducts which later become extruded or from plugs in bronchioles). Numerous eosinophils and **Charcot-Leyden crystals** are present; the latter are collections of crystalloid made up of an eosinophil lysophospholipase binding protein called galectin-10.[42] The other characteristic histologic findings of asthma, collectively called **"airway remodeling"** (Fig. 15-10B), include:

- Overall thickening of airway wall

- Sub-basement membrane fibrosis (due to deposition of type I and III collagen beneath the classic basement membrane composed of type IV collagen and laminin) (Fig. 15-11)
- Increased vascularity
- An increase in size of the submucosal glands and mucous metaplasia of airway epithelial cells
- Hypertrophy and/or hyperplasia of the bronchial wall muscle (this has led to the novel therapy of bronchial thermoplasty in which radiofrequency current is applied to the walls of the central airways through a bronchoscopically placed probe, which reduces airway hyper-responsiveness for up to at least a year).[43]

While acute airflow obstruction is primarily attributed to muscular bronchoconstriction, acute edema, and mucus plugging, airway remodeling may also contribute. Airway remodeling is commonly thought to contribute to chronic irreversible airway obstruction as well, although this is difficult to prove.

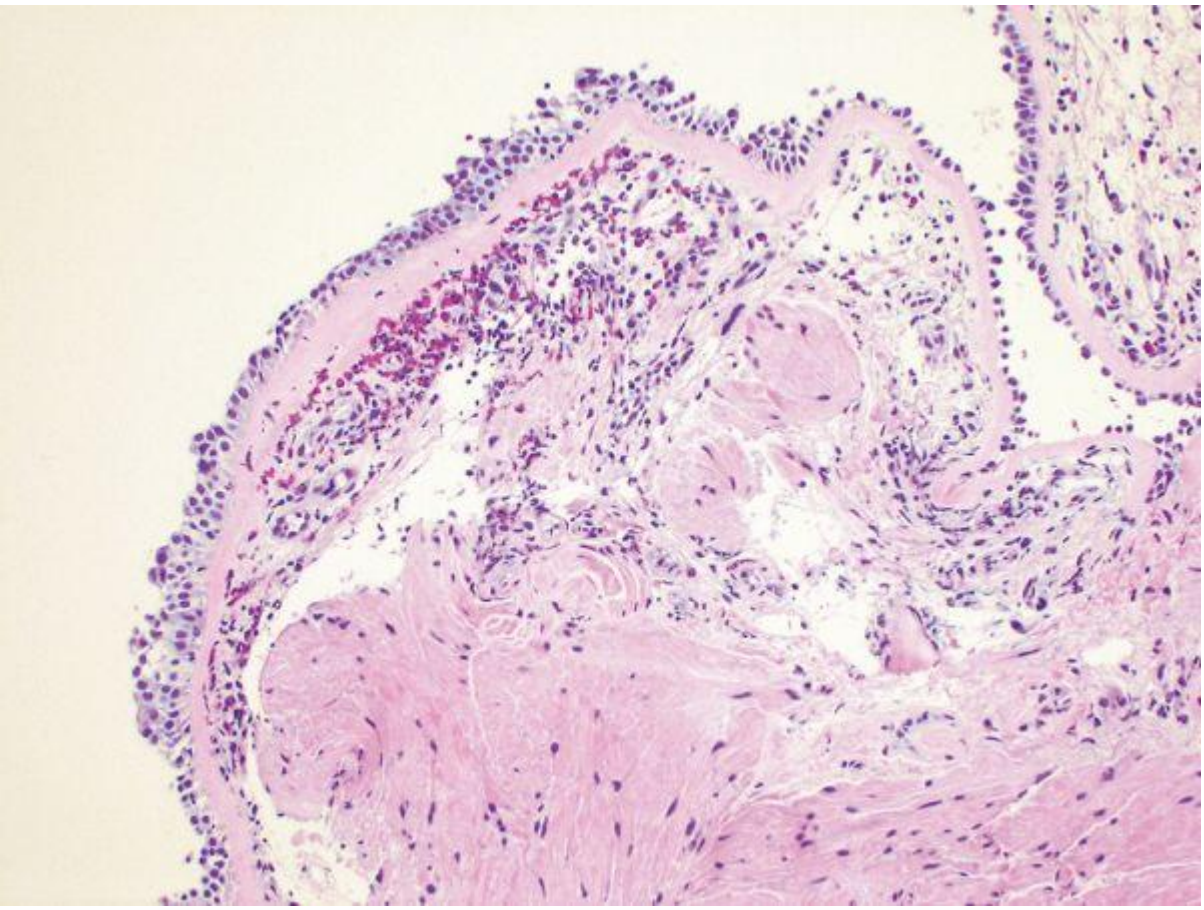

FIGURE 15-11 Bronchial biopsy specimen from an asthmatic patient showing sub-basement membrane fibrosis, eosinophilic inflammation, and muscle hyperplasia.

Clinical Course.

The classic acute asthmatic attack lasts up to several hours. In some patients these symptoms of chest tightness, dyspnea, wheezing, and cough with or without sputum production, persist at a low level constantly. In its most severe form, *status asthmaticus*, the severe acute paroxysm persists for days and

even weeks, and under these circumstances airflow obstruction might be so extreme as to cause severe cyanosis and even death. The clinical diagnosis is aided by the demonstration of an increase in airflow obstruction (from baseline levels), difficulty with exhalation (prolonged expiration, wheeze), and elevated eosinophil count in the peripheral blood and the finding of eosinophils, Curschmann spirals, and Charcot-Leyden crystals in the sputum (particularly in patients with atopic asthma). In the usual case, with intervals of freedom from respiratory difficulty, the disease is more discouraging and disabling than lethal, being more of a problem in adult women than men. With appropriate therapy to relieve the attacks, most individuals with asthma are able to maintain a productive life. Up to 50% of childhood asthma remits in adolescence only to return in adulthood in a significant number of patients. In other cases there is a variable decline in baseline lung function.

BRONCHIECTASIS

Bronchiectasis is a disease characterized by permanent dilation of bronchi and bronchioles caused by destruction of the muscle and elastic tissue, resulting from or associated with chronic necrotizing infections. To be considered bronchiectasis the dilation must be permanent; reversible bronchial dilation often accompanies viral and bacterial pneumonia. Because of better control of lung infections, bronchiectasis is now an uncommon condition. Bronchiectasis develops in association with a variety of conditions, which include the following[44,][45]:

- Congenital or hereditary conditions, including cystic fibrosis, intralobar sequestration of the lung, immunodeficiency states,[46] and primary ciliary dyskinesia and Kartagener syndromes
- *Postinfectious conditions*, including necrotizing pneumonia caused by bacteria (*Mycobacterium tuberculosis*, *Staphylococcus aureus*, *Haemophilus influenzae*, *Pseudomonas*), viruses (adenovirus, influenza virus, human immunodeficiency virus [HIV]), and fungi (*Aspergillus* species)
- *Bronchial obstruction*, due to tumor, foreign bodies, and occasionally mucus impaction, in which the bronchiectasis is localized to the obstructed lung segment
- Other conditions, including rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, and post-transplantation (chronic lung rejection, and chronic graft-versus-host disease after bone marrow transplantation)

Etiology and Pathogenesis.

Obstruction and *infection* are the major conditions associated with bronchiectasis, and it is likely that both are necessary for the development of full-fledged lesions, although either may come first. After bronchial obstruction, normal clearing mechanisms are impaired, there is pooling of secretions distal to the obstruction, and there is inflammation of the airway. Conversely, severe infections of the bronchi lead to inflammation, often with necrosis, fibrosis, and eventually dilation of airways.

These mechanisms, infection and obstruction, are most readily apparent in the severe form of bronchiectasis associated with cystic fibrosis (Chapter 10). In cystic fibrosis the primary defect in ion transport leads to defective mucociliary action, and accumulation of thick viscid secretions that obstruct the airways. This leads to a marked susceptibility to bacterial infections, which further damage the airways. With repeated infections there is widespread damage to airway walls, with destruction of supporting smooth muscle and elastic tissue, fibrosis, and further dilatation of bronchi. The smaller bronchioles become progressively obliterated as a result of fibrosis (bronchiolitis obliterans).[47]

In *primary ciliary dyskinesia*, an autosomal recessive syndrome with variable penetrance and a frequency of 1 in 15,000 to 40,000 births, poorly functioning cilia contribute to the retention of secretions and recurrent infections that in turn lead to bronchiectasis. There is an absence or shortening of the dynein arms that are responsible for the coordinated bending of the cilia. Approximately half of the patients with primary ciliary dyskinesia have *Kartagener syndrome* (bronchiectasis, sinusitis, and

situs inversus or partial lateralizing abnormality).[48] The lack of ciliary activity interferes with bacterial clearance, predisposes the sinuses and bronchi to infection, and affects cell motility during embryogenesis, resulting in the situs inversus. Males with this condition tend to be infertile, as a result of sperm dysmotility.

Allergic bronchopulmonary aspergillosis is a condition that results from a hypersensitivity reaction to the fungus *Aspergillus fumigatus*. It is also an important complication of asthma and cystic fibrosis.[49] Characteristics are high serum IgE levels, serum antibodies to *Aspergillus*, intense airway inflammation with eosinophils, and the formation of mucus plugs, which play a primary role in its pathogenesis. There is evidence that neutrophil-mediated inflammation and a relative deficiency of anti-inflammatory cytokines such as IL-10 may also play a role.[50] Clinically, there are periods of exacerbation and remission that may lead to proximal bronchiectasis and fibrotic lung disease.

Morphology. Bronchiectasis usually affects the lower lobes bilaterally, particularly air passages that are vertical, and is most severe in the more distal bronchi and bronchioles. When tumors or aspiration of foreign bodies lead to bronchiectasis, the involvement may be sharply localized to a single segment of the lung. **The airways are dilated, sometimes up to four times normal size**. Characteristically, the bronchi and bronchioles are sufficiently dilated that they can be followed almost to the pleural surfaces. By contrast, in the normal lung, the bronchioles cannot be followed by ordinary gross dissection beyond a point 2 to 3 cm from the pleural surfaces. On the cut surface of the lung, the transected dilated bronchi appear as cysts filled with mucopurulent secretions (Fig. 15-12).

The histologic findings vary with the activity and chronicity of the disease. In the full-blown, active case there is an intense acute and chronic inflammatory exudation within the walls of the bronchi and bronchioles, associated with desquamation of the lining epithelium and extensive areas of necrotizing ulceration. There may be pseudostratification of the columnar cells or squamous metaplasia of the remaining epithelium. In some instances the necrosis completely destroys the bronchial or bronchiolar walls and forms a lung abscess. Fibrosis of the bronchial and bronchiolar walls and peribronchiolar fibrosis develop in the more chronic cases, leading to varying degrees of subtotal or total obliteration of bronchiolar lumens.

In the usual case of bronchiectasis, a mixed flora can be cultured from the involved bronchi, including staphylococci, streptococci, pneumococci, enteric organisms, anaerobic and microaerophilic bacteria, and (particularly in children) *Haemophilus influenzae* and *Pseudomonas aeruginosa*.[51] In allergic bronchopulmonary aspergillosis a few fungal hyphae can be seen on special stains within the muco-inflammatory contents of the cylindrically dilated segmental bronchi. In late stages the fungus may infiltrate the bronchial wall.

FIGURE 15-12 Bronchiectasis in a patient with cystic fibrosis, who underwent lung transplantation. Cut surface of lung shows markedly distended peripheral bronchi filled with mucopurulent secretions.

Clinical Course.

Bronchiectasis causes severe, persistent cough; expectoration of foul-smelling, sometimes bloody sputum; dyspnea and orthopnea in severe cases; and occasional life-threatening hemoptysis. These symptoms are oftenepisodic and are precipitated by upper respiratory tract infections or the introduction of new pathogenic agents. Paroxysms of cough are particularly frequent when the patient rises in the morning, when changes in position lead to drainage of collections of pus and secretions into the bronchi. Obstructive respiratory insufficiency can lead to marked dyspnea and cyanosis. Cor pulmonale, brain abscesses, and amyloidosis are less frequent complications of bronchiectasis. However, due to current treatment with better antibiotics and physical therapy, outcome has improved considerably and life expectancy has almost doubled.

3.5.7 Chronic Diffuse Interstitial (Restrictive) Diseases

Chronic interstitial diseases are a heterogeneous group of disorders *characterized predominantly by inflammation and fibrosis of the pulmonary connective tissue, principally the most peripheral and delicate interstitium in the alveolar walls*. Many of the entities are of unknown cause and pathogenesis, some have an intra-alveolar as well as an interstitial component, and there is frequent overlap in histologic features among the different conditions. These disorders account for about 15% of noninfectious diseases seen by pulmonary physicians.

In general, the clinical and pulmonary functional changes are those of *restrictive lung disease* (see the earlier discussion of obstructive versus restrictive pulmonary diseases). Patients have dyspnea, tachypnea, end-inspiratory crackles, and eventual cyanosis, without wheezing or other evidence of airway obstruction. The classic physiologic features are reductions in carbon monoxide diffusing capacity, lung volume, and compliance. *Chest radiographs show bilateral infiltrative lesions in the form of small nodules, irregular lines, or ground-glass shadows,* hence the term *infiltrative*. Eventually, secondary pulmonary hypertension and right-sided heart failure with cor pulmonale may result. Although the entities can often be distinguished in the early stages, the advanced forms are hard to differentiate because they result in scarring and gross destruction of the lung, often referred to as *end-stage lung* or *honeycomb lung*. Diffuse restrictive diseases are categorized based on histology and clinical features (Table 15-5).

TABLE 15-5 -- Major Categories of Chronic Interstitial Lung Disease

FIBROSING

Pulmonary alveolar proteinosis

FIBROSING DISEASES

Idiopathic Pulmonary Fibrosis

The term *idiopathic pulmonary fibrosis* (IPF) refers to a clinicopathologic syndrome with characteristic radiologic, pathologic, and clinical features. In Europe the term *cryptogenic fibrosing alveolitis* is more popular. The histologic pattern of fibrosis is referred to as usual interstitial pneumonia (UIP), which is required for the diagnosis of IPF but can also be seen in other diseases, notably connective tissue diseases, chronic hypersensitivity pneumonia, and asbestosis. The International Multidisciplinary Consensus Classification is an excellent reference for definitions and understanding of idiopathic interstitial pneumonias.[52,][53]

Pathogenesis.

While the causative agent(s) of IPF remain unknown, our concepts of pathogenesis have evolved over the past several years.[54] The earlier view was that IPF is initiated by an unidentified insult that gives rise to chronic inflammation resulting in fibrosis. The dismal failure of potent anti-inflammatory therapy in altering the course of the disease did not support this view. *The current concept is that IPF is caused by "repeated cycles" of epithelial activation/injury by some unidentified agent*. There is inflammation and induction of T_H2 type T cell response characterized by the presence of eosinophils, mast cells, IL-4 and IL-13 in the lesions. But the significance of this inflammatory response is unknown. Abnormal epithelial repair at these sites gives rise to exuberant fibroblastic/myofibroblastic proliferation, leading to the "fibroblastic foci" that are so characteristic of IPF (Fig. 15-13). The circuits that drive such aberrant epithelial repair are not fully understood, but all evidence points to *TGF-β1 as the driver of the process*. TGF-β1 is known to be fibrogenic and is released from injured type I alveolar epithelial cells (Fig. 15-13). It favors the transformation of fibroblasts into myofibroblasts and deposition of collagen and other extracellular matrix molecules.[55]

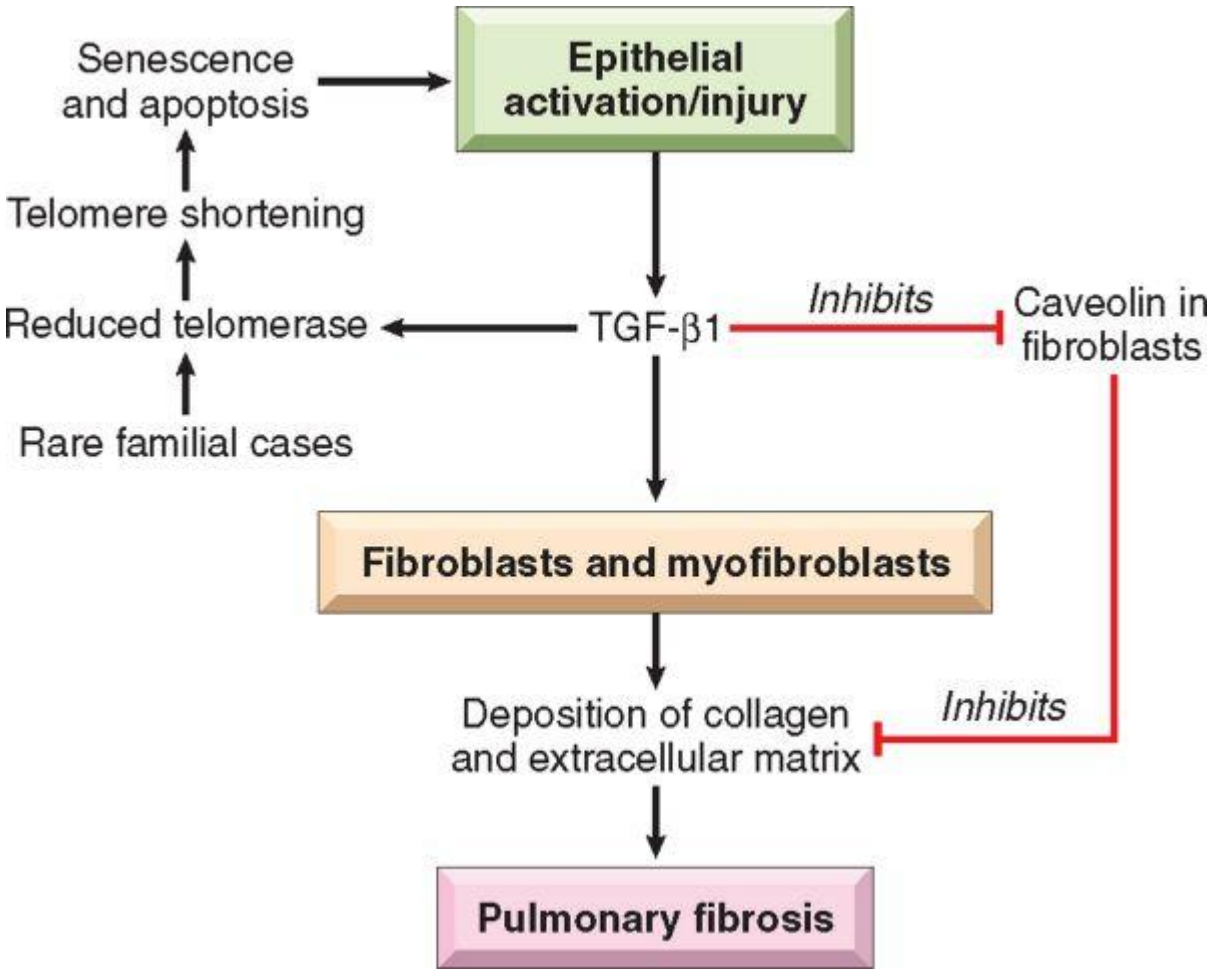

FIGURE 15-13 Schematic representation of current understanding of the pathogenesis of idiopathic pulmonary fibrosis.

The concept that there is an intrinsic abnormality of tissue repair in IPF is supported by the finding that some patients with familial pulmonary fibrosis have mutations that shorten telomeres. Recall that telomeres control cell replications (see Chapters 1 and 7 and with shortening of telomeres alveolar epithelial cells undergo rapid senescence and apoptosis.[56,][57] Interestingly, *TGF-β1 negatively regulates telomerase activity*, thus facilitating epithelial cell apoptosis and the cycle of death and repair.[58] Another molecule regulated by TGF-β1 is *caveolin-1*, the predominant structural protein of caveolae, flask-shaped invaginations of the plasma membrane present in many terminally differentiated cells. *Caveolin-1 acts as an endogenous inhibitor of pulmonary fibrosis* by limiting TGF-β1–induced production of extracellular matrix and restoring alveolar epithelial repair processes. Caveolin-1 is decreased in epithelial cells and fibroblasts of IPF patients, and overexpression of caveolin-1 in a mouse model limits fibrosis.[59] Such down-regulation may be mediated by the ability of TGF-β1 to attenuate the expression of caveolin-1 in fibroblasts. Thus, it seems that TGF-β1 has its fingerprints on multiple pathways that regulate pulmonary fibrosis. Therapeutics directed toward neutralizing TGF-β1, enhancing telomerase activity or delaying telomere shortening, or augmenting caveolin-1 may lead to novel treatments for IPF in the future.[60]

Morphology. Grossly, the pleural surfaces of the lung are cobblestoned as a result of the retraction of scars along the interlobular septa. The cut surface shows fibrosis (firm, rubbery white areas) of the lung parenchyma with lower-lobe predominance and a distinctive distribution in the **subpleural regions** and along the **interlobular septa**. Microscopically, the hallmark of UIP is **patchy interstitial fibrosis**, which varies in intensity (Fig. 15-14) and age. The earliest lesions contain exuberant fibroblastic proliferation **(fibroblastic foci)**. With time these areas become more collagenous and less cellular. Quite typical is the coexistence of both early and late lesions (Fig. 15-15).The dense fibrosis causes the destruction of alveolar architecture and formation of cystic spaces lined by hyperplastic type II pneumocytes or bronchiolar epithelium (**honeycomb fibrosis**). With adequate sampling, these diagnostic histologic changes (i.e., areas of dense collagenous fibrosis with relatively normal lung and fibroblastic foci) can be identified even in advanced IPF. There is mild to moderate inflammation within the fibrotic areas, consisting of mostly lymphocytes, and a few plasma cells, neutrophils, eosinophils, and mast cells. Foci of squamous metaplasia and smooth muscle hyperplasia may be present. Pulmonary arterial hypertensive changes (intimal fibrosis and medial thickening) are often present. In acute exacerbations diffuse alveolar damage is superimposed on the UIP pattern.[61]

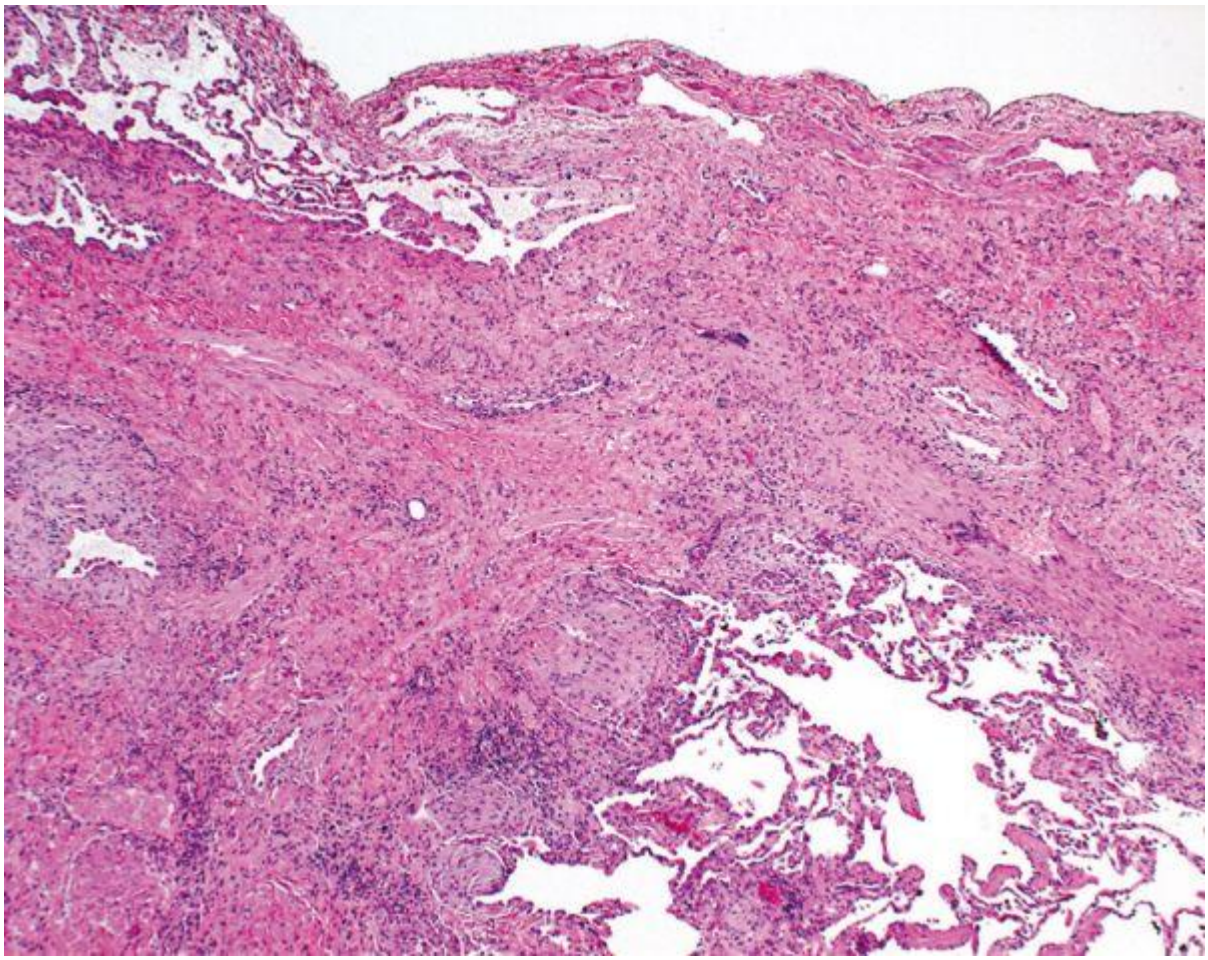

FIGURE 15-14 Usual interstitial pneumonia. The fibrosis is more pronounced in the subpleural region. *(Courtesy of Dr. Nicole Cipriani, Department of Pathology, University of Chicago, Chicago, IL.)*

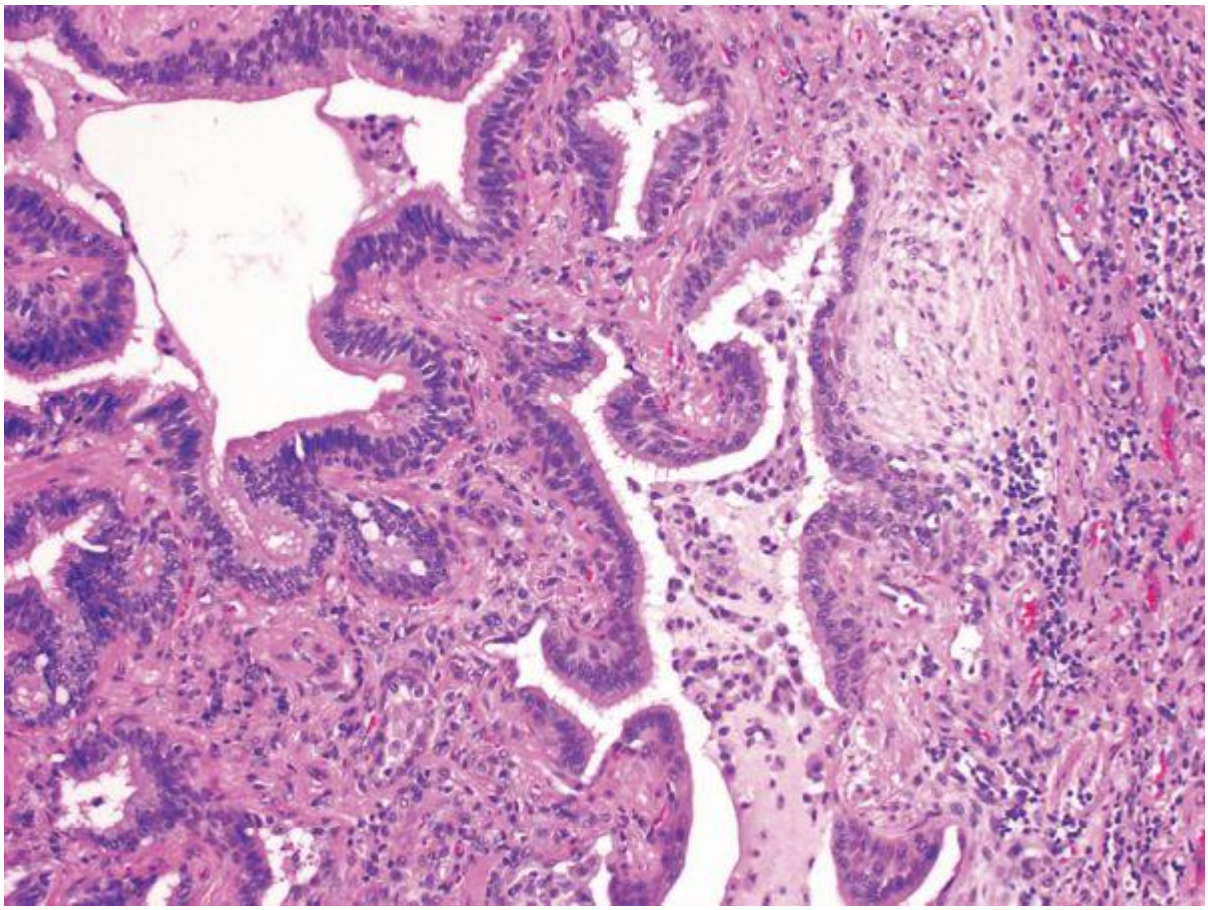

FIGURE 15-15 Usual interstitial pneumonia. Fibroblastic focus with fibers running parallel to surface and bluish myxoid extracellular matrix. Honeycombing is present on the *left*.

Clinical Course.

IPF begins insidiously, with gradually increasing *dyspnea on exertion* and dry cough. Most patients are 40 to 70 years old at the time of presentation. Hypoxemia, *cyanosis*, and clubbing occur late in the course. The progression in an individual patient is unpredictable. Most patients have a gradual deterioration of their pulmonary status, despite medical treatment (steroids, cyclophosphamide, or azathioprine). In some IPF patients, there are acute exacerbations of the underlying disease with a rapid downhill clinical course. The mean survival is 3 years or less. Lung transplantation is the only definitive therapy currently available.[62]

Nonspecific Interstitial Pneumonia

The concept of nonspecific interstitial pneumonia (NSIP) emerged when it was realized that there is a group of patients with diffuse interstitial lung disease of unknown etiology whose lung biopsies fail to show diagnostic features of any of the other well-characterized interstitial diseases. Despite its "nonspecific" name, NSIP has distinct radiologic and histologic features and is important to recognize, since these patients have a much better prognosis than do those with UIP.[63]

Morphology. On the basis of its histology, NSIP is divided into cellular and fibrosing patterns. The cellular pattern consists primarily of mild to moderate chronic interstitial inflammation, containing lymphocytes and a few plasma cells, in a uniform or patchy distribution. The fibrosing pattern consists of diffuse or patchy interstitial fibrosis without the temporal heterogeneity that is characteristic of UIP. Fibroblastic foci and honeycombing are absent. However, in some patients both NSIP and UIP patterns can be seen in different areas of the lung; the prognosis in these is the same as for UIP.[64]

Clinical Course.

Patients present with dyspnea and cough of several months' duration. They are typically between 46 and 55 years of age. Those having the NSIP cellular pattern are somewhat younger than those with the fibrosing pattern or UIP. Patients with the cellular pattern have a better outcome than do those with fibrosing pattern and UIP.[65]

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia is synonymous with the popular term *bronchiolitis obliterans organizing pneumonia*; however, the former is now preferred, since it conveys the essential features of a clinicopathologic syndrome of unknown etiology and avoids confusion with airway diseases such as bronchiolitis obliterans. Patients present with cough and dyspnea and have subpleural or peribronchial patchy areas of airspace consolidation radiographically. Histologically, cryptogenic organizing pneumonia is characterized by the presence of polypoid plugs of loose organizing connective tissue (Masson bodies) within alveolar ducts, alveoli (Fig. 15-16), and often bronchioles. The connective tissue is all of the same age, and the underlying lung architecture is normal. There is no interstitial fibrosis or honeycomb lung. Some patients recover spontaneously, but most need treatment with oral steroids for 6 months or longer for complete recovery.

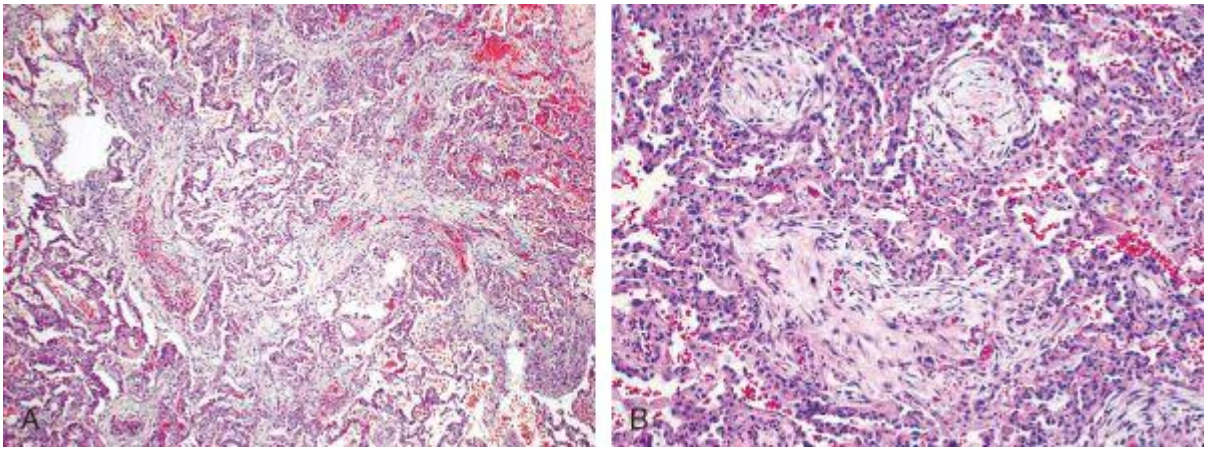

FIGURE 15-16 Cryptogenic organizing pneumonia. Some alveolar spaces are filled with balls of fibroblasts (Masson bodies), while the alveolar walls are relatively normal. **A**, Low power; **B**, high power.

It is important to recognize that organizing pneumonia with intra-alveolar fibrosis is also often seen as a response to infections or inflammatory injury of the lungs.[66] These include viral and bacterial pneumonia, inhaled toxins, drugs, connective tissue disease, and graft-versus-host disease in bone

marrow transplant recipients. The prognosis for these patients is the same as that for the underlying disorder.

Pulmonary Involvement in Connective Tissue Diseases

Many connective tissue diseases, notably systemic lupus erythematosus, rheumatoid arthritis, progressive systemic sclerosis (scleroderma), dermatomyositis-polymyositis, and mixed connective tissue disease, can involve the lung to a lesser or greater degree at some time in their course. Pulmonary involvement can occur in different patterns; NSIP, UIP (similar to that seen in IPF), vascular sclerosis, organizing pneumonia, and bronchiolitis are the most common.

- *Rheumatoid arthritis*: pulmonary involvement may occur in 30% to 40% of patients as (1) chronic pleuritis, with or without effusion; (2) diffuse interstitial pneumonitis and fibrosis; (3) intrapulmonary rheumatoid nodules; or (4) pulmonary hypertension
- *Systemic sclerosis* (scleroderma): diffuse interstitial fibrosis (NSIP pattern more common than UIP)
- *Lupus erythematosus*: patchy, transient parenchymal infiltrates, and occasionally severe lupus pneumonitis

Pulmonary involvement in these diseases is usually associated with a variable prognosis, partly dependent on the type of pulmonary disease, although it is still better than that of idiopathic UIP.[67]

Pneumoconioses

The term *pneumoconiosis* was originally coined to describe the non-neoplastic lung reaction to inhalation of mineral dusts encountered in the workplace. Now it also includes diseases induced by organic as well as inorganic particulates and chemical fumes and vapors. A simplified classification is presented in Table 15-6 . Regulations limiting worker exposure have resulted in a marked decrease in dust-associated diseases.

TABLE 15-6 -- Lung Diseases Caused by Air Pollutants

Agent	Disease	Exposure
MINERAL DUSTS		
Coal dust	Anthracosis	Coal mining (particularly hard coal)
	Macules	
	Progressive massive fibrosis	
	Caplan syndrome	
Silica	Silicosis	Foundry work, sandblasting, hard rock mining, stone cutting, others
	Caplan syndrome	
Asbestos	Asbestosis	Mining, milling, fabrication, and installation and removal of insulation
	Pleural plaques	
	Caplan syndrome	
	Mesothelioma	
	Carcinoma of the lung, larynx, stomach, colon	
Beryllium	Acute berylliosis	Mining, fabrication
	Beryllium granulomatosis	
	Lung carcinoma (?)	

Agent	Disease	Exposure
Iron oxide	Siderosis	Welding
Barium sulfate	Baritosis	Mining
Tin oxide	Stannosis	Mining
ORGANIC DUSTS THAT INDUCE HYPERSENSITIVITY PNEUMONITIS		
Moldy hay	Farmer's lung	Farming
Bagasse	Bagassosis	Manufacturing wallboard, paper
Bird droppings	Bird-breeder's lung	Bird handling
ORGANIC DUSTS THAT INDUCE ASTHMA		
Cotton, flax, hemp	Byssinosis	Textile manufacturing
Red cedar dust	Asthma	Lumbering, carpentry
CHEMICAL FUMES AND VAPORS		
Nitrous oxide, sulfur dioxide, ammonia, benzene, insecticides	Bronchitis, asthma	Occupational and accidental exposure
	Pulmonary edema	
	ARDS	
	Mucosal injury	
	Fulminant poisoning	

ARDS, acute respiratory distress syndrome.

Although the pneumoconioses result from well-defined occupational exposure to specific airborne agents, particulate air pollution also has deleterious effects on the general population, especially in urban areas. Studies have found increased morbidity (e.g., asthma incidence) and mortality rates in populations that are exposed to high ambient air particulate levels,[68,][69] leading to calls for greater efforts to reduce the levels of particulates in urban air.

Pathogenesis.

The development of a pneumoconiosis depends on (1) the amount of dust retained in the lung and airways; (2) the size, shape, and therefore buoyancy of the particles; (3) particle solubility and physiochemical reactivity; and (4) the possible additional effects of other irritants (e.g., concomitant tobacco smoking).

The amount of dust retained in the lungs is determined by the dust concentration in ambient air, the duration of exposure, and the effectiveness of clearance mechanisms. Any influence, such as cigarette smoking, that affects the integrity of the mucociliary apparatus significantly predisposes to the accumulation of dust. *The most dangerous particles range from 1 to 5 μm in diameter because they may reach the terminal small airways and air sacs and settle in their linings*. Under normal conditions there is a small pool of intra-alveolar macrophages, and this is expanded by recruitment of more macrophages when dust reaches the alveolar spaces. The protection provided by phagocytosis of particles, however, can be overwhelmed by a large dust burden by specific chemical interactions of the particles with cells.

The *solubility and cytotoxicity of particles*, which are influenced to a considerable extent by their size, modify the nature of the pulmonary response. In general, the smaller the particle, the more likely it is to appear in the pulmonary fluids and reach toxic levels rapidly, depending, of course, on the solubility of the agent. Therefore, smaller particles tend to cause acute lung injury. Larger particles resist dissolution and so may persist within the lung parenchyma for years. These tend to evoke fibrosing collagenous pneumoconioses, such as is characteristic of silicosis. Some of the particles may be taken up by epithelial cells or may cross the epithelial cell lining and interact directly with fibroblasts and interstitial macrophages. Some may reach the lymphatics by direct drainage or within migrating macrophages and thereby initiate an immune response to components of the particulates or to self-proteins modified by the particles or both. This response amplifies the intensity and the duration of the local reaction. Although tobacco smoking worsens the effects of all inhaled mineral dusts, the effects of asbestos are particularly magnified by smoking. The effects of inhaled particles are not confined to the lung alone, since solutes from particles can enter the blood and lung inflammation invokes systemic responses.[70]

In general, only a small percentage of exposed people develop occupational respiratory diseases, implying a genetic predisposition to their development.[71] In one study, genetic variation of serum and erythrocytic proteins was shown to correlate with susceptibility to developing silicosis, chronic bronchitis, and occupational asthma.[72] Many of the diseases listed in Table 15-6 are quite uncommon. Hence only a selected few that cause fibrosis of the lung are presented next.

Coal Workers' Pneumoconiosis

Dust reduction measures in coal mines around the globe have drastically reduced the incidence of coal workers' pneumoconiosis (CWP). The spectrum of lung findings in coal workers is wide, varying from (1) asymptomatic anthracosis to (2) simple CWP with little to no pulmonary dysfunction to (3) complicated CWP, or progressive massive fibrosis (PMF), in which lung function is compromised.[73] The pathogenesis of complicated CWP, particularly what causes the lesions of simple CWP to progress to PMF, is incompletely understood. Contaminating silica in the coal dust can favor progressive disease. In most cases, carbon dust itself is the major culprit, and studies have shown that complicated lesions contain much more dust than simple lesions.

Morphology. Anthracosis is the most innocuous coal-induced pulmonary lesion in coal miners and is also seen to some degree in urban dwellers and tobacco smokers. Inhaled carbon pigment is engulfed by alveolar or interstitial macrophages, which then accumulate in the connective tissue along the lymphatics, including the pleural lymphatics, or in organized lymphoid tissue along the bronchi or in the lung hilus.

Simple CWP is characterized by **coal macules** (1 to 2 mm in diameter) and the somewhat larger **coal nodules**. The coal macule consists of carbon-laden macrophages; the nodule also contains small amounts of a delicate network of collagen fibers. Although these lesions are scattered throughout the lung, the upper lobes and upper zones of the lower lobes are more heavily involved. They are located primarily adjacent to respiratory bronchioles, the site of initial dust accumulation. In due course dilation of adjacent alveoli occurs, a condition sometimes referred to as **centrilobular emphysema**.

Complicated CWP (progressive massive fibrosis) occurs on a background of simple CWP and generally requires many years to develop. It is characterized by intensely blackened scars larger than 2 cm, sometimes up to 10 cm in greatest diameter. They are usually multiple (Fig. 15-17). Microscopically the lesions consist of dense collagen and pigment. The center of the lesion is often necrotic, most likely due to local ischemia.

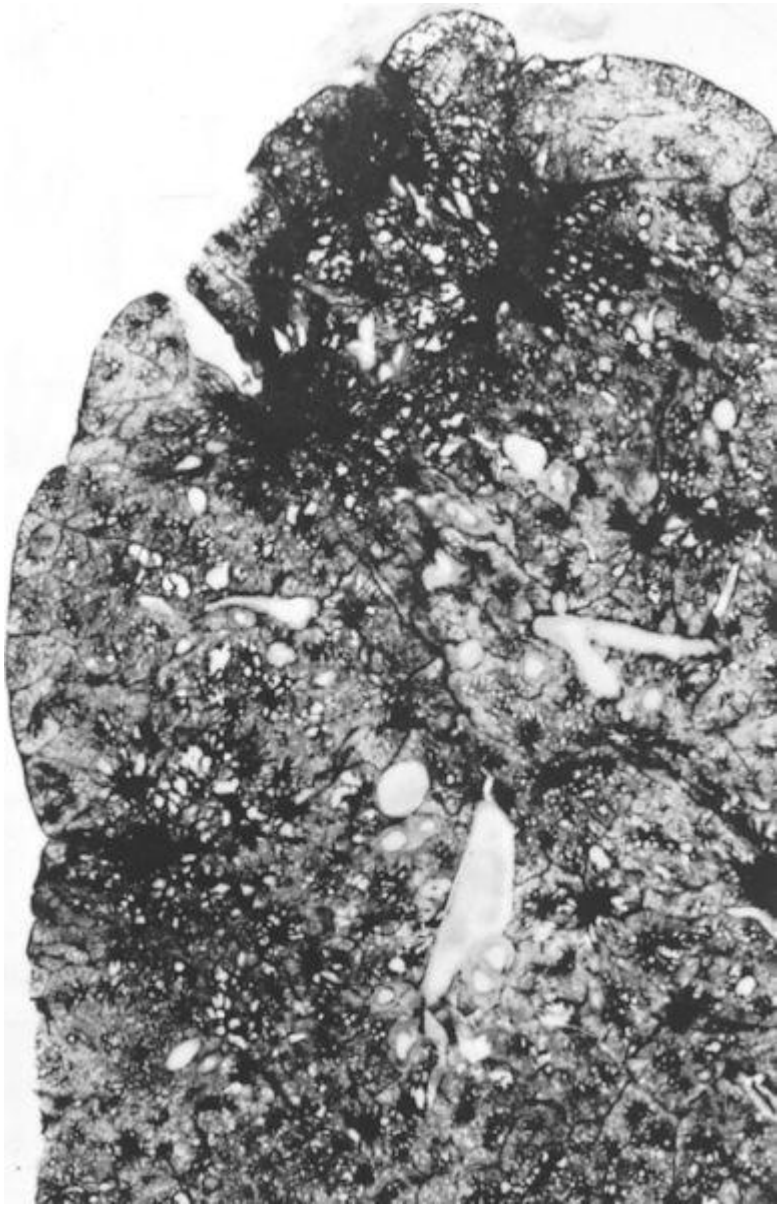

FIGURE 15-17 Progressive massive fibrosis superimposed on coal workers' pneumoconiosis. The large, blackened scars are located principally in the upper lobe. Note the extensions of scars into surrounding parenchyma and retraction of adjacent pleura. *(Courtesy of Drs. Werner Laquer and Jerome Kleinerman, the National Institute of Occupational Safety and Health, Morgantown, WV.)*

Clinical Course.

CWP is usually a benign disease that causes little decrement in lung function. Even mild forms of complicated CWP fail to demonstrate abnormalities of lung function. In a minority of cases (fewer than 10%), PMF develops, leading to increasing pulmonary dysfunction, pulmonary hypertension, and cor pulmonale. Once PMF develops, it may become progressive even if further exposure to dust is prevented. Unlike silicosis (discussed later), there is no convincing evidence that coal dust increases susceptibility to tuberculosis. There is some evidence that exposure to coal dust increases the incidence of chronic bronchitis and emphysema, independent of smoking. Thus far, however, there is no compelling evidence that CWP in the absence of smoking predisposes to cancer.

Silicosis

Silicosis is a lung disease caused by inhalation of crystalline silicon dioxide (silica).[74] *Currently the most prevalent chronic occupational disease in the world*, silicosis usually presents after decades of exposure as a slowly progressing, nodular, fibrosing pneumoconiosis. As shown in Table 15-6 , workers in a large number of occupations are at risk, especially sandblasters and many mine workers. Less commonly, heavy exposure over months to a few years can result in acute silicosis, a disorder characterized by the accumulation of abundant lipoproteinaceous material within alveoli (identical morphologically to alveolar proteinosis, which is discussed later).

Pathogenesis.

Silica occurs in both crystalline and amorphous forms, but crystalline forms (including quartz, crystobalite, and tridymite) are much more fibrogenic. Of these, quartz is most commonly implicated in silicosis.After inhalation, the particles interact with epithelial cells and macrophages. Within the macrophages *silica causes activation and release of mediators*. Such mediators include IL-1, TNF, fibronectin, lipid mediators, oxygen-derived free radicals, and fibrogenic cytokines.[75,][76] Especially compelling is evidence incriminating TNF, since anti-TNF monoclonal antibodies can block lung collagen accumulation in mice given silica intratracheally. It has been noted that when mixed with other minerals, quartz has a reduced fibrogenic effect. This phenomenon is of practical importance because quartz in the workplace is rarely pure. Thus, miners of the iron-containing ore hematite may have more quartz in their lungs than some quartz-exposed workers and yet have relatively mild lung disease because the hematite somehow provides a protective effect. Although amorphous silicates are biologically less active than crystalline silica, heavy lung burdens of these minerals may also produce lesions.

Morphology. Silicosis is characterized grossly in its early stages by tiny, barely palpable, discrete pale to blackened (if coal dust is also present) nodules in the upper zones of the lungs. As the disease progresses, these nodules may coalesce into **hard, collagenous scars** (Fig. 15-18). Some nodules may undergo central softening and cavitation. This change may be due to superimposed tuberculosis or to ischemia. Fibrotic lesions may also occur in the hilar lymph nodes and pleura. Sometimes, thin sheets of calcification occur in the lymph nodes and are seen radiographically as **eggshell** calcification (i.e., calcium surrounding a zone lacking calcification). If the disease continues to progress, expansion and coalescence of lesions may produce progressive massive fibrosis. Histologic examination reveals that the nodular lesions consist of concentric layers of hyalinized collagen surrounded by a dense capsule of more condensed collagen (Fig. 15-19). Examination of the nodules by polarized microscopy reveals the birefringent silica particles.

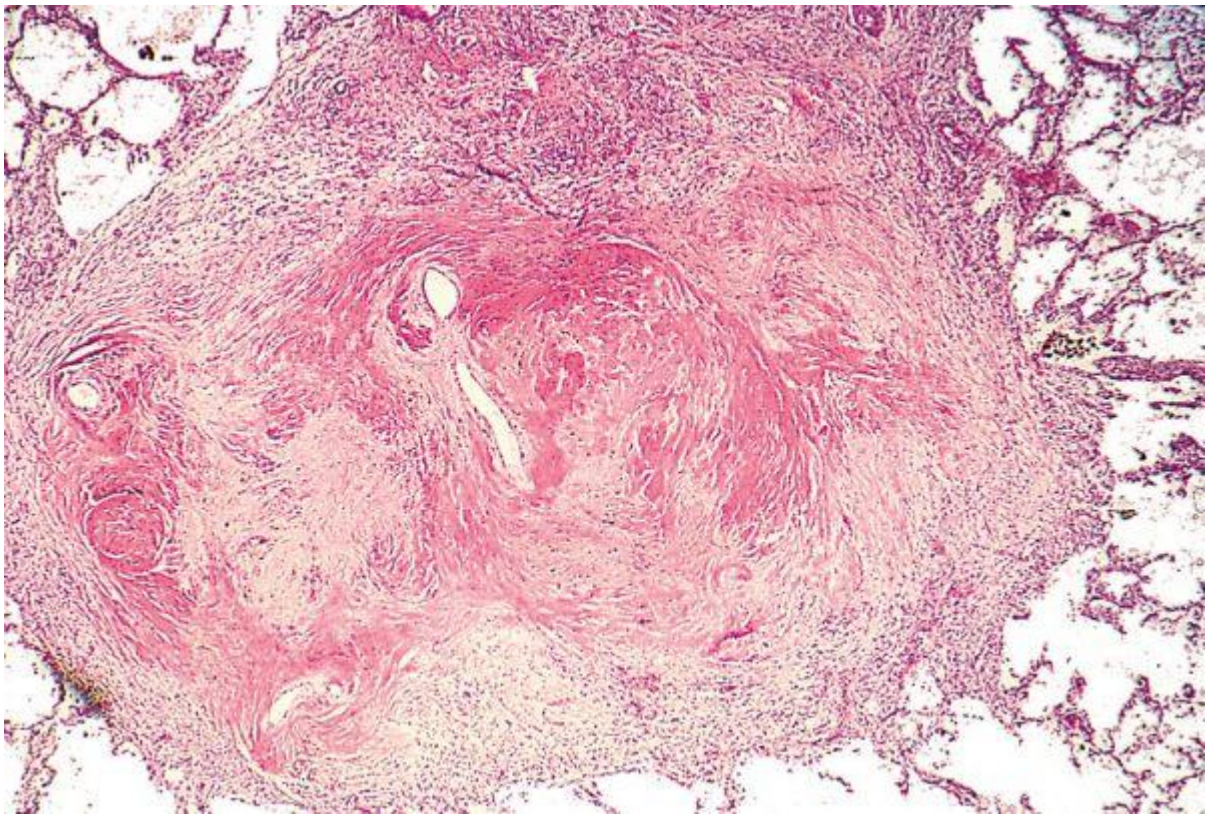

FIGURE 15-19 Several coalescent collagenous silicotic nodules. *(Courtesy of Dr. John Godleski, Brigham and Women's Hospital, Boston, MA.)*

Clinical Course.

Chest radiographs typically show a fine nodularity in the upper zones of the lung, but pulmonary functions are either normal or only moderately affected. Most patients do not develop shortness of breath until late in the course, after progressive massive fibrosis is present. The disease may be progressive even if the patient is no longer exposed. The disease is slow to kill, but impaired pulmonary function may severely limit activity. Silicosis is associated with an increased susceptibility to *tuberculosis*. It is postulated that silicosis results in a depression of cell-mediated immunity, and crystalline silica may inhibit the ability of pulmonary macrophages to kill phagocytosed mycobacteria. Nodules of silicotuberculosis often display a central zone of caseation. The relationship between silica and *lung cancer* is contentious. In 1997, the International Agency for Research on Cancer (IARC) concluded that *crystalline silica from occupational sources is carcinogenic in humans*. However, this subject continues to be controversial.

Asbestos-Related Diseases

Asbestos is a family of crystalline hydrated silicates that form fibers. Use of asbestos is seriously restricted in many developed countries; however, there is little, if any, control in less developed parts of the world.[77] On the basis of epidemiologic studies, *occupational exposure* to asbestos is linked to[78]:

- Localized fibrous plaques or, rarely, diffuse pleural fibrosis

- Pleural effusions
- Parenchymal interstitial fibrosis *(asbestosis)*
- Lung carcinoma
- Mesotheliomas
- Laryngeal and perhaps other extrapulmonary neoplasms, including colon carcinomas

An increased incidence of asbestos-related cancer in family members of asbestos workers has alerted the general public to the potential hazards of asbestos in the environment. The proper public health policy toward low-level exposures that might be encountered in old buildings or schools is unsettled: some experts question the wisdom of expensive asbestos abatement programs for environments with airborne fiber counts that are as much as 100-fold lower than allowed by occupational standards.

Pathogenesis.

Concentration, size, shape, and solubility of the different forms of asbestos dictate whether it causes disease.[79] There are two distinct geometric forms of asbestos: *serpentine* and *amphibole*. The serpentine chrysotile chemical form accounts for most of the asbestos used in industry. Amphiboles, even though less prevalent, are more pathogenic than chrysotiles particularly with respect to induction of malignant pleural tumors (mesotheliomas).

The greater pathogenicity of amphiboles is apparently related to their aerodynamic properties and solubility. Chrysotiles, with their more flexible, curled structure, are likely to become impacted in the upper respiratory passages and removed by the mucociliary elevator. Furthermore, once trapped in the lungs, chrysotiles are gradually leached from the tissues because they are more soluble than amphiboles. In contrast, the straight, stiff amphiboles may align themselves in the airstream and thus be delivered deeper into the lungs, where they can penetrate epithelial cells and reach the interstitium. *Both amphiboles and serpentines are fibrogenic*, and increasing doses are associated with a higher incidence of all asbestos-related diseases except mesothelioma, which is only associated with amphibole exposure.

In contrast to other inorganic dusts, asbestos can also act as a tumor initiator and promoter. Some of its *oncogenic effects* are mediated by reactive free radicals generated by asbestos fibers, which preferentially localize in the distal lung, close to the mesothelial layers. Potentially toxic chemicals adsorbed onto the asbestos fibers most likely contribute to the oncogenicity of the fibers. For example, the adsorption of carcinogens in tobacco smoke onto asbestos fibers may well contribute to the remarkable *synergy between tobacco smoking and the development of lung carcinoma* in asbestos workers. One study of asbestos workers found a fivefold increase of lung carcinoma with asbestos exposure alone, while asbestos exposure and smoking together led to a 55-fold increase in the risk of lung cancer.[80]

The occurrence of asbestosis, like the other pneumoconioses, depends on the interaction of inhaled fibers with lung macrophages and other parenchymal cells. The initial injury occurs at bifurcations of small airways and ducts, where the asbestos fibers land and penetrate. Macrophages, both alveolar and interstitial, attempt to ingest and clear the fibers and are activated to release chemotactic factors and fibrogenic mediators that amplify the response. Chronic deposition of fibers and persistent release of mediators eventually lead to generalized interstitial pulmonary inflammation and interstitial fibrosis.

Morphology. Asbestosis is marked by **diffuse pulmonary interstitial fibrosis**, which is indistinguishable from diffuse interstitial fibrosis resulting from other causes, except for the presence of multiple **asbestos bodies**. Asbestos bodies appear as **golden brown, fusiform or beaded rods**

with a translucent center and consist of asbestos fibers coated with an iron-containing proteinaceous material (Fig. 15-20). They arise when macrophages attempt to phagocytose asbestos fibers; the iron is presumably derived from phagocyte ferritin. Other inorganic particulates may become coated with similar iron-protein complexes and are called **ferruginous bodies**. Rare single asbestos bodies can be found in the lungs of normal people.

Asbestosis begins as fibrosis around respiratory bronchioles and alveolar ducts and extends to involve adjacent alveolar sacs and alveoli. The fibrous tissue distorts the architecture, creating enlarged airspaces enclosed within thick fibrous walls; eventually the affected regions become honeycombed. The pattern of fibrosis is similar to that seen in UIP, with fibroblastic foci and varying degrees of fibrosis, the onlydifference being the presence of numerous asbestos bodies. In contrast to CWP and silicosis, asbestosis begins in the lower lobes and subpleurally. The middle and upper lobes of the lungs become affected as fibrosis progresses. The scarring may trap and narrow pulmonary arteries and arterioles, causing pulmonary hypertension and cor pulmonale.

Pleural plaques, the most common manifestation of asbestos exposure, are well-circumscribed plaques of dense collagen (Fig. 15-21), often containing calcium. They develop most frequently on the anterior and posterolateral aspects of the **parietal pleura** and over the domes of the diaphragm. The size and number of pleural plaques do not correlate with the level of exposure to asbestos or the time since exposure.[81] They do not contain asbestos bodies; however, only rarely do they occur in individuals who have no history or evidence of asbestos exposure. Uncommonly, asbestos exposure induces pleural effusions, which are usually serous but may be bloody. Rarely, diffuse visceral pleural fibrosis may occur and, in advanced cases, bind the lung to the thoracic cavity wall.

Both lung carcinomas and mesotheliomas (pleural and peritoneal) develop in workers exposed to asbestos. The risk of lung carcinoma is increased about fivefold for asbestos workers; the relative risk of mesotheliomas, normally a rare tumor (2 to 17 cases per 1 million persons), is more than 1000-fold greater. Concomitant cigarette smoking greatly increases the risk of lung carcinoma but not that of mesothelioma.

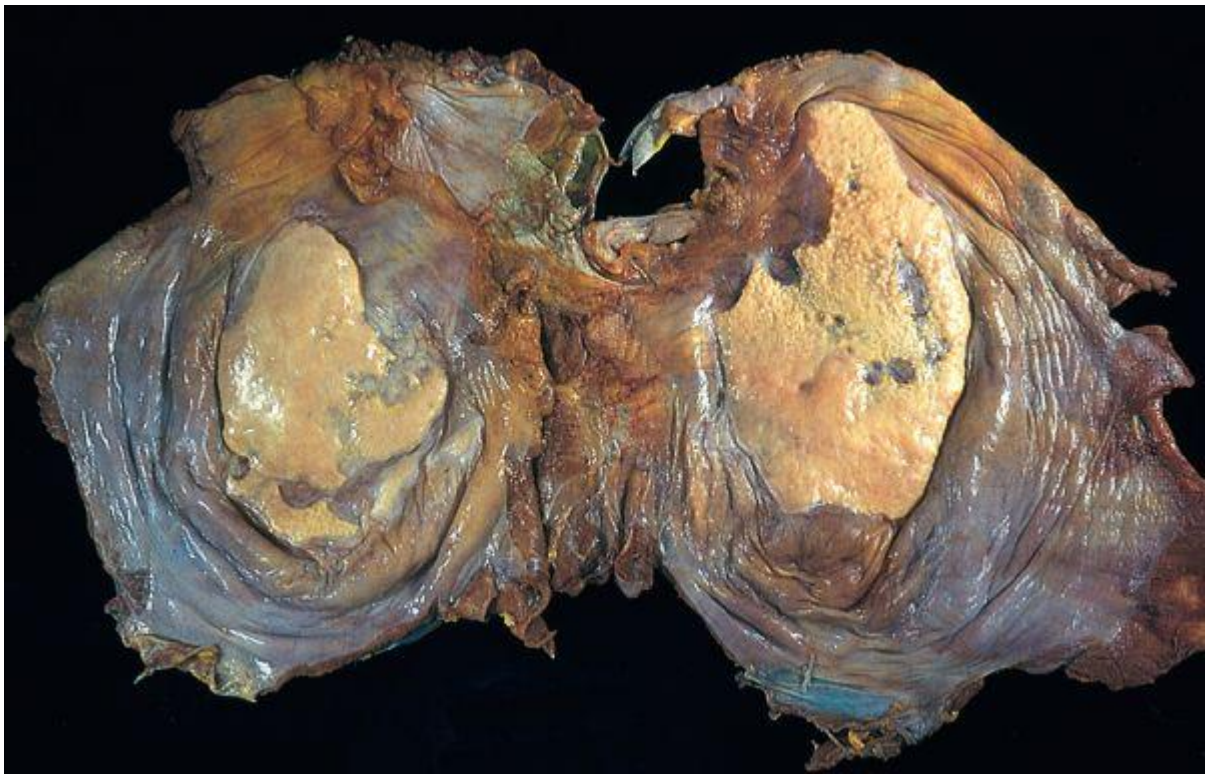

FIGURE 15-21 Asbestos-related pleural plaques. Large, discrete fibrocalcific plaques are seen on the pleural surface of the diaphragm. *(Courtesy of Dr. John Godleski, Brigham and Women's Hospital, Boston, MA.)*

Clinical Course.

The clinical findings in asbestosis are very similar to those caused by other diffuse interstitial lung diseases (discussed earlier). Dyspnea is usually the first manifestation; at first, it is provoked by exertion, but later it is present even at rest. The dyspnea is usually accompanied by a cough associated with production of sputum. These manifestations rarely appear fewer than 10 years after first exposure and are more common after 20 years or more. Chest x-rays reveal irregular linear densities, particularly in both lower lobes. With advancement of the pneumoconiosis, a honeycomb pattern develops. The disease may remain static or progress to respiratory failure, cor pulmonale, and death. Pleural plaques are usually asymptomatic and are detected on radiographs as circumscribed densities. Asbestosis complicated by lung or pleural cancer is associated with a particularly grim prognosis.

Complications of Therapies

Drug-Induced Lung Diseases.

Drugs can cause a variety of both acute and chronic alterations in respiratory structure and function, interstitial fibrosis, bronchiolitis obliterans, and eosinophilic pneumonia (Table 15-7).[82] For example, cytotoxic drugs used in cancer therapy (e.g., bleomycin) cause pulmonary damage and fibrosis as a result of direct toxicity of the drug and by stimulating the influx of inflammatory cells into the alveoli. Amiodarone, a drug used to treat cardiac arrhythmias, is preferentially concentrated in the lung and causes significant pneumonitis in 5% to 15% of patients receiving it.

TABLE 15-7 -- Examples of Drug-Induced Pulmonary Disease

Drug	Pulmonary Disease
Bleomycin	Pneumonitis and fibrosis
Methotrexate	Hypersensitivity pneumonitis
Amiodarone	Pneumonitis and fibrosis
Nitrofurantoin	Hypersensitivity pneumonitis
Aspirin	Bronchospasm
β-Antagonists	Bronchospasm

Radiation-Induced Lung Diseases.

Radiation pneumonitis is a well-known complication of therapeutic radiation of thoracic tumors (lung, esophageal, breast, mediastinal).[83] It most often involves the lung within the radiation port but occasionally may extend to other areas of the same lung or even the contralateral lung. It occurs in acute and chronic forms. One to six months after fractionated irradiation, *acute radiation pneumonitis* (lymphocytic alveolitis or hypersensitivity pneumonitis) occurs in 10% to 20% of patients. It is manifest by fever, dyspnea out of proportion to the volume of lung irradiated, pleural effusion, and radiologic infiltrates that usually correspond to an area of previous irradiation. With steroid therapy, these symptoms may resolve completely in some patients without long-term effects,[84] while in others there is progression to *chronic radiation pneumonitis* (pulmonary fibrosis). The latter is a consequence of the

repair of injured endothelial and epithelial cells within the radiation portal. Morphologic changes are those of diffuse alveolar damage, including severe atypia of hyperplastic type II cells and fibroblasts. Epithelial cell atypia and foam cells within vessel walls are also characteristic of radiation damage.

GRANULOMATOUS DISEASES

Sarcoidosis

Sarcoidosis is a systemic disease of unknown cause characterized by noncaseating granulomas in many tissues and organs. Sarcoidosis presents many clinical patterns, but bilateral hilar lymphadenopathy or lung involvement is visible on chest radiographs in 90% of cases. Eye and skin lesions occur next in frequency. Since other diseases, including mycobacterial and fungal infections and berylliosis, can also produce noncaseating *(hard)* granulomas, the histologic diagnosis of sarcoidosis is made by exclusion.[85]

The prevalence of sarcoidosis is higher in women than in men but varies widely in different countries and populations. In the United States the rates are highest in the Southeast; they are 10 times higher in American blacks than in whites. In contrast, the disease is rare among Chinese and Southeast Asians.

Etiology and Pathogenesis.

Although the etiology of sarcoidosis remains unknown, several lines of evidence suggest that it is a disease of disordered immune regulation in genetically predisposed individuals exposed to certain environmental agents.[86] The role of each of these three contributory factors is summarized below.

Immunological Factors.

There are several *immunological abnormalities* in the local milieu of sarcoid granulomas that suggest the development of a cell-mediated response to an unidentified antigen.[87] The process is driven by CD4+ helper T cells. These abnormalities include[88]:

- Intra-alveolar and interstitial accumulation of CD4+ T cells, resulting in CD4/CD8 T-cell ratios ranging from 5 : 1 to 15 : 1. There is oligoclonal expansion of T-cell subsets as determined by analysis of T-cell receptor rearrangement, suggesting an antigen-driven proliferation.
- Increased levels of T cell–derived T_H1 cytokines such as IL-2 and IFN-γ, resulting in T-cell expansion and macrophage activation, respectively.
- Increased levels of several cytokines in the local environment (IL-8, TNF, macrophage inflammatory protein 1α) that favor recruitment of additional T cells and monocytes and contribute to the formation of granulomas. TNF in particular is released at high levels by activated alveolar macrophages, and the TNF concentration in the bronchoalveolar fluid is a marker of disease activity.

Additionally, there are *systemic immunological abnormalities* in individuals with sarcoidosis:

- Anergy to common skin test antigens such as *Candida* or tuberculosis purified protein derivative (PPD)
- Polyclonal hypergammaglobulinemia, another manifestation of helper T-cell dysregulation.

Genetic Factors.

Evidence of genetic influences are the familial and racial clustering of cases and the association with certain HLA genotypes (e.g., HLA-A1 and HLA-B8).

Environmental Factors.

These are possibly the most tenuous of all the associations in the pathogenesis of sarcoidosis. As with many other diseases of unknown etiology, suspicion falls on microbes. Indeed several putative microbes

have been proposed as the inciting agent for sarcoidosis (e.g., mycobacteria, *Propionibacterium acnes*, and *Rickettsia* species).[89] Alas *there is no unequivocal evidence that sarcoidosis is caused by an infectious agent*.

Morphology. Histologically, all involved tissues show the classic well-formed **noncaseating granulomas** (Fig. 15-22), each composed of an aggregate of tightly clustered epithelioid cells, often with Langhans or foreign body–type giant cells. Central necrosis is unusual. With chronicity the granulomas may become enclosed within fibrous rims or may eventually be replaced by hyaline fibrous scars. Laminated concretions composed of calcium and proteins known as Schaumann bodies and stellate inclusions known as asteroid bodies enclosed within giant cells are found in approximately 60% of the granulomas. Though characteristic, these microscopic features are notpathognomonic of sarcoidosis, because asteroid and Schaumann bodies may be encountered in other granulomatous diseases (e.g., tuberculosis). Pathologic involvement of virtually every organ in the body has been cited at one time or another.

The **lungs** are common sites of involvement.[90] Macroscopically there is usually no demonstrable alteration, although in advanced cases the coalescence of granulomas produces small nodules that are palpable or visible as 1 to 2 cm, noncaseating, noncavitated consolidations. Histologically, the lesions are distributed primarily along the lymphatics, around bronchi and blood vessels, although alveolar lesions are also seen. The relative frequency of granulomas in the bronchial submucosa accounts for the high diagnostic yield of bronchoscopic biopsies. There seems to be a strong tendency for lesions to heal in the lungs, so varying stages of fibrosis and hyalinization are often found. The pleural surfaces are sometimes involved.

Lymph nodes are involved in almost all cases, particularly the hilar and mediastinal nodes, but any other node in the body may be involved. Nodes are characteristically enlarged, discrete, and sometimes calcified. The tonsils are affected in about one quarter to one third of cases.

The **spleen** is affected microscopically in about three quarters of cases, but it is enlarged in only one fifth. On occasion, granulomas may coalesce to form small nodules that are barely visible macroscopically. The capsule is not involved. The **liver** is affected slightly less often than the spleen. It may also be moderately enlarged and contains scattered granulomas, more in portal triads than in the lobular parenchyma. Needle biopsy can be diagnostic.

The **bone marrow** is involved in about one fifth of cases of systemic sarcoidosis. The radiologically visible bone lesions have a particular tendency to involve phalangeal bones of the hands and feet, creating small circumscribed areas of bone resorption within the marrow cavity and a diffuse reticulated pattern throughout the cavity, with widening of the bony shafts or new bone formation on the outer surfaces.

Skin lesions are encountered in one third to one half of cases. Sarcoidosis of the skin assumes a variety of macroscopic appearances (e.g., discrete subcutaneous nodules; focal, slightly elevated, erythematous plaques; or flat lesions that are slightly reddened and scaling, and resemble those of lupus erythematosus). Lesions may also appear on the mucous membranes of the oral cavity, larynx, and upper respiratory tract. The **eye, its associated glands, and the salivary glands** are involved in about one fifth to one half of cases. The ocular involvement takes the form of iritis or iridocyclitis, either bilaterally or unilaterally. Consequently, corneal opacities, glaucoma, and total loss of vision may occur. These ocular lesions are frequently accompanied by inflammation of the lacrimal glands, with suppression of lacrimation. Bilateral sarcoidosis of the parotid, submaxillary, and sublingual glands constitutes the combined uveoparotid involvement designated as Mikulicz syndrome (Chapter

16). **Muscle** involvement is often underdiagnosed, since it may be asymptomatic. Muscle weakness, aches, tenderness, and fatigue should prompt consideration of occult sarcoid myositis.[91] Muscle biopsy can be useful for diagnosis when clinical features point to sarcoidosis. Sarcoid granulomas occasionally occur in the heart, kidneys, central nervous system, and endocrine glands, particularly in the pituitary, as well as in other body tissues.

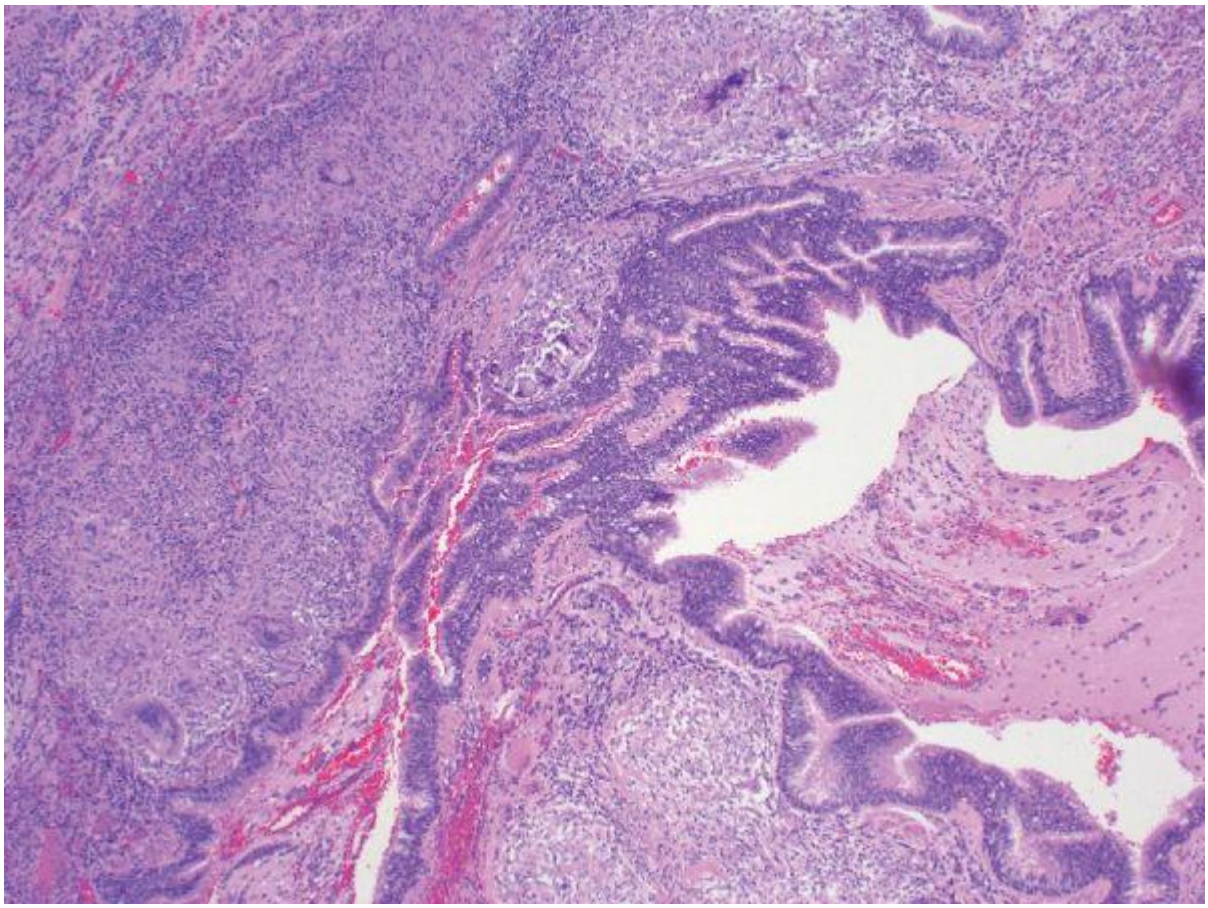

FIGURE 15-22 Characteristic sarcoid noncaseating granulomas, peribronchial, with many giant cells.

Clinical Course.

Because of its varying severity and the inconstant distribution of the lesions, sarcoidosis is a protean clinical disease. It may be discovered unexpectedly on routine chest films as bilateral hilar adenopathy or may present with peripheral lymphadenopathy, cutaneous lesions, eye involvement, splenomegaly, or hepatomegaly. In the great majority of cases, however, individuals seek medical attention because of the insidious onset of respiratory abnormalities (shortness of breath, cough, chest pain, hemoptysis) or of constitutional signs and symptoms (fever, fatigue, weight loss, anorexia, night sweats).

Sarcoidosis follows an unpredictable course characterized by either progressive chronicity or periods of activity interspersed with remissions, sometimes permanent, that may be spontaneous or induced by steroid therapy. Overall, 65% to 70% of affected patients recover with minimal or no residual manifestations. Twenty percent have permanent loss of some lung function or some permanent visual

impairment. Of the remaining 10% to 15%, some die of cardiac or central nervous system damage, but most succumb to progressive pulmonary fibrosis and cor pulmonale.

Hypersensitivity Pneumonitis

The term *hypersensitivity pneumonitis* describes a spectrum of immunologically mediated, predominantly interstitial, lung disorders caused by intense, often prolonged exposure to inhaled organic antigens.[92] Affected individuals have an abnormal sensitivity or heightened reactivity to the antigen, which, in contrast to that occurring in asthma, involves primarily the *alveoli* (thus the synonym "allergic alveolitis").[93] *It is important to recognize these diseases early in their course because progression to serious chronic fibrotic lung disease can be prevented by removal of the environmental agent*.

Most commonly, hypersensitivity results from the inhalation of organic dust containing antigens made up of spores of thermophilic bacteria, true fungi, animal proteins, or bacterial products. Numerous specifically named syndromes are described, depending on the occupation or exposure of the individual. *Farmer's lung* results from exposure to dusts generated from harvested humid, warm hay that permits the rapid proliferation of the spores of thermophilic actinomycetes. *Pigeon breeder's lung* (bird fancier's disease) is provoked by proteins from serum, excreta, or feathers of birds. *Humidifier* or *air-conditioner lung* is caused by thermophilic bacteria in heated water reservoirs.

Several lines of evidence suggest that hypersensitivity pneumonitis is an immunologically mediated disease:

- Bronchoalveolar lavage specimens obtained during the acute phase show increased levels of proinflammatory chemokines such as macrophage inflammatory protein 1α and IL-8.
- Bronchoalveolar lavage specimens also consistently demonstrate increased numbers of T lymphocytes of both CD4+ and CD8+ phenotypes.
- Most patients have specific antibodies in their serum, a feature that is suggestive of type III (immune complex) hypersensitivity.
- Complement and immunoglobulins have been demonstrated within vessel walls by immunofluorescence, also indicating a type III hypersensitivity.

Finally, the presence of noncaseating granulomas in two thirds of the patients suggests the development of a T cell–mediated (type IV) delayed-type hypersensitivity against the implicated antigen(s).

Morphology. Histologic changes in subacute and chronic forms are characteristically centered on bronchioles.[94] They include (1) interstitial pneumonitis consisting primarily of lymphocytes, plasma cells, and macrophages; (2) noncaseating granulomas in two thirds of patients (Fig. 15-23); and (3) interstitial fibrosis, honeycombing, and obliterative bronchiolitis (in late stages). In more than half the patients there is also evidence of an intra-alveolar infiltrate.

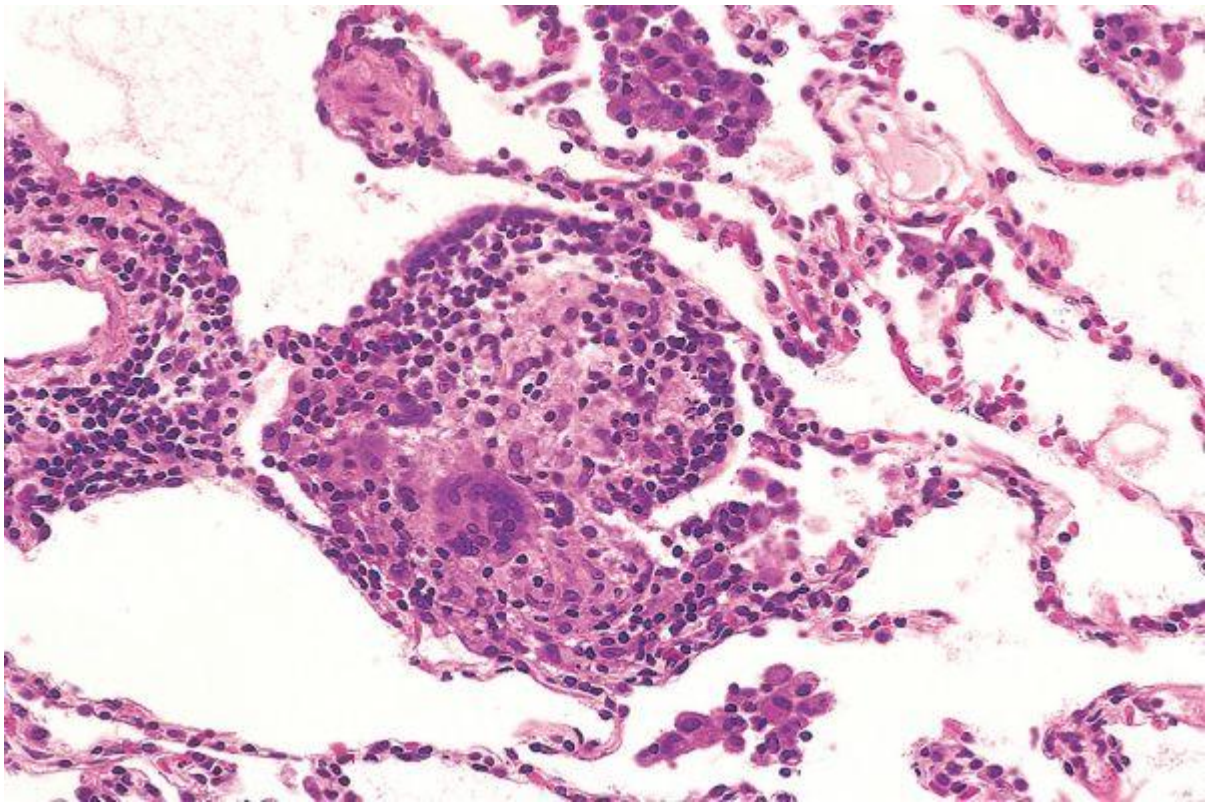

FIGURE 15-23 Hypersensitivity pneumonitis, histologic appearance. Loosely formed interstitial granulomas and chronic inflammation are characteristic.

Clinical Features.

The clinical manifestations are varied. Acute attacks, which follow inhalation of antigenic dust in sensitized patients, consist of recurring episodes of fever, dyspnea, cough, and leukocytosis. Diffuse and nodular infiltrates appear in the chest radiograph, and pulmonary function tests show an acute restrictive disorder. Symptoms usually appear 4 to 6 hours after exposure. If exposure is continuous and protracted, a chronic form of the disease supervenes with progressive respiratory failure, dyspnea, and cyanosis and a decrease in total lung capacity and compliance—a picture similar to other forms of chronic interstitial disease.

PULMONARY EOSINOPHILIA

Several clinical and pathologic pulmonary entities are characterized by an infiltration of eosinophils, recruited in part by elevated alveolar levels of eosinophil attractants such as IL-5.[95]

Pulmonary eosinophilia is divided into the following categories[96]:

- Acute eosinophilic pneumonia with respiratory failure
- Simple pulmonary eosinophilia or Löffler syndrome
- Tropical eosinophilia, caused by infection with microfilariae
- Secondary eosinophilia (which occurs in a number of parasitic, fungal, and bacterial infections; in hypersensitivity pneumonitis; in drug allergies; and in association with asthma, allergic bronchopulmonary

aspergillosis, or vasculitis)

- So-called idiopathic chronic eosinophilic pneumonia

Acute eosinophilic pneumonia with respiratory failure is an acute illness of unknown cause. It has a rapid onset with fever, dyspnea, and hypoxemic respiratory failure. The chest radiograph shows diffuse infiltrates, and bronchoalveolar lavage fluid contains more than 25% eosinophils. There is a prompt response to corticosteroids.

Simple pulmonary eosinophilia is characterized by transient pulmonary lesions, eosinophilia in the blood, and a benign clinical course. CT scans are often quite striking, with shadows of varying size and shape in any of the lobes, suggesting irregular intrapulmonary densities. The alveolar septa are thickened by an infiltrate composed of eosinophils and occasional interspersed giant cells, but there is no vasculitis, fibrosis, or necrosis.

Chronic eosinophilic pneumonia is characterized by focal areas of cellular consolidation of the lung substance distributed chiefly in the periphery of the lung fields. Prominent in these lesions are heavy aggregates of lymphocytes and eosinophils within both the septal walls and the alveolar spaces. These patients have high fever, night sweats, and dyspnea, all of which respond to corticosteroid therapy. Chronic eosinophilic pneumonia is diagnosed when other causes of chronic pulmonary eosinophilia are excluded.

SMOKING-RELATED INTERSTITIAL DISEASES

Smoking-related diseases can be grouped into obstructive diseases (emphysema and chronic bronchitis, already discussed) and restrictive or interstitial diseases. A majority of individuals with idiopathic pulmonary fibrosis are smokers; however, the role of cigarette smoking in its pathogenesis has not been clarified yet. Desquamative interstitial pneumonia (DIP) and respiratory bronchiolitis-associated interstitial lung disease are thought to represent two ends of a spectrum of smoking-associated interstitial lung diseases.[97]

Desquamative Interstitial Pneumonia

The large collections of airspace macrophages that char-acterize DIP were originally thought to be desquamated pneumocytes, thus the misnomer “desquamative interstitial pneumonia.”

Morphology. The most striking histologic finding is the accumulation of a large number of macrophages with abundant cytoplasm containing dusty brown pigment **(smokers' macrophages)** in the airspaces. Finely granular iron may be seen in the macrophage cytoplasm. Some of the macrophages contain lamellar bodies (composed of surfactant) within phagocytic vacuoles, presumably derived from necrotic type II pneumocytes. The alveolar septa are thickened by a sparse inflammatory infiltrate of lymphocytes, plasma cells, and occasional eosinophils (Fig. 15-24). The septa are lined by plump, cuboidal pneumocytes. Interstitial fibrosis, when present, is mild. Emphysema is often present.

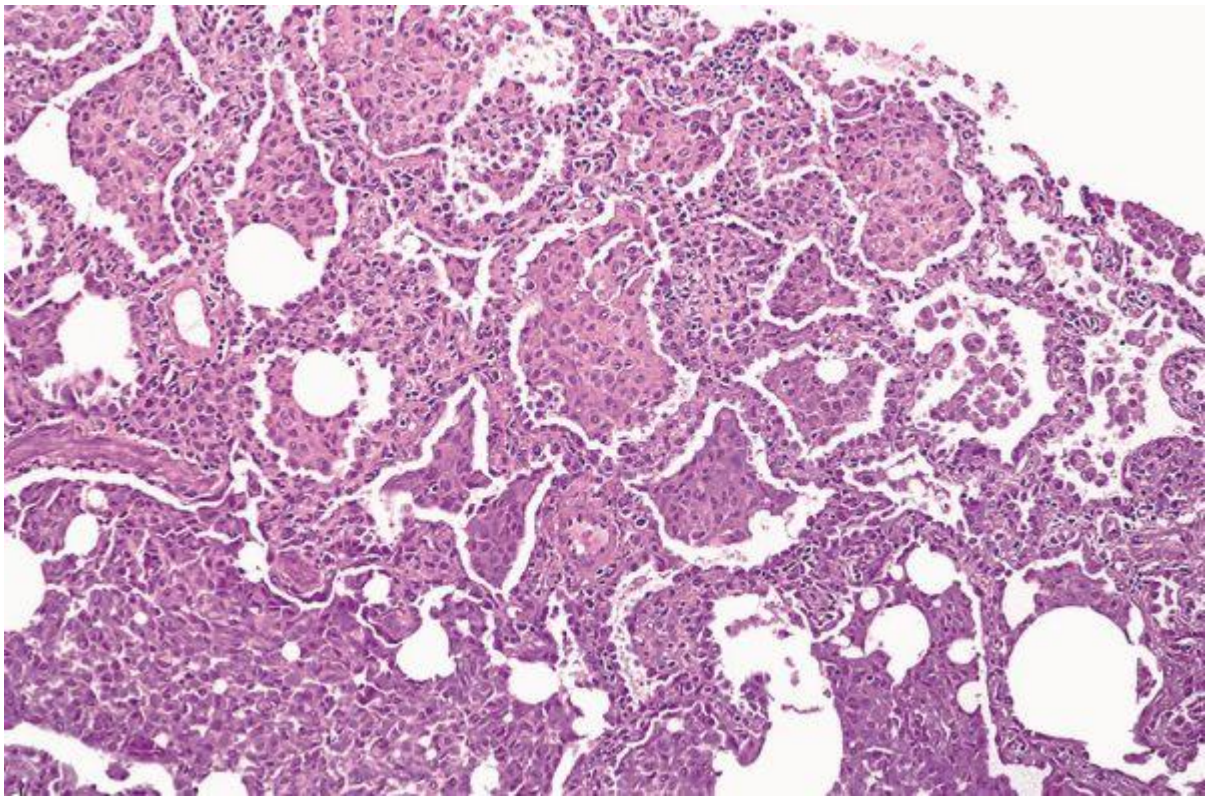

FIGURE 15-24 Desquamative interstitial pneumonia. Medium-power detail of lung demonstrates the accumulation of large numbers of macrophages within the alveolar spaces and only mild fibrous thickening of the alveolar walls.

DIP usually presents in the fourth or fifth decade of life, and is more common in men than in women by a ratio of 2 : 1. Virtually all patients are cigarette smokers. Presenting symptoms include an insidious onset of dyspnea and dry cough over weeks or months, often associated with clubbing of digits. Pulmonary function tests usually show a mild restrictive abnormality with a moderate reduction of the diffusing capacity of carbon dioxide. Patients with DIP typically have a good prognosis with close to 100% response to steroid therapy and cessation of smoking.[65,][98]

Respiratory Bronchiolitis-Associated Interstitial Lung Disease

Respiratory bronchiolitis is a common histologic lesion found in cigarette smokers. It is characterized by the presence of pigmented intraluminal macrophages within first- and second-order respiratory bronchioles. In its mildest form, it is seen most often as an incidental histologic finding in the lungs of smokers or ex-smokers.[99] The term *respiratory bronchiolitis-associated interstitial lung disease* is used for patients who develop significant pulmonary symptoms, abnormal pulmonary function, and imaging abnormalities.

Morphology. The changes are patchy at low magnification and have a bronchiolocentric distribution. Respiratory bronchioles, alveolar ducts, and peribronchiolar spaces contain aggregates of dusty brown macrophages **(smokers' macrophages)** similar to those seen in DIP. There is a patchy submucosal and peribronchiolar infiltrate of lymphocytes and histiocytes. Mild peribronchiolar fibrosis is also

seen, which expands contiguous alveolar septa. Centrilobular emphysema is common but not severe. Histologic overlap with DIP is often found in different parts of the same lung.

Symptoms are usually mild, consisting of gradual onset of dyspnea and cough in patients who are typically current smokers in the fourth or fifth decade of life with average exposures of over 30 pack-years of cigarette smoking. There is a 2 : 1 male predominance. Cessation of smoking usually results in improvement.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis (PAP) is a rare disease that is characterized radiologically by bilateral patchy asymmetric pulmonary opacifications and histologically by *accumulation of acellular surfactant in the intra-alveolar and bronchiolar spaces*. There are three distinct classes of this disease—acquired, congenital, and secondary PAP—each with a different pathogenesis but with a similar spectrum of histologic changes.

Acquired PAP represents 90% of all cases of PAP and lacks any familial predisposition. Unexpectedly, researchers working with knockout mice lacking the gene for the hematopoietic growth factor granulocyte-macrophage colony-stimulating factor (GM-CSF) found that these mice had impaired surfactant clearance by alveolar macrophages, leading to a condition that resembled human PAP. Subsequently, a GM-CSF–neutralizing autoantibody was found in the serum and bronchial fluid of individuals with acquired PAP that was not present in those with congenital or secondary PAP. Currently, it is thought that the *anti–GM-CSF antibody* is responsible for the development of the disease.[100] These antibodies inhibit the activity of endogenous GM-CSF, leading to a state of functional GM-CSF deficiency. The systemic production of the antibody also provides an explanation for the recurrence of PAP following bilateral-lung transplantation. Thus, acquired PAP is an autoimmune disorder.

Congenital PAP is a rare cause of immediate-onset neonatal respiratory distress. Thus far, mutations have been identified in multiple genes including those encoding ATP-binding cassette protein member A3 (ABCA3) (which may be the most frequent), surfactant protein B (SP-B), surfactant protein C (SP-C), GM-CSF, and GM receptor (GM-CSF/IL-3/IL-5) β chain. ABCA3 is localized to the lamellar body membrane andis probably involved in transport of surfactant components.[101] SP-B deficiency is transmitted in an autosomal recessive manner and is most often caused by a frameshift mutation in the *SP-B* gene. This leads to an unstable SP-B messenger RNA, reduced or absent SP-B, secondary disturbances of SP-C, and intra-alveolar accumulation of SP-A and SP-C.

Secondary PAP is uncommon. The underlying causes include hematopoietic disorders, malignancies, immunodeficiency disorders, lysinuric protein intolerance, and acute silicosis and other inhalational syndromes.

Morphology. The disease is characterized by a peculiar homogeneous, granular precipitate within the alveoli, causing focal-to-confluent consolidation of large areas of the lungs with minimal inflammatory reaction (Fig. 15-25). On section, turbid fluid exudes from these areas. As a consequence there is a marked increase in the size and weight of the lung. The alveolar precipitate is periodic acid–Schiff positive and also contains cholesterol clefts. Immunohistochemical stains show the presence of surfactant proteins A and C in congenital SP-B deficiency and all three proteins in the acquired form. Ultrastructurally, abnormalities in lamellar bodies in type II pneumocytes can be seen

in mutations of *SP-B*, *SP-C*, and *ABCA3*.[102]

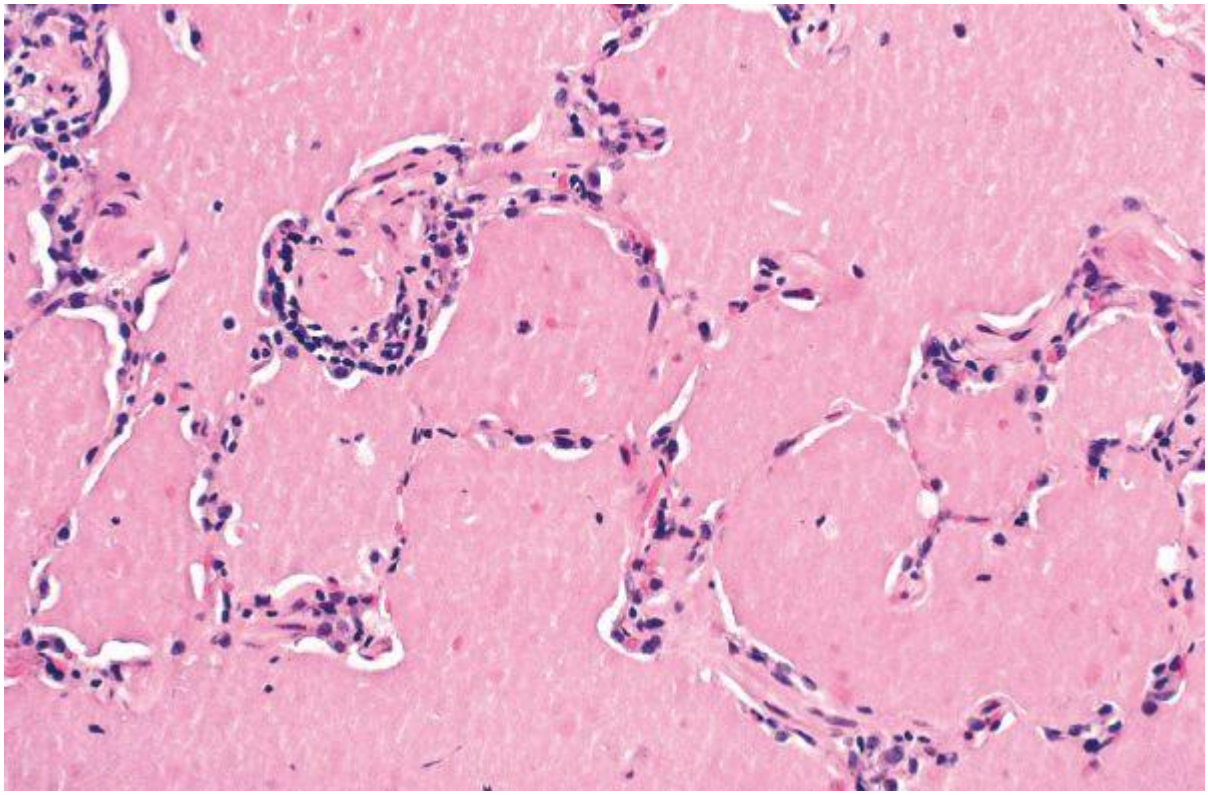

FIGURE 15-25 Pulmonary alveolar proteinosis, histologic appearance. The alveoli are filled with a dense, amorphous, protein-lipid granular precipitate, while the alveolar walls are normal.

Adult patients, for the most part, present with nonspecific respiratory difficulty of insidious onset, cough, and abundant sputum that often contains chunks of gelatinous material. Some have symptoms lasting for years, often with febrile illnesses. These patients are at risk for developing secondary infections with a variety of organisms. Progressive dyspnea, cyanosis, and respiratory insufficiency may occur, but some patients tend to have a benign course, with eventual resolution of the lesions. Whole-lung lavage remains the current standard of care, while GM-CSF therapy is effective in 50% of patients.[103]

Congenital PAP is a fatal respiratory disorder that is usually immediately apparent in the newborn. Typically, the infant is full term and rapidly develops progressive respiratory distress shortly after birth. Without lung transplantation, death ensues between 3 and 6 months of age.

3.5.8 Diseases of Vascular Origin

PULMONARY EMBOLISM, HEMORRHAGE, AND INFARCTION

Blood clots that occlude the large pulmonary arteries are almost always embolic in origin. Large-vessel in situ thromboses are rare and develop only in the presence of pulmonary hypertension, pulmonary atherosclerosis, and heart failure. The usual source of pulmonary emboli—thrombi in the deep veins of the leg in more than 95% of cases—and the magnitude of the clinical problem were discussed in Chapter 4 , in which the disturbing frequency of pulmonary embolism and infarction was emphasized.

Pulmonary embolism causes more than 50,000 deaths in the United States each year. Its incidence at autopsy has varied from 1% in the general population of hospital patients to 30% in patients dying after severe burns, trauma, or fractures to 65% of hospitalized patients in one study in which special techniques were applied to discover emboli at autopsy. It is the sole or a major contributing cause of death in about 10% of adults who die acutely in hospitals.

Pulmonary embolism is a complication principally in patients who are already suffering from some underlying disorder, such as cardiac disease or cancer, or who are immobilized for several days or weeks, those with hip fracture being at high risk. Hypercoagulable states, either *primary* (e.g., factor V Leiden, prothrombin mutations, and antiphospholipid syndrome) or *secondary* (e.g., obesity, recent surgery, cancer, oral contraceptive use, pregnancy), are frequent risk factors. Indwelling central venous lines can be a nidus for right atrial thrombus, which can be a source of pulmonary embolism.

The pathophysiologic response and clinical significance of pulmonary embolism depend on the extent to which the pulmonary artery blood flow is obstructed, the size of the occluded vessel(s), the number of emboli, the overall status of the cardiovascular system, and the release of vasoactive factors such as thromboxane A_2 from platelets that accumulate at the site of the thrombus. Emboli result in two main pathophysiologic consequences: *respiratory compromise* due to the nonperfused, though ventilated, segment and *hemodynamic compromise* due to increased resistance to pulmonary blood flow engendered by the embolic obstruction.

Morphology. Large emboli lodge in the main pulmonary artery or its major branches or at the bifurcation as a saddle embolus (Fig. 15-26). Sudden death often ensues, largely as a result of the blockage of blood flow through the lungs. Death may also be caused by acute failure of the right side of the heart **(acute cor pulmonale)**. Smaller emboli travel out into the more peripheral vessels, where they may cause hemorrhage or infarction. In patients with adequate cardiovascular function, the bronchial arterial supply can sustain the lung parenchyma. Hemorrhages may occur, but there is no infarction. The underlyingpulmonary architecture is preserved, and resorption of the blood permits reconstitution of the preexisting architecture.

Only about 10% of emboli actually cause infarction, which occurs when the circulation is already inadequate, as in patients with heart or lung disease. Thus, pulmonary infarcts tend to be uncommon in the young. About three fourths of all infarcts affect the lower lobes, and in more than half, multiple lesions occur. They vary in size from lesions that are barely visible to the naked eye to massive involvement of large parts of an entire lobe. Typically, they extend to the periphery of the lung substance as a wedge with the apex pointing toward the hilus of the lung. In many cases, an occluded vessel can be identified near the apex of the infarct. Pulmonary embolus can be distinguished from a post-mortem clot by the presence of the lines of Zahn in the thrombus (Chapter 4).

The pulmonary infarct is classically hemorrhagic and appears as a raised, red-blue area in the early stages (Fig. 15-27). Often, the apposed pleural surface is covered by a fibrinous exudate. The red cells begin to lyse within 48 hours, and the infarct becomes paler and eventually red-brown as hemosiderin is produced. With the passage of time, fibrous replacement begins at the margins as a gray-white peripheral zone and eventually converts the infarct into a contracted scar. Histologically, the diagnostic feature of acute pulmonary infarction is the ischemic necrosis of the lung substance within the area of hemorrhage, affecting the alveolar walls, bronchioles, and vessels. If the infarct is caused by an infected embolus, it is modified by a more intense neutrophilic inflammatory reaction. Such lesions are referred to as **septic infarcts**, and some convert to abscesses.

FIGURE 15-26 Large saddle embolus from the femoral vein lying astride the main left and right pulmonary arteries. *(From the teaching collection of the Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

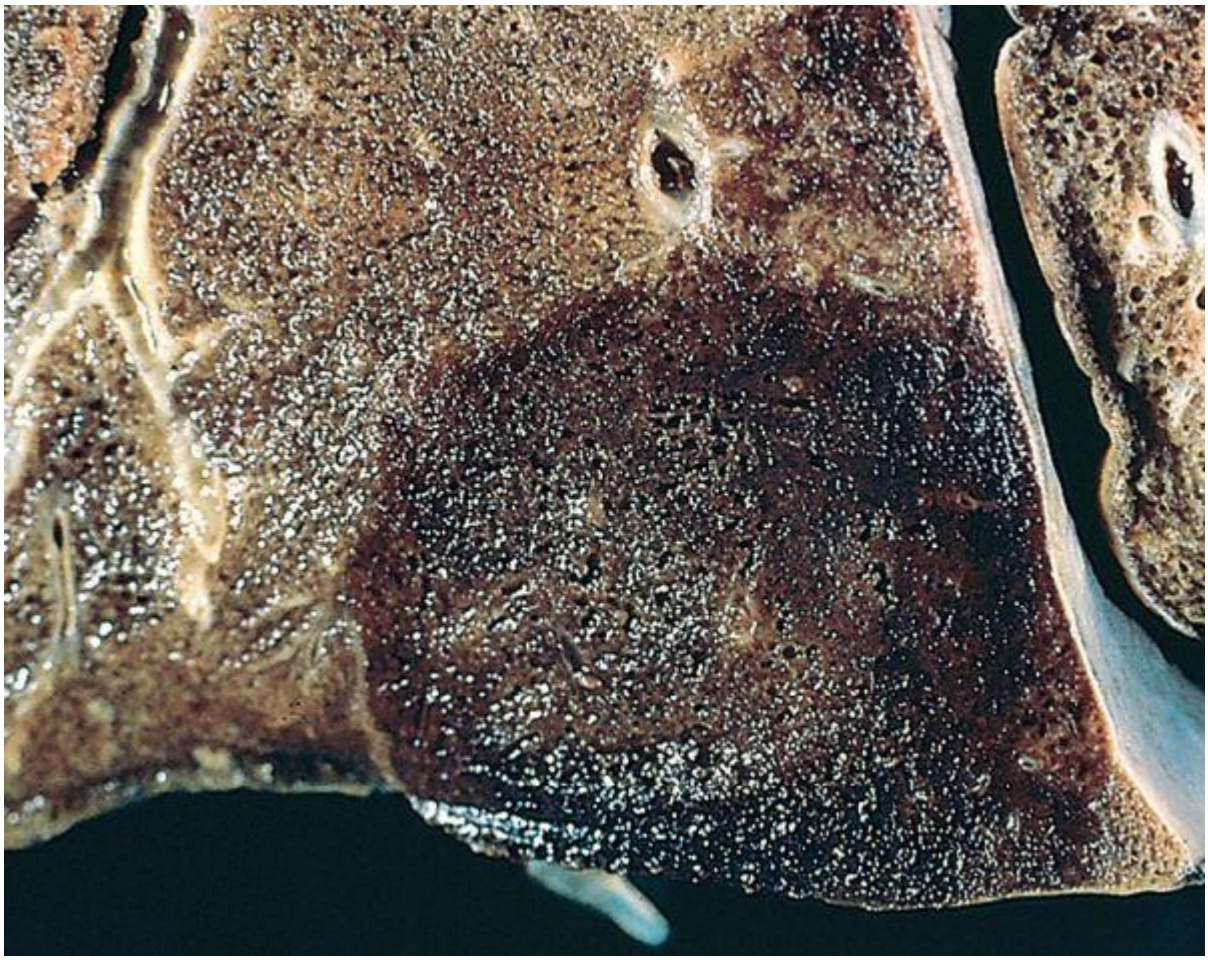

FIGURE 15-27 Recent, small, roughly wedge-shaped hemorrhagic pulmonary infarct.

Clinical Course.

A large pulmonary embolus is one of the few causes of virtually instantaneous death. During cardiopulmonary resuscitation in such instances, the patient frequently is said to have *electromechanical dissociation*, in which the electrocardiogram has a rhythm but no pulses are palpated because no blood is entering the pulmonary arterial circulation. If the patient survives after a sizable pulmonary embolus, however, the clinical syndrome may mimic myocardial infarction, with severe chest pain, dyspnea, shock, fever, and increased levels of serum lactate dehydrogenase. Pulmonary hemorrhages due to *small emboli* induce only transient chest pain and cough. Infarcts manifest as dyspnea, tachypnea, fever, chest pain, cough, and hemoptysis. An overlying fibrinous pleuritis may produce a pleural friction rub.

Findings on *chest radiograph* are variable and can be normal or disclose a pulmonary infarct, usually 12 to 36 hours after it has occurred, as a *wedge-shaped infiltrate*. The diagnosis of pulmonary embolism is usually made with spiral computed tomographic angiography. Rarely, other diagnostic methods, such as ventilation perfusion scanning or pulmonary angiography are required. Alternatively, deep vein thrombosis can be diagnosed with duplex ultrasonography. After the initial acute insult, emboli often resolve via contraction and fibrinolysis, particularly in the relatively young. *Unresolved, multiple small emboli over the course of time may lead to pulmonary hypertension*, pulmonary vascular sclerosis, and chronic cor pulmonale. Perhaps most important is that a small embolus may presage a larger one. In the

presence of an underlying predisposing condition, *patients with a pulmonary embolus have a 30% chance of developing a second embolus*. Repeated emboli can result in pulmonary arterial hypertension.

Prevention of pulmonary embolism constitutes a major clinical problem for which there is no easy solution. Prophylactic therapy includes early ambulation in postoperative and postpartum patients, elastic stockings and graduated compression stockings for bedridden patients, and anticoagulation in high-risk individuals. It is sometimes necessary to resort to insertion of a filter ("umbrella") into the inferior vena cava or to ligation of this vein, which are not minor procedures in an already seriously ill patient. Treatment of existing pulmonary embolism often includes anticoagulation, preceded by thrombolysis in some cases.

PULMONARY HYPERTENSION

The pulmonary circulation is normally one of low resistance, and pulmonary blood pressure is only about one eighth of systemic blood pressure. Pulmonary hypertension (PH) occurs when mean pulmonary pressure reaches one fourth of systemic levels. The clinical classification of PH groups entities that share similarities in pathophysiologic mechanisms, clinical presentation, and therapeutic options. The groups are (1) pulmonary arterial hypertension, (2) PH with left heart disease, (3) PH associated with lung diseases and/or hypoxemia, (4) PH due to chronic thrombotic and/or embolic disease, and (5) miscellaneous PH.[104]

PH is most frequently associated with structural cardiopulmonary conditions that increase pulmonary blood flow or pressure (or both), pulmonary vascular resistance, or left heart resistance to blood flow. These include the following:

- *Chronic obstructive or interstitial lung diseases:* Patients with these diseases have hypoxia as well as destruction of lung parenchyma and hence have fewer alveolar capillaries. This causes increased pulmonary arterial resistance and, secondarily, elevated pressure.
- *Antecedent congenital or acquired heart disease:* PH occurs in patients with mitral stenosis, for example, because of an increase in left atrial pressure that leads to an increase in pulmonary venous pressure and, consequently, to an increase in pulmonary artery pressure.
- *Recurrent thromboemboli:* Patients with recurrent pulmonary emboli may have PH primarily due to a reduction in the functional cross-sectional area of the pulmonary vascular bed brought about by the obstructing emboli, which, in turn, leads to an increase in pulmonary vascular resistance.
- *Connective tissue diseases:* Several of these diseases (most notably systemic sclerosis) involve the pulmonary vasculature, leading to inflammation, intimal fibrosis, medial hypertrophy, and PH.
- *Obstructive sleep apnea* is a common disorder that is associated with obesity and is now recognized to be a significant contributor to the development of pulmonary hypertension and cor pulmonate.

Uncommonly, PH is encountered sporadically in patients in whom all known causes of increased pulmonary pressure are excluded; this is referred to as *idiopathic pulmonary arterial hypertension*. Even less common is the familial form of pulmonary arterial hypertension with autosomal dominant mode of inheritance. Within these families, there is incomplete penetrance, and only 10% to 20% of the family members actually develop overt disease.

Pathogenesis.

As is often the case, much has been learned about the pathogenesis of PH by investigating the molecular basis of the uncommon familial form of the disease. These studies have revealed that *familial PH is caused by mutations in the bone morphogenetic protein receptor type 2 (BMPR2) signaling pathway*.[105]

To understand how such a mutation causes PH, it is essential to review the vascular pathology of the disease and to understand the physiologic functions of BMPR2 signaling. PH is associated with obstruction to the vasculature caused by proliferation of endothelial, smooth muscle, and intimal cells accompanied by concentric laminar intimal fibrosis. How does BMPR2 cause these changes?

BMPR2 is a cell surface protein belonging to the TGF-β receptor superfamily, which binds a variety of cytokines, including TGF-β, bone morphogenetic protein (BMP), activin, and inhibin. Although originally described in the context of bone growth, BMP-BMPR2 signaling is now known to be important for embryogenesis, apoptosis, and cell proliferation and differentiation. The specific effects depend on the tissue and its microenvironment. *In vascular smooth muscle cells BMPR2 signaling causes inhibition of proliferation and favors apoptosis*. Thus, in the absence of such signaling, increased smooth muscle survival and proliferation may be expected. In keeping with this, *inactivating germline mutations in the BMPR2 gene are found in 50% of the familial cases of pulmonary arterial hypertension and 25% of sporadic cases*. In many families, even without mutations in the coding regions of the *BMPR2* gene, linkage to the *BMPR2* locus on chromosome 2q33 can be established, thus indicating that other possible lesions such as gene rearrangements, large deletions, or insertions could be involved.

Despite these discoveries, several questions remain unanswered. First, *how does loss of a single allele of the BMPR2 gene lead to complete loss of signaling?* Two possibilities exist: the mutation might act as a dominant negative (Chapter 5), or a secondary loss of the normal allele might occur in the vascular wall, thus leading to a homozygous loss of *BMPR2*. This is reminiscent of how germline mutations in tumor suppressor genes give rise to neoplasia. Interestingly, in some studies microsatellite instability has been reported in the proliferating endothelial cells within the vascular lesions. This could be a mechanism by which the normal allele is lost in the vasculature. Note that a similar mechanism can inactivate TGF-β receptors in hereditary nonpolyposis colon cancer (Chapters 7 and 17 . The second unanswered question is why the phenotypic disease occurs only in 10% to 20% of individuals with *BMPR2* mutations. This strongly points toward the existence of *modifier genes and/or environmental triggers*. Among the modifier genes are those that control vascular tone, including endothelin, prostacyclin synthetase, and angiotensinconverting enzymes. The nature of the environmental factors remains unknown, but presumably they cause dysfunction of vasoregulatory mechanisms. Thus, as with tumor suppressor genes, a two-hit model has been proposed whereby a genetically susceptible individual with a *BMPR2* mutation requires additional genetic or environmental insults to develop the disease (Fig. 15-28).

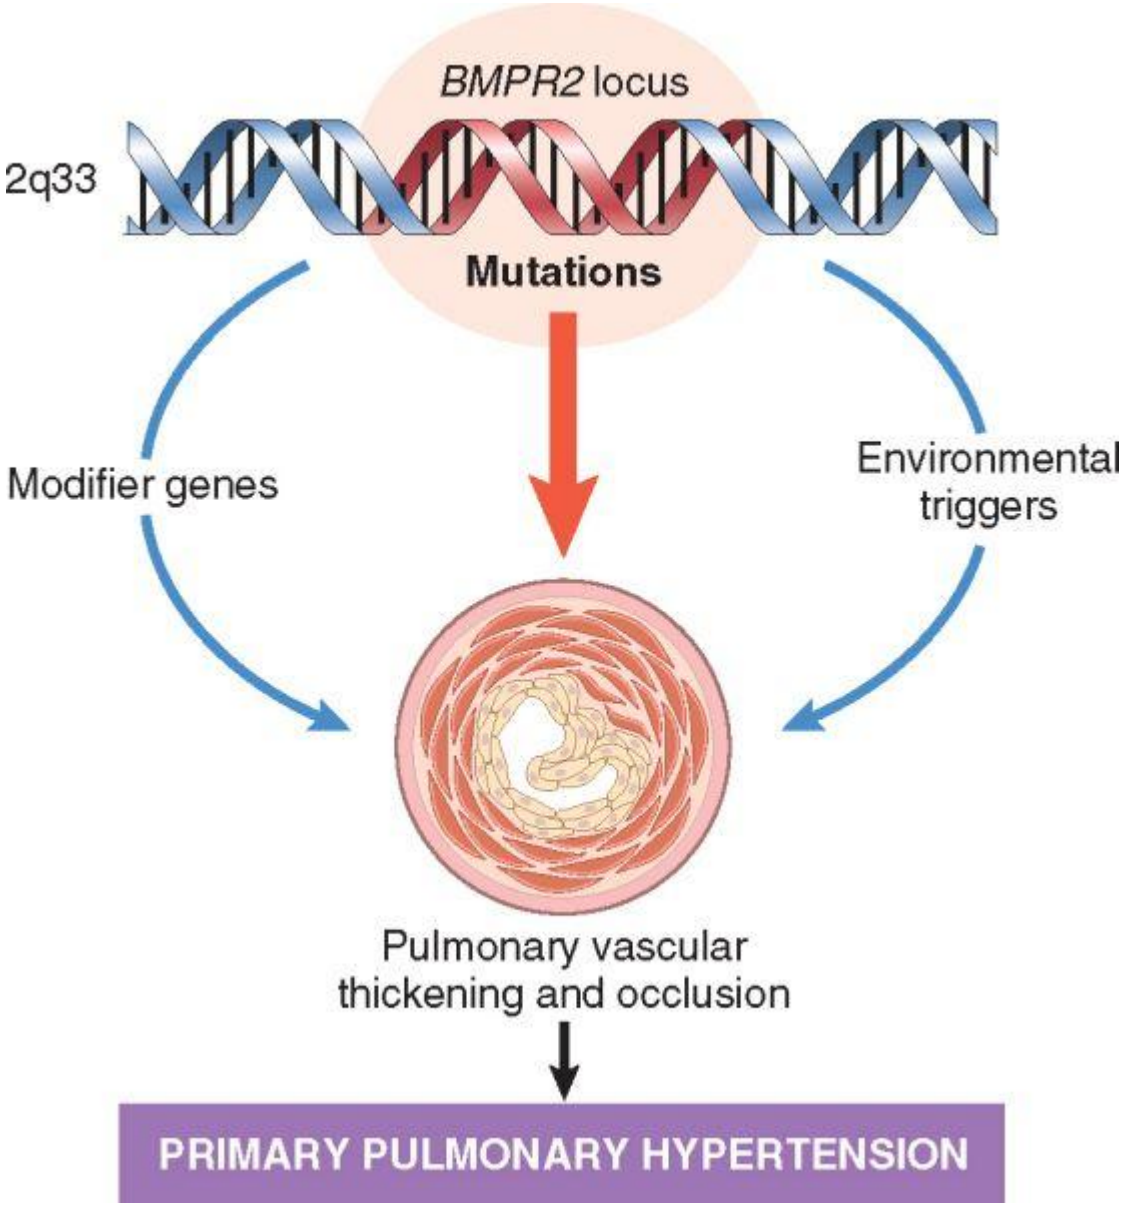

FIGURE 15-28 Pathogenesis of primary pulmonary hypertension. See text for details.

In *secondary forms of PH*, endothelial cell dysfunction is produced by the process that initiates the disorder, such as the increased shear and mechanical injury associated with leftto-right shunts or the biochemical injury produced by fibrin in thromboembolism. Decreased elaboration of prostacyclin, decreased production of nitric oxide, and increased release of endothelin all promote pulmonary vasoconstriction. Also, decreased elaboration of prostacyclin and nitric oxide promotes platelet adhesion and activation. Moreover, endothelial activation, as detailed in Chapter 11 , makes endothelial cells thrombogenic and promotes the persistence of fibrin. Finally, production and release of growth factors and cytokines induce the migration and replication of vascular smooth muscle cells and elaboration of extracellular matrix.

Some individuals with PH have a vasospastic component; in such patients, pulmonary vascular resistance can be rapidly decreased with vasodilators. Pulmonary arterial hypertension has also been

reported after ingestion of certain plants ormedicines, including the leguminous plant *Crotalaria spectabilis*, which is indigenous to the tropics and used medicinally in *bush tea*; the appetite depressant *aminorex*; adulterated olive oil; and the anti-obesity drugs fenfluramine and phentermine.[106] It has been suggested that such substances might act through effects on serotonin transporter expression or activity.

Morphology. All forms of PH have some common pathologic features regardless of their etiology, that is, **medial hypertrophy of muscular and elastic arteries, atheromas of pulmonary artery** and its major branches, and right ventricular hypertrophy.[107] The presence of many organizing or recanalized thrombi favors recurrent pulmonary emboli as the cause, and the coexistence of diffuse pulmonary fibrosis, or severe emphysema and chronic bronchitis, points to chronic hypoxia as the initiating event. The vessel changes can involve the entire arterial tree, from the main pulmonary arteries down to the arterioles (Fig. 15-29). In the most severe cases, atheromatous deposits form in the pulmonary artery and its major branches, resembling (but lesser in degree than) systemic atherosclerosis. The arterioles and small arteries (40 to 300 μm in diameter) are most prominently affected, with striking increases in the muscular thickness of the media (medial hypertrophy) and intimal fibrosis, sometimes narrowing the lumens to pinpoint channels. One extreme in the spectrum of pathologic changes, present most prominently in idiopathic and familial pulmonary arterial hypertension, unrepaired congenital heart disease with left-to-right shunts, and PH associated with drugs and HIV, is the **plexiform lesion**, so called because a tuft of capillary formations is present, producing a network, or web, that spans the lumens of dilated thin-walled, small arteries and may extend outside the vessel. Dilated vessels and arteritis may also be present. Rarely, extensive occlusion of the veins by fibrous tissue can be the cause of PH.[108]

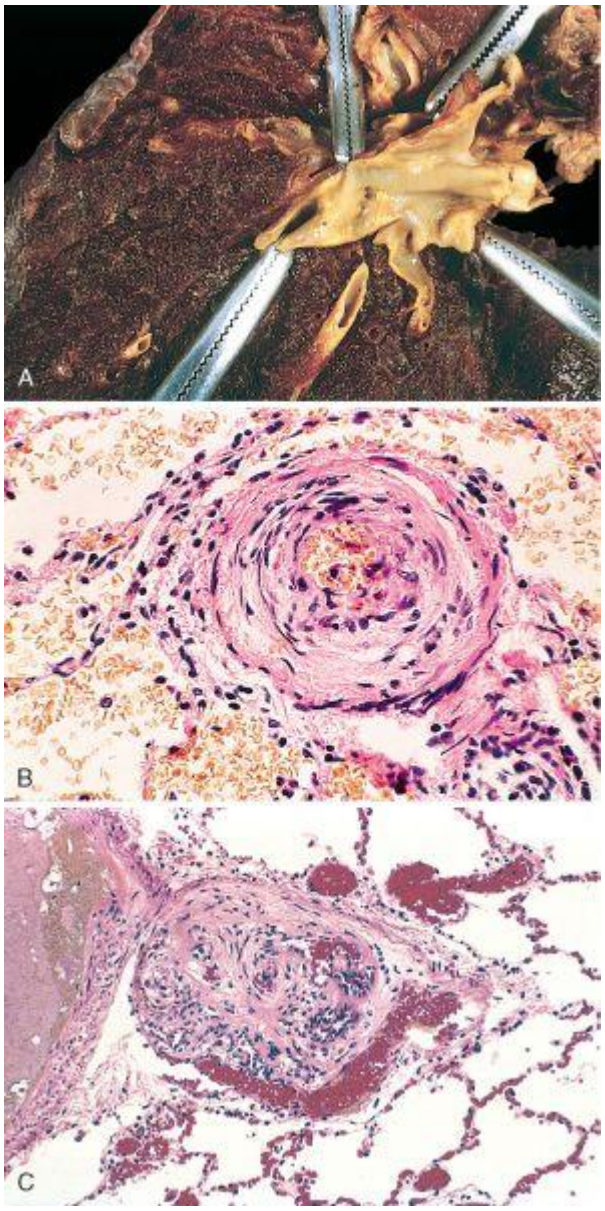

FIGURE 15-29 Vascular changes in pulmonary hypertension. **A**, Gross photograph of atheroma formation, a finding usually limited to large vessels. **B**, Marked medial hypertrophy. **C**, Plexiform lesion characteristic of advanced pulmonary hypertension seen in small arteries.

Clinical Course.

Idiopathic PH is most common in women who are 20 to 40 years of age and is also seen occasionally in young children. Clinical signs and symptoms of all forms of hypertension become evident only with advanced disease. In cases of idiopathic disease, the presenting features are usually dyspnea and fatigue, but some patients have chest pain of the anginal type. Over time, severe respiratory distress, cyanosis, and right ventricular hypertrophy occur, and death from decompensated cor pulmonale, often with superimposed thromboembolism and pneumonia, usually ensues within 2 to 5 years in 80% of patients.[109]

Conventional therapies (oxygen supplementation, calcium channel blockers, anticoagulation, digoxin, and diuretics) are helpful in the short course.[110] However, recently developed specific therapies such as prostacyclin analogues, endothelial receptor antagonists, inhaled nitric oxide, and phosphodiesterase-5 inhibitors [111] [112] [113] have improved the outcome in many patients. Lung transplantation provides definitive treatment for selected patients. Gene therapy has been successful in animals and may be possible for humans in the future.[114]

DIFFUSE PULMONARY HEMORRHAGE SYNDROMES

Hemorrhage from the lung is a dramatic complication of some interstitial lung disorders.[115,][116] Among these so-called *pulmonary hemorrhage syndromes* (Fig. 15-30) are (1) Goodpasture syndrome, (2) idiopathic pulmonary hemosiderosis, and (3) vasculitis-associated hemorrhage, which is found in conditions such as hypersensitivity angiitis, Wegener granulomatosis, and lupus erythematosus (Chapter 11).

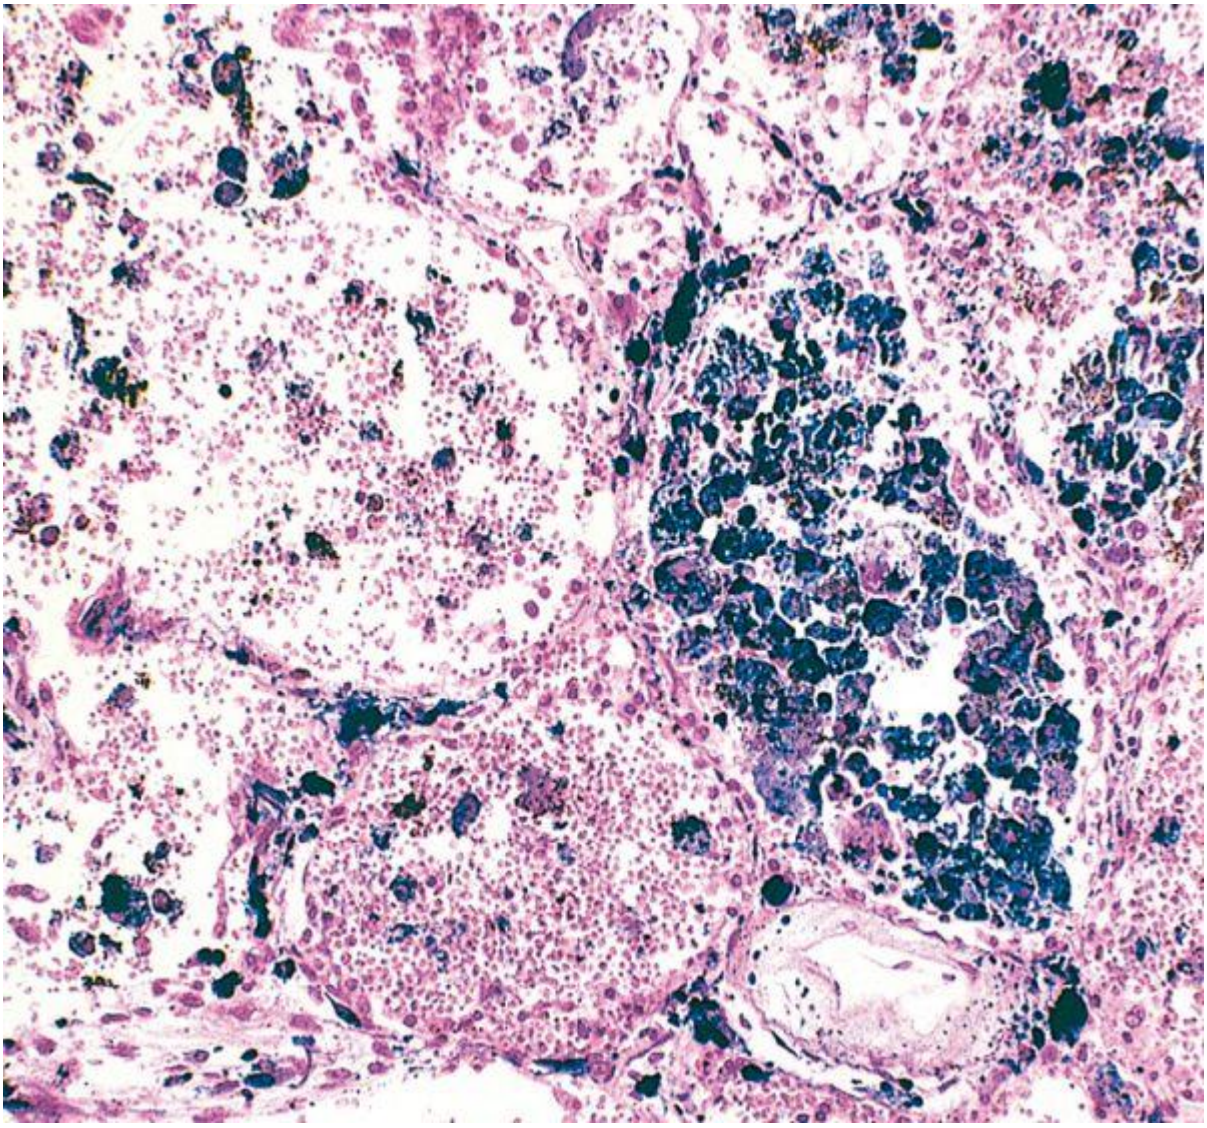

FIGURE 15-30 Diffuse pulmonary hemorrhage syndrome. Acute intra-alveolar hemorrhage and hemosiderin-laden macrophages, reflecting previous hemorrhage, are common features (Prussian blue stain for iron).

Goodpasture Syndrome

Goodpasture syndrome is an uncommon autoimmune disease in which kidney and lung injury are caused by circulating autoantibodies against the noncollagenous domain of the α3 chain of collagen IV. The antibodies initiate inflammatory destruction of the basement membrane in renal glomeruli and pulmonary alveoli,[117] giving rise to *proliferative, usually rapidly progressive glomerulonephritis and a necrotizing hemorrhagic interstitial pneumonitis*. Most cases occur in the teens or 20s, and in contrast to many other autoimmune diseases, there is a male preponderance. In one study 89% of patients were active smokers.[118]

Pathogenesis.

The immunopathogenesis of the syndrome and the nature of the Goodpasture antigens are described in Chapter 20 . The trigger that initiates the anti–basement membrane antibodies is still unknown. Since the epitopes that evoke anti-collagen antibodies are normally hidden within the molecule, it is presumed that some environmental insult such as viral infection, exposure to hydrocarbon solvents (used in the dry cleaning industry), or smoking is required to unmask the cryptic epitopes. As in other autoimmune disorders, a genetic predisposition is indicated by association with certain HLA subtypes (e.g., HLA-DRB1*1501 and *1502).[115]

Morphology. In the classic case, the lungs are heavy, with areas of red-brown consolidation. Histologically, there is focal necrosis of alveolar walls associated with intra-alveolar hemorrhages. Often the alveoli contain hemosiderin-laden macrophages (see Fig. 15-30). In later stages there may be fibrous thickening of the septae, hypertrophy of type II pneumocytes, and organization of blood in alveolar spaces. In many cases immunofluorescence studies reveal linear deposits of immunoglobulins along the basement membranes of the septal walls. The kidneys have the characteristic findings of focal proliferative glomerulonephritis in early cases or crescentic glomerulonephritis in patients with rapidly progressive glomerulonephritis. Diagnostic linear deposits of immunoglobulins and complement are seen by immunofluorescence studies along the glomerular basement membranes even in the few patients without renal disease.

Clinical Features.

Most cases begin clinically with respiratory symptoms, principally hemoptysis, and radiographic evidence of focal pulmonary consolidations. Soon, manifestations of glomerulonephritis appear, leading to rapidly progressive renal failure. The most common cause of death is uremia. The once dismal prognosis for this disease has been markedly improved by intensive *plasmapheresis*. This procedure is thought to be beneficial by removing circulating anti–basement membrane antibodies as well as chemical mediators of immunological injury. Simultaneous immunosuppressive therapy inhibits further antibody production, ameliorating both lung hemorrhage and glomerulonephritis.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis is a rare disorder characterized by intermittent, diffuse alveolar hemorrhage. Most cases occur in young children, although the disease has been reported in adults as well.[119] It usually presents with an insidious onset of productive cough, hemoptysis, anemia, and weight loss associated with diffuse pulmonary infiltrations similar to Goodpasture syndrome.

The cause and pathogenesis are unknown, and no anti–basement membrane antibodies are detectable in serum or tissues. However, favorable response to long-term immunosuppression with prednisone and/or azathioprine indicates that an immunological mechanism could be involved in the pulmonary capillary damage underlying alveolar bleeding. In addition, long-term follow-up of patients shows that some of them develop other immune disorders.[120]

Wegener Granulomatosis

This autoimmune disease most often involves the upper respiratory tract and/or the lungs, with hemoptysis being the common presenting symptom. Its features are discussed in Chapter 11 . Here, it is enough to emphasize that a transbronchial lung biopsy might provide the only tissue available for diagnosis. Since the amount of tissue is small, necrosis and granulomatous vasculitis might not be present. Rather, the diagnostically important features are *capillaritis and scattered, poorly formed granulomas* (unlike those of sarcoidosis, which are rounded and well-defined).

3.5.9 Pulmonary Infections

Respiratory tract infections are more frequent than infections of any other organ and account for the largest number of workdays lost in the general population. The vast majority are upper respiratory tract infections caused by viruses (common cold, pharyngitis), but bacterial, viral, mycoplasmal, and fungal infections of the lung (pneumonia) still account for an enormous amount of morbidity and are responsible for one sixth of all deaths in the United States.[121] Pneumonia can be very broadly defined as any infection of the lung parenchyma.

Pulmonary defense mechanisms are described in Chapter 8 . Pneumonia can result whenever these local defense mechanisms are impaired or the systemic resistance of the host is lowered. Factors that affect resistance in general include chronic diseases, immunological deficiency, treatment with immunosuppressive agents, and leukopenia. The local defense mechanisms of the lung can be interfered with by many factors, such as the following:

- *Loss or suppression of the cough reflex*, as a result of coma, anesthesia, neuromuscular disorders, drugs, or chest pain (may lead to *aspiration* of gastric contents)
- *Injury to the mucociliary apparatus*, by either impairment of ciliary function or destruction of ciliated epithelium, due to cigarette smoke, inhalation of hot or corrosive gases, viral diseases, or genetic defects of ciliary function (e.g., the immotile cilia syndrome)
- *Accumulation of secretions* in conditions such as cystic fibrosis and bronchial obstruction
- *Interference with the phagocytic* or bactericidal action of alveolar macrophages by alcohol, tobacco smoke, anoxia, or oxygen intoxication
- Pulmonary *congestion and edema*

Defects in innate immunity (including neutrophil and complement defects) and humoral immunodeficiency typically lead to an increased incidence of infections with pyogenic bacteria. On the other hand, cell-mediated immune defects (congenital and acquired) lead to increased infections with intracellular microbes such as mycobacteria and herpesviruses as well as with microorganisms of very low virulence, such as *Pneumocystis jiroveci*.

Several other points should be emphasized. First, *one type of pneumonia sometimes predisposes to another, especially in debilitated patients*. For example, the most common cause of death in viral influenza epidemics is superimposed bacterial pneumonia. Second, although the portal of entry for most pneumonias is the respiratory tract, *hematogenous spread from one organ to other organs can occur*, and secondary seeding of the lungs may be difficult to distinguish from primary pneumonia. Finally,

many *patients with chronic diseases acquire terminal pneumonias while hospitalized (nosocomial infection)*. Bacteria common to the hospital environment may have acquired resistance to antibiotics; opportunities for spread are increased; invasive procedures, such as intubations and injections, are common; and bacteria may contaminate equipment used in respiratory care units.

Pneumonias are classified by the specific etiologic agent, which determines the treatment, or, if no pathogen can be isolated, by the clinical setting in which the infection occurs. The latter considerably narrows the list of suspected pathogens for administering empirical antimicrobial therapy. As Table 15-8 indicates, pneumonia can arise in seven distinct clinical settings ("pneumonia syndromes"), and the implicated pathogens are reasonably specific to each category.

TABLE 15-8 -- The Pneumonia Syndromes

COMMUNITY-ACQUIRED ACUTE PNEUMONIA
Streptococcus pneumoniae
Haemophilus influenzae
Moraxella catarrhalis
Staphylococcus aureus
Legionella pneumophila
Enterobacteriaceae (*Klebsiella pneumoniae*) and *Pseudomonas* spp.
COMMUNITY-ACQUIRED ATYPICAL PNEUMONIA
Mycoplasma pneumoniae
Chlamydia spp. (*C. pneumoniae*, *C. psittaci*, *C. trachomatis*)
Coxiella burnetii (Q fever)
Viruses: respiratory syncytial virus, parainfluenza virus (children); influenza A and B (adults); adenovirus (military recruits); SARS virus
HOSPITAL-ACQUIRED PNEUMONIA
Gram-negative rods, Enterobacteriaceae (*Klebsiella* spp., *Serratia marcescens*, *Escherichia coli*) and *Pseudomonas* spp.
Staphylococcus aureus (usually penicillin resistant)
ASPIRATION PNEUMONIA
Anaerobic oral flora (*Bacteroides*, *Prevotella*, *Fusobacterium*, *Peptostreptococcus*), admixed with aerobic bacteria (*Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*)
CHRONIC PNEUMONIA
Nocardia
Actinomyces
Granulomatous: *Mycobacterium tuberculosis* and atypical mycobacteria, *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*
NECROTIZING PNEUMONIA AND LUNG ABSCESS
Anaerobic bacteria (extremely common), with or without mixed aerobic infection
Staphylococcus aureus, *Klebsiella pneumoniae*, *Streptococcus pyogenes*, and type 3 pneumococcus (uncommon)

PNEUMONIA IN THE IMMUNOCOMPROMISED HOST
Cytomegalovirus
Pneumocystis jiroveci
Mycobacterium avium-intracellulare
Invasive aspergillosis
Invasive candidiasis
“Usual” bacterial, viral, and fungal organisms (listed above)

SARS, severe acute respiratory syndrome.

COMMUNITY-ACQUIRED ACUTE PNEUMONIAS

Community-acquired pneumonias may be bacterial or viral. Often, the bacterial infection follows an upper respiratory tract viral infection. Bacterial invasion of the lung parenchyma causes the alveoli to be filled with an inflammatory exudate, thus causing consolidation (“solidification”) of the pulmonary tissue. Many variables, such as the specific etiologic agent, the host reaction, and the extent of involvement, determine the precise form of pneumonia. Predisposing conditions include extremes of age, chronic diseases (congestive heart failure, COPD, and diabetes), congenital or acquired immune deficiencies, and decreased or absent splenic function (sickle cell disease or post-splenectomy, which puts the patient at risk for infection with encapsulated bacteria such as pneumococcus).

Streptococcus pneumoniae

Streptococcus pneumoniae, or *pneumococcus*, is the most common cause of community-acquired acute pneumonia. Examination of Gram-stained sputum is an important step in the diagnosis of acute pneumonia. The presence of numerous neutrophils containing the typical gram-positive, lancet-shaped diplococci supports the diagnosis of pneumococcal pneumonia, but it must be remembered that *S. pneumoniae* is a part of the endogenous flora in 20% of adults, and therefore false-positive results may be obtained. Isolation of pneumococcifrom blood cultures is more specific but less sensitive (in the early phase of illness, only 20% to 30% of patients have positive blood cultures). Pneumococcal vaccines containing capsular polysaccharides from the common serotypes are used in patients at high risk.

Haemophilus influenzae

Haemophilus influenzae is a pleomorphic, gram-negative organism that is a major cause of life-threatening acute lower respiratory tract infections and meningitis in young children. In adults it is a very common cause of community-acquired acute pneumonia.[122] This bacterium is a ubiquitous colonizer of the pharynx, where it exists in two forms: encapsulated (5%) and unencapsulated (95%). Typically, the encapsulated form dominates the unencapsulated forms by secreting an antibiotic called haemocin that kills the unencapsulated *H. influenzae*.[123] Although there are six serotypes of the encapsulated form (types a to f), type b, which has a polyribosephosphate capsule, used to be the most frequent cause of severe invasive disease. With routine use of *H. influenzae* conjugate vaccines, the incidence of disease caused by the b serotype has declined significantly. By contrast, infections with nonencapsulated forms are increasing. Also called nontypeable forms, they spread along the surface of the upper respiratory tract and produce otitis media (infection of the middle ear), sinusitis, and bronchopneumonia.

Pili on the surface of *H. influenzae* mediate adherence of the organisms to the respiratory epithelium.[124] In addition, *H. influenzae* secretes a factor that disorganizes ciliary beating and a protease that degrades IgA, the major class of antibody secreted into the airways. Survival of *H. influenzae* in the bloodstream correlates with the presence of the capsule, which, like that of pneumococcus, prevents opsonization by complement and phagocytosis by host cells. Antibodies against the capsule protect the host from *H. influenzae* infection; hence the capsular polysaccharide b is incorporated in the vaccine against *H. influenzae* used for children.

H. influenzae pneumonia, which may follow a viral respiratory infection, is a pediatric emergency and has a high mortality rate. Descending laryngotracheobronchitis results in airway obstruction as the smaller bronchi are plugged by dense, fibrin-rich exudate of polymorphonuclear cells, similar to that seen in pneumococcal pneumonias. Pulmonary consolidation is usually lobular and patchy but may be confluent and involve the entire lung lobe. Before a vaccine became widely available, *H. influenzae* was a common cause of suppurative meningitis in children up to 5 years of age. *H. influenzae* also causes an acute, purulent conjunctivitis (pink eye) in children and, in predisposed older patients, may cause septicemia, endocarditis, pyelonephritis, cholecystitis, and suppurative arthritis. *H. influenzae* is the most common bacterial cause of acute exacerbation of COPD.

Moraxella catarrhalis

Moraxella catarrhalis is being increasingly recognized as a cause of bacterial pneumonia, especially in the elderly. It is the second most common bacterial cause of acute exacerbation of COPD. Along with *S. pneumoniae* and *H. influenzae*, *M. catarrhalis* constitutes one of the three most common causes of otitis media in children.

Staphylococcus aureus

Staphylococcus aureus is an important cause of secondary bacterial pneumonia in children and healthy adults following viral respiratory illnesses (e.g., measles in children and influenza in both children and adults). Staphylococcal pneumonia is associated with a high incidence of complications, such as lung abscess and empyema. *Intravenous drug abusers* are at high risk of developing staphylococcal pneumonia in association with endocarditis. It is also an important cause of hospital-acquired pneumonia, as will be discussed later.

Klebsiella pneumoniae

Klebsiella pneumoniae is the most frequent cause of gram-negative bacterial pneumonia. It commonly afflicts debilitated and malnourished people, particularly *chronic alcoholics*. Thick and gelatinous sputum is characteristic, because the organism produces an abundant viscid capsular polysaccharide, which the patient may have difficulty expectorating.

Pseudomonas aeruginosa

Although *Pseudomonas aeruginosa* most commonly causes hospital-acquired infections, it is mentioned here because of its occurrence in cystic fibrosis patients. It is common in patients who are neutropenic and it has a propensity to invade blood vessels with consequent extrapulmonary spread. *Pseudomonas* septicemia is a very fulminant disease.

Legionella pneumophila

Legionella pneumophila is the agent of Legionnaires' disease, an eponym for the epidemic and sporadic forms of pneumonia caused by this organism. It also causes Pontiac fever, a related self-limited upper respiratory tract infection. This organism flourishes in artificial aquatic environments, such as water-

cooling towers and within the tubing system of domestic (potable) water supplies. The mode of transmission is either inhalation of aerosolized organisms or aspiration of contaminated drinking water. *Legionella* pneumonia is common in individuals with some predisposing condition such as cardiac, renal, immunological, or hematologic disease. *Organ transplant recipients are particularly susceptible*. It can be quite severe, frequently requiring hospitalization, and immunosuppressed patients may have fatality rates of up to 50%. Rapid diagnosis is facilitated by demonstration of *Legionella* antigens in the urine or by a positive fluorescent antibody test on sputum samples; culture remains the gold standard of diagnosis.

Morphology. Bacterial pneumonia has two patterns of anatomic distribution: lobular bronchopneumonia and lobar pneumonia (Fig. 15-31). Patchy consolidation of the lung is the dominant characteristic of **bronchopneumonia** (Fig. 15-32), while fibrinosuppurative consolidation of a large portion of a lobe or of an entire lobe defines **lobar pneumonia** (Fig. 15-33). These anatomic but still classic categorizations are often difficult to apply in individual cases because patterns overlap. The patchy involvement may become confluent, producing virtually total lobar consolidation; in contrast, effective antibiotic therapy for any form of pneumonia may limit involvement to a subtotal consolidation. Moreover, the same organisms may produce either pattern depending on patient susceptibility. **Most important from the clinical standpoint are identification of the causative agent and determination of the extent of disease**.

In **lobar pneumonia**, four stages of the inflammatory response have classically been described: congestion, red hepatization, gray hepatization, and resolution. Current effective antibiotic therapy frequently slows or halts the progression. In the first stage of **congestion** the lung is heavy, boggy, and red. It is characterized by vascular engorgement, intra-alveolar fluid with few neutrophils, and often the presence of numerous bacteria. The stage of **red hepatization** that follows is characterized by massive confluent exudation with neutrophils, red cells, and fibrin filling the alveolar spaces (Fig. 15-34A). On gross examination, the lobe now appears distinctly red, firm, and airless, with a liver-like consistency, hence the term **hepatization**. The stage of **gray hepatization** follows with progressive disintegration ofred cells and the persistence of a fibrinosuppurative exudate (Fig. 15-34B), giving the gross appearance of a grayish brown, dry surface. In the final stage of **resolution** the consolidated exudate within the alveolar spaces undergoes progressive enzymatic digestion to produce granular, semifluid debris that is resorbed, ingested by macrophages, expectorated, or organized by fibroblasts growing into it (Fig. 15-34C). Pleural fibrinous reaction to the underlying inflammation, often present in the early stages if the consolidation extends to the surface **(pleuritis)**, may similarly resolve. More often it undergoes organization, leaving fibrous thickening or permanent adhesions.

Foci of **bronchopneumonia** are consolidated areas of acute suppurative inflammation. The consolidation may be patchy through one lobe but is more often multilobar and frequently bilateral and basal because of the tendency of secretions to gravitate into the lower lobes. Well-developed lesions are slightly elevated, dry, granular, gray-red to yellow, and poorly delimited at their margins (see Fig. 15-32). Histologically, the reaction usually elicits a suppurative, neutrophil-rich exudate that fills the bronchi, bronchioles, and adjacent alveolar spaces (Fig. 15-34A).

Complications of pneumonia include (1) tissue destruction and necrosis, causing **abscess formation** (particularly common with type 3 pneumococci or *Klebsiella* infections); (2) spread of infection to the pleural cavity, causing the intrapleural fibrinosuppurative reaction known as **empyema**; and (3) **bacteremic dissemination** to the heart valves, pericardium, brain, kidneys, spleen, or joints, causing metastatic abscesses, endocarditis, meningitis, or suppurative arthritis.

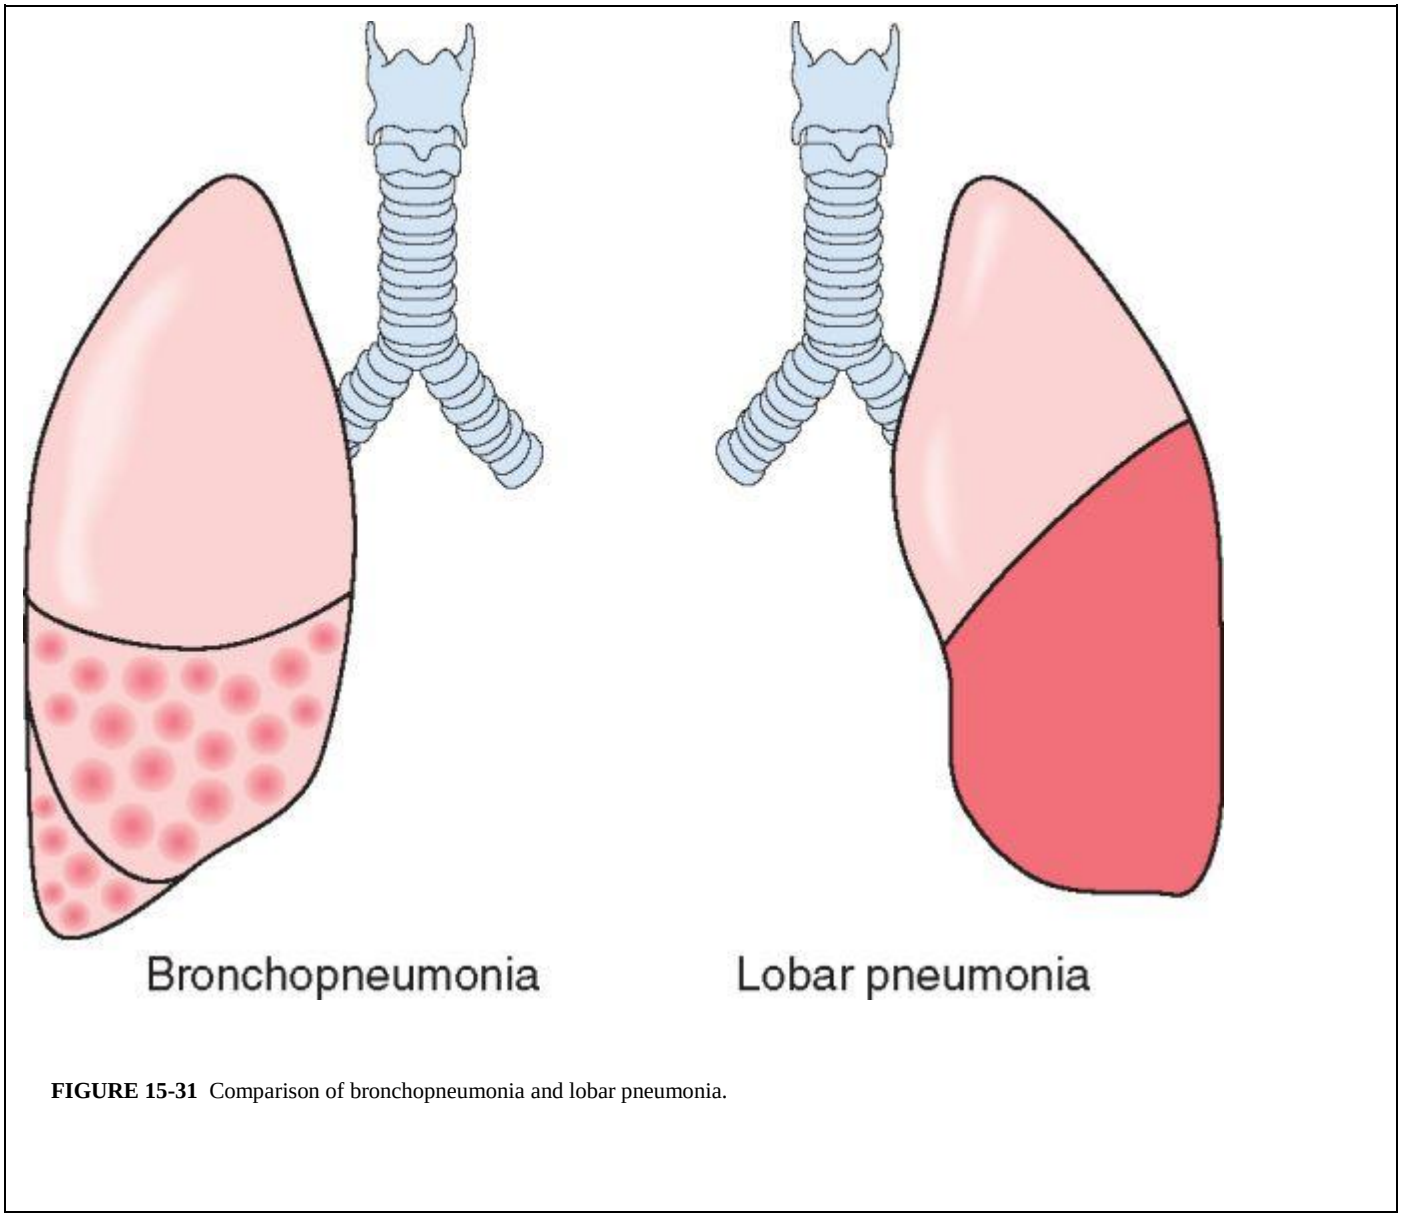

FIGURE 15-31 Comparison of bronchopneumonia and lobar pneumonia.

FIGURE 15-32 Bronchopneumonia. Gross section of lung showing patches of consolidation *(arrows)*.

FIGURE 15-33 Lobar pneumonia—gray hepatization, gross photograph. The lower lobe is uniformly consolidated.

Clinical Course.

The major symptoms of community-acquired acute pneumonia are abrupt onset of high fever, shaking chills, and cough productive of mucopurulent sputum; occasional patients may have hemoptysis. When fibrinosuppurative pleuritis is present it is accompanied by pleuritic pain and pleural friction rub. The whole lobe is radiopaque in lobar pneumonia, whereas there are focal opacities in bronchopneumonia.

The clinical picture is markedly modified by the administration of antibiotics. Treated patients may be relatively afebrile with few clinical signs 48 to 72 hours after the initiation of antibiotics. The identification of the organism and the determination of its antibiotic sensitivity are the keystones to appropriate therapy. Fewer than 10% of patients with pneumonia severe enough to merit hospitalization now succumb, and in most such instances death may be attributed either to a complication, such as

empyema, meningitis, endocarditis, or pericarditis, or to some predisposing influence, such as debility or chronic alcoholism.

COMMUNITY-ACQUIRED ATYPICAL (VIRAL AND MYCOPLASMAL) PNEUMONIAS

The term *primary atypical pneumonia* was initially applied to an acute febrile respiratory disease characterized by patchy inflammatory changes in the lungs, largely confined to the alveolar septa and pulmonary interstitium. The term *atypical* denotes the moderate amount of sputum, no physical findings of consolidation, only moderate elevation of white cell count, and lack of alveolar exudate. The pneumonitis is caused by a variety of organisms, the most common being *Mycoplasma pneumoniae*. *Mycoplasma* infections are particularly common among children and young adults. They occur sporadically or as local epidemics in closed communities (schools, military camps, and prisons). Other etiologic agents are viruses, including influenza virus types A and B, the respiratory syncytial viruses, human metapneumovirus, adenovirus, rhinoviruses, rubeola, and varicella viruses; *Chlamydia pneumoniae*; and *Coxiella burnetii* (Q fever).[124,][125] In some cases the cause cannot be determined. Any one of these agents can cause merely an upper respiratory tract infection, recognized as the common cold, or a more severe lower respiratory tract infection. Factors that favor such extension of the infection include extremes of age, malnutrition, alcoholism, and underlying debilitating illnesses.

The common pathogenetic mechanism is attachment of the organisms to the upper respiratory tract epithelium followed by necrosis of the cells and an inflammatory response. When the process extends to the alveoli there is usually interstitial inflammation, but there may also be some outpouring of fluid into alveolar spaces, so that on chest x-ray the changes may mimic bacterial pneumonia. Damage to and denudation of the respiratory epithelium inhibit mucociliary clearance and predispose to secondary bacterial infections.

Morphology. All causal agents produce essentially similar morphologic patterns. The lung involvement may be quite patchy or may involve whole lobes bilaterally or unilaterally. The affected areas are red-blue and congested. The pleura is smooth, and pleuritis or pleural effusions are infrequent.

The histologic pattern depends on the severity of the disease. **Predominant is the interstitial nature of the inflammatory reaction, virtually localized within the walls of the alveoli**. The alveolar septa are widened and edematous and usually have a mononuclear inflammatory infiltrate of lymphocytes, macrophages, and occasionally plasma cells. In acute cases neutrophils may also be present. The alveoli may be free from exudate, but in many patients there is intra-alveolar proteinaceous material and a cellular exudate. When complicated by ARDS, characteristically pink hyaline membranes lining the alveolar walls are present (see Fig. 15-3). Eradication of the infection is followed by reconstitution of the normal architecture of the lung.

Superimposed bacterial infection modifies the histologic picture by causing ulcerative bronchitis, bronchiolitis, and bacterial pneumonia. Some viruses, such as herpes simplex, varicella, and adenovirus, may be associated with necrosis of bronchial and alveolar epithelium and acute inflammation. Characteristic viral cytopathic changes are described in Chapter 8 .

Clinical Course.

The clinical course is extremely varied. Many cases masquerade as severe upper respiratory tract infections or as *chest colds*. Even individuals with welldeveloped atypical pneumonia have few localizing symptoms. Cough may be absent, and the major manifestations may consist only of fever, headache, muscle aches, and pains in the legs. The edema and exudation are both strategically located to

cause mismatching of ventilation and blood flow and thus evoke symptoms out of proportion to the scanty physical findings.

The ordinary sporadic form of the disease is usually mild with a low mortality rate, below 1%. Interstitial pneumonia, however, may assume epidemic proportions with intensified severity and greater mortality, as documented in the devastating influenzal pandemics of 1915 and 1918 and the many smaller epidemics since then. Secondary bacterial infection by staphylococci or streptococci is common in such circumstances.

Influenza Infections

The genome of influenza virus is composed of eight helices of single-stranded RNA, each encoding a single gene and each bound by a nucleoprotein that determines the type of influenza virus (A, B, or C). The spherical surface of influenza virus is a lipid bilayer (envelope) containing the viral hemagglutinin and neuraminidase, which determine the subtype of the virus (H1 to H3; N1 or N2). Host antibodies to the hemagglutinin and neuraminidase prevent and ameliorate, respectively, future infection with the influenza virus. Two mechanisms account for the clearance of primary influenza virus infection: cytotoxic T cells kill virus-infected cells, and an intracellular anti-influenza protein (called Mx1) is induced in macrophages by the cytokines IFN-α and IFN-β.[126]

Influenza viruses of type A infect humans, pigs, horses, and birds and are the major cause of pandemic and epidemic influenza infections. A single subtype of influenza virus A predominates throughout the world at a given time.[127] Epidemics of influenza occur through mutations of the hemagglutinin and neuraminidase that allow the virus to escape most host antibodies *(antigenic drift)*. Pandemics, which are longer and more widespread than epidemics, may occur when both the hemagglutinin and the neuraminidase are replaced through recombination of RNA segments with those of animal viruses, making all individuals susceptible to the new influenza virus *(antigenic shift)*. Polymerase chain reaction (PCR) analysis of influenza virus from the lungs of a soldier who died in the 1918 influenza pandemic that killed between 20 million and 40 million people worldwide identified a swine influenza virus belonging to the same family of influenza viruses causing illness today.[128] Current antiviral drugs are effective against recombinant influenza viruses bearing the 1918 hemagglutinin, neuraminidase, and matrix genes.[129] Influenza virus types B and C, which do not show antigenic drift or shift, infect mostly children, who develop antibodies that prevent reinfection. Rarely, influenza virus may cause interstitial myocarditis or, after aspirin therapy, Reye syndrome (Chapter 18).

Avian influenza refers to strains of influenza which primarily infect birds. One such strain with the *antigenic type H5N1 is of great concern* because infection is frequently lethal in humans (approximately 60%) and since 2003 the virus is spreading throughout the world in wild and domestic birds. As of the fall of 2008, a total of 387 H5N1 influenza virus infections in humans have been reported to the WHO. Nearly all cases of H5N1 influenza in humans have been acquired by close contact with domestic birds. The severity of the disease results from the ability of the virus to cause widespread infection in the human body, instead of infection being limited to the lung. *The tissue tropism of H5N1 influenza is increased due to the unusual structure of its hemagglutinin protein*. Cleavage of viral hemagglutinin by host proteases is required for the influenza virus to enter host cells. The hemagglutinin protein of H5N1 influenza virus, and other highly pathogenic influenza viruses, is unusual in that it can be cleaved by ubiquitous proteases in the human, while the hemagglutinin of less virulent influenza virus stains can only be cleaved by proteases found in limited organs, including the lung. Fortunately, the transmission of the current H5N1 virus is inefficient. Most patients with H5NI infection present with pneumonia. However, if antigenic recombination occurs between H5N1 influenza and a strain of influenza which is highly infectious for humans, sustained human-to-human transmission could give rise to a pandemic, similar to the Spanish pandemic of 1918. This concern has spurred efforts to develop a vaccine.[130]

Morphology. Viral upper respiratory infections are marked by mucosal hyperemia and swelling with a predominantly lymphomonocytic and plasmacytic infiltration of the submucosa accompanied by overproduction of mucus secretions. The swollen mucosa and viscous exudate may plug the nasal channels, sinuses or the Eustachian tubes, and lead to suppurative secondary bacterial infection. Virus-induced tonsillitis with enlargement of the lymphoid tissue within the Waldeyer ring is frequent in children, although lymphoid hyperplasia is not usually associated with suppuration or abscess formation, such as is encountered with streptococci or staphylococci.

In **laryngotracheobronchitis** and **bronchiolitis** there is vocal cord swelling and abundant mucus exudation. Impairment of bronchociliary function invites bacterial superinfection with more marked suppuration. Plugging of small airways may give rise to focal lung atelectasis. In the more severe bronchiolar involvement widespread plugging of secondary and terminal airways by cell debris, fibrin, and inflammatory exudate may, when prolonged, cause organization and fibrosis, resulting in obliterative bronchiolitis and permanent lung damage.

Human Metapneumovirus (MPV)

Human MPV, a paramyxovirus discovered in 2001, is found worldwide and is associated with upper and lower respiratory tract infections, most commonly in young children, elderly subjects, and immunocompromised patients. Human MPV can cause severe infections such as bronchiolitis and pneumonia and is responsible for 5% to 10% of hospitalizations and 12% to 20% of outpatient visits of children suffering from acute respiratory tract infections. Such infections are clinically indistinguishable from those caused by human respiratory syncytial virus. The first human MPV infection occurs during early childhood, but reinfections are common throughout life, especially in older subjects. Molecular methods such as reverse transcriptase–PCR are the preferred diagnostic modality because of fastidious growth in cell culture. No commercial treatments are yet available for human MPV, although ribavirin has shown activity both in vitro and in animal models. Live attenuated vaccines produced by genetically altered virus have also shown good efficacy in animals.[131]

Severe Acute Respiratory Syndrome (SARS)

SARS first appeared in November 2002 in the Guangdong Province of China and subsequently spread to Hong Kong, Taiwan, Singapore, Vietnam, and Toronto, where large outbreaks also occurred.[132] The ease of travel between continents clearly contributed to this pandemic. Between Fall 2002 and Spring 2003, there were more than 8000 cases of SARS, including 774 deaths. The worldwide epidemic was halted, perhaps in part because of public health measures, and the last cases of SARS were laboratory-associated infections reported in April 2004.[125]

After an incubation period of 2 to 10 days, SARS begins with a dry cough, malaise, myalgias, fever, and chills. A third of patients improve and resolve the infection, but the rest progress to severe respiratory disease with shortness of breath, tachypnea, and pleurisy, and nearly 10% of patients die from the illness, for which there is no specific treatment.

The cause of SARS is a previously undiscovered coronavirus. Nearly a third of upper respiratory infections are caused by coronaviruses, but the SARS virus differs from previously known coronaviruses in that it infects the lower respiratory tract and spreads throughout the body. *The SARS virus seems to have been first transmitted to humans through contact with wild masked palm civets that are eaten in China*. Subsequent cases were spread person-to-person, mainly through infected respiratory secretions, although some cases may have been contracted from stool.

SARS can be diagnosed either by detection of the virus by PCR or by detection of antibodies to the virus. Levels of the virus are low initially and peak 10 days after onset of illness, so testing of different specimens (respiratory secretions, blood, and stool) collected on several days may be needed to detect the virus. Detection of antibodies specific for the SARS virus is a very sensitive and specific test; however, patients may not have a measurable antibody response for up to 28 days after infection.

The pathophysiology of SARS is not understood, nor is it known why the virus moved from animals to humans. Most human SARS coronaviruses have a 29-nucleotide deletion in the RNA when compared to the virus found in wild animals, which may enhance its transmission or pathogenicity. In patients who have died of SARS the lungs show diffuse alveolar damage and multinucleated giant cells. Coronaviruses can be seen within pneumocytes by electron microscopy.

HOSPITAL-ACQUIRED PNEUMONIA

Hospital-acquired pneumonias are defined as pulmonary infections acquired in the course of a hospital stay. They are common in patients with severe underlying disease, immunosuppression, prolonged antibiotic therapy, or invasive access devices such as intravascular catheters. Patients on mechanical ventilation are at particularly high risk. Superimposed on an underlying disease (that caused hospitalization), hospital-acquired infections are serious and often lifethreatening complications. Gram-negative rods (Enterobacteriaceae and *Pseudomonas* species) and *S. aureus* are the most common isolates; unlike community-acquired pneumonias, *S. pneumoniae* is not a major pathogen.

ASPIRATION PNEUMONIA

Aspiration pneumonia occurs in markedly debilitated patients or those who aspirate gastric contents either while unconscious (e.g., after a stroke) or during repeated vomiting. These patients have abnormal gag and swallowing reflexes that predispose to aspiration. The resultant pneumonia is partly chemical because of the extremely irritating effects of the gastric acid, and partly bacterial (from the oral flora). Typically, more than one organism is recovered on culture, aerobes being more common than anaerobes. This type of pneumonia is often necrotizing, pursues a fulminant clinical course, and is a frequent cause of death. In those who survive, lung abscess is a common complication.

LUNG ABSCESS

The term "pulmonary abscess" describes a local suppurative process within the lung, characterized by necrosis of lung tissue. Oropharyngeal surgical procedures, sinobronchial infections, dental sepsis, and bronchiectasis play important roles in their development.

Etiology and Pathogenesis.

Although under appropriate circumstances any pathogen can produce an abscess, the commonly isolated organisms include aerobic and anaerobic streptococci, *S. aureus*, and a host of gram-negative organisms. Mixed infections often occur because of the important causal role played by inhalation of foreign material.[133] *Anaerobic organisms* normally found in the oral cavity, including members of the *Bacteroides*, *Fusobacterium*, and *Peptococcus* species, are the exclusive isolates in about 60% of cases. The causative organisms are introduced by the following mechanisms:

- *Aspiration of infective material* (the most frequent cause): This is particularly common in acute alcoholism, coma, anesthesia, sinusitis, gingivodental sepsis, and debilitation in which the cough reflexes are depressed.
- *Antecedent primary lung infection*: Post-pneumonic abscess formations are usually associated with *S. aureus*, *K. pneumoniae*, and the type 3 pneumococcus. Posttransplant or otherwise immunosuppressed individuals are at special risk.

- *Septic embolism*: Infected emboli from thrombophlebitis in any portion of the systemic venous circulation or from the vegetations of infective bacterial endocarditis on the right side of the heart are trapped in the lung.
- *Neoplasia*: Secondary infection is particularly common in the bronchopulmonary segment obstructed by a primary or secondary malignancy *(postobstructive pneumonia)*.
- *Miscellaneous*: Direct traumatic penetrations of the lungs; spread of infections from a neighboring organ, such as suppuration in the esophagus, spine, subphrenic space, or pleural cavity; and hematogenous seeding of the lung by pyogenic organisms all may lead to lung abscess formation.

When all these causes are excluded, there are still cases in which no reasonable basis for the abscess formation can be identified. These are referred to as *primary cryptogenic lung abscesses*.

Morphology. Abscesses vary in diameter from lesions of a few millimeters to large cavities of 5 to 6 cm. They may affect any part of the lung and may be single or multiple. Pulmonary abscesses due to aspiration are more common on the right (because of the more vertical right main bronchus) and are most often single. Abscesses that develop in the course of pneumonia or bronchiectasis are usually multiple, basal, and diffusely scattered. Septic emboli and pyemic abscesses are multiple and may affect any region of the lungs.

The abscess cavity might be filled with suppurative debris. If there is communication with an air passage, the contained exudate may be partially drained to create an air-containing cavity. Superimposed saprophytic infections are prone to flourishing within the already necrotic debris of the abscess cavity. Continued infection leads to large, fetid, green-black, multilocular cavities with poor demarcation of their margins, designated **gangrene of the lung**. The **cardinal histologic change in all abscesses is suppurative destruction of the lung parenchyma within the central area of cavitation** (Fig. 15-35). In chronic cases considerable fibroblastic proliferation produces a fibrous wall.

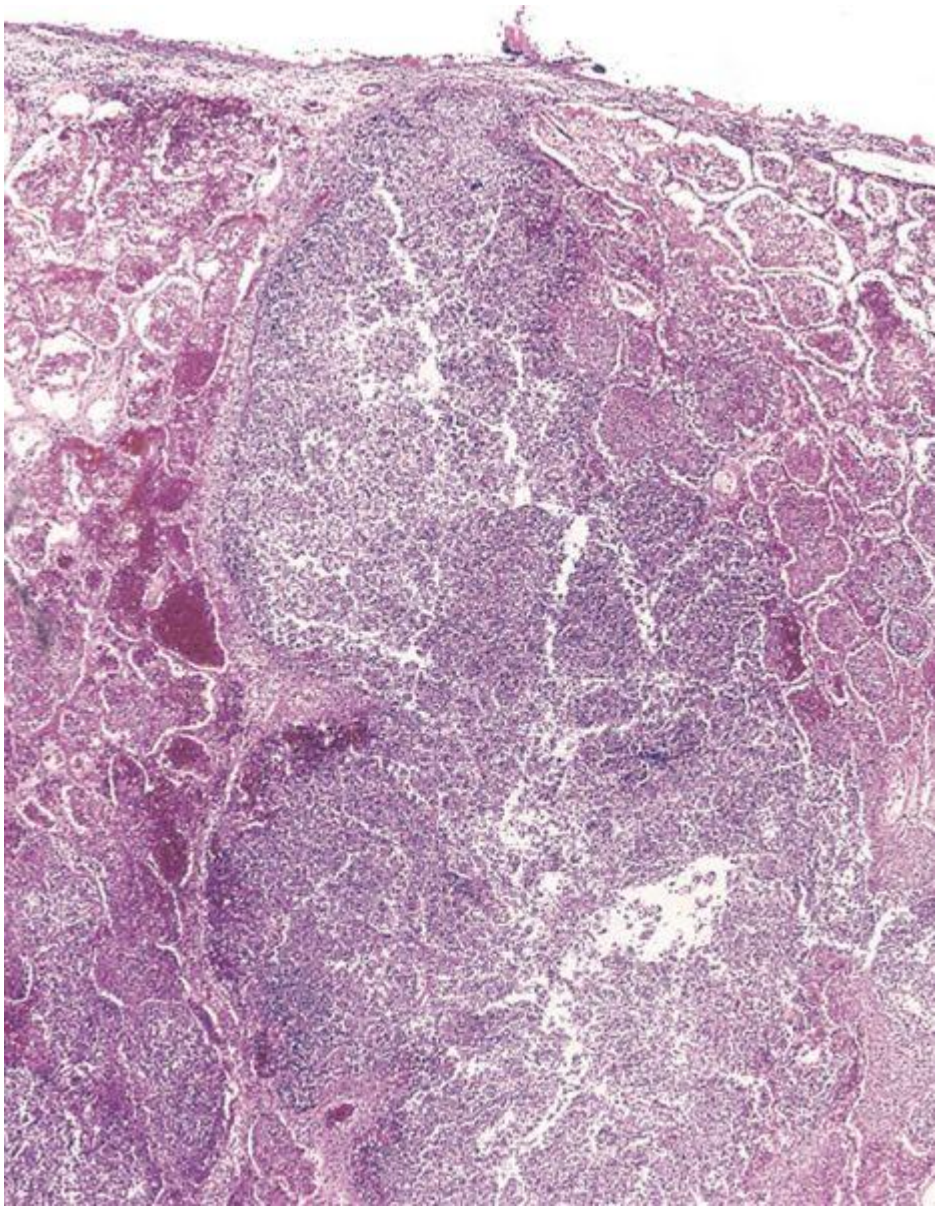

FIGURE 15-35 Pyemic lung abscess (center) with complete destruction of underlying parenchyma within the focus of involvement.

Clinical Course.

The manifestations of pulmonary abscesses are much like those of bronchiectasis and are characterized principally by cough, fever, and copious amounts of foul-smelling purulent or sanguineous sputum. Fever, chest pain, and weight loss are common. Clubbing of the fingers and toes may appear within a few weeks after the onset of an abscess. Diagnosis of this condition can be only suspectedfrom the clinical findings and must be confirmed radiologically. Whenever an abscess is discovered in older individuals, it is important to rule out an underlying carcinoma, because this is present in 10% to 15% of cases.

The course of abscesses is variable. With antimicrobial therapy, most resolve leaving behind a scar. Complications include extension of the infection into the pleural cavity, hemorrhage, the development of *brain abscesses* or *meningitis* from septic emboli, and (rarely) secondary amyloidosis (type AA).

CHRONIC PNEUMONIA

Chronic pneumonia is most often a localized lesion in the immunocompetent patient, with or without regional lymph node involvement. Typically, the inflammatory reaction is granulomatous, and is caused by bacteria (e.g., *M. tuberculosis*) or fungi (e.g., *Histoplasma capsulatum*). Tuberculosis of the lung and other organs was described in Chapter 8 . Here we will discuss chronic pneumonias caused by fungi.

Histoplasmosis, *blastomycosis*, and *coccidioidomycosis* are discussed together because (1) they are granulomatous diseases of the lungs that may resemble tuberculosis, (2) they are caused by fungi that are thermally dimorphic in that they grow as hyphae that produce spores at environmental temperatures but grow as yeasts (spherules or ellipses) at body temperature within the lungs, and (3) each fungus is geographic in that it causes disease primarily among immunocompetent individuals living along the Ohio and Mississippi rivers and in the Caribbean (*Histoplasma*), in the central and southeastern United States (*Blastomyces*), and in the Southwest and Far West of the United States and in Mexico (*Coccidioides*).

Histoplasmosis

Histoplasma capsulatum infection is acquired by inhalation of dust particles from soil contaminated with bird or bat droppings that contain small spores (microconidia), the infectious form of the fungus. Like *M. tuberculosis*, *H. capsulatum* is an intracellular parasite of macrophages. The *clinical presentations and morphologic lesions of histoplasmosis also strikingly resemble those of tuberculosis*, including (1) a self-limited and often latent primary pulmonary involvement, which may result in coin lesions on chest radiography; (2) chronic, progressive, secondary lung disease, which is localized to the lung apices and causes cough, fever, and night sweats; (3) localized lesions in extrapulmonary sites, including mediastinum, adrenals, liver, or meninges; and (4) a widely disseminated disease in immunocompromised patients.

The pathogenesis of histoplasmosis is incompletely understood. It is known that macrophages are the major target of infection. *H. capsulatum* may be internalized into macrophages after opsonization with antibody. *Histoplasma* yeasts can multiply within the phagosome, and lyse the host cells. *Histoplasma* infections are controlled by helper T cells that recognize fungal cell wall antigens and heat-shock proteins and subsequently secrete IFN-γ, which activates macrophages to kill intracellular yeasts. In addition, *Histoplasma* induces macrophages to secrete TNF, which recruits and stimulates other macrophages to kill *Histoplasma*. Lacking cellular immunity, patients with acquired immunodeficiency syndrome are susceptible to disseminated infection with *Histoplasma*, which is an opportunistic pathogen in this disease.

Morphology. In the lungs of otherwise healthy adults, *Histoplasma* infections produce epithelioid cell granulomas, which usually undergo caseation necrosis and coalesce to produce large areas of consolidation but may also liquefy to form cavities (seen in patients with COPD). With spontaneous or drug control of the infection, these lesions undergo fibrosis and concentric calcification (tree-bark appearance) (Fig. 15-36A). Histologic differentiation from tuberculosis, sarcoidosis, and coccidioidomycosis requires identification of the 3- to 5-μm thin-walled yeast forms that may persist in tissues for years.

In **fulminant disseminated histoplasmosis**, which occurs in immunosuppressed individuals,

epithelioid cell granulomas are not formed; instead, there are focal accumulations of mononuclear phagocytes filled with fungal yeasts throughout the tissues and organs of the body (Fig. 15-36B).

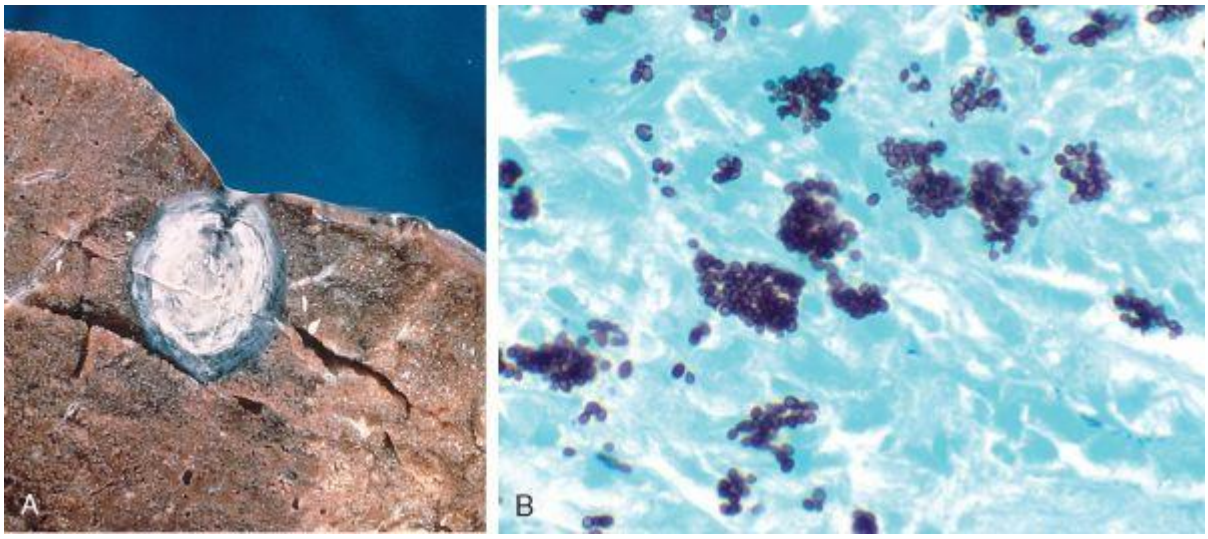

FIGURE 15-36 Histoplasmosis. **A**, Laminated *Histoplasma* granuloma of the lung. **B**, *Histoplasma capsulatum* yeast forms fill phagocytes in the lung of a patient with disseminated histoplasmosis (silver stain).

The diagnosis of histoplasmosis is established by culture or identification of the fungus in tissue lesions. In addition, serologic tests for antibodies and antigen are also available. Antigen detection in body fluids is most useful in the early stages, because antibodies are formed 2 to 6 weeks after infection.[134]

Blastomycosis

Blastomyces dermatitidis is a soil-inhabiting, dimorphic fungus that is remarkably difficult to isolate. It is a cause of disease in people living in or visiting the central and southeastern United States; infection also occurs in Canada, Mexico, the Middle East, Africa, and India. *There are three clinical forms: pulmonary blastomycosis, disseminated blastomycosis, and a rare primary cutaneous* form that results from direct inoculation of organisms into the skin. Pulmonary blastomycosis most often presents as an abrupt illness with productive cough, headache, chest pain, weight loss, fever, abdominal pain, night sweats, chills, and anorexia. Chest radiographs reveal lobar consolidation, multilobar infiltrates, perihilar infiltrates, multiple nodules, or miliary infiltrates. The upper lobes are most frequently involved. The process may resolve spontaneously, persist, or progress to a chronic lesion.

Morphology. In the normal host the lung lesions of blastomycosis are suppurative granulomas. Macrophages have a limited ability to ingest and kill *B. dermatitidis*, and the persistence of the yeast cells leads to continued recruitment of neutrophils. In tissue, *B. dermatitidis* is a round, 5- to 15-µm yeast cell that divides by broad-based budding. It has a thick, double -contoured cell wall and multiple nuclei (Fig. 15-37). Involvement of the skin and larynx is associated with marked epithelial hyperplasia, which may be mistaken for squamous cell carcinoma.

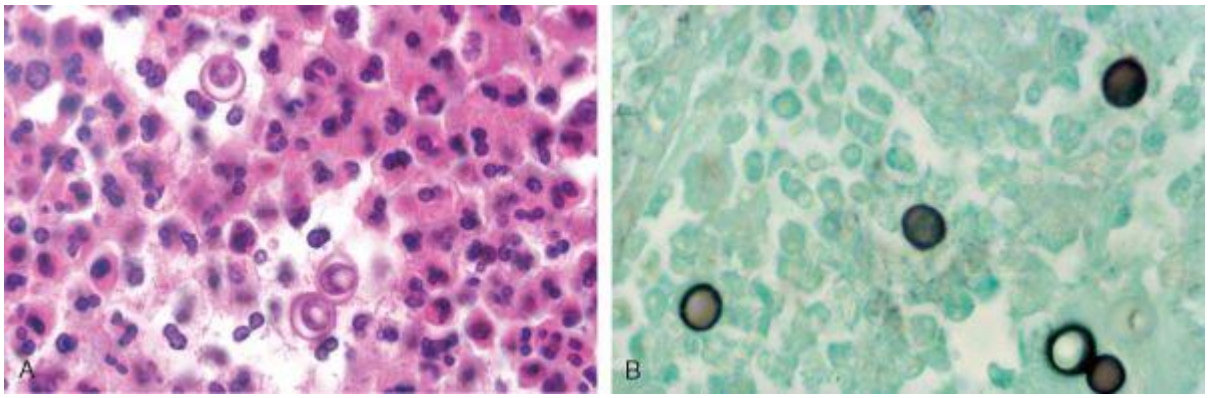

FIGURE 15-37 Blastomycosis. **A**, Rounded budding yeasts, larger than neutrophils, are present. Note the characteristic thick wall and nuclei (not seen in other fungi). **B**, Silver stain.

Coccidioidomycosis

Almost everyone who inhales the spores of *Coccidioides immitis* becomes infected and develops a delayed-type hypersensitivity to the fungus, so more than 80% of people in endemic areas of the southwestern and western United States have a positive skin test reaction. One reason for the high rate of infectivity by *C. immitis* is that infective arthroconidia, when ingested by alveolar macrophages, block fusion of the phagosome and lysosome and so resist intracellular killing. As is the case with *Histoplasma*, most primary infections with *C. immitis* are asymptomatic, but 10% of people have lung lesions, fever, cough, and pleuritic pains, accompanied by erythema nodosum or erythema multiforme (the San Joaquin Valley fever complex). Less than 1% of people develop disseminated *C. immitis* infection, which frequently involves the skin and meninges.

Morphology. The primary and secondary lung lesions of *C. immitis* are similar to the granulomatous lesions of *Histoplasma*. Within macrophages or giant cells, *C. immitis* is present as thick-walled, nonbudding spherules 20 to 60 μm in diameter, often filled with small endospores. A pyogenic reaction is superimposed when the spherules rupture to release the endospores (Fig. 15-38). Rare progressive *C. immitis* disease involves the lungs, meninges, skin, bones, adrenals, lymph nodes, spleen, or liver. At all these sites, the inflammatory response may be purely granulomatous, pyogenic, or mixed. Purulent lesions dominate in patients with diminished resistance and with widespread dissemination.

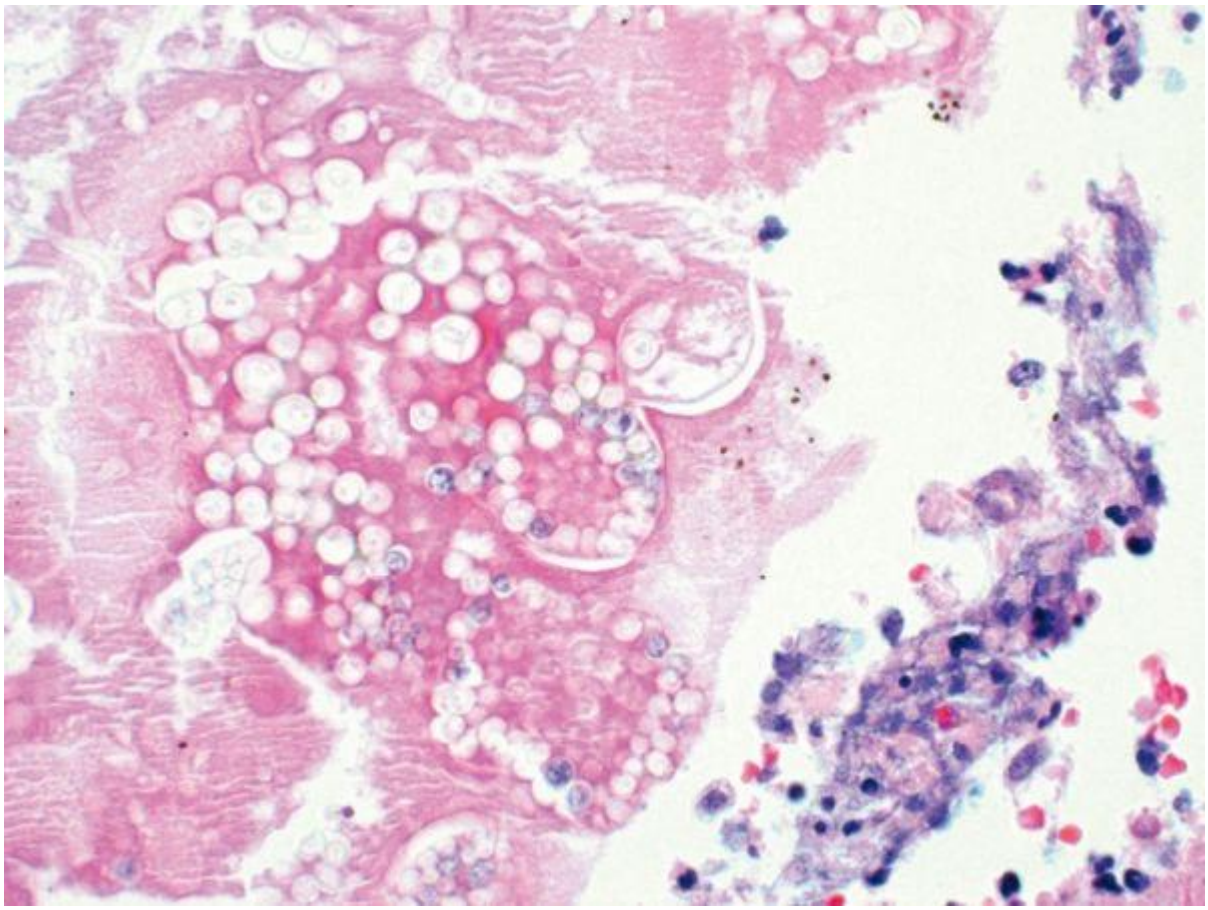

FIGURE 15-38 Coccidioidomycosis with intact and ruptured spherules.

PNEUMONIA IN THE IMMUNOCOMPROMISED HOST

The appearance of a pulmonary infiltrate, with or without signs of infection (e.g., fever), is one of the most common and serious complications in patients whose immune defenses are suppressed by disease, immunosuppressive therapy for organ transplants, chemotherapy for tumors, or irradiation.[135] A wide variety of so-called opportunistic infectious agents, many of which rarely cause infection in normal hosts, can cause these pneumonias, and often more than one agent is involved. Mortality from these opportunistic infections is high. Table 15-9 lists some of the opportunistic agents according to their prevalence and whether they cause local or diffuse pulmonary infiltrates. The differential diagnosis of such infiltrates includes drug reactions and involvement of the lung by tumor. The specific infections are discussed in Chapter 8 . Of these, the ones that commonly involve the lung can be classified according to the etiologic agent: (1) bacteria (*P. aeruginosa*, *Mycobacterium* species, *L. pneumophila*, and *Listeria monocytogenes*), (2) viruses (cytomegalovirus [CMV] and herpesvirus), and (3) fungi (*P. jiroveci*, *Candida* species, *Aspergillus* species, the Phycomycetes, and *Cryptococcus neoformans*).

TABLE 15-9 -- Causes of Pulmonary Infiltrates in Immunocompromised Hosts

Diffuse Infiltrate	Focal Infiltrate
COMMON	
Cytomegalovirus	Gram-negative rods

Diffuse Infiltrate	Focal Infiltrate
Pneumocystis jiroveci	*Staphylococcus aureus*
Drug reaction	*Aspergillus*
	Candida
	Malignancy
UNCOMMON	
Bacteria	*Cryptococcus*
Aspergillus	*Mucor*
Cryptococcus	*Pneumocystis jiroveci*
Malignancy	*Legionella pneumophila*

PULMONARY DISEASE IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Pulmonary disease continues to be the leading cause of morbidity and mortality in HIV-infected individuals. Although the use of potent antiretroviral agents and effective chemoprophylaxis has markedly altered the incidence and outcome of pulmonary disease in HIV-infected persons, the plethora of infectious agents and other pulmonary lesions make diagnosis and treatment a distinct challenge. Some of the individual microbial agents afflicting HIV-infected individuals have already been discussed; this section will focus only on the general principles of HIV-associated pulmonary disease.

- Despite the emphasis on “opportunistic” infections, it must be remembered that bacterial lower respiratory tract infection caused by the “usual” pathogens is one of the most serious pulmonary disorders in HIV infection. The implicated organisms include *S. pneumoniae, S. aureus, H. influenzae*, and gram-negative rods. Bacterial pneumonias in HIV-infected persons are more common, more severe, and more often associated with bacteremia than in those without HIV infection.
- Not all pulmonary infiltrates in HIV-infected individuals are infectious in etiology. A host of noninfectious diseases, including Kaposi sarcoma (Chapters 6 and 11 , pulmonary non-Hodgkin lymphoma (Chapter 13), and primary lung cancer, occur with increased frequency and must be excluded.
- *The CD4+ T-cell count can define the risk of infection with specific organisms*. As a rule of thumb, bacterial and tubercular infections are more likely at higher CD4+ counts (>200 cells/mm^3). *Pneumocystis* pneumonia usually strikes at CD4+ counts below 200 cells/mm^3, while cytomegalovirus and *Mycobacterium avium* complex infections are uncommon until the very late stages of immunosuppression (CD4+ counts <50 cells/mm^3).

Finally, it is useful to remember that pulmonary disease in HIV-infected persons may result from more than one cause, and even common pathogens may present with atypical manifestations. Therefore, the diagnostic work-up of these patients may be more extensive (and expensive) than would be necessary in an immunocompetent individual.

3.5.10 Lung Transplantation

Indications for transplantation may include almost all non-neoplastic terminal lung diseases, provided that the patient does not have any other serious disease, which would preclude lifelong immunosuppressive therapy. *The most common indications are end-stage emphysema, idiopathic pulmonary fibrosis, cystic fibrosis, and idiopathic/familial pulmonary arterial hypertension*. While bilateral lung and heart-lung transplants are possible, in many cases a single-lung transplant is performed, offering sufficient improvement in pulmonary function for each of two recipients from a single (and all too scarce) donor. When bilateral chronic infection is present (e.g., cystic fibrosis, bronchiectasis), both lungs of the recipient must be replaced to remove the reservoir of infection.

Morphology. With improving surgical and organ preservation techniques, postoperative complications (e.g., anastomotic dehiscence, vascular thrombosis, primary graft dysfunction) are fortunately becoming rare. The transplanted lung is subject to two major complications: infection and rejection.

Pulmonary infections in lung transplant patients are essentially those of any immunocompromised host, discussed earlier. In the early post-transplant period (the first few weeks), bacterial infections are most common. With ganciclovir prophylaxis and matching of donor-recipient CMV status, CMV pneumonia occurs less frequently and is less severe, although some resistant strains are emerging. Most infections occur in the third to twelfth month after transplantation. *Pneumocystis jiroveci* pneumonia is rare, since almost all patients receive adequate prophylaxis, usually with Bactrim (trimethoprimsulfamethoxazole). Fungal infections are mostly due to *Candida* and *Aspergillus* species, and they involve the bronchial anastomotic site and/or the lung.

Acute rejection of the lung occurs to some degree in all patients despite routine immunosuppression. It often occurs during the early weeks to months after surgery but may occur years later whenever immunosuppression is decreased. Patients present with fever, dyspnea, cough, and radiologic infiltrates. Since these are similar to the picture of infections, diagnosis often relies on transbronchial biopsy. The morphologic features of acute rejection are primarily those of inflammatory infiltrates (lymphocytes, plasma cells, and few neutrophils and eosinophils), either around small vessels, in the submucosa of airways, or both.[136]

Chronic rejection is a significant problem in at least half of all lung transplant patients by 3 to 5 years. It is manifested by cough, dyspnea, and an irreversible decrease in lung function tests. The major morphologic correlate of chronic rejection is **bronchiolitis obliterans**, the partial or complete occlusion of small airways by fibrosis, with or without active inflammation (Fig. 15-39). Bronchiolitis obliterans is patchy and therefore difficult to diagnose via transbronchial biopsy. Bronchiectasis and pulmonary fibrosis may develop in long-standing cases.

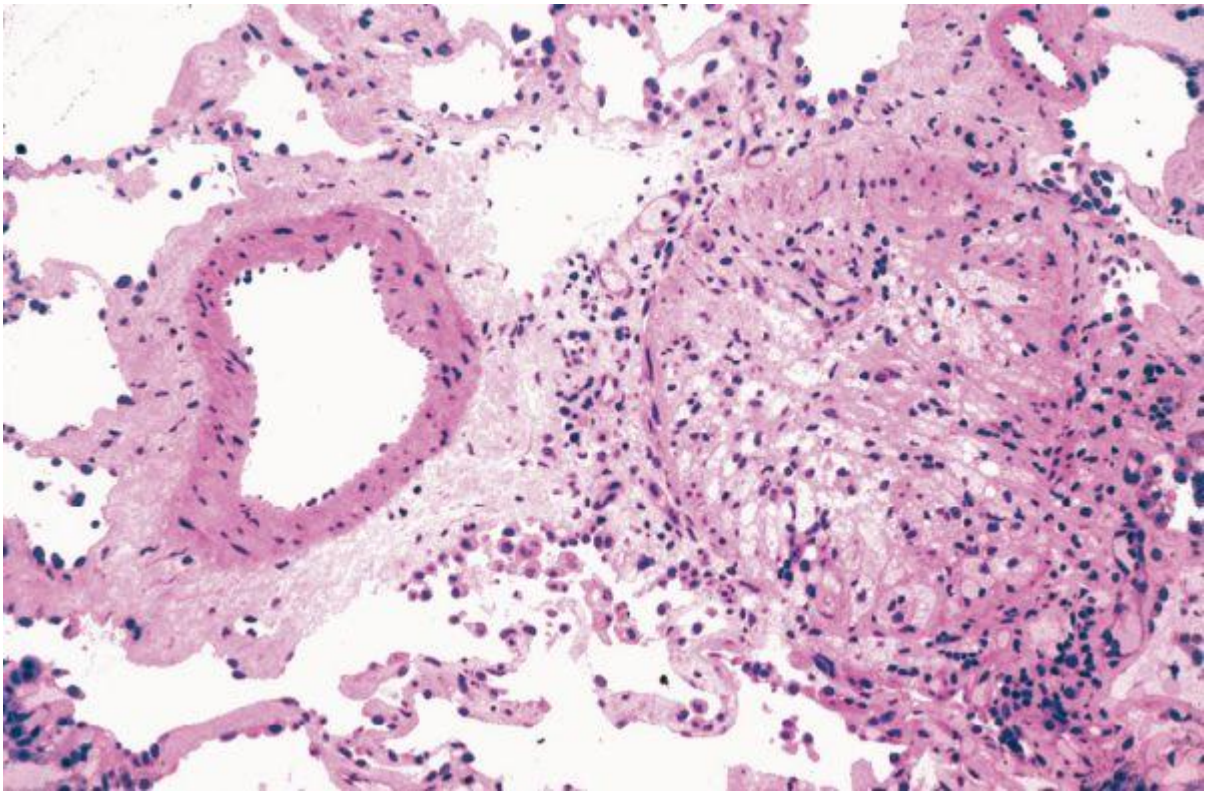

FIGURE 15-39 Chronic rejection of lung allograft, with total occlusion of bronchiole (bronchiolitis obliterans). Adjacent pulmonary artery branch is normal. *(Courtesy of Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, IL.)*

Acute cellular airway rejection (the presumed forerunner of later, fibrous obliteration of these airways) is generally responsive to therapy, but the treatment of established bronchiolitis obliterans has been disappointing. Its progress may be slowed or even halted for some time, but it cannot be reversed. Infrequent complications of lung transplantation include accelerated pulmonary arteriosclerosis in the graft and lymphoproliferative disease. With continuing improvement in surgical, immunosuppressive, and antimicrobial therapies, the short-term outcome of lung transplantation has improved considerably, although it is still not as good as that for renal or cardiac transplantation. One-, five-, and ten-year survival rates are 78%, 50%, and 26%, respectively.[137]

3.5.11 Tumors

A variety of benign and malignant tumors may arise in the lung, but 90% to 95% are carcinomas, about 5% are bronchial carcinoids, and 2% to 5% are mesenchymal and other miscellaneous neoplasms.[60]

CARCINOMAS

Lung cancer is currently the most frequently diagnosed major cancer in the world and the most common cause of cancer mortality worldwide. This is largely due to the carcinogenic effects of cigarette smoke. Over the coming decades, changes in smoking habits will greatly influence lung cancer incidence and mortality as well as the prevalence of various histologic types of lung cancer.[138]

The number of new cases of lung cancer occurring in 2008 in the United States is estimated to be 215,020 (note that in 1950 it was 18,000), accounting for about 15% of cancer diagnoses and 29% of cancer-related deaths. The annual number of deaths from lung cancer in the United States is estimated to be 161,840 in 2008.[139] Since the early 1990s lung cancer incidence and mortality rates have been decreasing in men, most likely from the decreased smoking rates over the past 30 years. However, decreases in smoking patterns among women lag behind those of men. Since 1987 more women have died each year of lung cancer than of breast cancer, which for over 40 years had been the major cause of cancer death in women. Cancer of the lung occurs most often between ages 40 and 70 years, with a peak incidence in the 50s or 60s. Only 2% of all cases appear before the age of 40. The outlook for individuals diagnosed with lung cancer is dismal. The 1-year survival rate has increased from 34% in 1975 to 41% in 2007, largely because of improvements in surgical techniques. However, the 5-year rate for all stages combined is only 16%.

Etiology and Pathogenesis.

Most carcinomas of the lung, similar to cancer at other sites, arise by a stepwise accumulation of genetic abnormalities that transform benign bronchial epithelium to neoplastic tissue. Unlike many other cancers, however, the major environmental insult that inflicts genetic damage is known. We begin our discussion with the well-known lung carcinogen—cigarette smoke.

Tobacco Smoking.

The evidence provided by statistical and clinical observations establishing a positive relationship between tobacco smoking and lung cancer is overwhelming. Experimental data have also been pursued, but this approach is limited by species differences.

Statistical evidence is most compelling: 87% of lung carcinomas occur in active smokers or those who stopped recently. In numerous retrospective studies, there was an invariable statistical association between the frequency of lung cancer and (1) *the amount of daily smoking*, (2) *the tendency to inhale*, and (3) *the duration of the smoking habit*. Compared with nonsmokers, average smokers of cigarettes have a tenfold greater risk of developing lung cancer, and heavy smokers (more than 40 cigarettes per day for several years) have a 60-fold greater risk. Women have a higher susceptibility to tobacco carcinogens than men do. Cessation of smoking for 10 years reduces risk but never to control levels. It should be noted, however, that despite compelling evidence supporting the role of cigarette smoking, only 11% of heavy smokers develop lung cancer in their lifetime. Clearly, there are other (genetic) factors involved as will be discussed later. Epidemiologic studies also show an association between cigarette smoking and carcinoma of the mouth, pharynx, larynx, esophagus, pancreas, uterine cervix, kidney, and urinary bladder. *Secondhand smoke*, or environmental tobacco smoke, contains numerous human carcinogens for which there is no safe level of exposure. It is estimated that each year about 3000 nonsmoking adults die of lung cancer as a result of breathing secondhand smoke.[140] Cigar and pipe smoking also increase risk, although much more modestly than smoking cigarettes. The use of smokeless tobacco is not a safe substitute for smoking cigarettes or cigars, as these products cause oral cancers and can lead to nicotine addiction.

Clinical evidence is obtained largely through observations of histologic changes in the lining epithelium of the respiratory tract in habitual smokers. These sequential changes have been best documented for squamous cell carcinoma, but they may also be present in other histologic subtypes. In essence, there is a linear correlation between the intensity of exposure to cigarette smoke and the appearance of ever more worrisome epithelial changes that begin with squamous metaplasia and progress to squamous dysplasia, carcinoma in situ, and invasive carcinoma. Lung tumors of smokers frequently contain a typical, though not specific, molecular fingerprint in the form of G : C > T : A mutations in the *p53* gene that are probably caused by benzo[*a*]pyrene, one of the many carcinogens in tobacco smoke.[138]

Experimental work has consisted mainly of attempts to induce cancer in experimental animals with extracts of tobacco smoke.[141] More than 1200 substances have been counted in cigarette smoke, many of which are potential carcinogens. They include both initiators (polycyclic aromatic hydrocarbons such as benzo[*a*]pyrene) and promoters, such as phenol derivatives. Radioactive elements may also be found (polonium-210, carbon-14, and potassium-40) as well as other contaminants, such as arsenic, nickel, molds, and additives. Protracted exposure of mice to these additives induces skin tumors. Efforts to produce lung cancer by exposing animals to tobacco smoke, however, have been unsuccessful. The few cancers that have developed have been bronchioloalveolar carcinomas, a type of tumor that is not strongly associated with smoking in humans.

Industrial Hazards.

Certain industrial exposures increase the risk of developing lung cancer. High-dose ionizing *radiation* is carcinogenic. There was an increased incidence of lung cancer among survivors of the Hiroshima and Nagasaki atomic bomb blasts. *Uranium* is weakly radioactive, but lung cancer rates among nonsmoking uranium miners are four times higher than those in the general population, and among smoking miners they are about 10 times higher.

The risk of lung cancer is increased with *asbestos*. Lung cancer is the most frequent malignancy in individuals exposed to asbestos, particularly when coupled with smoking.[80] Asbestos workers who do not smoke have a five times greater risk of developing lung cancer than do nonsmoking control subjects, and those who smoke have a 50 to 90 times greater risk. The latent period before the development of lung cancer is 10 to 30 years.

Air Pollution.

Atmospheric pollutants may play some role in the increased incidence of lung carcinoma today. Attention has been drawn to the potential problem of *indoor* air pollution, especially by radon.[142,][143] Radon is a ubiquitous radioactive gas that has been linked epidemiologically to increased lung cancer in miners exposed to relatively high concentrations. The pathogenic mechanism is believed to be inhalation and bronchial deposition of radioactive decay products that become attached to environmental aerosols. These data have generated concern that low-level indoor exposure (e.g., in homes in areas of high radon in soil) could also lead to increased incidence of lung tumors; some attribute the bulk of lung cancers in nonsmokers to this insidious carcinogen (Chapter 9).[144]

Molecular Genetics.

Ultimately, the exposures cited previously are thought to act by causing genetic alterations in lung cells, which accumulate and eventually lead to the neoplastic phenotype. It has been estimated that 10 to 20 genetic mutations have occurred by the time the tumor is clinically apparent.[145]

As will be discussed below, for all practical purposes lung cancers can be divided into two clinical subgroups: *small cell carcinoma* and *non-small cell carcinoma*. Some molecular lesions are common to both types, whereas others are relatively specific. The dominant oncogenes that are frequently involved in lung cancer include *c-MYC*, *KRAS*, *EGFR*, *c-MET*, and *c-KIT*. The commonly deleted or inactivated tumor suppressor genes include *p53*, *RB1*, *p16(INK4a)*, and multiple loci on chromosome 3p. At this locale there are numerous candidate tumor suppressor genes, such as *FHIT*, *RASSF1A*, and others that remain to be identified. Of the various cancer associated genes, *C-KIT* (40–70%), *MYCN* and *MYCL* (20–30%), p53 (90%), 3p (100%), RB (90%), and *BCL2* (75–90%) are most commonly involved in small cell lung carcinoma. By comparison, *EGFR* (25%), *KRAS* (10–15%), *p53* (50%), *p16 INK4a* (70%) are the ones most commonly affected in non-small cell lung carcinoma. In addition recent studies show that *LKB1*, *PTEN*, and *TSC*, all relating to the m-TOR pathway are also mutated in up to 30% of

lung cancers (mostly non-small cell lung carcinoma).[146] It should be noted that *C-KIT* is over expressed but only rarely mutated. Hence, drugs that target its tyrosine kinase domain (such as imatinib) are ineffective. Recall that in tumors with mutation of that kinase domain (e.g., gastrointestinal stromal tumor) this drug is useful for treatment. *Telomerase* activity is increased in over 80% of lung tumor tissues.

There are several signal transduction molecules that are activated in lung cancer, such as AKT, phosphatidylinositol-3-kinase, ERK1/2, STAT5, and focal adhesion proteins such as paxillin. Although certain genetic changes are known to be early (inactivation of chromosome 3p suppressor genes) or late (activation of *KRAS*), the temporal sequence is not yet well defined. More importantly, certain genetic changes such as loss of chromosome 3p material can be found in benign bronchial epithelium of individuals with lung cancer, as well as in the respiratory epithelium of smokers without lung cancers, suggesting that large areas of the respiratory mucosa are mutagenized after exposure to carcinogens ("field effect").[147] On this fertile soil, the cells that accumulate additional mutations ultimately develop into cancer.

Occasional *familial clustering* has suggested a genetic predisposition, as has the variable risk even among heavy smokers. Attempts at defining markers of genetic susceptibility are ongoing and have, for example, identified a role for polymorphisms in the cytochrome P-450 gene *CYP1A1* (Chapter 7).[148] People with certain alleles of *CYP1A1* have an increased capacity to metabolize procarcinogens derived from cigarette smoke and, conceivably, incur the greatest risk of developing lung cancer. Similarly, individuals whose peripheral blood lymphocytes undergo chromosomal breakages following exposure to tobacco-related carcinogens (mutagen sensitivity genotype) have a greater than tenfold risk of developing lung cancer compared with controls. In addition, large scale linkage studies point to an autosomal susceptibility locus on 6q23-25. More recently, genome-wide association studies have revealed an intriguing link to polymorphisms in the nicotine acetylcholine receptor gene located on chromosome 15q25 and lung cancer in both smokers and nonsmokers.[149]

It should also be pointed out that 25% of lung cancers worldwide arise in nonsmokers and these are pathogenetically distinct. They occur more commonly in women, and most are adenocarcinomas. They tend to have *EGFR* mutations, almost never have *KRAS* mutations and *p53* mutations, although common, occur less commonly. The nature of the *p53* mutations are also distinct.[150]

Precursor Lesions.

Three types of precursor epithelial lesions are recognized: (1) squamous dysplasia and carcinoma in situ, (2) atypical adenomatous hyperplasia, and (3) diffuse idiopathic pulmonary neuroendocrine cell hyperplasia. It should be noted that the term *precursor* does not imply that progression to cancer will occur in all cases. Currently it is not possible to distinguish between precursor lesions that progress and those that remain localized or regress.

Classification.

Tumor classification is important for consistency in patient treatment and because it provides a basis for epidemiologic and biologic studies. The most recent classification of the World Health Organization[138] has gained wide acceptance (Table 15-10). Several histologic variants of each type of lung cancer are described; however, their clinical significance is still undetermined, except as mentioned below. The relative proportions of the major categories are[151]:

- Adenocarcinoma (males 37%, females 47%)
- Squamous cell carcinoma (males 32%, females 25%)

- Small cell carcinoma (males 14%, females 18%)
- Large cell carcinoma (males 18%, females 10%)

TABLE 15-10 -- Histologic Classification of Malignant Epithelial Lung Tumors

Squamous cell carcinoma
Small-cell carcinoma
Combined small-cell carcinoma
Adenocarcinoma
Acinar; papillary, bronchioloalveolar, solid, mixed subtypes
Large-cell carcinoma
Large-cell neuroendocrine carcinoma
Adenosquamous carcinoma
Carcinomas with pleomorphic, sarcomatoid, or sarcomatous elements
Carcinoid tumor
Typical, atypical
Carcinomas of salivary gland type
Unclassified carcinoma

The incidence of adenocarcinoma has increased significantly in the last two decades; it is now the most common form of lung cancer in women and, in many studies, men as well.[152] The basis for this change is unclear. A possible factor is the increase in women smokers, but this only highlights our lack of knowledge about why women tend to develop more adenocarcinomas. One interesting postulate is that changes in cigarette type (filter tips, lower tar and nicotine) have caused smokers to inhale more deeply and thereby expose more peripheral airways and cells (with a predilection to adenocarcinoma) to carcinogens.[153] There may be *mixtures of histologic patterns*, even in the same cancer. Thus, combined types of squamous cell carcinoma and adenocarcinoma or of small-cell and squamous cell carcinoma occur in about 10% of patients. For common clinical use, however, the various histologic types of lung cancer can be clustered into two groups on the basis of likelihood of metastases and response to available therapies: *small cell carcinomas* (almost always metastatic, high initial response to chemotherapy) versus *non-small cell carcinomas* (less often metastatic, less responsive). The strongest relationship to smoking is with squamous cell and small cell carcinoma.

Morphology. Lung carcinomas arise most often in and about the hilus of the lung. About three fourths of the lesions take their origin from first-order, second-order, and third-order bronchi. An increasing number of primary carcinomas of the lung arise in the periphery of the lung from the alveolar septal cells or terminal bronchioles. These are predominantly adenocarcinomas, including those of the bronchioloalveolar type, to be discussed separately.

The preneoplastic lesions that antedate, and usually accompany, invasive squamous cell carcinoma are well characterized. Squamous cell carcinomas are often preceded for years by **squamous metaplasia or dysplasia** in the bronchial epithelium, which then transforms to **carcinoma in situ**, a phase that may last for several years (Fig. 15-40). By this time, atypical cells may be identified in cytologic smears of sputum or in bronchial lavage fluids or brushings, although the lesion is

asymptomatic and undetectable on radiographs. Eventually, the growing neoplasm reaches a symptomatic stage, when a well-defined tumor mass begins to obstruct the lumen of a major bronchus, often producing distal atelectasis and infection. The tumor may then follow a variety of paths. It may continue to fungate into the bronchial lumen to produce an intraluminal mass. It can also rapidly penetrate the wall of the bronchus to infiltrate along the peribronchial tissue (Fig. 15-41) into the adjacent region of the carina or mediastinum. In other instances, the tumor grows along a broad front to produce a cauliflower-like intraparenchymal mass that appears to push lung substance ahead of it. In almost all patterns the neoplastic tissue is gray-white and firm to hard. Especially when the tumors are bulky, focal areas of hemorrhage or necrosis may appear to produce red or yellow-white mottling and softening. Sometimes these necrotic foci cavitate. Often these tumors erode the bronchial epithelium and can be diagnosed by cytologic examination of sputum, bronchoalveolar lavage fluid, or fine-needle aspiration (Fig. 15-42).

Extension may occur to the pleural surface and then within the pleural cavity or into the pericardium. Spread to the tracheal, bronchial, and mediastinal nodes can be found in most cases. The frequency of nodal involvement varies slightly with the histologic pattern but averages greater than 50%.

Distant spread of lung carcinoma occurs through both lymphatic and hematogenous pathways. These tumors often spread early throughout the body except for squamous cell carcinoma, which metastasizes outside the thorax late. Metastasis may be the first manifestation of an underlying occult pulmonary lesion. No organ or tissue is spared in the spread of these lesions, but the adrenals, for obscure reasons, are involved in more than half the cases. The liver (30% to 50%), brain (20%), and bone (20%) are additional favored sites of metastases.

Adenocarcinoma. This is a malignant epithelial tumor with glandular differentiation or mucin production by the tumor cells. Adenocarcinomas grow in various patterns, including acinar, papillary, bronchioloalveolar, and solid with mucin formation. Of these, only pure bronchioloalveolar carcinoma has distinct gross, microscopic, and clinical features and will be discussed separately.

Adenocarcinoma is the most common type of lung cancer in women and nonsmokers. As compared with squamous cell cancers, the lesions are usually more peripherally located, and tend to be smaller. They vary histologically from well-differentiated tumors with obvious glandular elements (Fig. 15-43A) to papillary lesions resembling other papillary carcinomas to solid masses with only occasional mucin-producing glands and cells. The majority are positive for thyroid transcription factor-1 (TTF-1) and about 80% contain mucin. At the periphery of the tumor there is often a bronchioloalveolar pattern of spread (see below). Adenocarcinomas grow more slowly than squamous cell carcinomas but tend to metastasize widely and earlier. Peripheral adenocarcinomas with a small central invasive component associated with scarring and a predominantly peripheral bronchioloalveolar growth pattern may have a better outcome than invasive carcinomas of the same size. Adenocarcinomas, including bronchioloalveolar carcinomas, are less frequently associated with a history of smoking (still, greater than 75% are found in smokers) than are squamous or small cell carcinomas (>98% in smokers).

KRAS mutations occur primarily in adenocarcinoma, and are seen at a much lower frequency in nonsmokers (5%) than in smokers (30%). *p53*, *RB1*, and *p16* mutations and inactivation have the same frequency in adenocarcinoma as in squamous cell carcinoma. Mutations and amplifications in the epidermal growth factor receptor gene (*EGFR*) occur in patients with adenocarcinoma (mostly women, nonsmokers, and those of Asian origin).[154] A prospective trial has demonstrated that patients with *EGFR* mutations have improved survival with upfront EGFR inhibitor treatment. *KRAS* mutations highly correlate with worse outcome and resistance to EGFR inhibitors. [154] Also, c-*MET* can be amplified or mutated in lung cancer, for which targeted therapies are being developed.

As the name implies, **bronchioloalveolar carcinoma** occurs in the pulmonary parenchyma in the terminal bronchioloalveolar regions. It represents, in various series, 1% to 9% of all lung cancers. Macroscopically, the tumor almost always occurs in the peripheral portions of the lung either as a single nodule or, more often, as multiple diffuse nodules that sometimes coalesce to produce a pneumonia-like consolidation. The parenchymal nodules have a mucinous, gray translucence when secretion is present but otherwise appear as solid, gray-white areas that can be confused with pneumonia on gross inspection.

Histologically, the tumor is characterized by a pure bronchioloalveolar growth pattern with no evidence of stromal, vascular, or pleural invasion. The key feature of bronchioloalveolar carcinomas is their growth along preexisting structures without destruction of alveolar architecture. This growth pattern has been termed *lepidic*, an allusion to the neoplastic cells resembling butterflies sitting on a fence. It has two subtypes: nonmucinous and mucinous. The former has columnar, peg-shaped, or cuboidal cells, while the latter has distinctive, tall, columnar cells with cytoplasmic and intra-alveolar mucin, growing along the alveolar septa (Fig. 15-44). Ultrastructurally, bronchioloalveolar carcinomas are a heterogeneous group, consisting of mucin-secreting bronchiolar cells, Clara cells, or, rarely, type II pneumocytes.[155]

Nonmucinous bronchioloalveolar carcinomas often consist of a peripheral lung nodule with only rare aerogenous spread and therefore are amenable to surgical resection with an excellent 5-year survival. Mucinous bronchioloalveolar carcinomas, on the other hand, tend to spread aerogenously, forming satellite tumors. These may present as a solitary nodule or as multiple nodules, or an entire lobe may be consolidated by tumor, resembling lobar pneumonia and thus are less likely to be cured by surgery.

Analogous to the adenoma-carcinoma sequence in the colon, it is proposed that adenocarcinoma of the lung arises from **atypical adenomatous hyperplasia progressing to bronchioloalveolar carcinoma**, which then transforms into invasive adenocarcinoma. This is supported by the observation that lesions of atypical adenomatous hyperplasia are monoclonal and they share many molecular aberrations such as *EGFR* mutations with nonmucinous bronchioloalveolar carcinomas and with invasive adenocarcinomas.[156] Microscopically, atypical adenomatous hyperplasia is recognized as a well-demarcated focus of epithelial proliferation composed of cuboidal to low columnar epithelium (Fig. 15-45). These cells demonstrate some cytologic atypia but not to the extent seen in frank adenocarcinoma. It should be pointed out, however, that not all adenocarcinomas arise in this manner, nor do all bronchioloalveolar carcinomas become invasive if left untreated.

***Squamous Cell Carcinoma*.** Squamous cell carcinoma is most commonly found in men and is **closely correlated with a smoking history**. Histologically, this tumor is characterized by the presence of keratinization and/or intercellular bridges. Keratinization may take the form of squamous pearls or individual cells with markedly eosinophilic dense cytoplasm (see Fig. 15-43B). These features are prominent in the well-differentiated tumors, are easily seen but not extensive in moderately differentiated tumors, and are focally seen in poorly differentiated tumors. Mitotic activity is higher in poorly differentiated tumors. In the past, most squamous cell carcinomas were seen to arise centrally from the segmental or subsegmental bronchi. However, the incidence of squamous cell carcinoma of the peripheral lung is increasing. Squamous metaplasia, epithelial dysplasia, and foci of frank carcinoma in situ may be seen in bronchial epithelium adjacent to the tumor mass (see Fig. 15-40).

Squamous cell carcinomas show the highest frequency of *p53* mutations of all histologic types of lung carcinoma. p53 protein overexpression and, less commonly, mutations may precede invasion. Abnormal p53 accumulation is reported in 10% to 50% of dysplasias. There is increasing frequency and intensity of p53 immunostaining with higher grade dysplasia, and positivity can be seen in 60% to 90% of squamous cell carcinoma in situ. Loss of protein expression of the tumor suppressor gene

RB1 is detected by immunohistochemistry in 15% of squamous cell carcinomas. The cyclin-dependent kinase inhibitor *p16(INK4a)* is inactivated, and its protein product is lost in 65% of tumors. Multiple allelic losses are observed in squamous cell carcinomas at locations bearing tumor suppressor genes. These losses, especially those involving 3p, 9p, and 17p, may precede invasion and be detected in histologically normal cells in smokers. Overexpression of EGFR has been detected in 80% of squamous cell carcinomas, but it is rarely mutated. HER-2/NEU is highly expressed in 30% of these cancers, but unlike in breast cancer, gene amplification is not the underlying mechanism.[157]

***Small Cell Carcinoma*.** This highly malignant tumor has a distinctive cell type. The epithelial cells are relatively small, with scant cytoplasm, ill-defined cell borders, finely granular nuclear chromatin (salt and pepper pattern), and absent or inconspicuous nucleoli (see Fig. 15-43C). The cells are round, oval, or spindle-shaped, and nuclear molding is prominent. There is no absolute size for the tumor cells, but in general they are smaller than three small resting lymphocytes. The mitotic count is high. The cells grow in clusters that exhibit neither glandular nor squamous organization. Necrosis is common and often extensive. Basophilic staining of vascular walls due to encrustation by DNA from necrotic tumor cells (Azzopardi effect) is frequently present. All small cell carcinomas are high grade. A single variant of small cell carcinoma is recognized: combined small cell carcinoma, in which there is a mixture of small cell carcinoma and any other non-small cell component, including large cell neuroendocrine carcinoma and sarcoma.

Electron microscopy shows dense-core neurosecretory granules, about 100 nm in diameter, in two thirds of cases. The granules are similar to those found in the neuroendocrine cells present along the bronchial epithelium, particularly in the fetus and neonate. Though distinctive, electron microscopy is not needed for diagnosis. The occurrence of neurosecretory granules, the ability of some of these tumors to secrete polypeptide hormones, and the presence of neuroendocrine markers such as chromogranin, synaptophysin, and CD57 (in 75% of cases) and parathormone-like and other hormonally active products suggest derivation of this tumor from neuroendocrine progenitor cells of the lining bronchial epithelium. This lung cancer type is most commonly associated with ectopic hormone production (discussed later).

Small cell carcinomas have a strong relationship to cigarette smoking; only about 1% occur in nonsmokers. They may arise in major bronchi or in the periphery of the lung. There is no known preinvasive phase or carcinoma in situ. They are the most aggressive of lung tumors, metastasize widely, and are virtually incurable by surgical means.

p53 and *RB1* tumor suppressor genes are frequently mutated (50% to 80% and 80% to 100% of small cell carcinomas, respectively). Immunohistochemistry demonstrates high levels of the anti-apoptotic protein BCL2 in 90% of tumors, in contrast with a low frequency of expression of the pro-apoptotic protein BAX.

***Large Cell Carcinoma*.** This is an undifferentiated malignant epithelial tumor that lacks the cytologic features of small-cell carcinoma and glandular or squamous differentiation. The cells typically have large nuclei, prominent nucleoli, and a moderate amount of cytoplasm (see Fig. 15-43D). Large cell carcinomas probably represent squamous cell carcinomas and adenocarcinomas that are so undifferentiated that they can no longer be recognized by light microscopy. Ultrastructurally, however, minimal glandular or squamous differentiation is common. One histologic variant is large cell neuroendocrine carcinoma. This is recognized by such features as organoid nesting, trabecular, rosette-like, and palisading patterns. These features suggest neuroendocrine differentiation, which can be confirmed by immunohistochemistry or electron microscopy. This tumor has the same molecular changes as small cell carcinoma.

***Combined Carcinoma*.** Approximately 10% of all lung carcinomas have a combined histology, including two or more of the above types.

Secondary Pathology.Lung carcinomas cause related anatomic changes in the lung substance distal to the point of bronchial involvement. **Partial obstruction may cause marked focal emphysema; total obstruction may lead to atelectasis**. The impaired drainage of the airways is a common cause for **severe suppurative or ulcerative bronchitis or bronchiectasis. Pulmonary abscesses** sometimes call attention to a silent carcinoma that has initiated the chronic suppuration. Compression or invasion of the superior vena cava can cause venous congestion and edema of the head and arm, and, ultimately, circulatory compromise—the **superior vena cava syndrome**. Extension to the pericardial or pleural sacs may cause **pericarditis** (Chapter 12) or **pleuritis** with significant effusions.

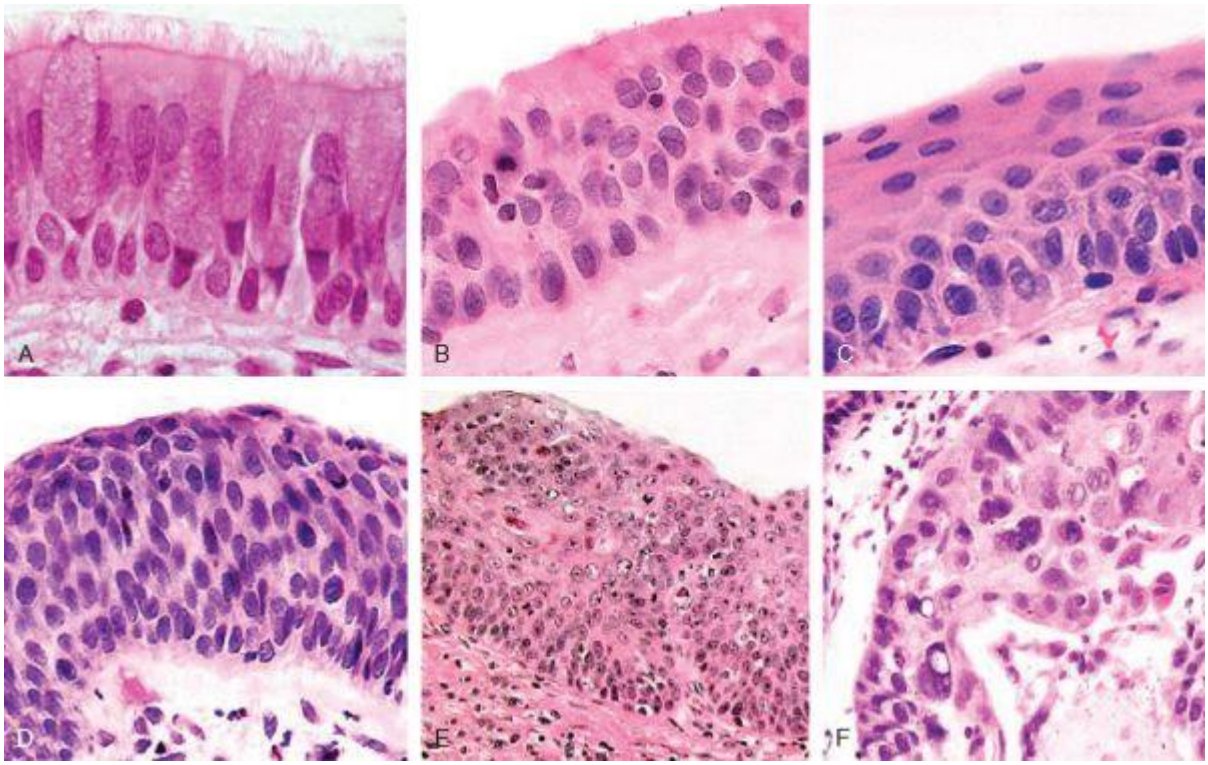

FIGURE 15-40 Precursor lesions of squamous cell carcinomas. Some of the earliest (and "mild") changes in smoking-damaged respiratory epithelium include goblet cell hyperplasia **(A)**, basal cell (or reserve cell) hyperplasia **(B)**, and squamous metaplasia **(C)**. More ominous changes include the appearance of squamous dysplasia **(D)**, characterized by the presence of disordered squamous epithelium, with loss of nuclear polarity, nuclear hyperchromasia, pleomorphism, and mitotic figures. Squamous dysplasia may, in turn, progress through the stages of mild, moderate, and severe dysplasia. Carcinoma-in-situ (CIS) **(E)** is the stage that immediately precedes invasive squamous carcinoma **(F)**, and apart from the lack of basement membrane disruption in CIS, the cytologic features are similar to those in frank carcinoma. Unless treated, CIS will eventually progress to invasive cancer. *(**A**–**E**, Courtesy of Dr. Adi Gazdar, Department of Pathology, University of Texas, Southwestern Medical School, Dallas. **F**, reproduced with permission from Travis WD, et al [eds]: World Health Organization Histological Typing of Lung and Pleural Tumors. Heidelberg, Springer, 1999.)*

Staging.

A uniform TNM system for staging cancer according to its anatomic extent at the time of diagnosis is extremely useful, chiefly for comparing treatment results from different centers (Table 15-11).

TABLE 15-11 -- International Staging System for Lung Cancer

T1	Tumor <3 cm without pleural or main stem bronchus involvement (T1a, <2 cm; T1b, 2–3 cm)
T2	Tumor 3–7 cm or involvement of main stem bronchus 2 cm from carina, visceral pleural involvement, or lobar atelectasis (T2a, 3–5 cm; T2b, 5–7 cm)
T3	Tumor >7 cm or one with involvement of chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, pericardium, main stem bronchus 2 cm from carina, or entire lung atelectasis, or separate tumor nodule(s) in the same lobe
T4	Tumor with invasion of mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina or separate tumor nodules in a different ipsilateral lobe
N0	No demonstrable metastasis to regional lymph nodes
N1	Ipsilateral hilar or peribronchial nodal involvement
N2	Metastasis to ipsilateral mediastinal or subcarinal lymph nodes

N3	Metastasis to contralateral mediastinal or hilar lymph nodes, ipsilateral or contralateral scalene, or supraclavicular lymph nodes
M0	No distant metastasis
M1	Distant metastasis (M1a, separate tumor nodule in contralateral lobe or pleural nodules or malignant pleural effusion; M1b, distant metastasis)

STAGE GROUPING			
Stage Ia	T1	N0	M0
Stage Ib	T2	N0	M0
Stage IIa	T1	N1	M0
Stage IIb	T2	N1	M0
	T3	N0	M0
Stage IIIa	T1–3	N2	M0
	T3	N1	M0
Stage IIIb	Any T	N3	M0
	T3	N2	M0
	T4	Any N	M0
Stage IV	Any T	Any N	M1

Clinical Course.

Lung cancer is one of the most insidious and aggressive neoplasms in the realm of oncology. In the usual case it is discovered in patients in their 50s whose symptoms are of several months' duration. *The major presenting complaints are cough* (75%), *weight loss* (40%), *chest pain* (40%), and *dyspnea* (20%). Some of the more common local manifestations of lung cancer and their pathologic bases are listed in Table 15-12 . Not infrequently the tumor is discovered by its secondary spread during the course of investigation of an apparent primary neoplasm elsewhere. Bronchioloalveolar carcinomas, by definition, are noninvasive tumors and do not metastasize; unless resected, they kill by suffocation.

TABLE 15-12 -- Local Effects of Lung Tumor Spread

Clinical Feature	Pathologic Basis
Pneumonia, abscess, lobar collapse	Tumor obstruction of airway
Lipoid pneumonia	Tumor obstruction; accumulation of cellular lipid in foamy macrophages
Pleural effusion	Tumor spread into pleura
Hoarseness	Recurrent laryngeal nerve invasion
Dysphagia	Esophageal invasion
Diaphragm paralysis	Phrenic nerve invasion
Rib destruction	Chest wall invasion
SVC syndrome	SVC compression by tumor
Horner syndrome	Sympathetic ganglia invasion
Pericarditis, tamponade	Pericardial involvement

SVC, superior vena cava.

The outlook is poor for most patients with lung carcinoma. Despite all efforts at early diagnosis by frequent radiologic examination of the chest, cytologic examination of sputum, and bronchial washings or brushings and the many improvements in thoracic surgery, radiation therapy, and chemotherapy, the overall 5-year survival rate is only 15%. In many large clinics, not more than 20% to 30% of lung cancer patients have lesions sufficiently localized to even permit resection. *In general, the adenocarcinoma and squamous cell patterns tend to remain localized longer and have a slightly better prognosis than do the undifferentiated cancers, which are usually advanced by the time they are discovered*. The survival rate is 48% for cases detected when the disease is still localized. Only 15% of lung cancers are diagnosed at this early stage, some of which can be cured by lobectomy or pneumonectomy. Late-stage disease is usually treated with palliative chemotherapy and/or radiation therapy. Treatment of patients with adenocarcinoma and activating mutations in *EGFR* with inhibitors of EGFR prolongs survival. Many tumors that recur carry new mutations that generate resistance to these inhibitors, proving that these drugs are "hitting" their target. In contrast, activating *KRAS* mutations appear to be associated with a worse prognosis, regardless of treatment, in an already grim disease. Untreated, the survival time for patients with small-cell carcinoma is 6 to 17 weeks. This cancer is particularly sensitive to radiation therapy and chemotherapy, and potential cure rates of 15% to 25% for limited disease have been reported in some centers. Most patients have distant metastases at diagnosis. Thus, even with treatment, the mean survival after diagnosis is only about 1 year.

Paraneoplastic Syndromes.

Lung carcinoma can be associated with several paraneoplastic syndromes[158] (Chapter 7), some of which may antedate the development of a detectablepulmonary lesion. The hormones or hormone-like factors elaborated include:

- *Antidiuretic hormone* (ADH), inducing hyponatremia due to inappropriate ADH secretion
- *Adrenocorticotropic hormone* (ACTH), producing Cushing syndrome
- *Parathormone*, *parathyroid hormone-related peptide*, *prostaglandin E*, *and some cytokines*, all implicated in the hypercalcemia often seen with lung cancer
- *Calcitonin*, causing hypocalcemia
- *Gonadotropins*, causing gynecomastia
- *Serotonin and bradykinin*, associated with the carcinoid syndrome

The incidence of clinically significant syndromes related to these factors ranges from 1% to 10% of all lung cancer patients, although a much higher proportion of patients show elevated serum levels of these (and other) peptide hormones. Any one of the histologic types of tumors may occasionally produce any one of the hormones, but tumors that produce *ACTH and ADH are predominantly small cell carcinomas, whereas those that produce hypercalcemia are mostly squamous cell tumors*. The carcinoid syndrome is more common with carcinoid tumors, described later, and is only rarely associated with small cell carcinoma. However, small cell carcinoma occurs much more commonly; therefore, one is much more likely to encounter carcinoid syndrome in these patients.

Other systemic manifestations of lung carcinoma include the *Lambert-Eaton myasthenic syndrome* (Chapter 27), in which muscle weakness is caused by auto-antibodies (possibly elicited by tumor ionic

channels) directed to the neuronal calcium channel[158]; *peripheral neuropathy*, usually purely sensory; dermatologic abnormalities, including *acanthosis nigricans* (Chapter 25); hematologic abnormalities, such as *leukemoid reactions*; and finally, a peculiar abnormality of connective tissue called *hypertrophic pulmonary osteoarthropathy*, associated with clubbing of the fingers.

Apical lung cancers in the superior pulmonary sulcus tend to invade the neural structures around the trachea, including the cervical sympathetic plexus, and produce a group of clinical findings that includes severe pain in the distribution of the ulnar nerve and *Horner syndrome* (enophthalmos, ptosis, miosis, and anhidrosis) on the same side as the lesion. Such tumors are also referred to as *Pancoast tumors*.

NEUROENDOCRINE PROLIFERATIONS AND TUMORS

The normal lung contains neuroendocrine cells within the epithelium as single cells or as clusters, the neuroepithelial bodies. While virtually all pulmonary neuroendocrine cell hyperplasias are secondary to airway fibrosis and/or inflammation, a rare disorder called diffuse idiopathic pulmonary neuroendocrine cell hyperplasia seems to be a precursor to the development of multiple tumorlets and typical or atypical carcinoids.

Neoplasms of neuroendocrine cells in the lung include benign *tumorlets*, small, inconsequential, hyperplastic nests of neuroendocrine cells seen in areas of scarring or chronic inflammation; *carcinoids*; and the (already discussed) highly aggressive small cell carcinoma and large cell neuroendocrine carcinoma of the lung. Neuroendocrine tumors are classified separately, since there are significant differences between them in incidence, clinical, epidemiologic, histologic, survival, and molecular characteristics. For example, in contrast to small cell and large cell neuroendocrine carcinomas, both typical and atypical carcinoids can occur in patients with multiple endocrine neoplasia type 1. Also note that neuroendocrine differentiation can be demonstrated by immunohistochemistry in 10% to 20% of lung carcinomas that do not show neuroendocrine morphology by light microscopy, the clinical significance of which is uncertain.

Carcinoid Tumors.

Carcinoid tumors represent 1% to 5% of all lung tumors. Most patients with these tumors are younger than 40 years of age, and the incidence is equal for both sexes. Approximately 20% to 40% of patients are nonsmokers. Carcinoid tumors are low-grade malignant epithelial neoplasms that are subclassified into *typical* and *atypical carcinoids*. Typical carcinoids have no *p53* mutations or abnormalities of *BCL2* and *BAX* expression, while atypical carcinoids show these changes in 20% to 40% and 10% to 20% of tumors, respectively. Some carcinoids also show loss of heterozygosity at 3p, 13q14 (*RB1*), 9p, and 5q22, which are found in all neuroendocrine tumors with increasing frequency from typical to atypical carcinoid to large cell neuroendocrine and small cell carcinoma.

Morphology. Carcinoids may arise centrally or may be peripheral. On gross examination, the central tumors grow as finger-like or spherical polypoid masses that commonly project into the lumen of the bronchus and are usually covered by an intact mucosa (Fig. 15-46A). They rarely exceed 3 to 4 cm in diameter. Most are confined to the main stem bronchi. Others, however, produce little intraluminal mass but instead penetrate the bronchial wall to fan out in the peribronchial tissue, producing the so-called **collar-button lesion**. Peripheral tumors are solid and nodular. Spread to local lymph nodes at the time of resection is more likely with atypical carcinoid.

Histologically, the tumor is composed of organoid, trabecular, palisading, ribbon, or rosette-like arrangements of cells separated by a delicate fibrovascular stroma. In common with the lesions of the gastrointestinal tract, the individual cells are quite regular and have uniform round nuclei and a

moderate amount of eosinophilic cytoplasm (see Fig. 15-46B). Typical carcinoids have fewer than two mitoses per ten high-power fields and lack necrosis, while atypical carcinoids have between two and ten mitoses per ten high-power fields and/or foci of necrosis.[159] Atypical carcinoids also show increased pleomorphism, have more prominent nucleoli, and are more likely to grow in a disorganized fashion and invade lymphatics. On electron microscopy the cells exhibit the dense-core granules characteristic of other neuroendocrine tumors and, by immunohistochemistry, are found to contain serotonin, neuron-specific enolase, bombesin, calcitonin, or other peptides.

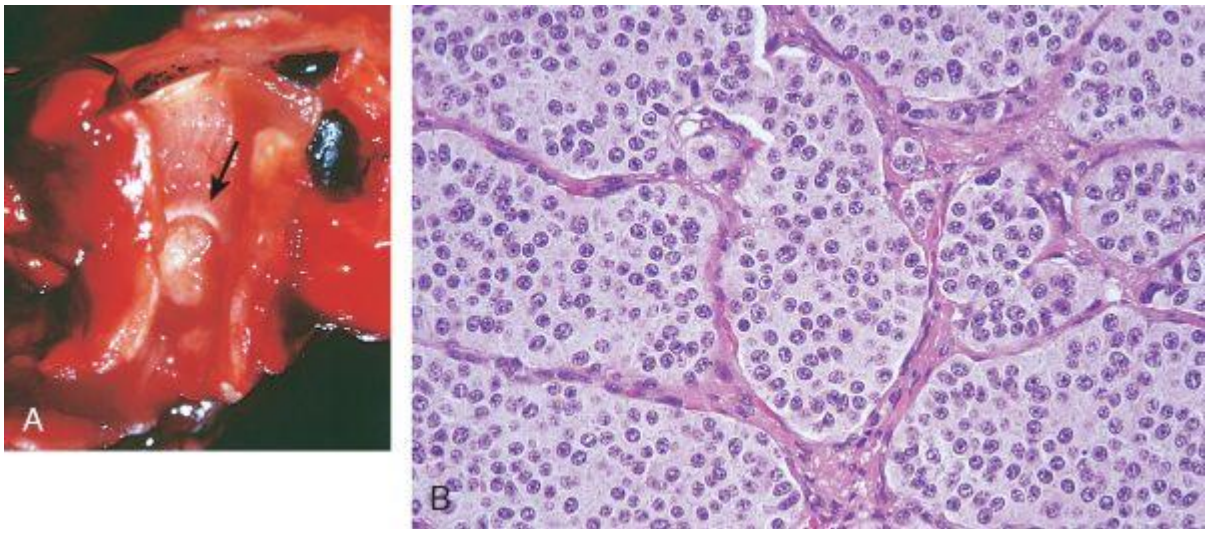

FIGURE 15-46 Bronchial carcinoid. **A**, Carcinoid growing as a spherical, pale mass *(arrow)* protruding into the lumen of the bronchus. **B**, Histologic appearance, demonstrating small, rounded, uniform nuclei and moderate cytoplasm. *(Courtesy of Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, IL.)*

Clinical Features.

The clinical manifestations of bronchial carcinoids emanate from their intraluminal growth, their capacity to metastasize, and the ability of some of the lesions to elaborate vasoactive amines. Persistent *cough*, *hemoptysis*, impairment of drainage of respiratory passages with *secondary infections, bronchiectasis, emphysema, and atelectasis* are all by-products of the intraluminal growth of these lesions.

Most interesting, albeit rare, are functioning lesions capable of producing the classic carcinoid syndrome, that is, intermittent attacks of diarrhea, flushing, and cyanosis. Overall, most bronchial carcinoids do not have secretory activity and do not metastasize to distant sites but follow a relatively benign course for long periods and are therefore amenable to resection. The reported 5- to 10-year survival rates are 87% and 87% for typical carcinoids, 56% and 35% for atypical carcinoids, 27% and 9% for large cell neuroendocrine carcinoma, and 9% and 5% for small cell carcinoma, respectively.[159]

MISCELLANEOUS TUMORS

Lesions of the complex category of benign and malignant mesenchymal tumors, such as inflammatory myofibroblastic tumor, fibroma, fibrosarcoma, lymphangioleiomyomatosis, leiomyoma, leiomyosarcoma, lipoma, hemangioma, hemangiopericytoma, and chondroma, may occur but are rare. Benign and malignant hematopoietic tumors, similar to those described in other organs, may also affect

the lung, either as isolated lesions or, more commonly, as part of a generalized disorder. These include Langerhans cell histiocytosis, non-Hodgkin and Hodgkin lymphomas, lymphomatoid granulomatosis, an unusual EBV-positive B cell lymphoma, and low-grade marginal zone B-cell lymphoma of the mucosa-associated lymphoid tissue (Chapter 13).

A lung *hamartoma* is a relatively common lesion that is usually discovered as an incidental, rounded focus of radio-opacity *(coin lesion)* on a routine chest film. The majority of these tumors are peripheral, solitary, less than 3 to 4 cm in diameter, and well circumscribed. Pulmonary hamartomaconsists of nodules of connective tissue intersected by epithelial clefts. Cartilage is the most common connective tissue, but there may also be cellular fibrous tissue and fat. The epithelial clefts are lined by ciliated columnar epithelium or nonciliated epithelium and probably represent entrapment of respiratory epithelium (Fig. 15-47). The traditional term *hamartoma* is retained for this lesion, but several features suggest that it is a neoplasm rather than a malformation, such as its rarity in childhood, its increasing incidence with age, and the finding of chromosomal aberrations involving either 6p21 or 12q14–q15, indicating a clonal origin.[138]

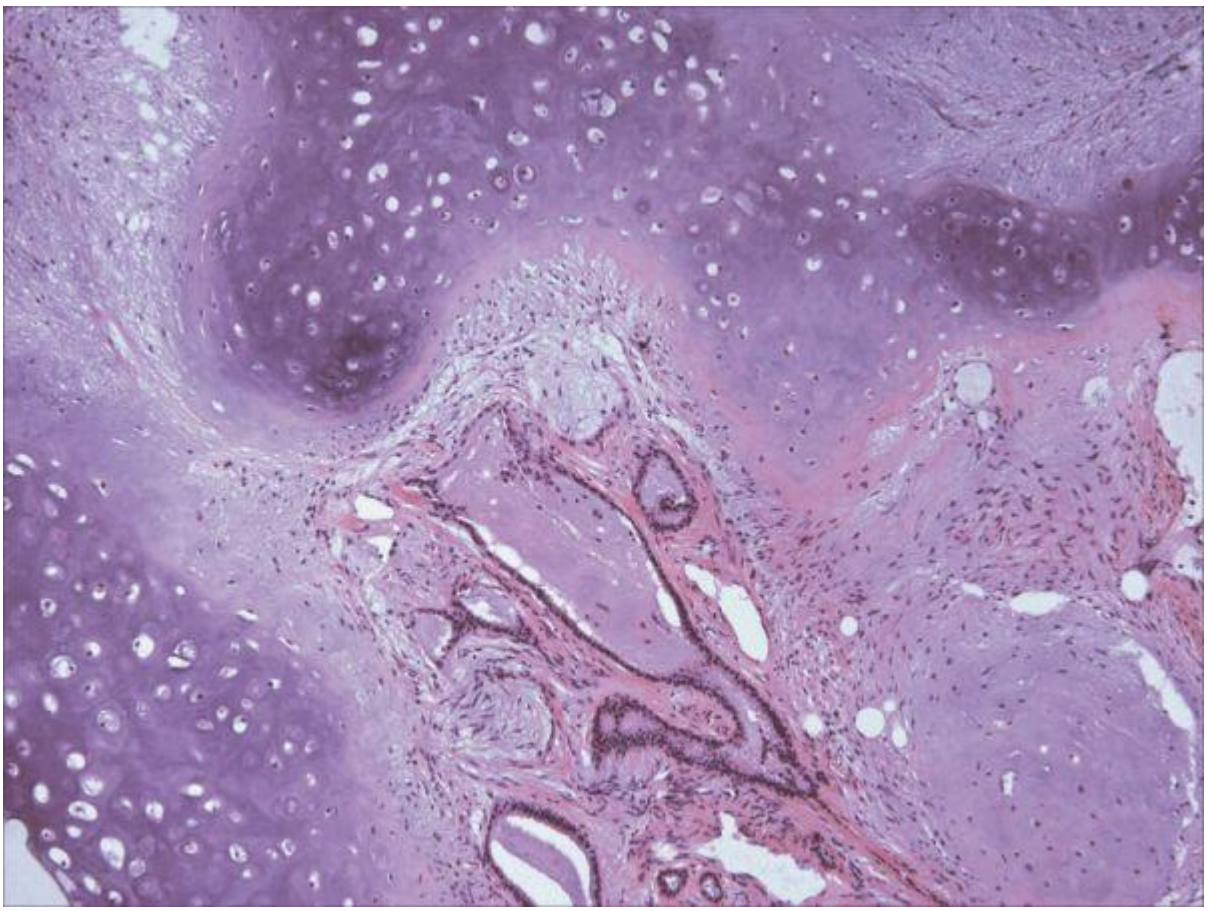

FIGURE 15-47 Pulmonary hamartoma. There are islands of cartilage and entrapped respiratory epithelium. *(Courtesy of Dr. Justine A. Barletta, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

Inflammatory myofibroblastic tumor, though rare, is more common in children, with an equal male-to-female ratio. Presenting symptoms include fever, cough, chest pain, and hemoptysis. It may also be

asymptomatic. Imaging studies show a single (rarely multiple) round, well-defined, usually peripheral mass with calcium deposits in about a quarter of cases. Grossly, the lesion is firm, 3 to 10 cm in diameter, and grayish white. Microscopically, there is proliferation of spindle-shaped fibroblasts and myofibroblasts, lymphocytes, plasma cells, and peripheral fibrosis. The anaplastic lymphoma kinase (*ALK*) gene, located on 2p23, has been implicated in the pathogenesis of this tumor.

Tumors in the mediastinum either may arise in mediastinal structures or may be metastatic from the lung or other organs. They may also invade or compress the lungs. Table 15-13 lists the most common tumors in the various compartments of the mediastinum. Specific tumor types are discussed in appropriate sections of this book.

METASTATIC TUMORS

The lung is the most common site of metastatic neoplasms. Both carcinomas and sarcomas arising anywhere in the body may spread to the lungs via the blood or lymphatics or by direct continuity. Growth of contiguous tumors into the lungs occurs most often with esophageal carcinomas and mediastinal lymphomas.

Morphology. The pattern of metastatic growth within the lungs is quite variable. In the usual case,

multiple discrete nodules (cannonball lesions) are scattered throughout all lobes, more being at the periphery (Fig. 15-48). Other patterns include solitary nodule, endobronchial, pleural, pneumonic consolidation, and mixtures of the above. Foci of lepidic growth similar to bronchioloalveolar carcinoma are seen occasionally with metastatic carcinomas and may be associated with any of the patterns listed above.

FIGURE 15-48 Numerous metastases to lung from a renal cell carcinoma. *(Courtesy of Dr. Michelle Mantel, Brigham and Women's Hospital, Boston, MA.)*

3.5.12 Pleura

Pathologic involvement of the pleura is, most often, a secondary complication of some underlying disease. Secondary infections and pleural adhesions are particularly commonfindings at autopsy. Important primary disorders include (1) primary intrapleural bacterial infections that imply seeding of this space as an isolated focus in the course of a transient bacteremia and (2) a primary neoplasm of the pleura: mesothelioma (discussed later).

PLEURAL EFFUSION

Pleural effusion is a common manifestation of both primary and secondary pleural diseases, which may be inflammatory or noninflammatory. Normally, no more than 15 mL of serous, relatively acellular, clear fluid lubricates the pleural surface. Accumulation of pleural fluid occurs in the following settings:

- Increased hydrostatic pressure, as in congestive heart failure
- Increased vascular permeability, as in pneumonia
- Decreased osmotic pressure, as in nephrotic syndrome
- Increased intrapleural negative pressure, as in atelectasis
- Decreased lymphatic drainage, as in mediastinal carcinomatosis

Inflammatory Pleural Effusions

Serous, *serofibrinous*, and fibrinous *pleuritis* all are caused by essentially the same processes. Fibrinous exudations generally reflect a later, more severe exudative reaction that, in an earlier developmental phase, might have presented as a serous or serofibrinous exudate.

The common causes of pleuritis are inflammatory diseases within the lungs, such as tuberculosis, pneumonia, lung infarcts, lung abscess, and bronchiectasis. Rheumatoid arthritis, disseminated lupus erythematosus, uremia, diffuse systemic infections, other systemic disorders, and metastatic involvement of the pleura can also cause serous or serofibrinous pleuritis. Radiation used in therapy for tumors in the lung or mediastinum often causes a serofibrinous pleuritis. In most instances the serofibrinous reaction is only minimal, and the fluid exudate is resorbed with either resolution or organization of the fibrinous component. Accumulation of large amounts of fluid can sufficiently encroach on lung space to cause respiratory distress.

A purulent pleural exudate *(empyema)* usually results from bacterial or mycotic seeding of the pleural space. Most commonly, this seeding occurs by contiguous spread of organisms from intrapulmonary infection, but occasionally, it occurs through lymphatic or hematogenous dissemination from a more distant source. Rarely, infections below the diaphragm, such as the subdiaphragmatic or liver abscess, may extend by continuity through the diaphragm into the pleural spaces, more often on the right side.

Empyema is characterized by loculated, yellow-green, creamy pus composed of masses of neutrophils admixed with other leukocytes. Although empyema may accumulate in large volumes (up to 500 to 1000 mL), usually the volume is small, and the pus becomes localized. Empyema may resolve, but this outcome is less common than organization of the exudate, with the formation of dense, tough fibrous adhesions that frequently obliterate the pleural space or envelop the lungs; either can seriously restrict pulmonary expansion.

True *hemorrhagic pleuritis* manifested by sanguineous inflammatory exudates is infrequent and is found in hemorrhagic diatheses, rickettsial diseases, and neoplastic involvement of the pleural cavity. The sanguineous exudate must be differentiated from hemothorax (discussed later). When hemorrhagic pleuritis is encountered, careful search should be made for the presence of exfoliated tumor cells.

Noninflammatory Pleural Effusions

Noninflammatory collections of serous fluid within the pleural cavities are called *hydrothorax*. The fluid is clear and straw colored. Hydrothorax may be unilateral or bilateral, depending on the underlying cause. The most common cause of hydrothorax is cardiac failure, and for this reason it is usually accompanied by pulmonary congestion and edema. Transudates may collect in any other systemic

disease associated with generalized edema and are therefore found in renal failure and cirrhosis of the liver.

The escape of blood into the pleural cavity is known as *hemothorax*. It is almost invariably a fatal complication of a ruptured aortic aneurysm or vascular trauma or it may occur post-operatively. Pure hemothorax is readily identifiable by the large clots that accompany the fluid component of the blood.

Chylothorax is an accumulation of milky fluid, usually of lymphatic origin, in the pleural cavity. Chyle is milky white because it contains finely emulsified fats. Chylothorax is most often caused by thoracic duct trauma or obstruction that secondarily causes rupture of major lymphatic ducts. This disorder is encountered in malignant conditions arising within the thoracic cavity that cause obstruction of the major lymphatic ducts. More distant cancers may metastasize via the lymphatics and grow within the right lymphatic or thoracic duct to produce obstruction.

PNEUMOTHORAX

Pneumothorax refers to air or gas in the pleural cavities and may be spontaneous, traumatic, or therapeutic. Spontaneous pneumothorax may complicate any form of pulmonary disease that causes rupture of an alveolus. An abscess cavity that communicates either directly with the pleural space or with the lung interstitial tissue may also lead to the escape of air. In the latter circumstance the air may dissect through the lung substance or back through the mediastinum (interstitial emphysema), eventually entering the pleural cavity. *Pneumothorax is most commonly associated with emphysema, asthma, and tuberculosis*. Traumatic pneumothorax is usually caused by some perforating injury to the chest wall, but sometimes the trauma pierces the lung and thus provides two avenues for the accumulation of air within the pleural spaces. Resorption of the pleural space air occurs slowly in spontaneous and traumatic pneumothorax, provided that the original communication seals itself.

Of the various forms of pneumothorax, the one that attracts greatest clinical attention is so-called *spontaneous idiopathic pneumothorax*. This entity is encountered in relatively young people, seems to be due to rupture of small, peripheral, usually apical subpleural blebs, and usually subsides spontaneously as the air is resorbed. Recurrent attacks are common and can be quite disabling.

Pneumothorax may have as much clinical significance as a fluid collection in the lungs because it also causes compression, collapse, and atelectasis of the lung and may be responsible for marked respiratory distress. Occasionally the lung collapse is marked. When the defect acts as a flap valve and permits the entrance of air during inspiration but fails to permit its escape during expiration, it effectively acts as a pump that creates the progressively increasing pressures of *tension pneumothorax*, which may be sufficient to compress the vital mediastinal structures and the contralateral lung.

PLEURAL TUMORS

The pleura may be involved by primary or secondary tumors. Secondary metastatic involvement is far more common than are primary tumors. The most frequent metastatic malignancies arise from primary neoplasms of the lung and breast. In addition to these cancers, malignancy from any organ of the body may spread to the pleural spaces. Ovarian carcinomas, for example, tend to cause widespread implants in both the abdominal and thoracic cavities. In most metastatic involvements, a serous or serosanguineous effusion follows that often contains neoplastic cells. For this reason, careful cytologic examination of the sediment is of considerable diagnostic value.

Solitary Fibrous Tumor

Previously called “benign mesothelioma” or “benign fibrous mesothelioma” in the pleura and “fibroma” in the lung, solitary fibrous tumor is now recognized as a soft-tissue tumor with a propensity to occur in the pleura and, less commonly, in the lung, as well as other sites. The tumor is often attached to the pleural surface by a pedicle.[160] It may be small (1 to 2 cm in diameter) or may reach an enormous size, but it tends to remain confined to the surface of the lung (Fig. 15-49). Grossly, it consists of dense fibrous tissue with occasional cysts filled with viscid fluid; microscopically, the tumor shows whorls of reticulin and collagen fibers among which are interspersed spindle cells resembling fibroblasts. Rarely, this tumor may be malignant, with pleomorphism, mitotic activity, necrosis, and large size (>10 cm). The tumor cells are CD34+ and keratin-negative by immunostaining. This feature can be diagnostically useful in distinguishing these lesions from malignant mesotheliomas (which show the opposite phenotype). The solitary fibrous tumor has no relationship to asbestos exposure.

FIGURE 15-49 Solitary fibrous tumor. Cut surface is solid with a whorled appearance. *(Courtesy of Dr. Justine A. Barletta, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

Malignant Mesothelioma

Malignant mesotheliomas in the thorax arise from either the visceral or the parietal pleura.[161,][162] Though uncommon, they have assumed great importance in the past few years because of their increased incidence among people with heavy exposure to asbestos (see “Pneumoconioses”). In coastal areas with shipping industries in the United States and Great Britain, and in Canadian, Australian, and South African mining areas, as many as 90% of reported mesotheliomas are asbestos-related. The lifetime risk of developing mesothelioma in heavily exposed individuals is as high as 7% to 10%. There is a long latent period of 25 to 45 years for the development of asbestos-related mesothelioma, and there

seems to be no increased risk of mesothelioma in asbestos workers who smoke. *This is in contrast to the risk of asbestos-related lung carcinoma, already high, which is markedly magnified by smoking. Thus, for asbestos workers (particularly those who are also smokers), the risk of dying of lung carcinoma far exceeds that of developing mesothelioma*.

Asbestos bodies (see Fig. 15-20) are found in increased numbers in the lungs of patients with mesothelioma. Another marker of *asbestos exposure*, the *asbestos plaque*, has been previously discussed.

Cytogenetic studies have shown that approximately 60% to 80% of malignant mesotheliomas have deletions in chromosomes 1p, 3p, 6q, 9p, or 22q, and 31% have *p16* mutations. There is a low frequency of *p53* mutations, although p53 accumulation can be detected immunohistochemicallyin 70% of malignant mesotheliomas. Some but not all studies have demonstrated the presence of SV40 (simian virus 40) viral DNA sequences in 60% to 80% of pleural malignant mesotheliomas and in a smaller fraction of peritoneal mesotheliomas. The SV40 T-antigen is a potent carcinogen that binds to and inactivates several critical regulators of growth, such as p53 and RB. Whether SV40 is involved in the pathogenesis of mesothelioma remains controversial.[163]

Morphology. Malignant mesothelioma is a diffuse lesion that spreads widely in the pleural space and is usually associated with extensive pleural effusion and direct invasion of thoracic structures. The affected lung becomes ensheathed by a thick layer of soft, gelatinous, grayish pink tumor tissue (Fig. 15-50).

Microscopically, malignant mesotheliomas may be epithelioid (60%), sarcomatoid (20%), or mixed (20%). This is in keeping with the fact that mesothelial cells have the potential to develop as epithelium-like cells or mesenchymal stromal cells.

The **epithelioid type** of mesothelioma consists of cuboidal, columnar, or flattened cells forming tubular or papillary structures resembling adenocarcinoma (Fig. 15-51A). Epithelioid mesothelioma may at times be difficult to differentiate grossly and histologically from pulmonary adenocarcinoma. Features that favor mesothelioma include (1) positive staining for acid mucopolysaccharide, which is inhibited by previous digestion by hyaluronidase; (2) lack of staining for carcinoembryonic antigen and other epithelial glycoprotein antigens, markers that are generally expressed by adenocarcinoma; (3) strong staining for keratin proteins, with accentuation of perinuclear rather than peripheral staining; (4) positive staining for calretinin (Fig. 15-51B), Wilms tumor 1 (WT-1), cytokeratin 5/6, and D2–40; and (5) on electron microscopy, the presence of long microvilli and abundant tonofilaments but absent microvillous rootlets and lamellar bodies (Fig. 15-52). The panel of special stains is diagnostic in a majority of cases when interpreted in the context of morphology and clinical presentation. The mesenchymal type of mesothelioma appears as a spindle cell sarcoma, resembling fibrosarcoma **(sarcomatoid type)**. The **mixed type** of mesothelioma contains both epithelioid and sarcomatoid patterns (see Fig. 15-51B).

FIGURE 15-50 Malignant mesothelioma. Note the thick, firm, white pleural tumor tissue that ensheaths this bisected lung.

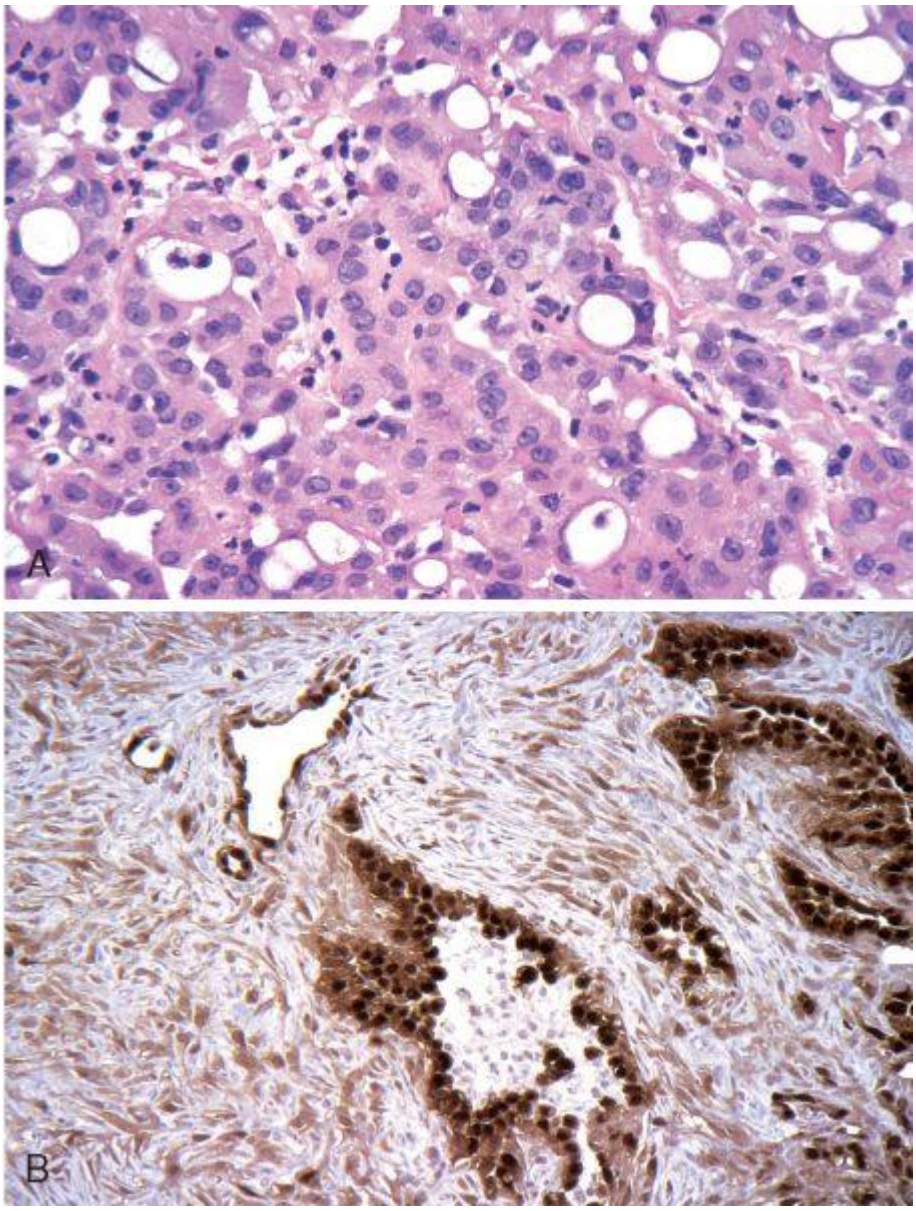

FIGURE 15-51 Histologic variants of malignant mesothelioma. **A**, Epithelioid type. **B**, Mixed type, stained for calretinin (immunoperoxidase method). The epithelial component is strongly positive (dark brown), while the sarcomatoid component is less so. *(Courtesy of Dr. Thomas Krausz, Department of Pathology, The University of Chicago, Pritzker School of Medicine, Chicago, IL.)*

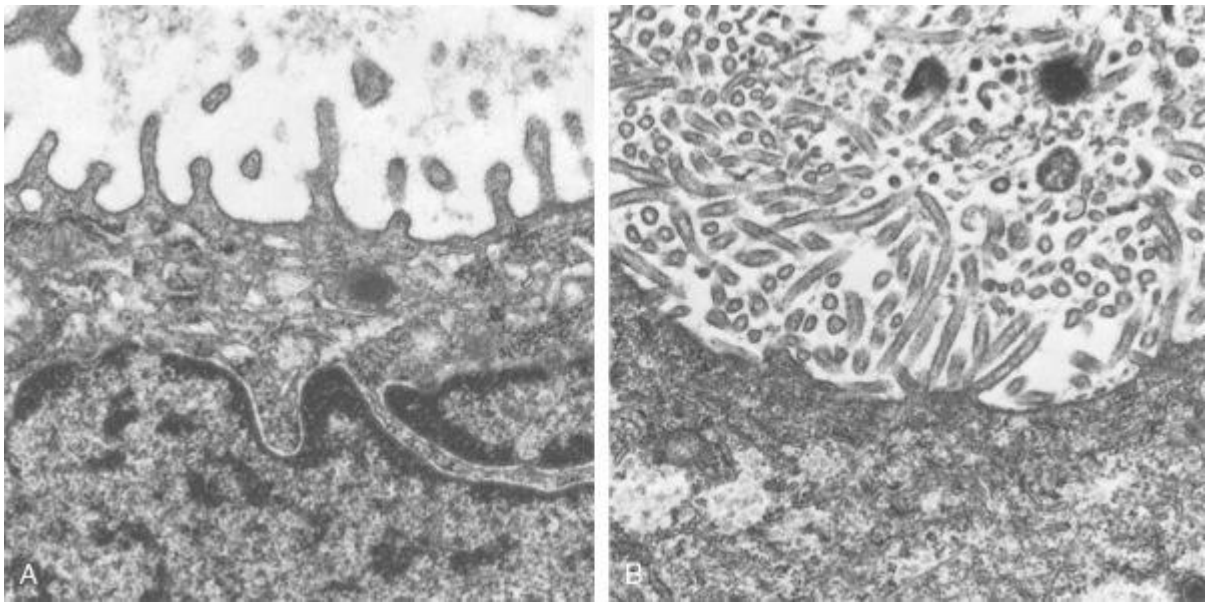

FIGURE 15-52 Ultrastructural features of pulmonary adenocarcinoma (**A**), characterized by short, plump microvilli, contrasted with those of mesothelioma (**B**), in which microvilli are numerous, long, and slender. *(Courtesy of Dr. Noel Weidner, University of California, San Francisco, School of Medicine, San Francisco, CA.)*

Clinical Course.

The presenting complaints are chest pain, dyspnea, and, as noted, recurrent pleural effusions. Concurrent pulmonary asbestosis (fibrosis) is present in only 20% of individuals with pleural mesothelioma. The lung is invaded directly, and there is often metastatic spread to the hilar lymph nodes and, eventually, to the liver and other distant organs. Fifty percent of patients die within 12 months of diagnosis, and few survive longer than 2 years. Aggressive therapy (extrapleural pneumonectomy, chemotherapy, radiation therapy) seems to improve this poor prognosis in some patients with epithelioid mesothelioma.

Mesotheliomas also arise in the peritoneum, pericardium, tunica vaginalis, and genital tract (benign adenomatoid tumor; see Chapter 21). *Peritoneal mesotheliomas* are particularly related to heavy asbestos exposure; 50% of such patients also have pulmonary fibrosis. Although in about 50% of cases the disease remains confined to the abdominal cavity, intestinal involvement frequently leads to death from intestinal obstruction or inanition.

3.6 16. Head & Neck

3.6.1 Oral Cavity

MARK W. LINGEN

Diseases of the head and neck range from the common cold to uncommon neoplasms of the nose. Those selected for discussion are assigned, sometimes arbitrarily, to one of the following anatomic sites: (1) oral cavity; (2) upper airways, including the nose, pharynx, larynx, and nasal sinuses; (3) ears; (4) neck; and (5) salivary glands.

ORAL CAVITY

The oral cavity is a fearsome orifice guarded by ranks of upper and lower “horns” (lamentably, quite subject to erosion), demanding constant gratification, and teeming with microorganisms, some of which are potentially harmful. Among the many disorders that affect its various parts, only the more important or frequent conditions involving the teeth and supporting structures, oral mucous membranes, lips, and tongue are considered.

3.6.1.1 Teeth & Supporting Structures

Teeth contribute to several important functions, including mastication and proper speech. It is useful to briefly review normal dental anatomy before we delve into the common pathologic conditions affecting teeth. As is well known, teeth are firmly implanted in the jaw and are surrounded by the gingival mucosa (Fig. 16-1). The anatomic crown of the tooth projects into the mouth and is covered by *enamel*, a hard, inert, acellular tissue—the most highly mineralized tissue in the body. The enamel rests upon *dentin*, which is a specialized form of connective tissue that makes up most of the remaining hard-tissue portion of the tooth. Unlike enamel, dentin is cellular and contains numerous dentinal tubules, which contain the cytoplasmic extensions of odontoblasts. These cells line the interface between the dentin and the pulp and can, when properly stimulated, produce new (secondary) dentin within the interior of the tooth. The pulp chamber itself is surrounded by the dentin and consists of loose connective tissue stroma rich in nerve bundles, lymphatics, and capillaries.

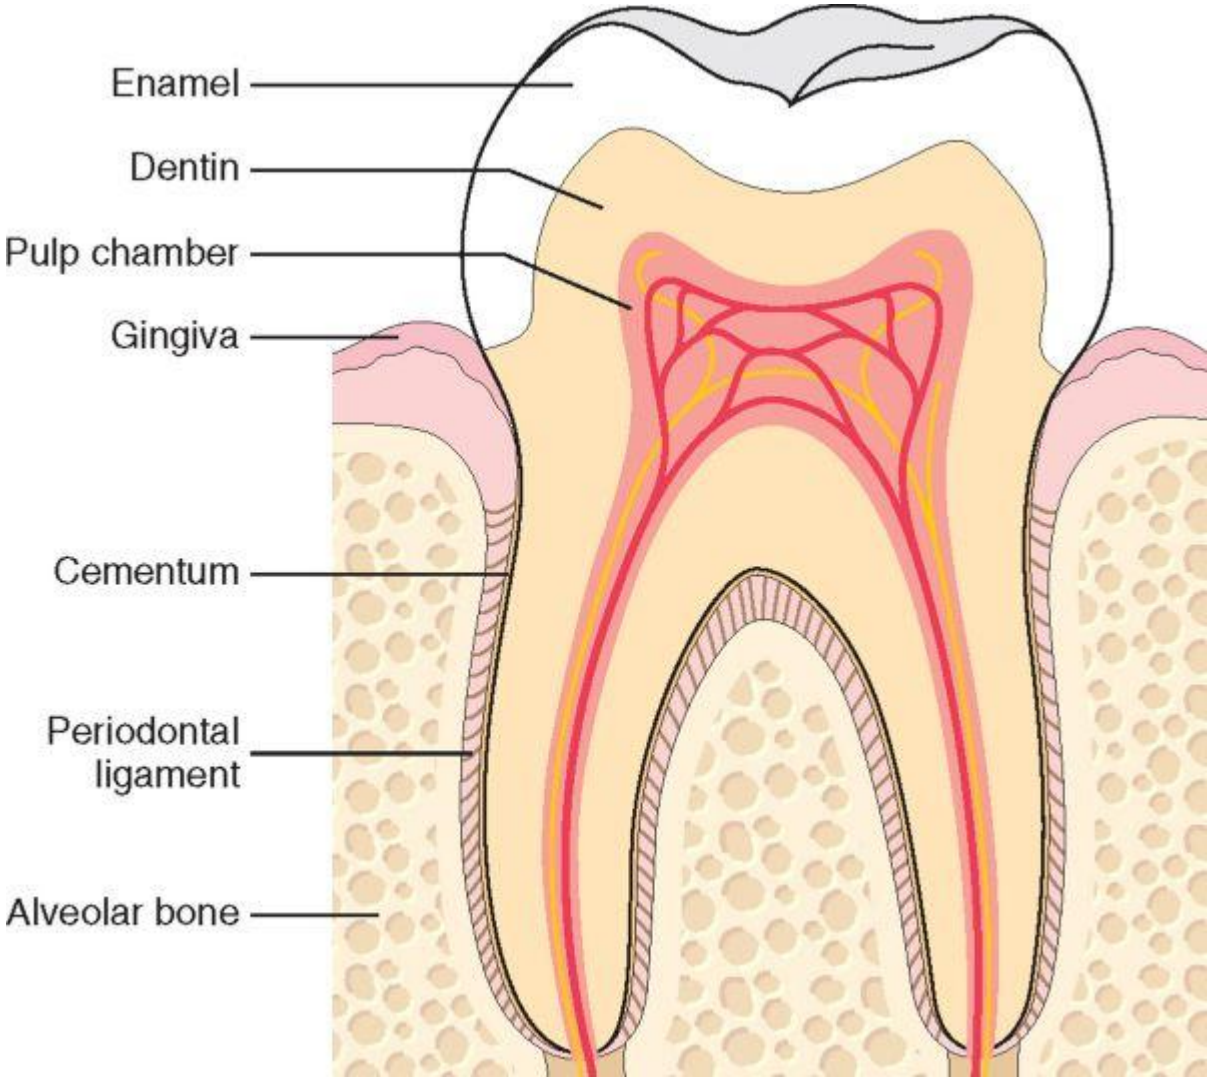

FIGURE 16-1 Schematic representation of the normal dental anatomy and surrounding supporting tissues.

To perform mastication, teeth must not only be composed of hard tissue but must also be firmly attached to the bones of the jaw. If this attachment were excessively firm, chewing would impose sufficient physical stress on the teeth to cause their loss or fracturing. Therefore, in mammals, teeth are attached to the alveolar ridge of the jaws by the *periodontal ligament*, which provides a strong yet flexible attachment that can withstand the forces of mastication. The periodontal ligament attaches to the alveolar bone of the jaw on one side and to *cementum*, present on the roots of the teeth, which acts as a "cement" to anchor the periodontal ligament to the tooth.

CARIES (TOOTH DECAY)

Dental caries, caused by focal degradation of the tooth structure, is one of the most common diseases throughout the world and is the most common cause of tooth loss before age 35. Carious lesions are the result of mineral dissolution of tooth structure by acid metabolic end products from bacteria that are present in the oral cavity and are capable of fermenting sugars. Traditionally, the rate of caries has been higher in industrialized countries, where there is ready access to processed foods containing large amounts of carbohydrates. However, global trends may change these demographics. First of all, the rate of caries has markedly dropped in countries such as the United States, where improved oral hygiene and fluoridation of the drinking water has become a standard practice. Fluoride incorporates into the crystalline structure of enamel, forming fluoroapatite, and contributes to resistance to degradation by bacterial acids. Second, with globalization of the world's economy, increased amounts of processed foods with high carbohydrate content are being imported into developing nations. With these trends, one can expect the rate of caries to increase dramatically in the less-developed world over the next several decades.

GINGIVITIS

Gingiva is the designation of the squamous mucosa in between the teeth and around them. Gingivitis is inflammation of the mucosa and the associated soft tissues. Typically, the development of gingivitis is the result of a lack of proper oral hygiene, leading to an accumulation of dental plaque and calculus. *Dental plaque* is a sticky, usually colorless, biofilm that builds in between and on the surface of the teeth. It is formed by a complex of the oral bacteria, proteins from the saliva, and desquamated epithelial cells. If plaque continues to build and is not removed, it becomes mineralized to form calculus (tartar). The bacteria in the plaque release acids from sugar-rich foods, which erode the enamel surface of the tooth. Repeated erosions lead to dental caries. Plaque build-up beneath the gumline can cause gingivitis. Chronic gingivitis is characterized by gingival erythema, edema, bleeding, changes in contour, and loss of soft-tissue adaptation to the teeth. Gingivitis occurs at any age but is most prevalent and severe in adolescence (ranging from 40% to 60%), after which the incidence tapers off. It is a reversible disease; therapy is primarily aimed at reducing the accumulation of plaque and calculus via brushing, flossing, and regular dental visits.[1]

PERIODONTITIS

Periodontitis refers to an inflammatory process that affects the supporting structures of the teeth: periodontal ligaments, alveolar bone, and cementum. With progression, periodontitis can lead to serious sequelae, including the loss of attachment caused by complete destruction of the periodontal ligament and alveolar bone. Loosening and eventual loss of teeth are possible. The pathogenesis of periodontal

inflammation is not entirely clear. Until the 1960s it was believed that long-standing gingivitis uniformly progressed to periodontal disease. However, this is no longer thought to be the case. Rather, the development of periodontal disease is now considered to be an independent process, which, for reasons that are still unclear, is associated with a marked shift in the types and proportions of bacteria along the gingiva.[2] This shift, along with other environmental conditions such as poor oral hygiene, is believed to be important in the pathogenesis of periodontitis. This view is supported by significant differences in the content of dental plaque in areas of healthy and diseased periodontium. For the most part, facultative gram-positive organisms colonize healthy sites, while plaque within areas of active periodontitis contains anaerobic and microaerophilic gram-negative flora. Although 300 types of bacteria reside in the oral cavity, adult periodontitis is associated primarily with *Aggregatibacter (Actinobacillus) actinomycetemcomitans*, *Porphyromonas gingivalis*, and *Prevotella intermedia*.

While it typically presents without any associated disorders, periodontal disease can also be a component of several different systemic diseases, including acquired immunodeficiency syndrome (AIDS), leukemia, Crohn's disease, diabetes mellitus, Down syndrome, sarcoidosis, and syndromes associated with polymorphonuclear defects (Chédiak-Higashi syndrome, agranulocytosis, and cyclic neutropenia). In addition to being a component of certain systemic diseases, periodontal infections can also be etiologic factors in several important systemic diseases. These include, for example, infective endocarditis, pulmonary and brain abscesses, and adverse pregnancy outcomes.[3,][4]

3.6.1.2 Inflammatory/Reactive Tumor-like Lesions

Several soft-tissue lesions of the oral cavity, which present as tumor masses or ulcerations, are reactive in nature and represent inflammations induced by irritation or by unknown mechanisms. All suspicious lesions, however, should be examined by biopsy. Reactive nodules of the oral cavity are fairly common and microscopically diverse. The most common fibrous proliferative lesions of the oral cavity include fibroma (61%), peripheral ossifying fibroma (22%), pyogenic granuloma (12%), and peripheral giant-cell granuloma (5%).[5] The most common inflammatory/reactive ulcerations of the oral cavity are traumatic and aphthous ulcers.

FIBROUS PROLIFERATIVE LESIONS

The so-called *irritation fibroma* (Fig. 16-2) primarily occurs in the buccal mucosa along the bite line or at the gingivodental margin. It consists of a nodular mass of fibrous tissue, with few inflammatory cells, covered by squamous mucosa. Treatment is complete surgical excision.

FIGURE 16-2 Fibroma. Smooth pink exophytic nodule on the buccal mucosa.

The *pyogenic granuloma* (Fig. 16-3) is a highly vascular pedunculated lesion, usually occurring in the gingiva of children, young adults, and, commonly, pregnant women (pregnancy tumor). The surface of the lesion is typically ulcerated and red to purple in color. In some cases growth is alarmingly rapid, raising the fear of a malignant neoplasm. Histologically these lesions demonstrate a highly vascular proliferation that is similar to granulation tissue. Because of this histologic picture, pyogenic granulomas are considered by some authorities to be a form of capillary hemangioma (Chapter 11). They either regress, particularly after pregnancy, or undergo fibrous maturation, and they may develop into a peripheral ossifying fibroma. Treatment is complete surgical excision.

FIGURE 16-3 Pyogenic granuloma. Erythematous, hemorrhagic, and exophytic mass arising from the gingival mucosa.

The *peripheral ossifying fibroma* is a relatively common growth of the gingiva that is considered to be reactive in nature rather than neoplastic. However, the etiology of the lesion is unknown. Some may arise as a result of the maturation of a long-standing pyogenic granuloma. With a peak incidence in young and teenage females, peripheral ossifying fibromas appear as red, ulcerated, and nodular lesions of the gingiva. They are often mistaken clinically for pyogenic granulomas. Complete surgical excision down to the periosteum is the treatment of choice, since these lesions have a recurrence rate of 15% to 20%.

The *peripheral giant cell granuloma* is a relatively common lesion of the gingiva. It is generally covered by intact gingival mucosa, but it may be ulcerated. The clinical appearance of peripheral giant-cell granuloma can be similar to that of pyogenic granuloma, but which is generally more bluish purple in color while the pyogenic granuloma is more bright red. Histologically, however, these lesions are distinct. Peripheral giant-cell granuloma is made up of a striking aggregation of multinucleate, foreign body–like giant cells separated by a fibroangiomatous stroma. Although not encapsulated, these lesions are usually well delimited and easily excised. They should be differentiated from central giant-cell granulomas found within the maxilla or the mandible and from the histologically similar but frequently multiple “brown tumors” seen in hyperparathyroidism (Chapter 24).

APHTHOUS ULCERS (CANKER SORES)

These extremely common superficial ulcerations of the oral mucosa affect up to 40% of the population in the United States.[6] They are more common in the first two decades of life, are extremely painful and often recurrent, and tend to be prevalent within certain families.

The lesions appear as single or multiple, shallow, hyperemic ulcerations covered by a thin exudate and rimmed by a narrow zone of erythema (Fig. 16-4). The underlying inflammatory infiltrate is at first largely mononuclear, but secondary bacterial infection introduces numerous neutrophils. The lesions may spontaneously resolve in 7 to 10 days or be stubbornly persistent for weeks. The causation of these lesions is obscure. Most ulcers are more painful than serious and require only symptomatic treatment. Recurrent apthous ulcers may be associated with celiac disease and inflammatory bowel disease.

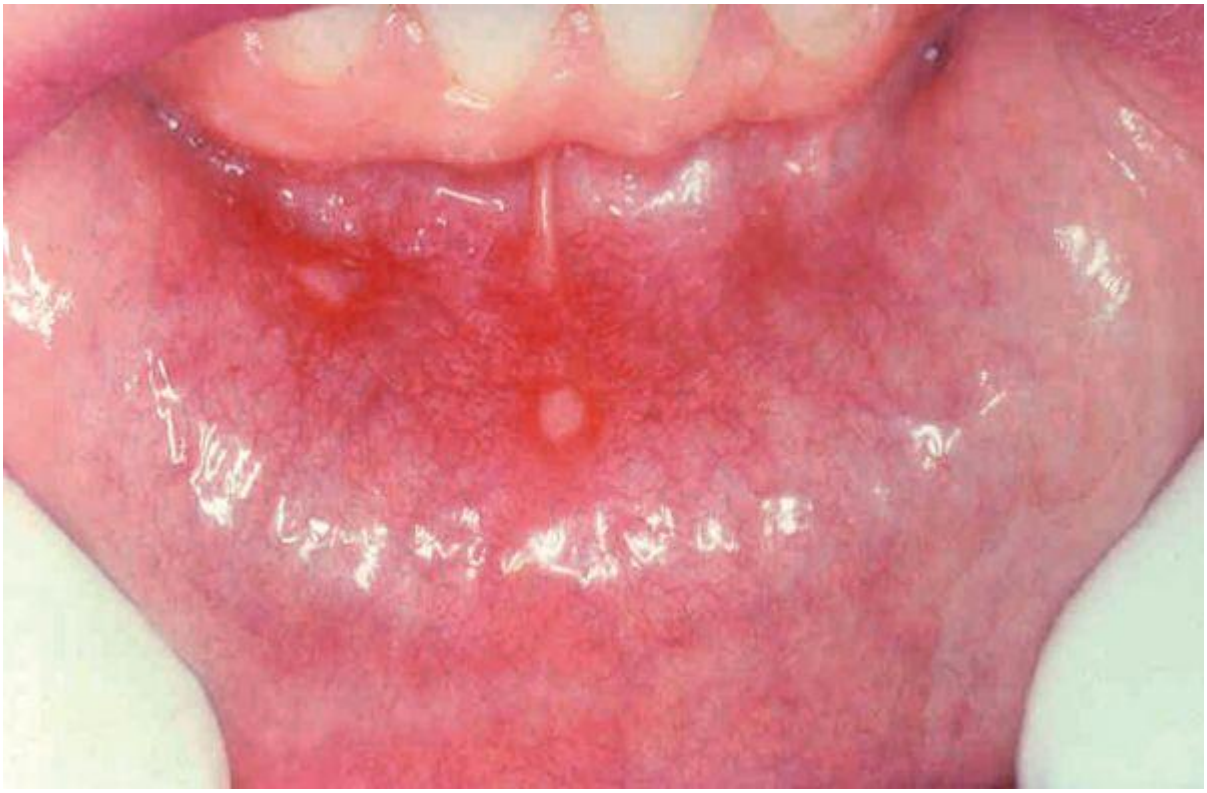

FIGURE 16-4 Aphthous ulcer. Single ulceration with an erythematous halo surrounding a yellowish fibrinopurulent membrane.

GLOSSITIS

Although the designation *glossitis* implies inflammation of the tongue, it is sometimes applied to the beefy-red tongue encountered in certain deficiency states; this change results from atrophy of the papillae of the tongue and thinning of the mucosa, exposing the underlying vasculature. In some instances the atrophic changes do indeed lead to inflammation and even shallow ulcerations. Such changes may be encountered in deficiencies of vitamin B_{12} (pernicious anemia), riboflavin, niacin, or pyridoxine. Similar alterations are sometimes encountered with sprue and iron-deficiency anemia, possibly complicated by deficiency in one of the B vitamins. *The combination of iron-deficiency anemia, glossitis, and esophageal dysphagia usually related to webs is known as the Plummer-Vinson or Paterson-Kelly syndrome*. Glossitis, characterized by ulcerative lesions (sometimes along the lateral borders of the tongue), may also be seen with jagged carious teeth, ill-fitting dentures, and, rarely, with syphilis, inhalation burns, or ingestion of corrosive chemicals.

3.6.1.3 Infections

The oral mucosa is highly resistant to its indigenous flora, having many defenses, including the competitive suppression of potential pathogens by organisms of low virulence, the elaboration of secretory IgA and other immunoglobulins by submucosal collections of lymphocytes and plasma cells, the antibacterial effects of saliva, and the irrigating effects of food and drink. Nonetheless, any lowering of these defenses, for example, with immunodeficiency or disruption of the microbiologic balance by antibacterial therapy, sets the stage for oral infections. Most of these infections are discussed in Chapter 8 , and here we only briefly recapitulate the principal features of the oral lesions.

HERPES SIMPLEX VIRUS INFECTIONS

Most orofacial herpetic infections are caused by herpes simplex virus type 1 (HSV-1). However, because of changes in sexual habits, an increase in HSV-2 (genital herpes) has been observed in the oral cavity. Primary HSV infection typically occurs in children age 2 to 4 years, is often asymptomatic, and does not cause significant morbidity. Approximately 10% to 20% of the time, primary infection presents as *acute herpetic gingivostomatitis*, in which there is an abrupt onset of vesicles and ulcerations throughout the oral cavity, especially in the gingiva. These lesions are also accompanied by lymphadenopathy, fever, anorexia, and irritability.

Morphology. The vesicles range from lesions of a few millimeters to large bullae and are at first filled with a clear, serous fluid, but they often rupture to yield extremely painful, red-rimmed, shallow ulcerations. On microscopic examination there is intracellular and intercellular edema (acantholysis), yielding clefts that may become transformed into macroscopic vesicles. Individual epidermal cells in the margins of the vesicle or lying free within the fluid sometimes develop eosinophilic **intranuclear viral inclusions**, or several cells may fuse to produce giant cells **(multinucleate polykaryons)**, changes that are demonstrated by the diagnostic **Tzanck test**, based on microscopic examination of the vesicle fluid. The vesicles and shallow ulcers usually spontaneously clear within 3 to 4 weeks, but the virus treks along the regional nerves and eventually becomes dormant in the local ganglia (e.g., the trigeminal).

The great preponderance of adults harbor latent HSV-1, but in some individuals, usually young adults, the virus becomes reactivated to produce the common but usually mild *cold sore*. The influences predisposing to activation are poorly understood but are thought to include trauma, allergies, exposure to ultraviolet light, upper respiratory tract infections, pregnancy, menstruation, immunosuppression, and exposure to extremes of temperature.

Recurrent herpetic stomatitis (in contrast to acute gingivostomatitis) occurs either at the site of primary inoculation or in adjacent mucosal areas that are associated with the same ganglion; it takes the form of groups of small (1–3 mm) vesicles. The lips (*Herpes labialis*), nasal orifices, buccal mucosa, gingiva, and hard palate are the most common locations for recurrent lesions. They resemble those already described in the primary infections but are much more limited in duration, are milder, usually dry up in 4 to 6 days, and heal within a week to 10 days.

OTHER VIRAL INFECTIONS

Additional viral infections that can be seen in the oral cavity as well as the head and neck region include herpes zoster, Epstein-Barr virus (EBV; mononucleosis), cytomegalovirus, enterovirus (herpangina, hand-foot-and-mouth disease, acute lymphonodular pharyngitis), and rubeola (measles).

ORAL CANDIDIASIS (THRUSH)

The many localizations of candidal infection are fully described in Chapter 8 , and so this discussion is limited to presentation in the oral cavity. Candidiasis is by far the most common fungal infection in the oral cavity. *Candida albicans* is a normal component of the oral flora in approximately 50% of the population. Three factors seem to influence the likelihood of a clinical infection: (1) immune status of the individual; (2) the strain of *C. albicans* present; and (3) the composition of an individual's oral flora. There are three major clinical forms of oral candidiasis, including pseudo-membranous (thrush), erythematous, and hyperplastic, with several different variations within these groups. Only the pseudo-membranous form, the most common of these, is discussed here. Also known as "*thrush*," pseudo-membranous candidiasis typically takes the form of a superficial, curdy, gray to white inflammatory membrane composed of matted organisms enmeshed in a fibrinosuppurative exudate that can be readily scraped off to reveal an underlying erythematous inflammatory base. This fungus causes mischief only in individuals who have some form of immunosuppression, as occurs in patients with diabetes mellitus, organ or bone marrow transplant recipients, those with neutropenia, chemotherapy-induced immunosuppression, or AIDS. In addition, broad-spectrum antibiotics that eliminate or alter the normal bacterial flora of the mouth can also result in the development of oral candidiasis.

DEEP FUNGAL INFECTIONS

In addition to their more common sites of infection, certain deep fungal infections have a significant predilection for the oral cavity and the head and neck region. Such fungi include histoplasmosis, blastomycosis, coccidioidomycosis, cryptococcosis, zygomycosis, and aspergillosis. With an increasing number of patients who are immunocompromised due to diseases such as AIDS or therapies for cancer and organ transplantation, the prevalence of fungal infections of the oral cavity has also increased in recent years.

3.6.1.4 Oral Manifestations of Systemic Disease

As oral clinicians are at pains to emphasize, the mouth is a part of the body and not merely a gateway for delicacies. Not surprisingly, then, many systemic diseases are associated with oral lesions. In fact, it is not uncommon for oral lesions to be the first sign of some underlying systemic condition. Some of the more common disease associations are cited in Table 16-1 , with a few words about the associated oral changes. Only one—hairy leukoplakia—is characterized in more detail.

TABLE 16-1 -- Oral Manifestantions of Some Systemic Diseases

Systemic Disease	Associated Oral Changes
INFECTIOUS DISEASES	
Scarlet fever	Fiery red tongue with prominent papillae (raspberry tongue); white-coated tongue through which hyperemic papillae project (strawberry tongue)
Measles	Spotty enanthema in the oral cavity often precedes the skin rash; ulcerations on the buccal mucosa about Stensen duct produce Koplik spots
Infectious mononucleosis	Acute pharyngitis and tonsillitis that may cause coating with a gray-white exudative membrane; enlargement of lymph nodes in the neck, palatal petechiae
Diphtheria	Characteristic dirty white, fibrinosuppurative, tough, inflammatory membrane over the tonsils and retropharynx
Human immunodeficiency virus	Predisposition to opportunistic oral infections, particularly herpesvirus, *Candida*, and other fungi; oral lesions of Kaposi sarcoma and hairy leukoplakia (described in text)
DERMATOLOGIC CONDITIONS[*]	

Systemic Disease	Associated Oral Changes
Lichen planus	Reticulate, lacelike, white keratotic lesions that rarely become bullous and ulcerated; seen in more than 50% of patients with cutaneous lichen planus; rarely, is the sole manifestation
Pemphigus	Vesicles and bullae prone to rupture, leaving hyperemic erosions covered with exudates
Bullous pemphigoid	Oral lesions resemble macroscopically those of pemphigus but can be differentiated histologically
Erythema multiforme	Maculopapular, vesiculobullous eruption that sometimes follows an infection elsewhere, ingestion of drugs, development of cancer, or a collagen vascular disease; when it involves the lips and oral mucosa, it is referred to as *Stevens-Johnson syndrome*
HEMATOLOGIC DISORDERS	
Pancytopenia (agranulocytosis, aplastic anemia)	Severe oral infections in the form of gingivitis, pharyngitis, tonsillitis; may extend to produce cellulitis of the neck (*Ludwig angina*)
Leukemia	With depletion of functioning neutrophils, oral lesions may appear like those in pancytopenia
Monocytic leukemia	Leukemic infiltration and enlargement of the gingivae, often with accompanying periodontitis
MISCELLANEOUS	
Melanotic pigmentation	May appear in Addison disease, hemochromatosis, fibrous dysplasia of bone (Albright syndrome), and Peutz-Jegher syndrome (gastrointestinal polyposis)
Phenytoin (Dilantin) ingestion	Striking fibrous enlargement of the gingivae
Pregnancy	A friable, red, pyogenic granuloma protruding from the gingiva (“pregnancy tumor”)
Rendu-Osler-Weber syndrome	Autosomal dominant disorder with multiple congenital aneurysmal telangiectasias beneath mucosal surfaces of the oral cavity and lips

* See Chapter 25 for details

HAIRY LEUKOPLAKIA

Hairy leukoplakia is a distinctive oral lesion that is usually seen in immunocompromised patients. Approximately 80% of patients with hairy leukoplakia are infected with the human immunodeficiency virus (HIV); the presence of this lesion sometimes calls attention to the existence of HIV infection. However, 20% of lesions are seen in patients who are immunocompromised for other reasons, such as cancer therapy or transplant immunosuppression. Hairy leukoplakia takes the form of *white, confluent patches of fluffy (“hairy”), hyperkeratotic thickenings, almost always situated on the lateral border of the tongue*. Unlike thrush, the lesion cannot be scraped off. The distinctive microscopic appearance consists of *hyperparakeratosis* and *acanthosis with “balloon cells” in the upper spinous layer*. Sometimes there is koilocytosis of the superficial, nucleated epidermal cells, suggesting human papillomavirus (HPV) infection, and HPV transcripts have occasionally been found within the cells. However, EBV is present in most cells and is now accepted as the cause of the condition.[7] Sometimes there is superimposed candidal infection on the surface of the lesions, adding to the “hairiness.” In HIV-positive individuals, with hairy leukoplarkia, symptoms of AIDS follow in 2 to 3 years.

3.6.1.5 Tumors & Precancerous Lesions

Many epithelial and connective tissue tumors of the head and neck region (e.g., papillomas, hemangiomas, lymphomas) also occur elsewhere in the body and are described adequately in other

chapters. Therefore, this discussion will consider only oral squamous cell carcinoma and its associated precancerous lesions.

LEUKOPLAKIA AND ERYTHROPLAKIA

As is discussed in more detail below, oral cancers are common worldwide, with a fairly high mortality. Screening and early detection in populations at risk have been proposed to decrease the morbidity and mortality associated with oral cancer.[8,][9] However, the visual detection of definitive premalignant oral lesions is problematic. This is in stark contrast to skin lesions, where visual screening for melanomas of the skin has been shown to have sensitivity and specificity rates of 93% and 98%.[10,][11] One explanation for this discrepancy is that the early lesions frequently do not demonstrate any of the clinical characteristics observed in advanced oral cancer such as ulceration, induration, pain, or cervical lymphadenopathy.[12] In addition, the clinical presentation of potentially premalignant lesions in the oral cavity is highly heterogeneous. We begin our discussion with two premalignant lesions: leukoplakia and erythroplakia.

The term *leukoplakia* is defined by the World Health Organization as "a white patch or plaque that cannot be scraped off and cannot be characterized clinically or pathologically as any other disease." Simply put, if a white lesion in the oral cavity can be given a specific diagnosis it is not a leukoplakia. This clinical term is reserved for lesions that are present in the oral cavity for no apparent reason. As such, white patches caused by entities such as lichen planus and candidiasis are not leukoplakias. Approximately 3% of the world's population have leukoplakic lesions, and somewhere between 5% and 25% of these lesions are premalignant.[13] *Thus, until it is proved otherwise via histologic evaluation, all leukoplakias must be considered precancerous*.

Related to leukoplakia, but much less common and much more ominous, is *erythroplakia*. It represents a red, velvety, possibly eroded area within the oral cavity that usually remains level with or may be slightly depressed in relation to the surrounding mucosa (Fig. 16-5). The epithelium in such lesions tends to be markedly atypical, incurring a much higher risk of malignant transformation than that seen with leukoplakia. Intermediate forms are occasionally encountered that have the characteristics of both leukoplakia and erythroplakia, termed *speckled leukoerythroplakia*.

FIGURE 16-5 Erythroplakia. **A**, Lesion of the maxillary gingiva. **B**, Red lesion of the mandibular alveolar ridge. Biopsy of both lesions revealed carcinoma in situ.

Both leukoplakia and erythroplakia may be seen in adults at any age, but they are usually found between ages 40 and 70, with a 2 : 1 male preponderance. *Although these lesions have multifactorial origins, the use of tobacco (cigarettes, pipes, cigars, and chewing tobacco) is the most common antecedent*.

Morphology. Leukoplakias may occur anywhere in the oral cavity (favored locations are buccal mucosa, floor of the mouth, ventral surface of the tongue, palate, and gingiva). They appear as solitary or multiple white patches or plaques, often with sharply demarcated borders. They may be slightly thickened and smooth or wrinkled and fissured, or they may appear as raised, sometimes corrugated, verrucous plaques (Fig. 16-6). On histologic examination they present a spectrum of epithelial changes ranging from hyperkeratosis overlying a thickened, acanthotic but orderly mucosal epithelium to lesions with markedly dysplastic changes sometimes merging into carcinoma in situ (Fig. 16-7). The more dysplastic or anaplastic the lesion, the more likely that a subjacent inflammatory infiltrate of lymphocytes and macrophages will be present.

The histologic changes in **erythroplakia** only rarely consist of orderly epidermal maturation; virtually all (approximately 90%) disclose superficial erosions with dysplasia, carcinoma in situ, or already developed carcinoma in the surrounding margins. Often, an intense subepithelial inflammatory reaction with vascular dilation is seen that likely contributes to the reddish clinical appearance.

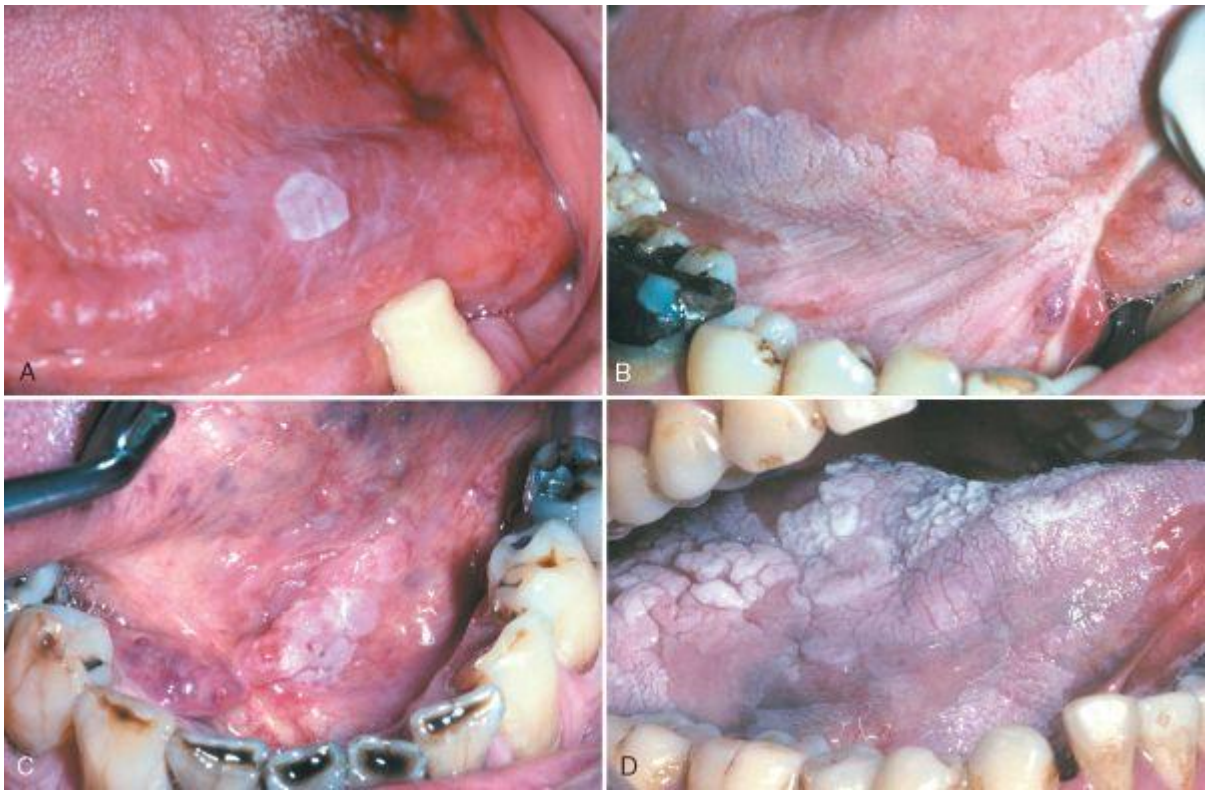

FIGURE 16-6 Leukoplakia. Clinical appearance of leukoplakias is highly variable and can range from (**A**) smooth and thin with well-demarcated borders, (**B**) diffuse and thick, (**C**) irregular with a granular surface, to (**D**) diffuse and corrugated. *(Courtesy of Drs. Neville, Damm, Allen, Bouquot [eds], Oral and Maxillofacial Pathology. Philadelphia, WB Saunders, 2008.)*

SQUAMOUS CELL CARCINOMA

At least 95% of cancers of the head and neck are squamous cell carcinomas (HNSCCs), arising most commonly in the oral cavity. The remainder includes adenocarcinomas (of salivary gland origin), melanomas, various carcinomas, and other rarities. Biologically, squamous cell carcinomas in the oral cavity are fairly similar to those elsewhere in the head and neck, hence they are described together here. Features that apply to squamous cell cancer at specific sites in the head and neck are mentioned in the following discussion. Laryngeal squamous cell cancers are described later.

HNSCC is an aggressive epithelial malignancy that is the sixth most common neoplasm in the world today. At current rates, approximately 45,000 cases in the United States and more than 650,000 cases worldwide will be diagnosed each year.[14,] [15] [16] [17] Despite numerous advances in treatment taking advantage of the most recent protocols for surgery, radiation therapy, and chemotherapy, the overall long-term survival has remained at less than 50% for the past 50 years.[16] The 5-year survival rate of early-stage oral cancer is approximately 80%, while survival drops to 19% for late-stage disease. This dismal outlook is due to several factors, including the fact that oral cancer is often diagnosed when the disease has already reached an advanced stage. In addition, the frequent development of multiple primary tumors markedly decreases survival. The rate of second primary tumors in these patients has been reported to be 3% to 7% per year, which is higher than for any other malignancy.[18,][19] This observation has led to the concept of "field cancerization." It is postulated that multiple individual primary tumors develop independently in the upper aerodigestive tract as a result of years of chronic exposure of the mucosa to carcinogens.[20,][21] Because of such field cancerization, an individual who is fortunate to live 5 years after the initial primary tumor has up to a 35% chance of developing at least one new primary tumor within that period of time. The occurrence of new primary tumors can be particularly devastating for individuals whose initial lesions were small. The 5-year survival rate for the first primary tumor is considerably better than 50%, but in such individuals, second primary tumors are

the most common cause of death.[22] Therefore, the early detection of all premalignant lesions is critical for the long-term survival of these patients.

Pathogenesis.

The pathogenesis of squamous cell carcinoma is multifactorial. Within North America and Europe it has classically been considered to be a disease of middle-aged men who have been chronic abusers of *smoked tobacco* and *alcohol*. The risk is magnified in those who smoke as well as consume alochol. Not unexpectedly, therefore, and concurrent with increased cigarette usage, the incidence of oral cancer in women is on the rise.

It is now known that at least 50% of oropharyngeal cancers, particularly those involving the tonsils, the base of the tongue, and the oropharynx harbor oncogenic variants of HPV.[23] It is predicted that the incidence of HPV-associated HNSCC will surpass that of cervical cancer in the next decade, in part because the anatomic sites of origin (tonsillar crypts, base of tongue, and oropharynx) are not readily accessible or amenable to cytologic screening (unlike the cervix). It should be noted, however, that *patients with HPV-positive HNSCC do better than those with HPV-negative tumors*. The HPV vaccine, which is protective against cervical cancer, offers hope to stem the tide of HPV-associated HNSCC, although it is not yet approved for this use.

There is increasing epidemiologic evidence that a family history of head and neck cancer is a risk factor for the disease, thought to be due to inherited genomic instability.[24] Finally, *actinic radiation* (sunlight) and, particularly, pipe smoking are known predisposing influences for cancer of the lower lip. Outside of North America and Europe, a major regional predisposing influence is the chewing of betel quid and paan in India and parts of Asia. The betel quid is a “witches' brew” that contains several ingredients such as areca nut, slaked lime, and tobacco, which are wrapped in a betel leaf. While protracted irritation from ill-fitting dentures, jagged teeth, or chronic infections is no longer thought to be a direct antecedent to oral cancer, chronic irritation of the mucosa could act as a “promoter” of cancer in much the same way as alcohol does.

The incidence of oral cancer in individuals under age 40 who have no known risk factors has been on the rise for the past several years. [25] [26] [27] The pathogenesis of this group of patients who are nonsmokers and not infected with HPV is unknown.

Molecular Biology of Squamous Cell Carcinoma.

Like all epithelial neoplasms, the development of squamous cell carcinoma is thought to be a multi-step process involving the sequential activation of oncogenes and inactivation of tumor suppressor genes in a clonal population of cells. Several genetic alterations, some definitively identified and some inferred from tumor-specific chromosomal alterations, have been found in HNSCC. While not all of the specific mutations required for progression have been delineated, a working molecular model has been established (see Fig. 16-7). The first change is the loss of chromosomal regions of 3p and 9p21.[28] Loss of heterozygosity (LOH) in conjunction with promoter hypermethylation at this locus results in the inactivation of the *p16* gene, an inhibitor of cyclin-dependent kinase (Chapter 7). This alteration is associated with the transition from normal to hyperplasia/hyperkeratosis and occurs before the development of histologic atypia, thus underscoring the histologic limitations for early diagnosis. Subsequent LOH at 17p with mutation of the *p53* tumor suppressor gene is associated with progression to dysplasia.[29] Recently it has been demonstrated that gross genomic alterations as well as deletions on 4q, 6p, 8p, 11q, 13q, and 14q may act as predictors of progression to frank malignancy.[30] Ultimately, amplification and overexpression of the cyclin D1 gene (located on chromosome 11q13), which constitutively activates cell cycle progression, is a common late event. Data suggest that alterations of this gene confer the ability to invade in certain clones.[31,][32]

However, while this model is a good working draft of the molecular changes involved in development of HNSCC, it is incomplete. First, while some of the gross genomic alterations correlate with genes known to be important in HNSCC (such as *p16*, *p53*, and *CyclinD1*), many of the specific genes are still unknown. Second, this model does not take into account alterations in genes such as the epidermal growth factor receptor (EFGR), which is overexpressed in a high percentage of HNSCC and has been successfully targeted in the treatment of this disease. Finally, as indicated above, it is increasingly clear that HNSCC is a heterogeneous disease in terms of etiology and its molecular mechanisms of development.

Morphology. Squamous cell carcinoma may arise anywhere in the oral cavity, but the favored locations are the ventral surface of the tongue, floor of the mouth, lower lip, soft palate, and gingiva (Fig. 16-8). The malignancies themselves are typically preceded by the presence of premalignant lesions that can be very heterogeneous in presentation (see above).

In the early stages, cancers of the oral cavity appear either as raised, firm, pearly plaques or as irregular, roughened, or verrucous areas of mucosal thickening, possibly mistaken for leukoplakia. Either pattern may be superimposed on a background of apparent leukoplakia or erythroplakia. As these lesions enlarge, they typically create ulcerated and protruding masses that have irregular and indurated (rolled) borders.

On histologic examination, these cancers begin as dysplastic lesions, which may or may not progress to full-thickness dysplasia (carcinoma in situ) before invading the underlying connective tissue stroma (Fig. 16-7). This difference in progression should be contrasted with cervical cancer (Chapter 22), in which, typically, full-thickness dysplasia, representing carcinoma in situ, develops before invasion. Squamous cell carcinomas range from well-differentiated keratinizing neoplasms to anaplastic, sometimes sarcomatoid, tumors, and from slowly to rapidly growing lesions. However, the degree of histologic differentiation, as determined by the relative degree of keratinization, is not correlated with behavior. As a group these tumors tend to infiltrate locally before they metastasize to other sites. The routes of extension depend on the primary site. The favored sites of local metastasis are the cervical lymph nodes, while the most common sites of distant metastasis are mediastinal lymph nodes, lungs, liver, and bones. Unfortunately, such distant metastases are often occult at the time of discovery of the primary lesion.

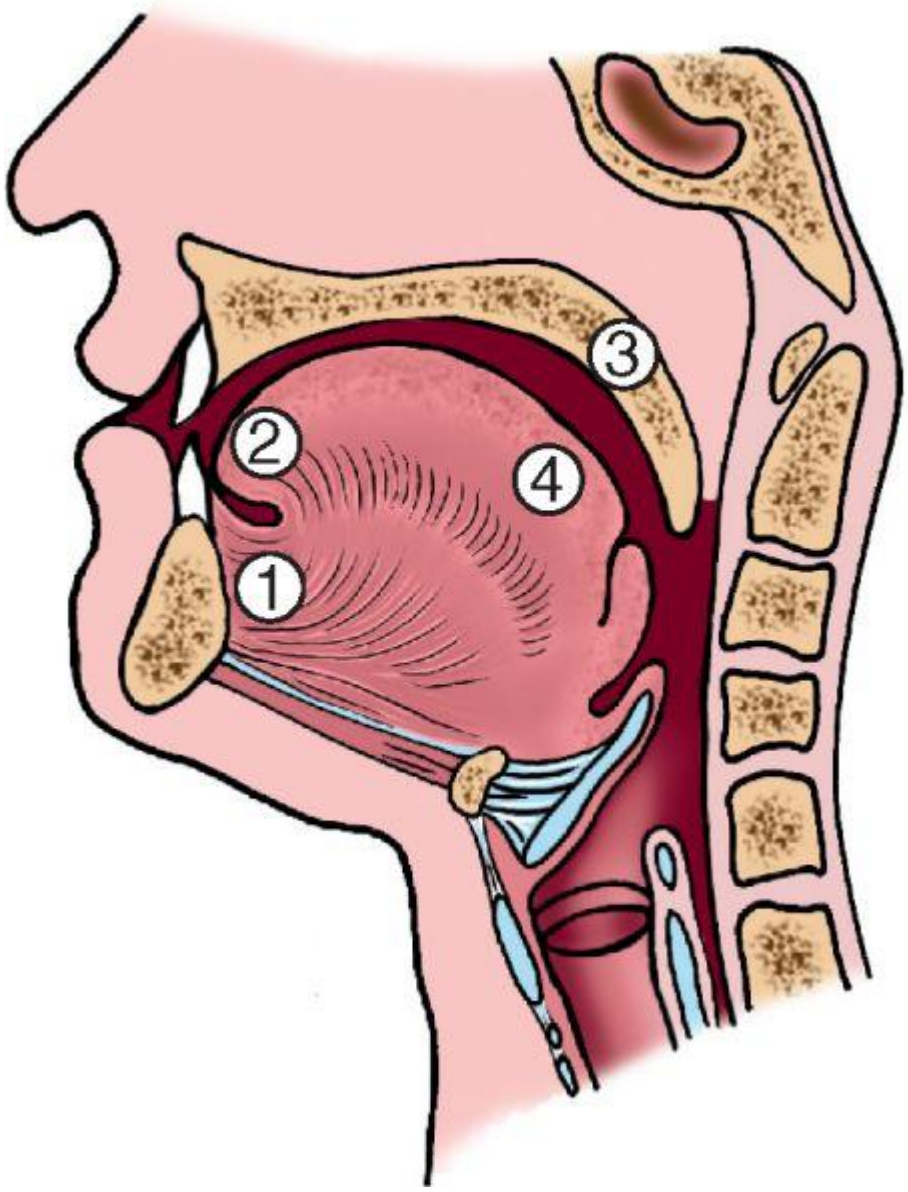

FIGURE 16-8 Schematic representation of the sites of origin of squamous cell carcinoma of the oral cavity, in numerical order of frequency.

3.6.1.6 Odontogenic Cysts & Tumors

In contrast to the rest of the skeleton, epithelial-lined cysts are quite common in the jaws. The overwhelming majority of these cysts are derived from remnants of odontogenic epithelium present within the jaws. In general, these cysts are subclassified as either inflammatory or developmental (Table 16-2). Only the most common of these lesions are described below.

TABLE 16-2 -- Histologic Classification of Odontogenic Cysts

1. INFLAMMATORY
Periapical cyst

Residual cyst
Paradental cyst
2. DEVELOPMENTAL
Dentigerous cyst
Odontogenic keratocyst
Gingival cyst of newborn
Gingival cyst of adult
Eruption cyst
Lateral periodontal cyst
Glandular odontogenic cyst
Calcifying epithelial odontogenic cyst (Gorlin cyst)

The *dentigerous cyst* is defined as a cyst that originates around the crown of an unerupted tooth and is thought to be the result of a degeneration of the dental follicle. Radiographically, they are unilocular lesions and are most often associated with impacted third molar (wisdom) teeth. Histologically they are lined by a thin layer of stratified squamous epithelium. Often, there is a very dense chronic inflammatory cell infiltrate in the connective tissue stroma. Complete removal of the lesion is curative. This is important, since incomplete excision may result in recurrence or, very rarely, neoplastic transformation into an ameloblastoma or a squamous cell carcinoma.

The *odontogenic keratocyst (OKC)* is an important entity to differentiate from other odontogenic cysts because it is locally aggressive and has a high rate of recurrence. OKCs can be seen at any age but are most often diagnosed in patients between ages 10 and 40. They occur most commonly in males within the posterior mandible. Radiographically, OKCs present as well-defined unilocular or multilocular radiolucencies. Histologically, the cyst lining consists of a thin layer of parakeratinized or orthokeratinized stratified squamous epithelium with a prominent basal cell layer and a corrugated appearance of the epithelial surface. Treatment requires aggressive and complete removal of the lesion, because recurrence rates for inadequately removed lesions can reach 60%. Multiple OKCs may occur; these patients should be evaluated for nevoid basal cell carcinoma syndrome (Gorlin syndrome), which, as we shall see, is related to mutations in the tumor suppressor gene *PTCH* located on chromosome 9q22 (Chapter 25).

The *periapical cyst*, in contrast to the developmental cysts described above, is inflammatory in origin. These are extremely common lesions found at the apex of teeth. They develop as a result of long-standing pulpitis, which may be caused by advanced carious lesions or by trauma to the tooth in question. The inflammatory process may result in necrosis of the pulpal tissue, which can traverse the length of the root and exit the apex of the tooth into the surrounding alveolar bone, giving rise to a periapical abscess. Over time, like any chronic inflammatory process, a lesion with granulation tissue (with or without an epithelial lining) may develop. While the term *periapical granuloma* is not the most appropriate terminology (as the lesion does not show true granulomatous inflammation), old terminology, like bad habits, is difficult to shed. Periapical inflammatory lesions persist as a result of the continued presence of bacteria or other offensive agents in the area. Successful treatment, therefore, necessitates the complete removal of offending material and appropriate restoration of the tooth or extraction.

Odontogenic tumors are a complex group of lesions with diverse histologic appearances and clinical behavior.[33] Some are true neoplasms (both benign and malignant), while others are more likely hamartomas. Odontogenic tumors are derived from odontogenic epithelium, ectomesenchyme, or both (Table 16-3). The two most common and clinically significant tumors are:

- *Ameloblastoma*, which arises from odontogenic epithelium and shows *no* ectomesenchymal differentiation. It is commonly cystic, slow growing, and locally invasive but has an indolent course in most cases.
- *Odontoma*, the most common type of odontogenic tumor, arises from epithelium but shows extensive depositions of enamel and dentin. Odontomas are probably hamartomas rather than true neoplasms and are cured by local excision.

TABLE 16-3 -- Histologic Classification of Odontogenic Tumors

1. TUMORS OF ODONTOGENIC EPITHELIUM
Benign
Ameloblastoma
Calcifying epithelial odontogenic tumor (Pindborg tumor)
Squamous odontogenic tumor
Malignant
Ameloblastic carcinoma
Malignant ameloblastoma
Clear-cell odontogenic carcinoma
2. TUMORS OF ODONTOGENIC ECTOMESENCHYME
Odontogenic fibroma
Odontogenic myxoma
Cementoblastoma
3. TUMORS OF ODONTOGENIC EPITHELIUM AND ECTOMESENCHYME
Benign
Ameloblastic fibroma
Ameloblastic fibro-odontoma
Ameloblastic fibrosarcoma
Adenomatoid odontogenic tumor
Odontoameloblastoma
Complex odontoma
Compound odontoma
Malignant
Ameloblastic fibrosarcoma

3.6.2 Upper Airways

The term *upper airways* is used here to include the nose, pharynx, and larynx and their related parts. Disorders of these structures are among the most common afflictions of humans, but fortunately the overwhelming majority are more nuisances than threats.

3.6.2.1 Nose

Inflammatory diseases, mostly in the form of the common cold, as everyone knows, are the most common disorders of the nose and accessory air sinuses. Most of these inflammatory conditions are viral in origin, but they are often complicated by superimposed bacterial infections having considerably greater significance. Much less common are a few destructive inflammatory nasal diseases and tumors primary in the nasal cavity or paranasal sinuses.

INFLAMMATIONS

Infectious Rhinitis.

Infectious rhinitis, the more elegant way of saying “common cold,” is in most instances caused by one or more viruses. Major offenders are adenoviruses, echoviruses, and rhinoviruses. They evoke a profuse catarrhal discharge that is familiar to all and the bane of the kindergarten teacher. During the initial acute stages, the nasal mucosa is thickened, edematous, and red; the nasal cavities are narrowed; and the turbinates are enlarged. These changes may extend, producing a concomitant pharyngotonsillitis. Secondary bacterial infection enhances the inflammatory reaction and produces an essentially mucopurulent or sometimes frankly suppurative exudate. But as all have learned from experience, these infections soon clear up—as the saying goes, in a week if treated but in 7 days if ignored.

Allergic Rhinitis.

Allergic rhinitis (hay fever) is initiated by hypersensitivity reactions to one of a large group of allergens, most commonly the plant pollens, fungi, animal allergens, and dust mites.[34] It affects 20% of the US population. As is the case with asthma, allergic rhinitis is an IgE–mediated immune reaction with an early- and late-phase response (see “Immediate (Type I) Hypersensitivity” in Chapter 6). The allergic reaction is characterized by marked mucosal edema, redness, and mucus secretion, accompanied by a leukocytic infiltration in which eosinophils are prominent.

Nasal Polyps.

Recurrent attacks of rhinitis may eventually lead to focal protrusions of the mucosa, producing so-called *nasal polyps*, which may reach 3 to 4 cm in length. On histologic examination these polyps consist of edematous mucosa having a loose stroma, often harboring hyperplastic or cystic mucous glands, infiltrated with a variety of inflammatory cells, including neutrophils, eosinophils, and plasma cells with occasional clusters of lymphocytes (Fig. 16-9). In the absence of bacterial infection, the mucosal covering of these polyps is intact, but with chronicity it may become ulcerated or infected. When multiple or large, the polyps may encroach on the airway and impair sinus drainage. Although the features of nasal polyps point to an allergic etiology, most people with nasal polyps are not atopic, and only 0.5% of atopic patients develop polyps.[35]

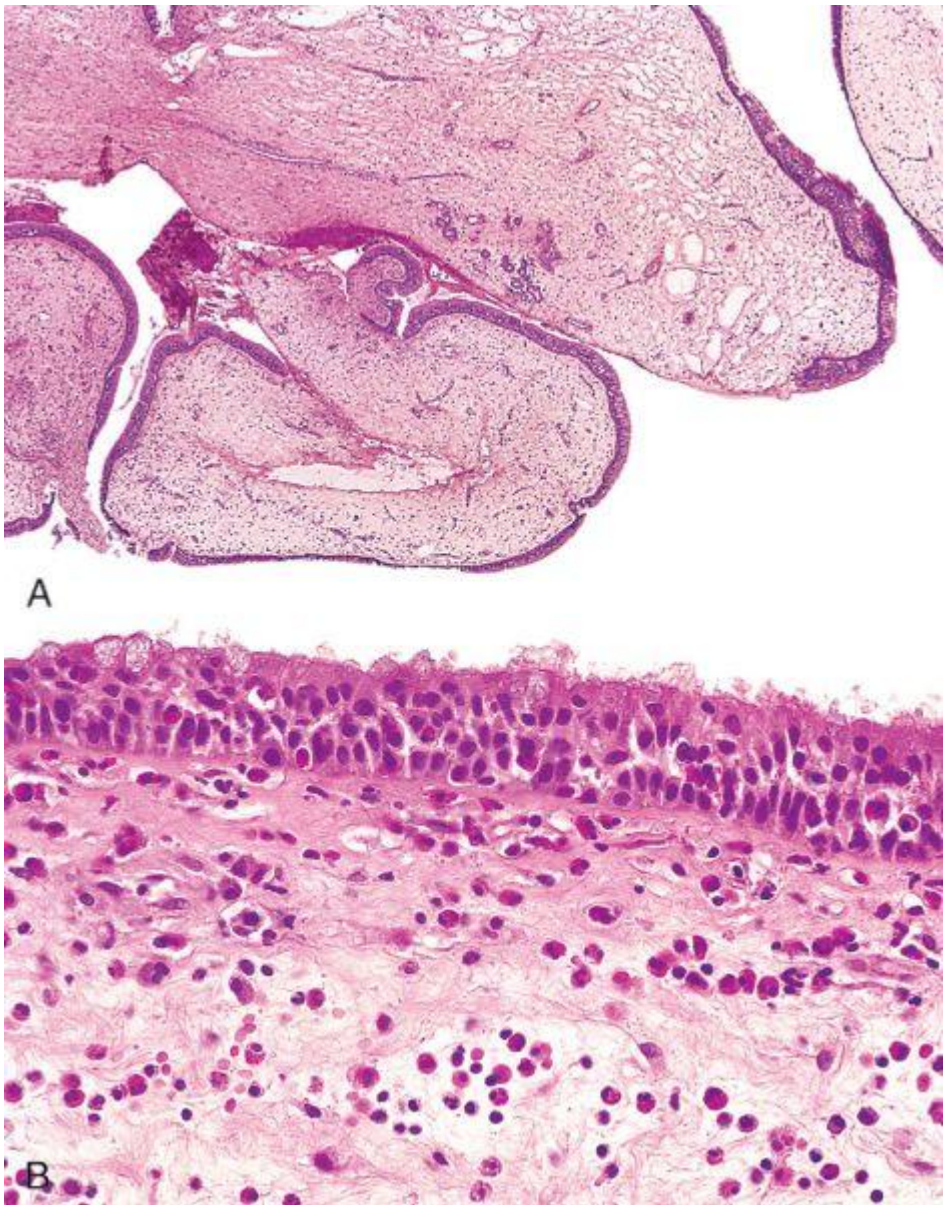

FIGURE 16-9 **A**, Nasal polyps. Low-power magnification showing edematous masses lined by epithelium. **B**, High-power view showing edema and eosinophil-rich inflammatory infiltrate.

Chronic Rhinitis.

Chronic rhinitis is a sequel to repeated attacks of acute rhinitis, either microbial or allergic in origin, with the eventual development of superimposed bacterial infection. A deviated nasal septum or nasal polyps with impaired drainage of secretions contribute to the likelihood of microbial invasion. Frequently, there is superficial desquamation or ulceration of the mucosal epithelium and a variable inflammatory infiltrate of neutrophils, lymphocytes, and plasma cells subjacent to the epithelium. These suppurative infections sometimes extend into the air sinuses.

Sinusitis.

Acute sinusitis is most commonly preceded by acute or chronic rhinitis, but maxillary sinusitis occasionally arises by extension of a periapical infection through the bony floor of the sinus. The offending agents are usually inhabitants of the oral cavity, and the inflammatory reaction is entirely nonspecific. Impairment of drainage of the sinus by inflammatory edema of the mucosa is an important contributor to the process and, when complete, may impound the suppurative exudate, producing *empyema* of the sinus. Obstruction of the outflow, most often from the frontal and less commonly from the anterior ethmoid sinuses, occasionally leads to an accumulation of mucous secretions in the absence of direct bacterial invasion, producing a so-called *mucocele*. Acute sinusitis may, in time, give rise to *chronic sinusitis*, particularly when there is interference with drainage. There is usually a mixed microbial flora, largely of normal inhabitants of the oral cavity. Particularly severe forms of chronic sinusitis are caused by fungi (e.g., mucormycosis), especially in diabetics. Uncommonly, sinusitis is a component of *Kartagener syndrome*, which also includes bronchiectasis and situs inversus (Chapter 15). All these features are secondary to defective ciliary action. Although most instances of chronic sinusitis are more uncomfortable than disabling or serious, the infections have the potential of spreading into the orbit or of penetrating into the surrounding bone to give rise to osteomyelitis or spreading into the cranial vault, causing septic thrombophlebitis of a dural venous sinus.

NECROTIZING LESIONS OF THE NOSE AND UPPER AIRWAYS

Necrotizing ulcerating lesions of the nose and upper respiratory tract may be produced by

- Acute fungal infections (including mucormycosis; Chapter 8), particularly in diabetic and immunosuppressed patients
- Wegener granulomatosis (discussed in Chapter 11)
- A condition once called *lethal midline granuloma* or *polymorphic reticulosis* and now known to be a lymphoma of natural killer cells infected with EBV[36] (Chapter 14). Ulceration and superimposed bacterial infection frequently complicate the process. At one time these lesions were almost always rapidly fatal as a result of uncontrolled growth of the lymphoma, possibly with penetration into the cranial vault, or because of tumor necrosis with secondary bacterial infection and blood-borne dissemination of the infection. Currently, localized cases can often be controlled with radiotherapy, but once the tumors spread, they are difficult to treat. Most of those affected die of the disease.

3.6.2.2 Nasopharynx

Although the nasopharyngeal mucosa, related lymphoid structures, and glands may be involved in a wide variety of specific infections (e.g., diphtheria, infectious mononucleosis) and by neoplasms, the only disorders mentioned here are nonspecific inflammations; tumors are discussed separately.

INFLAMMATIONS

Pharyngitis and *tonsillitis* are frequent in the usual viral upper respiratory infections. Most commonly implicated are the multitudinous rhinoviruses, echoviruses, and adenoviruses, and, less frequently, respiratory syncytial viruses and the various strains of influenza virus. In the usual case, there is reddening and slight edema of the nasopharyngeal mucosa, with reactive enlargement of the related lymphoid structures. Bacterial infections may be superimposed on these viral involvements, or may be primary invaders. The most common offenders are the β-hemolytic streptococci, but sometimes *Staphylococcus aureus* or other pathogens may be implicated. The inflamed nasopharyngeal mucosa may be covered by an exudative membrane (pseudo-membrane), and the nasopalatine and palatine tonsils may be enlarged and covered by exudate. A typical appearance is of enlarged, reddened tonsils (due to reactive lymphoid hyperplasia) dotted by pinpoints of exudate emanating from the tonsillar crypts, so-called *follicular tonsillitis*.

The major importance of streptococcal “sore throats” lies in the possible development of late sequelae, such as, rheumatic fever (Chapter 12) and glomerulonephritis (Chapter 20). Whether recurrent episodes of acute tonsillitis favor the development of chronic tonsillitis (true chronic tonsillitis is extremely rare) is open to debate, but the result is residual enlargement of the lymphoid tissue, inviting the tender mercies of the otolaryngologist.

3.6.2.3 Tumors of the Nose, Sinuses & Nasopharynx

Tumors in these locations are infrequent but include the entire category of mesenchymal and epithelial neoplasms.[36,][37] Brief mention is made of some distinctive types.

Nasopharyngeal Angiofibroma.

This is a highly vascular tumor that occurs almost exclusively in adolescent males. Despite its benign nature, it may cause serious clinical problems because of its tendency to bleed profusely during surgery.

Sinonasal (Schneiderian) Papilloma.

These are benign neoplasms arising from the sinonasal mucosa and are composed of squamous or columnar epithelium. Although their etiology is still unproven, HPV types 6 and 11 have been identified in the lesions. These lesions occur in three forms: *exophytic* (most common), *inverted* (most important biologically), and *cylindrical*. Because of its uniquely aggressive biologic behavior, only inverted papilloma is discussed here. Inverted papillomas are benign but locally aggressive neoplasms occurring in both the nose and the paranasal sinuses. As the name implies, the papillomatous proliferation of squamous epithelium, instead of producing an exophytic growth (like the septal and cylindrical papillomas), extends into the mucosa, that is, it is inverted (Fig. 16-10). If not adequately excised, it has a high rate of recurrence, with the potentially serious complication of invasion of the orbit or cranial vault; rarely, frank carcinoma may also develop.

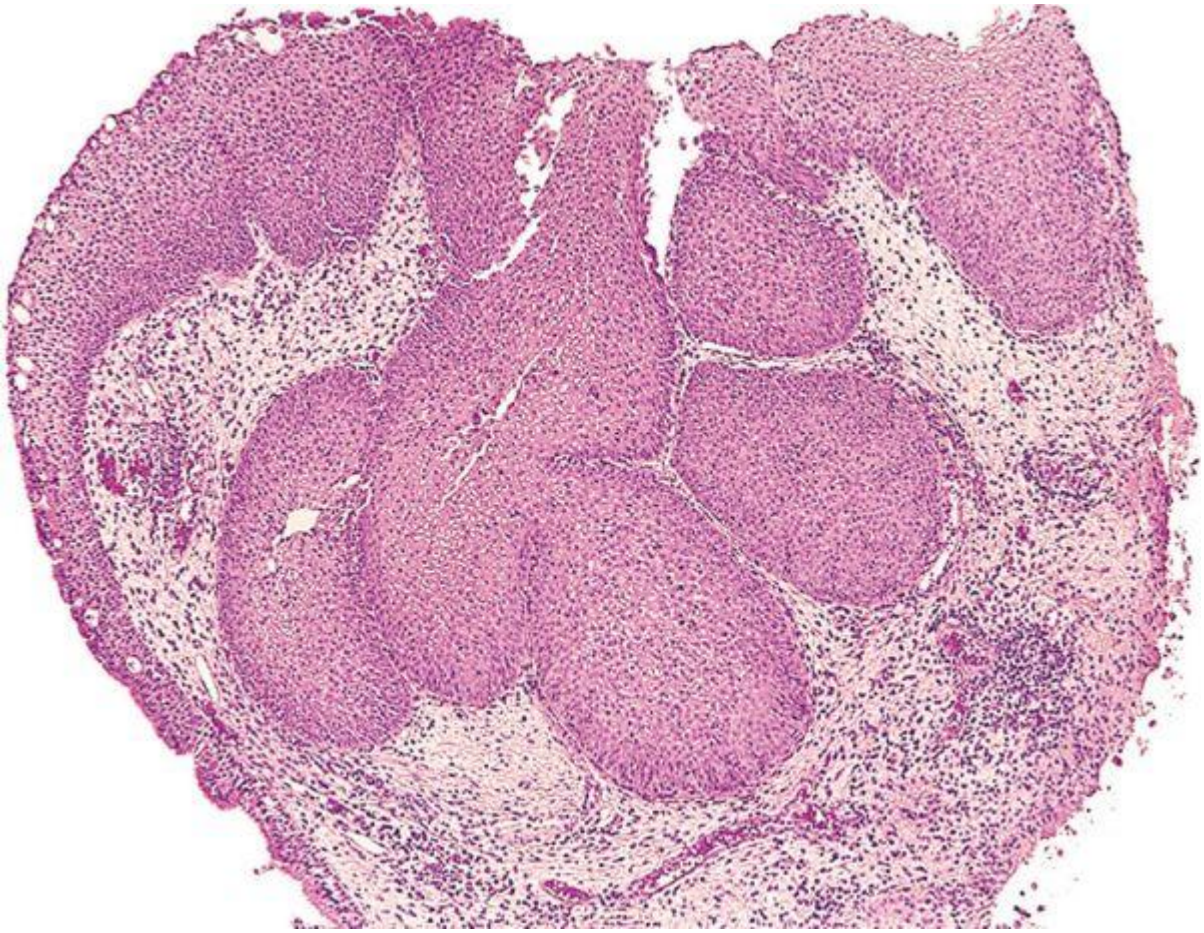

FIGURE 16-10 Inverted papilloma. The masses of squamous epithelium are growing inward; hence, the term *inverted*. *(Courtesy of Dr. James Gulizia, Brigham and Women's Hospital, Boston, MA.)*

Olfactory Neuroblastoma (Esthesioneuroblastoma).

These are uncommon, malignant tumors composed of small round cells, resembling neuroblasts, which form lobular nests encircled by vascularized connective tissue. They arise most often superiorly and laterally in the nose from the neuroendocrine cells dispersed in the olfactory mucosa. The differential diagnosis of these neoplasms includes all other small-cell tumors (Chapter 10), such as lymphoma, Ewing sarcoma, and embryonal rhabdomyosarcoma.[38] The cells are of neuroendocrine origin and thus exhibit membrane-bound secretory granules on electron microscopy and express neuron-specific enolase, synaptophysin, CD56, and chromogranin by immunohistochemistry. While the name implies that they are primitive neuroectodermal tumors, many do not share the 11;22 translocation or fusion-gene products typical of Ewing sarcoma of bone (Chapter 26) and other primitive neuroectodermal tumors. Some of these tumors reveal trisomy 8. Depending on the stage and grade of a particular neoplasm, combinations of surgery, radiation therapy, and chemotherapy yield 5-year survival rates of 40% to 90%.[39]

Nasopharyngeal Carcinoma.

This tumor is characterized by a distinctive geographic distribution, a close anatomic relationship to lymphoid tissue, and an association with EBV infection.[40] The nomenclature for nasopharyngeal

carcinomas is in constant flux. However, at present the disease is thought to take one of three patterns: (1) keratinizing squamous cell carcinomas, (2) nonkeratinizing squamous cell carcinomas, and (3) undifferentiated carcinomas that have an abundant non-neoplastic, lymphocytic infiltrate. The last pattern has often been called *lymphoepithelioma*. However, while widely used in clinical practice, this highly descriptive term should be avoided.

Three factors affect the origins of these neoplasms: (1) heredity, (2) age, and (3) infection with EBV. Nasopharyngeal carcinomas are particularly common in some parts of Africa, where they are the most frequent childhood cancer. In contrast, in southern China, they are very common in adults but rarely occur in children. In the United States they are rare in both adults and children. In addition to EBV infection, diets high in nitrosamines, such as fermented foods and salted fish, as well as other environmental factors such as smoking and chemical fumes, have been linked to the disease. Components of the EBV genome such as EBNA-1 can be identified in the tumor epithelial cells (not the lymphocytes) of most undifferentiated and nonkeratinizing squamous cell nasopharyngeal carcinomas, particularly when in situ hybridization is performed.[41]

Morphology. On histologic examination, the keratinizing and nonkeratinizing squamous cell lesions resemble usual well-differentiated and poorly differentiated squamous cell carcinomas arising in other locations. The undifferentiated variant is composed of large epithelial cells with oval or round vesicular nuclei, prominent nucleoli, and indistinct cell borders disposed in a syncytium-like array (Fig. 16-11). Admixed with the epithelial cells are abundant, mature, normal-appearing lymphocytes, which are predominantly T cells.

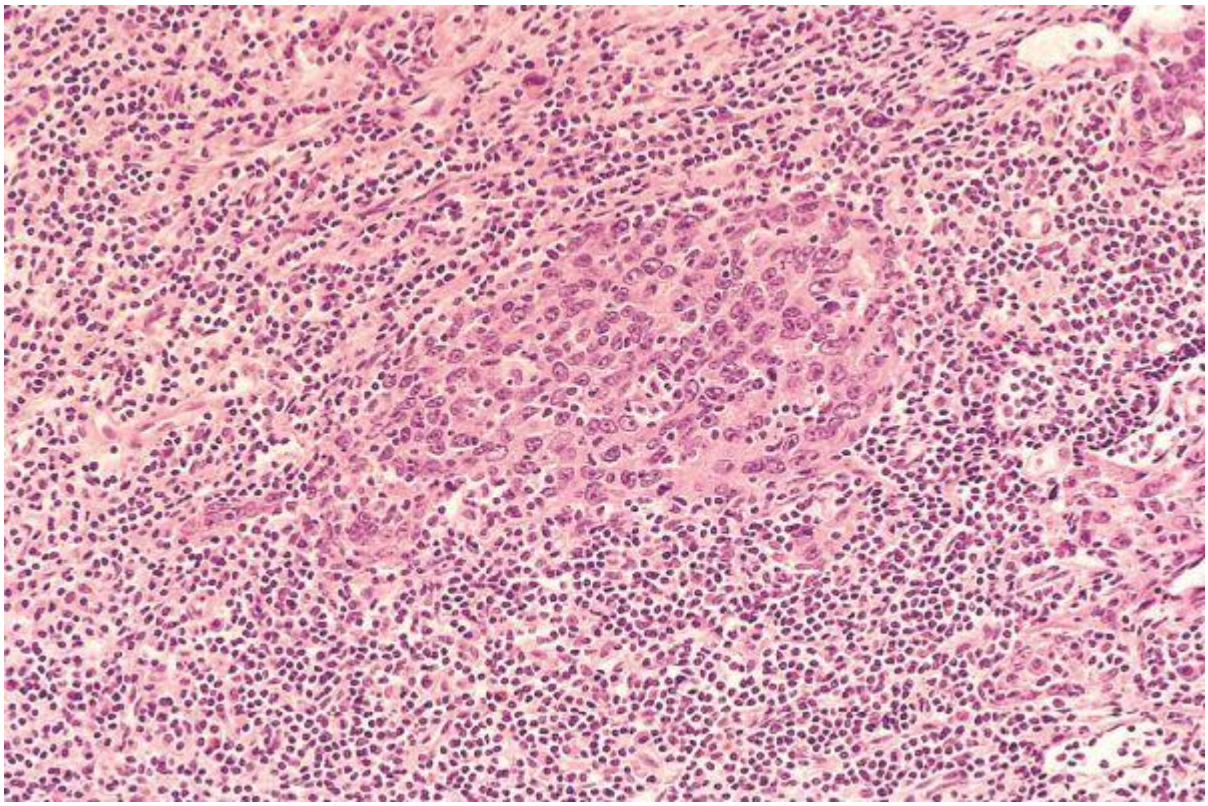

FIGURE 16-11 Nasopharyngeal carcinoma, undifferentiated type. The syncytium-like nests of epithelium are surrounded by lymphocytes. *(Courtesy of Dr. James Gulizia, Brigham and Women's Hospital, Boston, MA.)*

Primary nasopharyngeal carcinomas are often clinically occult for long periods, and present as metastases in the cervical lymph nodes in as many as 70% of the patients. Radiotherapy is the standard modality of treatment, yielding 50% to 70% 3-year survival rate. The undifferentiated carcinoma is the most radiosensitive and the keratinizing squamous cell carcinoma is the least radiosensitive.

3.6.2.4 Larynx

The most common disorder that affects the larynx is inflammation. Tumors are uncommon but are amenable to resection, though often at the price of loss of natural voice.

INFLAMMATIONS

Laryngitis may occur as the sole manifestation of allergic, viral, bacterial, or chemical insult, but it is more commonly part of a generalized upper respiratory tract infection or the result of heavy exposure to environmental toxins such as tobacco smoke. It may also occur in association with gastroesophageal reflux due to the irritating effect of gastric contents. The larynx may also be affected in systemic infections, such as tuberculosis and diphtheria. Although most infections are self-limited, they may at times be serious, especially in infancy or childhood, when mucosal congestion, exudation, or edema may cause laryngeal obstruction. In particular, laryngoepiglottitis, caused by respiratory syncitial virus, *Haemophilus influenzae*, or β-hemolytic streptococci in infants and young children with their small airways, may induce such sudden swelling of the epiglottis and vocal cords that a potentially lethal medical emergency is created. This form of disease is uncommon in adults because of the larger size of the larynx and the stronger accessory muscles of respiration. *Croup* is the name given to laryngotracheobronchitis in children, in which the inflammatory narrowing of the airway produces the inspiratory stridor so frightening to parents. The most common form of laryngitis, encountered in heavy smokers, predisposes to squamous epithelial metaplasia and sometimes overt carcinoma.

REACTIVE NODULES (VOCAL CORD NODULES AND POLYPS)

Reactive nodules, also called polyps, sometimes develop on the vocal cords, most often in heavy smokers or in individuals who impose great strain on their vocal cords *(singers' nodules)* (Fig. 16-12). By convention, singers' nodules are bilateral lesions and polyps are unilateral. Adults, predominantly men, are most often affected. These nodules are smooth, rounded, sessile or pedunculated excrescences, generally only a few millimeters in the greatest dimension, located usually on the true vocal cords. They are typically covered by squamous epithelium that may become keratotic, hyperplastic, or even slightly dysplastic. The core of the nodule is a loose myxoid connective tissue that may be variably fibrotic or punctuated by numerous vascular channels. When nodules on opposing vocal cords impinge on each other, the mucosa may undergo ulceration. Because of their strategic location and accompanying inflammation, they characteristically change the character of the voice and often cause progressive hoarseness. They virtually never give rise to cancers.

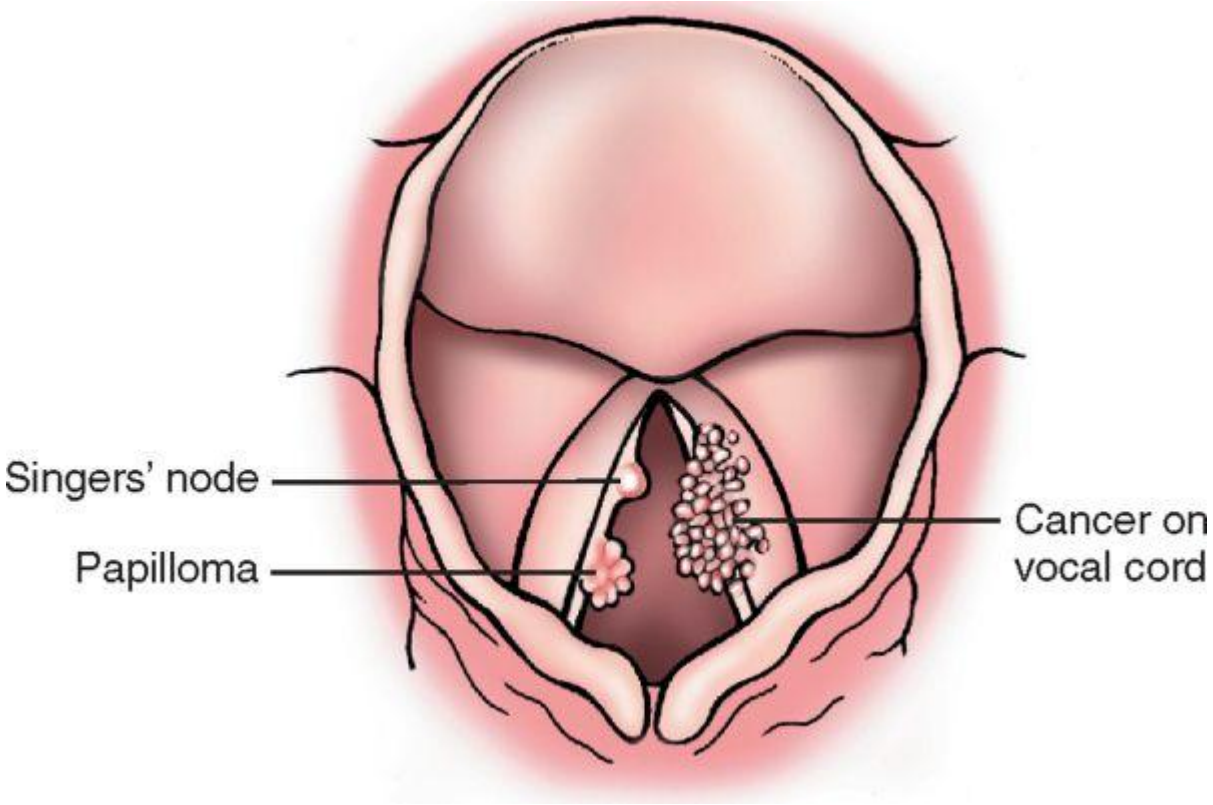

FIGURE 16-12 Diagrammatic comparison of a benign papilloma and an exophytic carcinoma of the larynx to highlight their quite different appearances.

SQUAMOUS PAPILLOMA AND PAPILLOMATOSIS

Laryngeal squamous papillomas are benign neoplasms, usually located on the true vocal cords, that form soft, raspberry-like excrescences rarely more than 1 cm in diameter (Fig. 16-12). On histologic examination, the papillomas are made up of multiple slender, finger-like projections supported by central fibrovascular cores and covered by an orderly stratified squamous epithelium. When the papillomas are on the free edge of the vocal cord, trauma may lead to ulceration that can be accompanied by hemoptysis.

Papillomas are usually single in adults but are often multiple in children, in whom they are referred to as *juvenile laryngeal papillomatosis*.[42] However, multiple recurring papillomas also occur in adults. *The lesions are caused by HPV types 6 and 11*. They do not become malignant, but frequently recur. They often spontaneously regress at puberty, but some affected patients endure numerous surgeries before this occurs. Cancerous transformation is rare.

CARCINOMA OF THE LARYNX

Sequence of Hyperplasia-Dysplasia-Carcinoma.

A spectrum of epithelial alterations is seen in the larynx. They range from *hyperplasia, atypical hyperplasia, dysplasia, carcinoma in situ, to invasive carcinoma*.[43] Macroscopically, the epithelial changes vary from smooth, white or reddened focal thickenings, sometimes roughened by keratosis, to irregular verrucous or ulcerated white-pink lesions that are similar in appearance to carcinoma.

There are all gradations of epithelial hyperplasia of the true vocal cords, and the likelihood of the development of an overt carcinoma is directly proportional to the level of atypia when the lesion is first seen. Orderly hyperplasias have almost no potential for malignant transformation, but the risk rises to 1% to 2% during the span of 5 to 10 years with mild dysplasia and 5% to 10% with severe dysplasia. Only histologic evaluation can determine the gravity of the changes.

The various changes described are most often related to tobacco smoke, the risk being proportional to the level of exposure. Indeed, up to the point of frank cancer, the changes often regress after cessation of smoking. Alcohol is also clearly a risk factor. Together smoking and alochol increase the risk substantially. Other factors that may contribute to increased risk include nutritional factors, exposure to asbestos, irradiation, and infection with HPV.[44,][45]

Morphology. About 95% of laryngeal carcinomas are typical squamous cell tumors. The tumor usually develops directly on the vocal cords, but it may arise above or below the cords, on the epiglottis or aryepiglottic folds, or in the pyriform sinuses. Those confined within the larynx proper are termed **intrinsic**, whereas those that arise or extend outside the larynx are called **extrinsic**. Squamous cell carcinomas of the larynx follow the growth pattern of other squamous cell carcinomas. They begin as in situ lesions that later appear as pearly gray, wrinkled plaques on the mucosal surface, ultimately ulcerating and fungating (Fig. 16-13). The degree of anaplasia of the laryngeal tumors is highly variable. Sometimes massive tumor giant cells and multiple bizarre mitotic figures are seen. As expected with lesions arising from recurrent exposure to environmental carcinogens, adjacent mucosa may demonstrate squamous cell hyperplasia with foci of dysplasia or even carcinoma in situ.

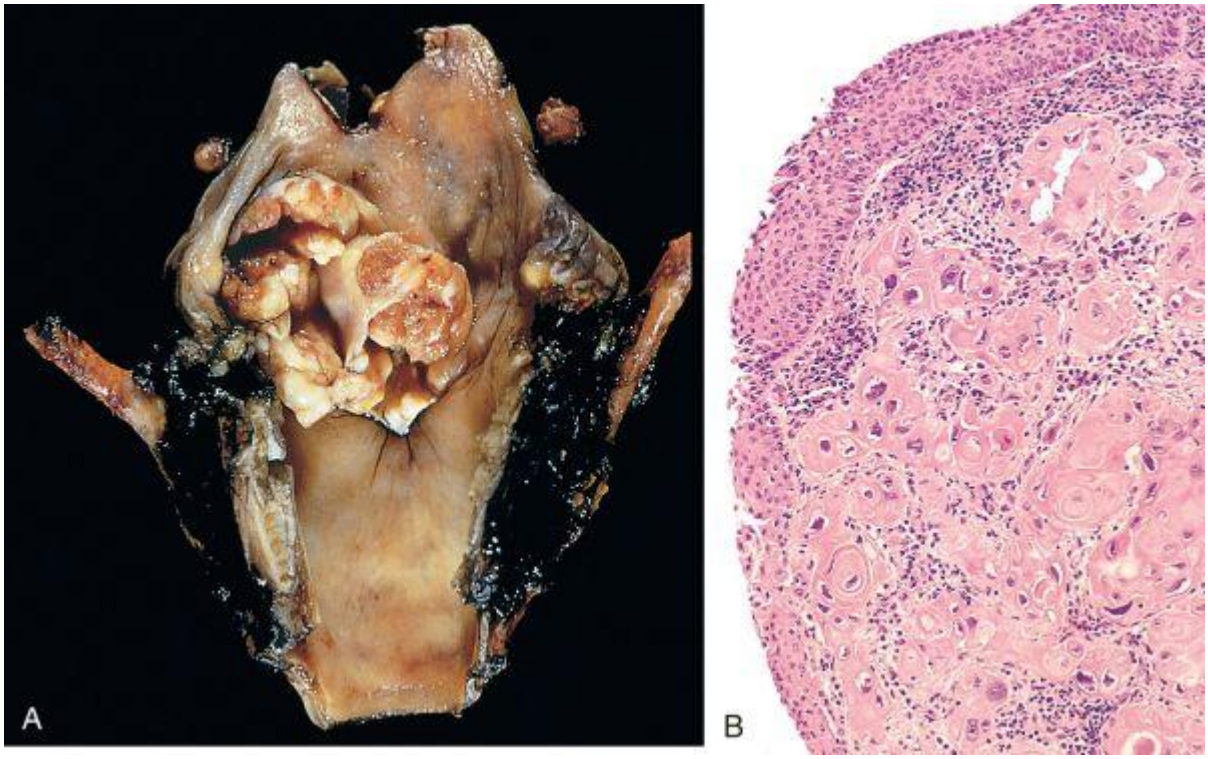

FIGURE 16-13 A, Laryngeal carcinoma. Note the large, ulcerated, fungating lesion involving the vocal cord and pyriform sinus. **B**, Histologic appearance of laryngeal squamous cell carcinoma. Note the atypical lining epithelium and invasive keratinizing cancer cells in the submucosa.

Carcinoma of the larynx manifests itself clinically by persistent hoarseness. At presentation, about 60% of these cancers are confined to the larynx. The prognosis for these is better than for those tumors that have spread into adjacent structures. Later, laryngeal tumors may produce pain, dysphagia, and hemoptysis. Patients are also extremely vulnerable to secondary infection of the ulcerating lesion. With surgery, irradiation, or combination therapy, many patients can be cured, but about one third die of the disease. The usual causes of death are infection of the distal respiratory passages or widespread metastases and cachexia.

3.6.3 Ears

Although disorders of the ear rarely shorten life, many impair its quality. The most common aural disorders, in descending order of frequency, are (1) acute and chronic otitis (most often involving the middle ear and mastoid), sometimes leading to a cholesteatoma; (2) symptomatic otosclerosis; (3) aural polyps; (4) labyrinthitis; (5) carcinomas, largely of the external ear; and (6) paragangliomas, found mostly in the middle ear. Only those conditions that have distinctive morphologic features (save for labyrinthitis) are described. Paragangliomas are discussed later.

3.6.3.1 Inflammatory Lesions

Inflammations of the ear—*otitis media, acute or chronic*—occur mostly in infants and children. These lesions are typically viral in nature and produce a serous exudate but may become suppurative with superimposed bacterial infection. The most common offenders are *Streptococcus pneumoniae*, non-typeable *H. influenzae*, and *Moraxella catarrhalis*.[46]

Repeated bouts of acute otitis media with failure of resolution lead to chronic disease. The causative agents of chronic disease are usually *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or a fungus; sometimes a mixed flora is the cause. Chronic infection has the potential to perforate the eardrum, encroach on the ossicles or labyrinth, spread into the mastoid spaces, and even penetrate into the cranial vault to produce a temporal cerebritis or abscess. Otitis media in the diabetic person, when caused by *P. aeruginosa*, is especially aggressive and spreads widely causing destructive necrotizing otitis media.

Cholesteatomas, associated with chronic otitis media, are not neoplasms, nor do they always contain cholesterol. Rather, they are cystic lesions 1 to 4 cm in diameter, lined by keratinizing squamous epithelium or metaplastic mucus-secreting epithelium, and filled with amorphous debris (derived largely from desquamated epithelium). Sometimes they contain spicules of cholesterol. The precise events involved in their development are not clear, but it is proposed that chronic inflammation and perforation of the eardrum with ingrowth of the squamous epithelium or metaplasia of the secretory epithelial lining of the middle ear are responsible for the formation of a squamous cell nest that becomes cystic. A chronic inflammatory reaction surrounds the keratinous cyst. Sometimes, the cyst ruptures, increasing the inflammatory reaction and inducing the formation of giant cells that enclose partially necrotic squames and other particulate debris. These lesions, by progressive enlargement, can erode into the ossicles, the labyrinth, the adjacent bone, or the surrounding soft tissue and sometimes produce visible neck masses.

3.6.3.2 Otosclerosis

As the name implies, otosclerosis refers to abnormal bone deposition in the middle ear about the rim of the oval window into which the footplate of the stapes fits. Both ears are usually affected. At first there is fibrous ankylosis of the footplate, followed in time by bony overgrowth anchoring it into the oval

window. The degree of immobilization governs the severity of the hearing loss. This condition usually begins in the early decades of life; minimal degrees of this derangement are exceedingly common in the United States in young to middle-aged adults, but fortunately more severe symptomatic otosclerosis is relatively uncommon. In most instances it is familial, following autosomal dominant transmission with variable penetrance. The basis for the osseous overgrowth is completely obscure, but it appears to represent uncoupling of normal bone resorption and bone formation. Thus, it begins with bone resorption, followed by fibrosis and vascularization of the temporal bone in the immediate vicinity of the oval window, in time replaced by dense new bone anchoring the footplate of the stapes. In most instances the process is slowly progressive over the span of decades, leading eventually to marked hearing loss.

3.6.3.3 Tumors

A large variety of epithelial and mesenchymal tumors that arise in the ear—external, middle, internal—all are rare save for basal cell or squamous cell carcinomas of the pinna (external ear). These carcinomas tend to occur in elderly men and are thought to be associated with actinic radiation. By contrast, those within the canal tend to be squamous cell carcinomas, which occur in middle-aged to elderly women and are not associated with sun exposure. Wherever they arise they morphologically resemble their counterparts in other skin locations, beginning as papules that extend and eventually erode and invade locally. Basal cell and squamous cell lesions of the pinna are locally invasive but they rarely spread. Squamous cell carcinomas arising in the external canal may invade the cranial cavity or metastasize to regional nodes accounting for a 5-year mortality of about 50%.

3.6.4 Neck

Most of the conditions that involve the neck are described elsewhere (e.g., squamous cell and basal cell carcinomas of the skin, melanomas, lymphomas), or they are a component of a systemic disorder (e.g., generalized rashes, the lymphadenopathy of infectious mononucleosis or tonsillitis). What remains for consideration here are a few uncommon lesions unique to the neck.

3.6.4.1 Branchial Cyst (Cervical Lymphoepithelial Cyst)

These benign cysts usually appear on the upper lateral aspect of the neck along the sternocleidomastoid muscle. The vast majority of these cysts are thought to arise from remnants of the second branchial arch and are most commonly observed in young adults between the ages of 20 and 40. Clinically, the cysts are well circumscribed, 2 to 5 cm in diameter, with fibrous walls usually lined by stratified squamous or pseudostratified columnar epithelium. The cyst wall typically contains lymphoid tissue with prominent germinal centers. The cystic contents may be clear, watery to mucinous fluid or may contain desquamated, granular cellular debris. The cysts enlarge slowly, are rarely the site of malignant transformation, and generally are readily excised. Similar lesions sometimes appear in the parotid gland or in the oral cavity beneath the tongue.

3.6.4.2 Thyroglossal Duct Cyst

Embryologically, the thyroid anlage begins in the region of the foramen cecum at the base of the tongue; as the gland develops it descends to its definitive location in the anterior neck. Remnants of this developmental tract may persist, producing cysts, 1 to 4 cm in diameter, which may be lined by stratified squamous epithelium, when located near the base of the tongue, or by pseudostratified columnar epithelium in lower locations. Transitional patterns are also encountered. The connective tissue wall of the cyst may harbor lymphoid aggregates or remnants of recognizable thyroid tissue. The treatment is excision. Malignant transformation within the lining epithelium has been reported but is rare.

3.6.4.3 Paraganglioma (Carotid Body Tumor)

Paraganglia are clusters of neuroendocrine cells associated with the sympathetic and parasympathetic nervous systems. As a result, these neoplasms can be seen throughout various regions of the body. While the most common location of these tumors is within the adrenal medulla, where they give rise to pheochromocytomas (Chapter 24), approximately 70% of extra-adrenal paragangliomas occur in the head and neck region.[47] The pathogenesis of paragangliomas is not fully understood. However, alterations in genes encoding subunits of succinate oxidoreductase, an enzyme involved in mitochondrial respiration, have been reported in both hereditary and spontaneous paragangliomas. Paragangliomas typically develop in two locations:

- Paravertebral paraganglia (e.g., organs of Zuckerkandl and, rarely, bladder). Such tumors have sympathetic connections and are chromaffin-positive, a stain that detects catecholamines.
- Paraganglia related to the great vessels of the head and neck, the so-called aorticopulmonary chain, including the *carotid bodies* (most common); aortic bodies; jugulotympanic ganglia; ganglion nodosum of the vagus nerve; and clusters located about the oral cavity, nose, nasopharynx, larynx, and orbit. These are innervated by the parasympathetic nervous system and infrequently release catecholamines.

Morphology. The **carotid body tumor** is a prototype of a parasympathetic paraganglioma. It rarely exceeds 6 cm in diameter and arises close to or envelops the bifurcation of the common carotid artery. The tumor tissue is red-pink to brown. The microscopic features of all paragangliomas, wherever they arise, are remarkably uniform. They are chiefly composed of nests **(Zellballen)** of round to oval chief cells (neuroectodermal in origin) that are surrounded by delicate vascular septae. The tumor cells contain abundant, clear or granular, eosinophilic cytoplasm and uniform, round to ovoid, sometimes vesicular, nuclei (Fig. 16-14).[48] In most tumors there is little cellular pleomorphism, and mitoses are scant. The chief cells stain strongly for neuroendocrine markers such as chromogranin, synaptophysin, neuron-specific enolase, CD56, and CD57. In addition, there is a supporting network of spindle-shaped stromal cells, collectively called sustentacular cells, that are positive for S-100 protein. Electron microscopy often discloses well-demarcated neuroendocrine granules in paravertebral tumors, but their number can be highly variable and they tend to be scant in nonfunctioning tumors.

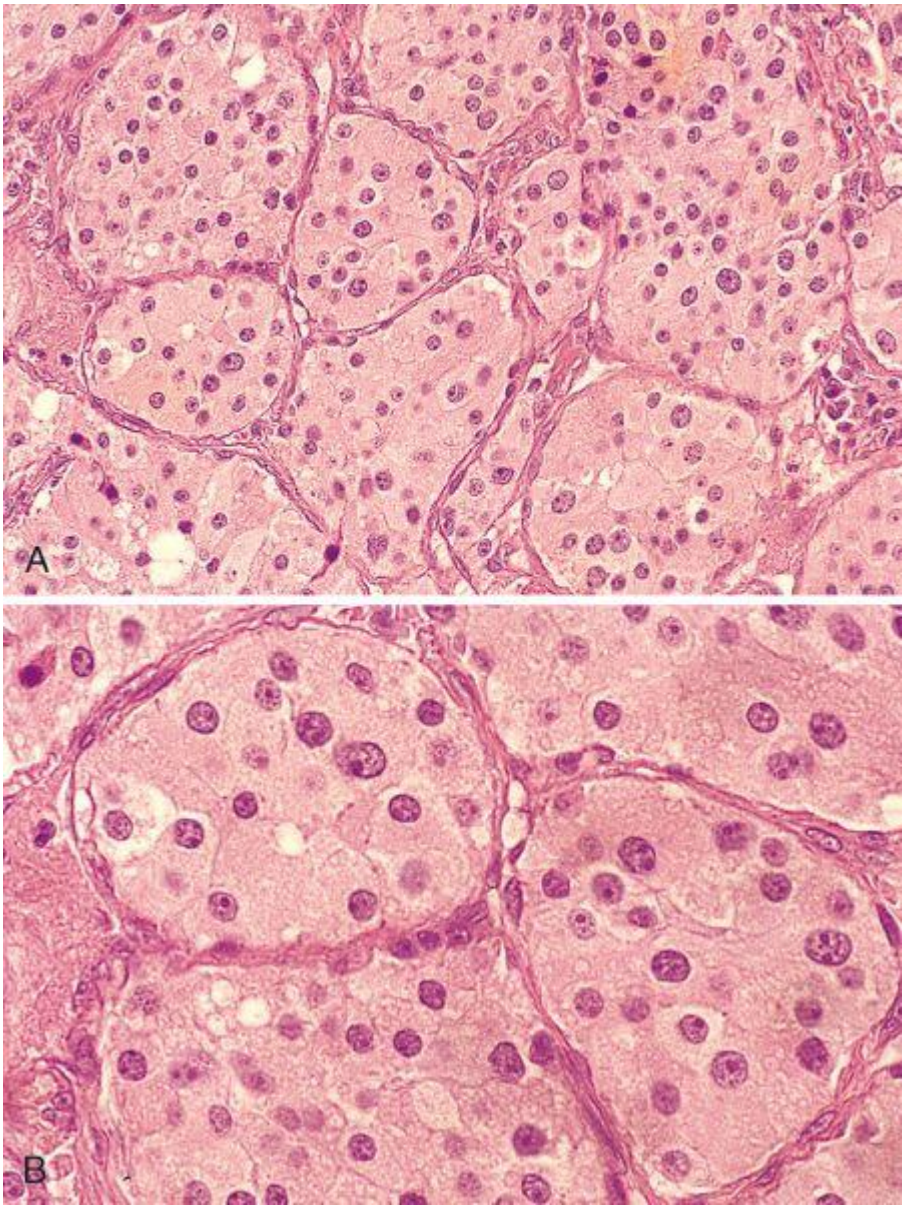

FIGURE 16-14 Carotid body tumor. **A**, Low-power view showing tumor clusters separated by septa (Zellballen). **B**, High-power view of large, eosinophilic, slightly vacuolated tumor cells with elongated sustentacular cells in the septa.

Carotid body tumors (and paragangliomas in general) are rare. They are slow-growing and painless masses that usually arise in the fifth and sixth decades of life. They commonly occur singly and sporadically but may be familial, with autosomal dominant transmission in the multiple endocrine neoplasia 2 syndrome (Chapter 24); in this setting they are often multiple and sometimes bilaterally symmetric. Carotid body tumors frequently recur after incomplete resection and, despite their benign appearance, may metastasize to regional lymph nodes and distant sites. About 50% ultimately prove fatal, largely because of infiltrative growth. Unfortunately, it is almost impossible histologically to judge the clinical course of a carotid body tumor—mitoses, pleomorphism, and even vascular invasion are not reliable indicators.[47]

3.6.5 Salivary Glands

There are three major salivary glands—parotid, submandibular, and sublingual—as well as innumerable minor salivary glands distributed throughout the mucosa of the oral cavity. All these glands are subject to inflammation or to the development of neoplasms.

3.6.5.1 Xerostomia

Xerostomia is defined as a *dry mouth* resulting from a decrease in the production of saliva. Its incidence among various populations has been reported to be as high as 29%.[48] It is a major feature of the autoimmune disorder Sjögren syndrome, in which it is usually accompanied by dry eyes (Chapter 6). A lack of salivary secretions is also a major complication of radiation therapy. However, xerostomia is most frequently observed as a result of many commonly prescribed classes of medications including: anticholinergic, antidepressant/antipsychotic, diuretic, antihypertensive, sedative, muscle relaxant, analgesic, and antihistamine agents. [48] [49] [50] The oral cavity may merely reveal dry mucosa and/or atrophy of the papillae of the tongue, with fissuring and ulcerations, or in Sjögren syndrome, concomitant inflammatory enlargement of the salivary glands. Complications of xerostomia include increased rates of dental caries, candidiasis, as well as difficulty in swallowing and speaking.

3.6.5.2 Inflammation (Sialadenitis)

Sialadenitis may be of traumatic, viral, bacterial, or autoimmune origin. Mucoceles are the most common type of inflammatory salivary gland lesion. The most common form of viral sialadenitis is *mumps*, in which the major salivary glands, particularly the parotids, are affected (Chapter 8). Other glands (e.g., the pancreas and testes) may also be involved. Autoimmune disease underlies the inflammatory salivary gland changes of Sjögren syndrome, discussed in Chapter 6 . In this condition the widespread involvement of the salivary glands and the mucus-secreting glands of the mucosa induces xerostomia. Associated involvement of the lacrimal glands produces dry eyes—*keratoconjunctivitis sicca*.

Mucocele.

This is the most common lesion of the salivary glands. It results from either blockage or rupture of a salivary gland duct, with consequent leakage of saliva into the surrounding connective tissue stroma. Mucoceles are most often found on the lower lip and are the result of trauma (Fig. 16-15A). As such, they are typically seen in toddlers and young adults as well as the geriatric population (as a result of falling). Clinically, they present as fluctuant swellings of the lower lip and have a blue translucent hue to them. Patients may report a history of changes in the size of the lesion, particularly in association with meals. Histologically, mucoceles demonstrate a cystlike space that is lined by inflammatory granulation tissue or by fibrous connective tissue. The cystic spaces are filled with mucin as well as inflammatory cells, particularly macrophages (Fig. 16-15B). Complete excision of the cyst with the minor salivary gland lobule of origin is required. Incomplete excision can result in recurrence.

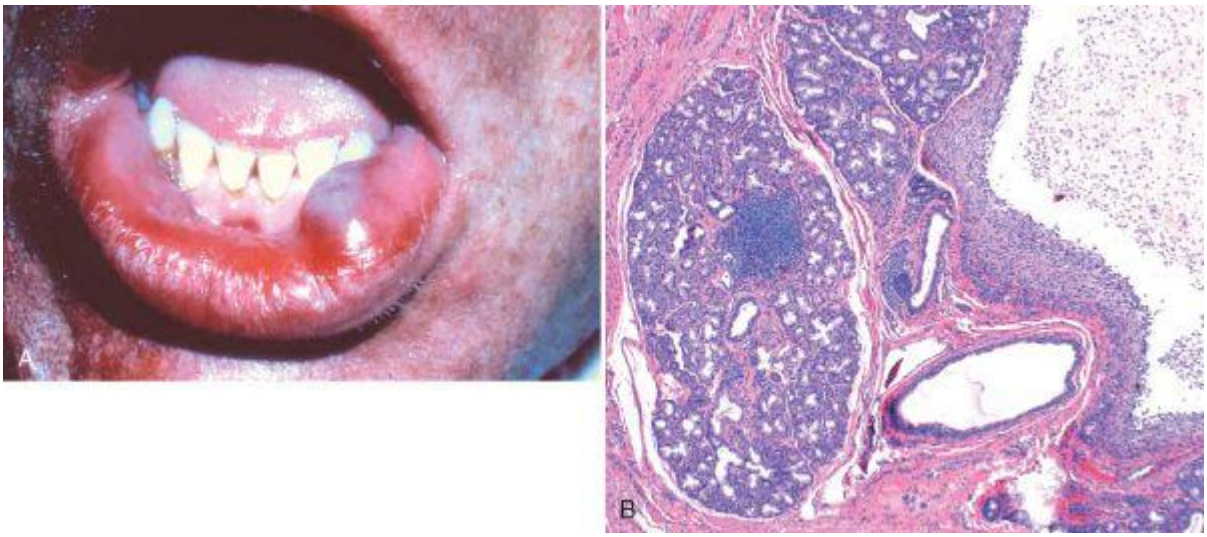

FIGURE 16-15 Mucocele. **A**, Fluctuant fluid-filled lesion on the lower lip subsequent to trauma. **B**, Cystlike cavity filled with mucinous material and lined by organizing granulation tissue.

A *ranula* is histologically identical to a mucocele. However, this term is reserved for mucoceles that arise when the duct of the sublingual gland has been damaged. A *ranula* can become extremely large and develop into a "plunging ranula" when it dissects its way through the connective tissue stroma connecting the two bellies of the mylohyoid muscle.

Sialolithiasis and Nonspecific Sialadenitis.

Nonspecific bacterial sialadenitis, most often involving the major salivary glands, particularly the submandibular glands, is a common condition, usually secondary to ductal obstruction produced by stones *(sialolithiasis)*. The common offenders are *S. aureus* and *Streptococcus viridans*. The stone formation is sometimes related to obstruction of the orifices of the salivary glands by impacted food debris or by edema about the orifice after some injury. Frequently, the stones are of obscure origin. Dehydration and decreased secretory function may also predispose to secondary bacterial invasion, as sometimes occurs in patients receiving long-term phenothiazines that suppress salivary secretion. Dehydration with decreased secretion may lead to the development of bacterial suppurative parotitis in elderly patients with a recent history of major thoracic or abdominal surgery.

Whatever the origin, the obstructive process and bacterial invasion lead to a nonspecific inflammation of the affected glands that may be largely interstitial or, when induced by staphylococcal or other pyogens, may be associated with overt suppurative necrosis and abscess formation. Unilateral involvement of a single gland is the rule. The inflammatory involvement causes painful enlargement and sometimes a purulent ductal discharge.

3.6.5.3 Neoplasms

Despite their relatively simple morphology, the salivary glands give rise to no fewer than 30 histologically distinct tumors. [51] [52] [53] A classification and the relative incidence of benign and malignant tumors is shown in Table 16-4 ; not included are the rare benign and malignant mesenchymal neoplasms.

TABLE 16-4 -- Histologic Classification and Incidence of Benign and Malignant Tumors of the Salivary Glands

Benign	Malignant
Pleomorphic adenoma (50%) (mixed tumor)	Mucoepidermoid carcinoma (15%)
Warthin tumor (5% to 10%)	Adenocarcinoma (NOS) (10%)
Oncocytoma (1%)	Acinic cell carcinoma (5%)
Other adenomas (5% to 10%)	Adenoid cystic carcinoma (5%)
Basal cell adenoma	Malignant mixed tumor (3% to 5%)
Canalicular adenoma	Squamous cell carcinoma (1%)
Ductal papillomas	Other carcinomas (2%)

Data from Ellis GL, Auclair PL: Tumors of the Salivary Glands. Atlas of Tumor Pathology, Third Series. Washington, DC, Armed Forces Institute of Pathology, 1996.

NOS, not otherwise specified.

As indicated in Table 16-4 , a small number of neoplasms makes up more than 90% of salivary gland tumors, and so our discussion is restricted to these. Overall, these neoplasms are relatively uncommon and represent less than 2% of all tumors in humans. *About 65% to 80% arise within the parotid, 10% in the submandibular gland*, and the remainder in the minor salivary glands, including the sublingual glands. Approximately 15% to 30% of tumors in the parotid glands are malignant. In contrast, approximately 40% of submandibular, 50% of minor salivary gland, and 70% to 90% of sublingual tumors are cancerous. *The likelihood, then, of a salivary gland tumor being malignant is more or less inversely proportional to the size of the gland*.

These tumors usually occur in adults, with a slight female predominance, but about 5% occur in children younger than age 16 years. For unknown reasons, Warthin tumors occur much more often in males than in females. The benign tumors most often appear in the fifth to seventh decades of life. The malignant ones tend, on average, to appear somewhat later. Whatever the histologic pattern, neoplasms in the parotid glands produce distinctive swellings in front of and below the ear. In general, when they are first diagnosed, both benign and malignant lesions range from 4 to 6 cm in diameter and are mobile on palpation except in the case of neglected malignant tumors. Although benign tumors are known to have been present usually for many months to several years before coming to clinical attention, cancers seem to demand attention more promptly, probably because of their more rapid growth. Ultimately, however, there are no reliable criteria to differentiate, on clinical grounds, the benign from the malignant lesions, and morphologic evaluation is necessary.

PLEOMORPHIC ADENOMA

Because of their remarkable histologic diversity, these neoplasms have also been called *mixed tumors*. They represent about *60% of tumors in the parotid*, are less common in the submandibular glands, and are relatively rare in the minor salivary glands. They are benign tumors that consist of a mixture of ductal (epithelial) and myoepithelial cells, and therefore they show both epithelial and mesenchymal differentiation. They reveal epithelial elements dispersed throughout the matrix along with varying degrees of myxoid, hyaline, chondroid (cartilaginous), and even osseous tissue. In some tumors the epithelial elements predominate; in others they are present only in widely dispersed foci.

Little is known about the origins of these neoplasms, except that radiation exposure increases the risk. Equally uncertain is the histogenesis of the various components. A currently popular view is that all neoplastic elements, including those that appear mesenchymal, are of either myoepithelial or ductal reserve cell origin (hence the designation *pleomorphic adenoma*).

Morphology. Most pleomorphic adenomas present as rounded, well-demarcated masses rarely exceeding 6 cm in the greatest dimension (Fig. 16-16). Although they are encapsulated, in some locations (particularly the palate) the capsule is not fully developed, and expansile growth produces protrusions into the surrounding gland, rendering enucleation of the tumor hazardous. The cut surface is gray-white with myxoid and blue translucent areas of chondroid (cartilage-like).

The dominant histologic feature is the great heterogeneity mentioned. The epithelial elements resembling ductal cells or myoepithelial cells are arranged in duct formations, acini, irregular tubules, strands, or sheets of cells. These elements are typically dispersed within a mesenchyme-like background of loose myxoid tissue containing islands of chondroid and, rarely, foci of bone (Fig. 16-17). Sometimes the epithelial cells form well-developed ducts lined by cuboidal to columnar cells with an underlying layer of deeply chromatic, small myoepithelial cells. In other instances there may be strands or sheets of myoepithelial cells. Islands of well-differentiated squamous epithelium may also be present. In most cases there is no epithelial dysplasia or evident mitotic activity. There is no difference in biologic behavior between the tumors composed largely of epithelial elements and those composed largely of seemingly mesenchymal elements.

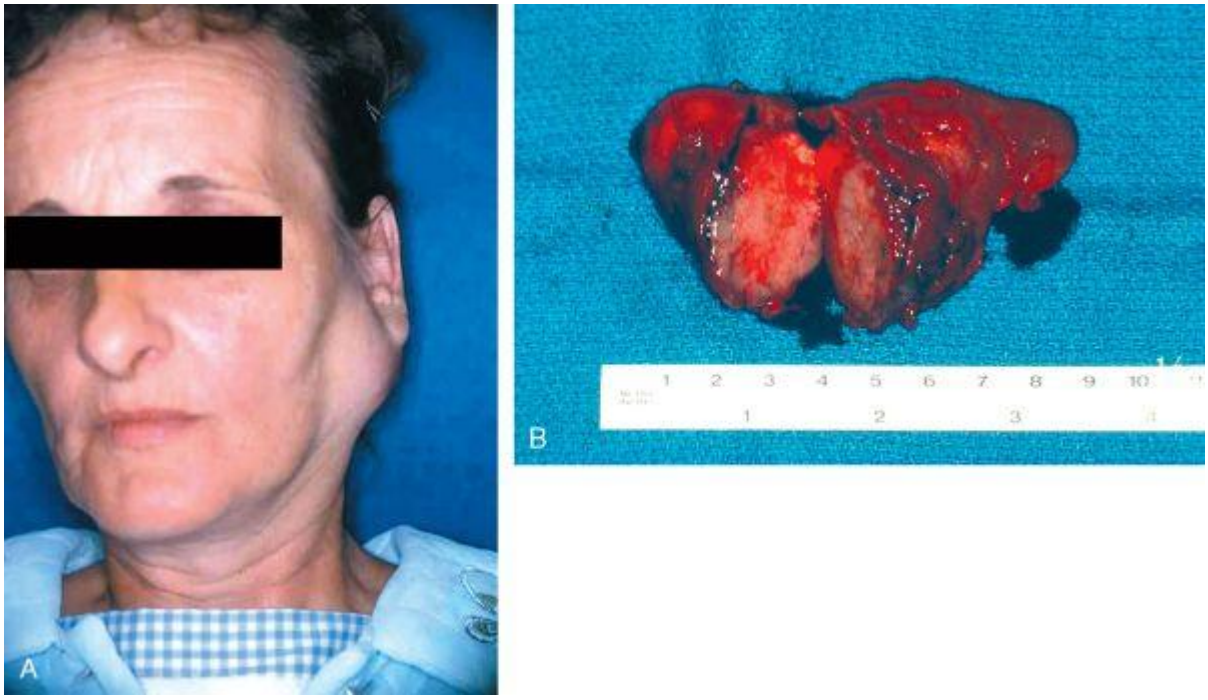

FIGURE 16-16 Pleomorphic adenoma. **A**, Slowly enlarging neoplasm in the parotid gland of many years duration. **B**, The bisected, sharply circumscribed, yellow-white tumor can be seen surrounded by normal salivary gland tissue.

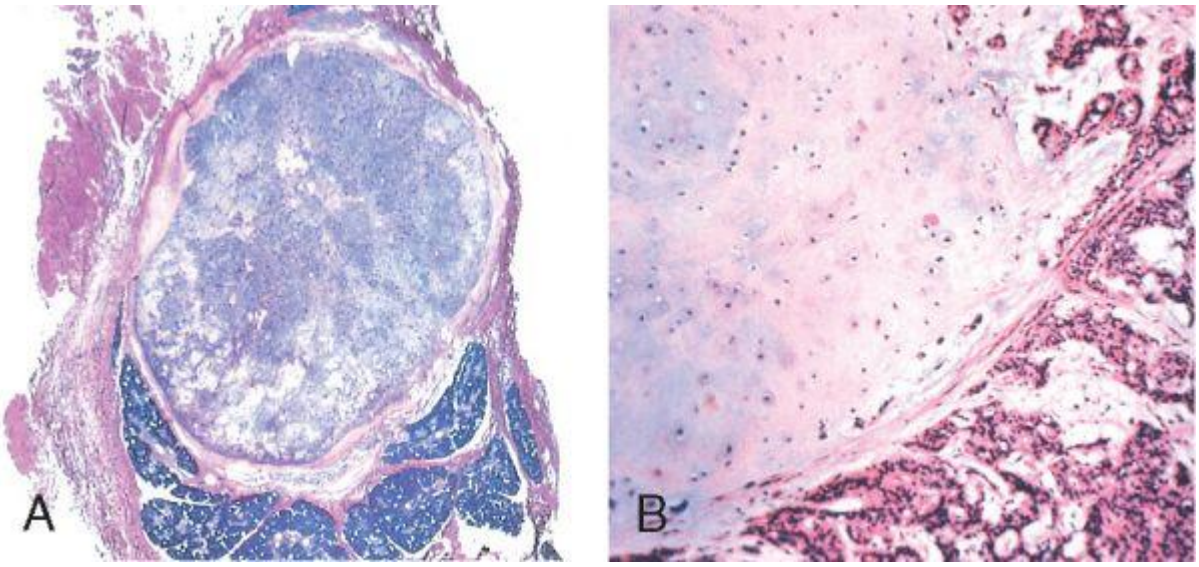

FIGURE 16-17 Pleomorphic adenoma. **A**, Low-power view showing a well-demarcated tumor with adjacent normal salivary gland parenchyma. **B**, High-power view showing epithelial cells as well as myoepithelial cells found within a chondroid matrix material.

Clinical Features.

These tumors present as painless, slow-growing, mobile discrete masses within the parotid (Fig. 16-16) or submandibular areas or in the buccal cavity. The recurrence rate (perhaps months to years later) with parotidectomy is about 4% but, with simple enucleation, approaches 25%. This high recurrence is because of failure to recognize minute protrusions from the main mass, into the surrounding tissue, at the time of surgery.

A carcinoma arising in a pleomorphic adenoma is referred to variously as a *carcinoma ex pleomorphic adenoma* or a *malignant mixed tumor*. The incidence of malignant transformation increases with the duration of the tumor, being about 2% for tumors present less than 5 years and almost 10% for those of more than 15 years' duration. The cancer usually takes the form of an adenocarcinoma or undifferentiated carcinoma, and often it virtually completely overgrows the last vestiges of the preexisting pleomorphic adenoma; but to substantiate the diagnosis of carcinoma ex pleomorphic adenoma, recognizable traces of the latter must be found. Regrettably, these cancers, when they appear, are among the most aggressive of all salivary gland malignant neoplasms, producing mortality rates of 30% to 50% at 5 years.

WARTHIN TUMOR (PAPILLARY CYSTADENOMA LYMPHOMATOSUM)

This curious benign neoplasm with its intimidating histologic name is the second most common salivary gland neoplasm. It arises almost *exclusively in the parotid gland* (the only tumor virtually restricted to the parotid) and occurs more commonly in males than in females, usually in the fifth to seventh decades of life. About 10% are multifocal and 10% bilateral. Smokers have eight times the risk of nonsmokers for developing these tumors.

Morphology. Most Warthin tumors are round to oval, encapsulated masses, 2 to 5 cm in diameter, usually arising in the superficial parotid gland, where they are readily palpable. Transection reveals a

pale gray surface punctuated by narrow cystic or cleftlike spaces filled with a mucinous or serous secretion. On microscopic examination these spaces are lined by a double layer of neoplastic epithelial cells resting on a dense lymphoid stroma sometimes bearing germinal centers (Fig. 16-18). The spaces are frequently narrowed by polypoid projections of the lymphoepithelial elements. The double layer of lining cells is distinctive; it consists of a surface palisade of columnar cells having an abundant, finely granular, eosinophilic cytoplasm, that imparts an oncocytic appearance, which rests on a layer of cuboidal to polygonal cells. Oncocytes are epithelial cells stuffed with mitochondria, which impart the granular appearance to the cytoplasm. Secretory cells are dispersed in the columnar cell layer, accounting for the secretions within the cystically dilated lumens. On occasion, there are foci of squamous metaplasia.

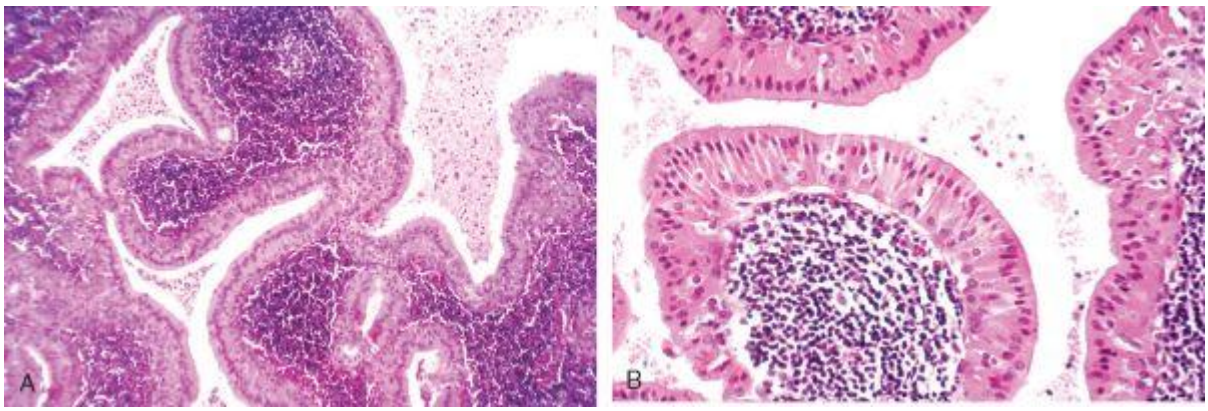

FIGURE 16-18 Warthin tumor. **A**, Low-power view showing epithelial and lymphoid elements. Note the follicular germinal center beneath the epithelium. **B**, Cystic spaces separate lobules of neoplastic epithelium consisting of a double layer of eosinophilic epithelial cells based on a reactive lymphoid stroma.

The histogenesis of these tumors has long been disputed. The occasional finding of small salivary gland rests in lymph nodes in the neck suggests that these tumors arise from the aberrant incorporation of similar inclusion-bearing lymphoid tissue in the parotids. Indeed, rarely, Warthin tumors have arisen within cervical lymph nodes, a finding that should not be mistaken for metastases. These neoplasms are benign, with recurrence rates of only 2% after resection.

MUCOEPIDERMOID CARCINOMA

These neoplasms are composed of variable mixtures of squamous cells, mucus-secreting cells, and intermediate cells. They represent about 15% of all salivary gland tumors, and while they occur mainly (60% to 70%) in the parotids, they account for a large fraction of salivary gland neoplasms in the other glands, particularly the minor salivary glands. In more than half the cases, this tumor is associated with a balanced (11;19) (q21;p13) chromosomal translocation that creates a fusion gene composed of portions of the *MECT1* and *MAML2* genes. The *MECT1-MAML2* gene is believed to play a key role in the genesis of this tumor, possibly by perturbing the notch and cAMP-dependent signaling pathways.[54,][55] Overall, they are the most common form of primary *malignant* tumor of the salivary glands.

Morphology. Mucoepidermoid carcinomas can grow as large as 8 cm in diameter and although they

are apparently circumscribed, they lack well-defined capsules and are often infiltrative at the margins. Pale and gray-white on transection, they frequently contain small, mucin-containing cysts. The basic histologic pattern is that of cords, sheets, or cystic configurations of squamous, mucous, or intermediate cells. The hybrid cell types often have squamous features, with small to large mucus-filled vacuoles, best seen when highlighted with mucin stains (Fig. 16-19). The tumor cells may be regular and benign appearing or, alternatively, highly anaplastic and unmistakably malignant. Accordingly, mucoepidermoid carcinomas are subclassified into low, intermediate, or high grade.

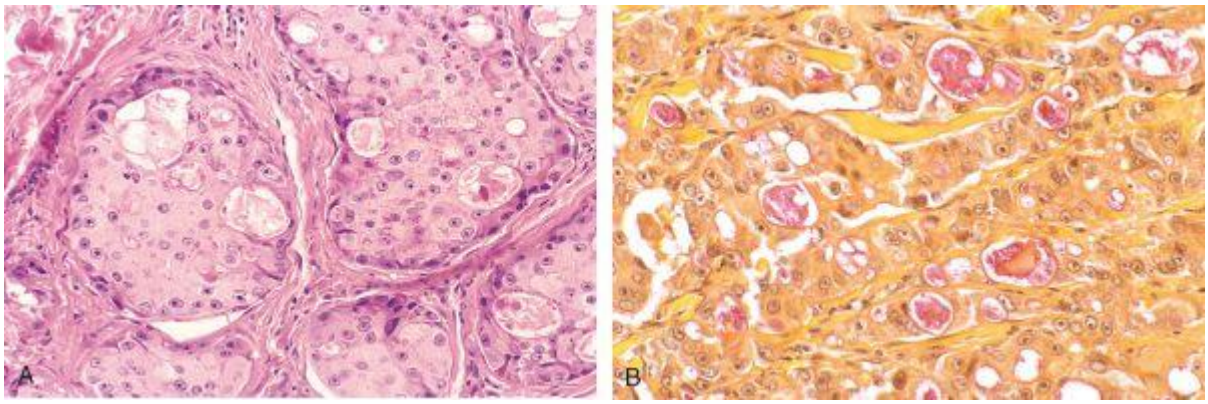

FIGURE 16-19 **A**, Mucoepidermoid carcinoma growing in nests composed of squamous cells as well as clear vacuolated cells containing mucin. **B**, Mucicarmine stains the mucin reddish pink. *(Courtesy of Dr. James Gulizia, Brigham and Women's Hospital, Boston, MA.)*

The clinical course and prognosis depend on the grade of the neoplasm. Low-grade tumors may invade locally and recur in about 15% of cases, but only rarely do they metastasize and so yield a 5-year survival rate of more than 90%. By contrast, high-grade neoplasms and, to a lesser extent, intermediate-grade tumors are invasive and difficult to excise and so recur in about 25% to 30% of cases and, in 30% of cases, metastasize to distant sites. The 5-year survival rate in patients with these tumors is only 50%.

OTHER SALIVARY GLAND TUMORS

Two less common neoplasms merit brief description: adenoid cystic carcinoma and acinic cell tumor.

Adenoid cystic carcinoma is a relatively uncommon tumor, which in approximately 50% of cases is found in the minor salivary glands (in particular the palate). Among the major salivary glands, the parotid and submandibular glands are the most common locations. Similar neoplasms have been reported in the nose, sinuses, and upper airways and elsewhere.

Morphology. In gross appearance, they are generally small, poorly encapsulated, infiltrative, gray-pink lesions. On histologic evaluation, they are composed of small cells having dark, compact nuclei and scant cytoplasm. These cells tend to be disposed in tubular, solid, or cribriform patterns reminiscent of cylindromas arising in the adnexa of the skin. The spaces between the tumor cells are often filled with a hyaline material thought to represent excess basement membrane (Fig. 16-20A). Other less common histologic patterns have been designated as tubular and solid variants.

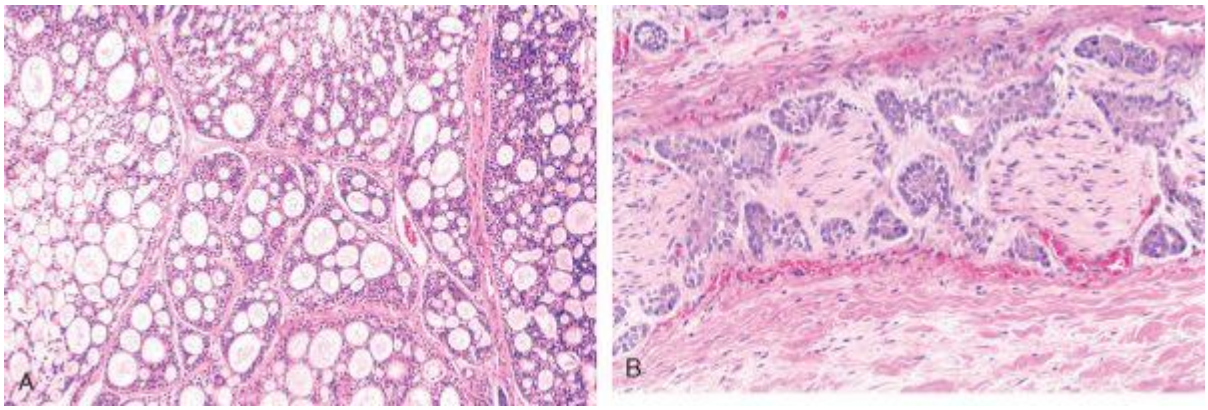

FIGURE 16-20 Adenoid cystic carcinoma in a salivary gland. **A**, Low-power view. The tumor cells have created a cribriform pattern enclosing secretions. **B**, Perineural invasion by tumor cells.

Although slow growing, adenoid cystic carcinomas are relentless and unpredictable tumors with a tendency to invade perineural spaces (Fig. 16-20B), and they are stubbornly recurrent. Eventually, 50% or more disseminate widely to distant sites such as bone, liver, and brain, sometimes decades after attempted removal. Thus, although the 5-year survival rate is about 60% to 70%, it drops to about 30% at 10 years and 15% at 15 years. Neoplasms arising in the minor salivary glands have, on average, a poorer prognosis than those primary in the parotids.

The *acinic cell tumor* is composed of cells resembling the normal serous acinar cells of salivary glands. They are relatively uncommon, representing only 2% to 3% of salivary gland tumors. Most arise in the parotids; the remainder arise in the submandibular glands. They rarely involve the minor glands, which normally have only a scant number of serous cells. Like Warthin tumor, they are sometimes bilateral or multicentric. They are generally small, discrete lesions that may appear encapsulated. On histologic examination, they reveal a variable architecture and cell morphology. Most characteristically, the cells have clear cytoplasm but the cells are sometimes solid and at other times vacuolated. The cells are disposed in sheets or microcystic, glandular, follicular, or papillary patterns. There is usually little anaplasia and few mitoses, but some tumors are occasionally slightly more pleomorphic.

The clinical course of these neoplasms is somewhat dependent on the level of pleomorphism. Overall, recurrence after resection is uncommon, but about 10% to 15% of these neoplasms metastasize to lymph nodes. The survival rate is in the range of 90% at 5 years and 60% at 20 years.

3.7 17. The Gastrointestinal Tract

3.7.1 Congenital Abnormalities

JERROLD R. TURNER

The gastrointestinal (GI) tract is a hollow tube extending from the oral cavity to the anus that consists of anatomically distinct segments, including the esophagus, stomach, small intestine, colon, rectum, and anus. Each of these segments has unique, complementary, and highly integrated functions, which together serve to regulate the intake, processing, and absorption of ingested nutrients and the disposal of waste products. The regional variations in structure and function are reflected in diseases of the GI tract, which often affect one or another segment preferentially. Accordingly, following consideration of several important congenital abnormalities, the discussion will be organized anatomically. Disorders affecting more than one segment of the GI tract, such as Crohn disease, will be discussed with the region that is involved most frequently.

CONGENITAL ABNORMALITIES

Depending on both the nature and timing of the insult, a variety of developmental anomalies can affect the GI tract. Importantly, because many organs develop simultaneously during embryogenesis, the presence of congenital GI disorders should prompt evaluation of other organs. Some defects are commonly associated with GI lesions.

3.7.1.1 Atresia, Fistulae & Duplications

Atresia, fistulae, and duplications may occur in any part of the GI tract. When present within the esophagus they are discovered shortly after birth, usually because they cause regurgitation during feeding. These must be corrected promptly, since they are incompatible with life. Absence, or *agenesis*, of the esophagus is extremely rare, but *atresia*, in which development is incomplete, is more common. In esophageal atresia a thin, noncanalized cord replaces a segment of esophagus, causing a mechanical obstruction (Fig. 17-1A). Proximal and distal blind pouches connect to the pharynx and stomach, respectively. Atresia occurs most commonly at or near the tracheal bifurcation and is usually associated with a *fistula* connecting the upper or lower esophageal pouches to a bronchus or the trachea (17–1B). Fistulae can lead to aspiration, suffocation, pneumonia, and severe fluid and electrolyte imbalances (Fig. 17-1B,C). Esophageal atresia is associated with congenital heart defects, genitourinary malformations, and neurologic disease. Intestinal atresia is less common than esophageal atresia but frequently involves the duodenum and is characterized by a segment of bowel lacking a lumen.

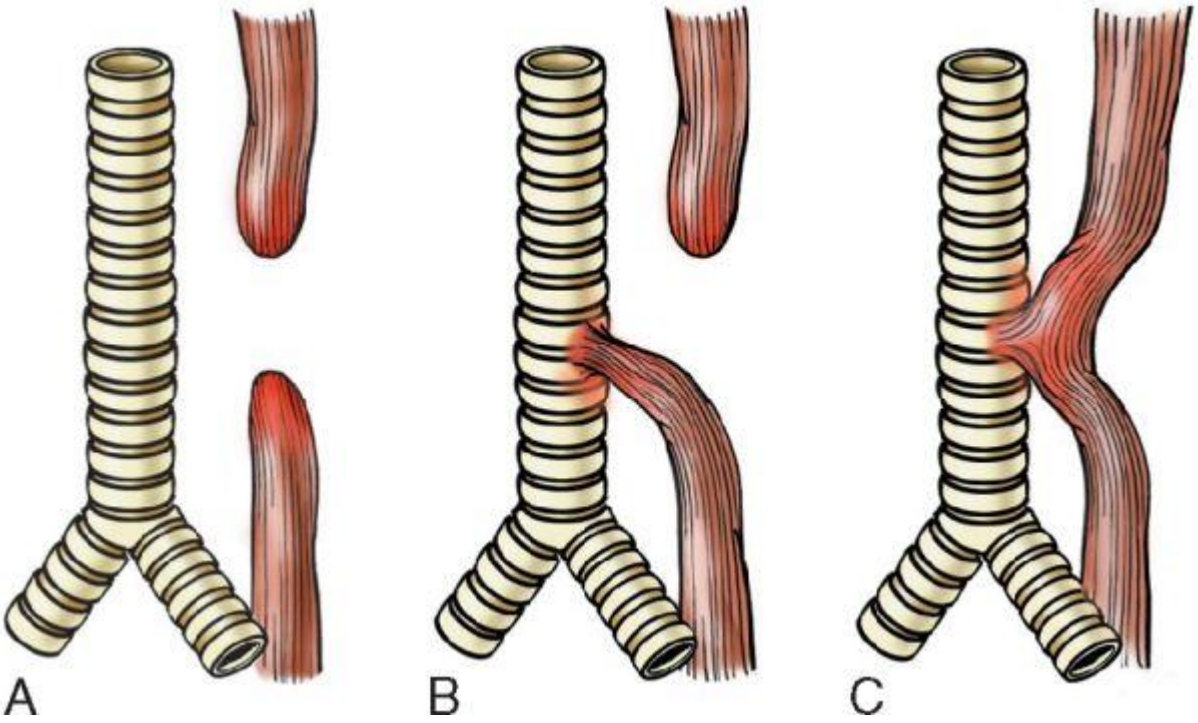

FIGURE 17-1 Esophageal atresia and tracheoesophageal fistula. **A**, Blind upper and lower esophageal segments. **B**, Blind upper segment with fistula between lower segment and trachea. **C**, Fistula between patent esophagus and trachea. Type **B** is the most common. *(Adapted from Morson BC, Dawson IMP, eds: Gastrointestinal Pathology. Oxford, Blackwell Scientific Publications, 1972, p 8.)*

Stenosis is an incomplete form of atresia in which the lumen is markedly reduced in caliber as a result of fibrous thickening of the wall, resulting in partial or complete obstruction. Stenosis may involve any part of the GI tract, although the esophagus and small intestine are affected most often. *Imperforate anus*, the most common form of congenital intestinal atresia, is due to a failure of the cloacal diaphragm to involute. Stenosis can also be caused by inflammatory scarring, as may occur with chronic gastroesophageal reflux, irradiation, scleroderma, or caustic injury.

Congenital duplication cysts are saccular or elongated cystic masses that contain redundant smooth muscle layers. These may be present in the esophagus, small intestine, or colon.

3.7.1.2 Diaphragmatic Hernia, Omphalocele & Gastroschisis

Diaphragmatic hernia occurs when incomplete formation of the diaphragm allows the abdominal viscera to herniate into the thoracic cavity. When severe, the space-filling effect of the displaced viscera can cause pulmonary hypoplasia that is incompatible with life after birth. *Omphalocele* occurs when closure of the abdominal musculature is incomplete and the abdominal viscera herniate into a ventral membranous sac. This may be repaired surgically, but as many as 40% of infants with an omphalocele have other birth defects, including diaphragmatic hernia and cardiac anomalies. *Gastroschisis* is another ventral wall defect similar to omphalocele except that it involves all of the layers of the abdominal wall, from the peritoneum to the skin.

3.7.1.3 Ectopia

Ectopic tissues *(developmental rests)* are common in the GI tract. The most frequent site of *ectopic gastric mucosa* is the upper third of the esophagus, where it is referred to as an *inlet patch*. While generally asymptomatic, acid released by gastric mucosa within the esophagus can result in dysphagia, esophagitis, Barrett esophagus, or, rarely, adenocarcinoma. *Ectopic pancreatic tissue* occurs less frequently and can be found in the esophagus or stomach. Like inlet patches, these nodules are most often asymptomatic but can produce damage and local inflammation. When ectopic pancreatic tissue is present in the pylorus, inflammation and scarring may lead to obstruction. Because the rests may be present within any layer of the gastric wall, they can mimic invasive cancer. *Gastric heterotopia*, small patches of ectopic gastric mucosa in the small bowel or colon, may present with occult blood loss due to peptic ulceration of adjacent mucosa.[1]

3.7.1.4 Meckel Diverticulum

A true diverticulum is a blind outpouching of the alimentary tract that is lined by mucosa, communicates with the lumen, and includes all three layers of the bowel wall. The most common type is the *Meckel diverticulum*, which occurs in the ileum.

The Meckel diverticulum occurs as a result of failed involution of the vitelline duct, which connects the lumen of the developing gut to the yolk sac. This solitary diverticulum is a small pouch extending from the antimesenteric side of the bowel (Fig. 17-2). It is a true diverticulum with a wall that includes mucosa, submucosa, and muscularis propria. Meckel diverticulae occur in approximately 2% of the population, are generally present within 2 feet (85 cm) of the ileocecal valve, are approximately 2 inches (5 cm) long, are twice as common in males as in females, and are most often symptomatic by age 2 (although only ~4% of Meckel diverticulae are symptomatic). These facts comprise the “rule of 2s” that is often used to help remember characteristics of Meckel diverticulae. The mucosal lining of Meckel diverticulae may resemble that of normal small intestine, but ectopic pancreatic or gastric tissue may also be present. The latter may result in *peptic ulceration* of adjacent small intestinal mucosa and present with occult bleeding or abdominal pain resembling acute appendicitis or intestinal obstruction.

FIGURE 17-2 Meckel diverticulum. The blind pouch is located on the antimesenteric side of the small bowel.

Less commonly, congenital diverticulae occur in other parts of the small intestine and ascending colon. Virtually all other diverticulae are acquired and either lack muscularis entirely or have an attenuated muscularis propria. Although acquired diverticulae may occur in the esophagus, stomach, and duodenum, the most common site is the sigmoid colon (discussed later).

3.7.1.5 Pyloric Stenosis

Congenital hypertrophic pyloric stenosis is three to four times more common in males and occurs once in 300 to 900 live births. Monozygotic twins have a high rate of corcordance, suggesting a genetic basis. Family studies suggest a complex polygenic inheritance. Turner syndrome and trisomy 18 are also associated with the disease. *Congenital hypertrophic pyloric stenosis generally presents in the second or third week of life as new-onset regurgitation and persistent, projectile, nonbilious vomiting*. Physical examination reveals hyperperistalsis and a firm, ovoid abdominal mass. These findings stem from hyperplasia of the pyloric muscularis propria, which obstructs the gastric outflow tract. Edema and inflammatory changes in the mucosa and submucosa may aggravate the narrowing. Surgical splitting of the muscularis (myotomy) is curative. Acquired pyloric stenosis occurs in adults as a consequence of antral gastritis or peptic ulcers close to the pylorus. Carcinomas of the distal stomach and pancreas may also narrow the pyloric channel due to fibrosis or malignant infiltration.

3.7.1.6 Hirschsprung Disease

Hirschsprung disease occurs in approximately 1 of 5000 live births. It may be isolated or occur in combination with other developmental abnormalities; 10% of all cases occur in children with Down syndrome and serious neurologic abnormalities are present in another 5%.

Pathogenesis.

You may recall that the enteric neuronal plexus develops from neural crest cells that migrate into the bowel wall during embryogenesis. Hirschsprung disease, also known as *congenital aganglionic megacolon*, results when the normal migration of neural crest cells from cecum to rectum is arrested prematurely or when the ganglion cells undergo premature death. This produces a distal intestinal segment that lacks both the Meissner submucosal and the Auerbach myenteric plexus ("aganglionosis"). Coordinated peristaltic contractions are absent and functional obstruction occurs, resulting in dilation proximal to the affected segment.

The mechanisms underlying defective neural crest cell migration in Hirschsprung disease are unknown, but a genetic component is present in nearly all cases and 4% of patients' siblings are affected.[2] However, simple Mendelian inheritance is not involved in most cases. *Heterozygous loss-of-function mutations in the receptor tyrosine kinase RET account for the majority of familial cases* and approximately 15% of sporadic cases.[3] Mutations also occur in at least seven other genes encoding proteins involved in enteric neurodevelopment, including the RET ligand glial-derived neurotrophic factor, endothelin, and the endothelin receptor, but, in aggregate, these account for fewer than 30% of patients, suggesting that other defects are yet to be discovered. Because penetrance is incomplete, modifying genes or environmental factors must also be important. In addition, it is clear that sex-linked factors exist, since males are affected preferentially while disease tends to be more extensive in females.

Morphology. Diagnosis of Hirschsprung disease requires documenting the absence of ganglion cells within the affected segment. Because migration of neural crest cells in the Meissner and Auerbach plexi are linked, it is possible to establish the diagnosis preoperatively by examining suction biopsy specimens. In addition to their characteristic morphology in hematoxylin and eosin (H&E)-stained sections, ganglion cells can be identified using immunohistochemical stains for acetylcholinesterase.

The rectum is always affected, but the length of the additional involved segments varies widely. Most cases are limited to the rectum and sigmoid colon, but severe cases can involve the entire colon. The aganglionic region may have a grossly normal or contracted appearance, while the normally innervated proximal colon may undergo progressive dilation (Fig. 17-3). With time the proximal colon may become massively distended **(megacolon)**, reaching diameters of as much as 20 cm. Dilation may stretch and thin the colonic wall to the point of rupture, which occurs most frequently near the cecum. Mucosal inflammation or shallow ulcers may also be present. These changes proximal to the diseased segment can make gross identification of the extent of aganglionosis difficult. Hence, intraoperative frozen-section analysis of transmural sections is commonly used to confirm the presence of ganglion cells at the anastamotic margin.

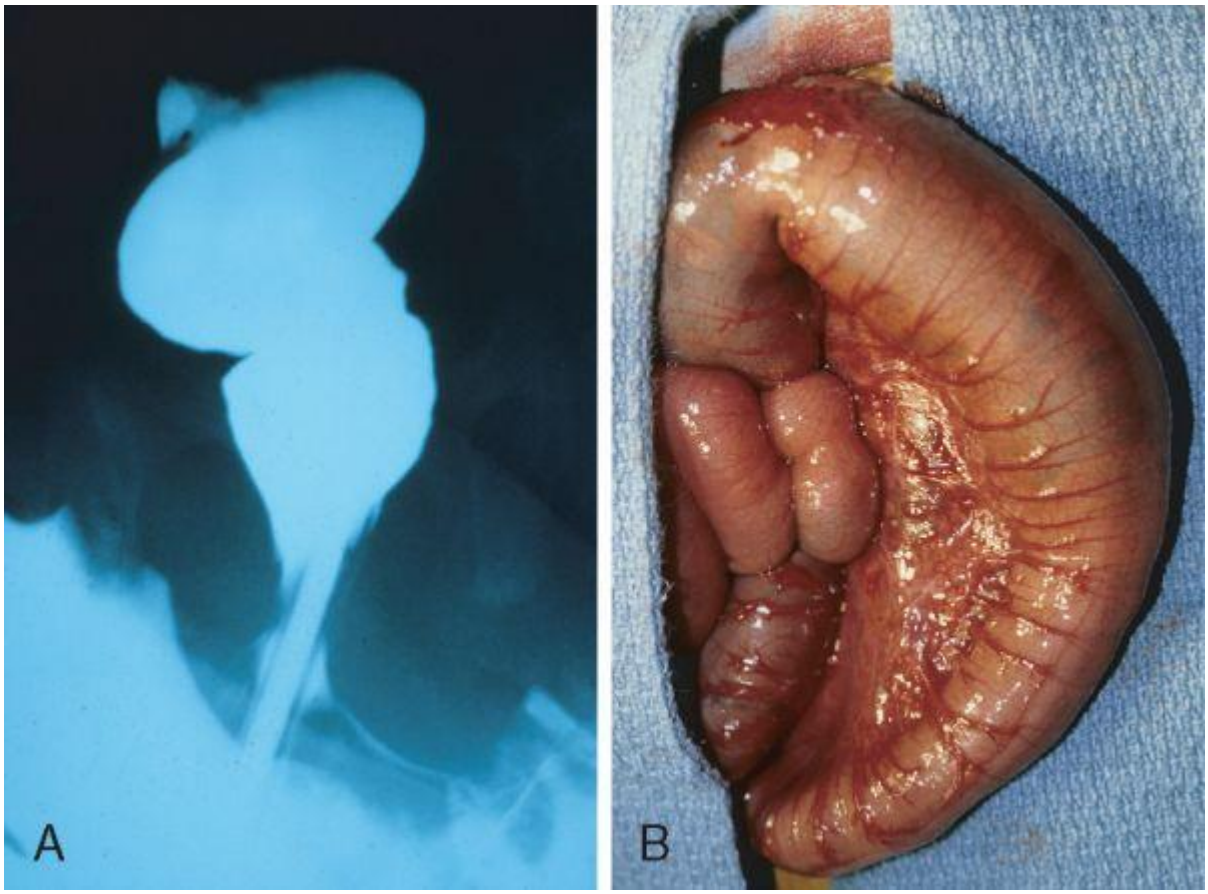

FIGURE 17-3 Hirschsprung disease. **A**, Preoperative barium enema study showing constricted rectum *(bottom of the image)* and dilated sigmoid colon. **B**, Corresponding intraoperative photograph showing constricted rectum and dilation of the sigmoid colon. *(Courtesy of Dr. Aliya Husain, The University of Chicago, Chicago, IL.)*

Clinical Features.

Patients typically present neonatally, often with a failure to pass meconium in the immediate postnatal period. Obstructive constipation follows, although in cases where only a few centimeters of the rectum are involved there may be occasional passage of stool. The major threats to life are enterocolitis, fluid and electrolyte disturbances, perforation, and peritonitis. The primary mode of treatment is surgical resection of the aganglionic segment and anastamosis of the normal colon to the rectum. Even after successful surgery, it may take years for patients to attain normal bowel function and continence.

In contrast to the congenital megacolon of Hirschsprung disease, *acquired megacolon* may occur at any age as a result of Chagas disease, obstruction by a neoplasm or inflammatory stricture, *toxic megacolon* complicating ulcerative colitis, visceral myopathy, or in association with functional psychosomatic disorders. Of these, only Chagas disease (discussed later) is associated with loss of ganglia.

3.7.2 Esophagus

The esophagus develops from the cranial portion of the foregut and is recognizable by the third week of gestation. It is a hollow, highly distensible muscular tube that extends from the epiglottis in the pharynx to the gastroesophageal junction. Acquired diseases of the esophagus run the gamut from highly lethal

cancers to the persistent “heartburn” that may be chronic and incapacitating or merely an occasional annoyance.

3.7.2.1 Esophageal Obstruction

For food and fluids to be delivered efficiently from the esophagus to the stomach, swallowing must be accompanied by a coordinated wave of peristaltic contractions. Esophageal dysmotility interferes with this process and can take several forms. High-amplitude esophageal contractions in which the outer longitudinal layer of smooth muscle contracts before the inner circular layer occur in some patients. Such lack of coordination results in a syndrome termed *nutcracker esophagus* that can cause periodic short-lived esophageal obstruction.[4] Other motor disorders of the esophagus include *diffuse esophageal spasm*, which can also result in functional obstruction. Because it increases esophageal wall stress, diffuse esophageal spasm can cause small *diverticulae* to form. These small mucosal outpouchings, which are more accurately described as pseudo-diverticulae because they lack a true muscularis, are uncommon, probably because of the dense and continuous esophageal musculature. The *Zenker diverticulum (pharyngoesophageal diverticulum)* is located immediately above the upper esophageal sphincter; the *traction diverticulum* occurs near the midpoint of the esophagus; and the *epiphrenic diverticulum* is immediately above the lower esophageal sphincter. Zenker diverticulae may reach several centimeters in size and accumulate significant amounts of food, producing a mass and symptoms that include regurgitation.

Passage of food can also be impeded by esophageal *stenosis*, or narrowing of the lumen. This is generally caused by fibrous thickening of the submucosa and is associated with atrophy of the muscularis propria as well as secondary epithelial damage. Although occasionally congenital, *stenosis is most often due to inflammation and scarring that may be caused by chronic gastroesophageal reflux, irradiation, or caustic injury*. The dysphagia associated with stenosis is usually progressive, first affecting the ability to eat solids and only later interfering with ingestion of liquids. Because obstruction develops slowly, patients may subconsciously modify their diet to favor soft foods and liquids and be unaware of their condition until the obstruction is nearly complete.

Esophageal mucosal webs are uncommon ledge-like protrusions of mucosa that may cause obstruction. The pathogenesis is unknown, but webs are encountered most frequently in women over age 40. Webs are often associated with gastroesophageal reflux, chronic graft-versus-host disease, or blistering skin diseases. Upper esophageal webs accompanied by iron-deficiency anemia, glossitis, and cheilosis are part of the *Paterson-Brown-Kelly* or *Plummer-Vinson syndrome*. Esophageal webs are most common in the upper esophagus, where they are generally semicircumferential, eccentric lesions that protrude less than 5 mm and have a thickness of 2 to 4 mm. Microscopically, webs are composed of a fibrovascular connective tissue and overlying epithelium. The main symptom of webs is dysphagia associated with incompletely chewed food.

Esophageal rings, or *Schatzki rings*, are similar to webs, but are circumferential and thicker. Rings include mucosa, submucosa, and, in some cases, hypertrophic muscularis propria. When present in the distal esophagus, above the gastroesophageal junction, they are termed *A rings* and are covered by squamous mucosa; in contrast those located at the squamocolumnar junction of the lower esophagus are designated *B rings* and may have gastric cardia-type mucosa on their undersurface.

ACHALASIA

Increased tone of the *lower esophageal sphincter* (LES), as a result of impaired smooth muscle relaxation, is an important cause of esophageal obstruction. Release of nitric oxide and vasoactive intestinal polypeptide from inhibitory neurons, along with interruption of normal cholinergic signaling, allows the LES to relax during swallowing. *Achalasia is characterized by the triad of incomplete LES*

relaxation, increased LES tone, and aperistalsis of the esophagus. Primary achalasia is caused by failure of distal esophageal inhibitory neurons and is, by definition, idiopathic.[5] Degenerative changes in neural innervation, either intrinsic to the esophagus or within the extraesophageal vagus nerve or the dorsal motor nucleus of the vagus, may also occur. Secondary achalasia may arise in Chagas disease, in which *Trypanosoma cruzi* infection causes destruction of the myenteric plexus, failure of peristalsis, and esophageal dilatation. Duodenal, colonic, and ureteric myenteric plexi can also be affected in Chagas disease. Achalasia-like disease may be caused by diabetic autonomic neuropathy; infiltrative disorders such as malignancy, amyloidosis, or sarcoidosis; and lesions of dorsal motor nuclei, particularly polio or surgical ablation. Treatment options for primary and secondary achalasia include laparoscopic myotomy and pneumatic balloon dilatation. Botulinum neurotoxin (Botox) injection, to inhibit LES cholinergic neurons, can also be effective.

3.7.2.2 Esophagitis

LACERATIONS

Longitudinal tears in the esophagus near the gastroesophageal junction are termed *Mallory-Weiss tears*, and are most often associated with severe retching or vomiting secondary to acute alcohol intoxication. Normally, a reflex relaxation of the gastroesophageal musculature precedes the antiperistaltic contractile wave associated with vomiting. It is speculated that this relaxation fails during prolonged vomiting, with the result that refluxing gastric contents overwhelm the gastric inlet and cause the esophageal wall to stretch and tear. The roughly *linear lacerations of Mallory-Weiss syndrome are longitudinally oriented and range in length from millimeters to several centimeters*. These tears usually cross the gastroesophageal junction but may also be located in the proximal gastric mucosa. Up to 10% of upper GI bleeding, which often presents as hematemesis (Table 17-1), is due to superficial esophageal lacerations such as those associated with Mallory-Weiss syndrome. These do not generally require surgical intervention, and healing tends to be rapid and complete. In contrast, *Boerhaave syndrome*, characterized by distal esophageal rupture and mediastinitis, occurs rarely and is a catastrophic event.

TABLE 17-1 -- Esophageal Causes of Hematemesis

Lacerations (Mallory-Weiss syndrome)
Esophageal perforation (cancer or Boerhaave syndrome)
Varices (cirrhosis)
Esophageal-aortic fistula (usually with cancer)
Chemical and pill esophagitis
Infectious esophagitis (*Candida*, Herpes)
Benign strictures
Vasculitis (autoimmune, cytomegalovirus)
Reflux esophagitis (erosive)
Eosinophilic esophagitis
Esophageal ulcers (many etiologies)
Barrett esophagus
Adenocarcinoma
Squamous cell carcinoma
Hiatal hernia

CHEMICAL AND INFECTIOUS ESOPHAGITIS

The stratified squamous mucosa of the esophagus may be damaged by a variety of irritants including alcohol, corrosive acids or alkalis, excessively hot fluids, and heavy smoking. The esophageal mucosa may also be injured when medicinal pills lodge and dissolve in the esophagus rather than passing into the stomach intact, a condition termed *pill-induced esophagitis*. Esophagitis due to chemical injury generally only causes self-limited pain, particularly *dysphagia* (pain with swallowing). Hemorrhage, stricture, or perforation may occur in severe cases. Iatrogenic esophageal injury may be caused by cytotoxic *chemotherapy*, *radiation therapy*, or *graft-versus-host disease*.

Infections may occur in otherwise healthy individuals but are most frequent in those who are debilitated or immunosuppressed as a result of disease or therapy. In these patients, esophageal infection by *Herpes simplex viruses, cytomegalovirus (CMV), or fungal organisms* is common. Among fungi, *candidiasis* is most common, although *mucormycosis* and *aspergillosis* may occur. The esophagus may also be involved by the desquamative skin diseases *bullous pemphigoid* and *epidermolysis bullosa* and, rarely, *Crohn disease*.

Morphology. The morphology of **chemical and infectious esophagitis** varies with etiology. Dense infiltrates of neutrophils are present in most cases but may be absent following injury induced by chemicals (lye, acids, or detergent), which may result in outright necrosis of the esophageal wall. Pill-induced esophagitis frequently occurs at the site of strictures that impede passage of luminal contents. When present, ulceration is accompanied by superficial necrosis with granulation tissue and eventual fibrosis.

Esophageal irradiation causes damage similar to that seen in other tissues and includes intimal proliferation and luminal narrowing of submucosal and mural blood vessels. The mucosal damage is, in part, often secondary to radiation-induced vascular injury as discussed in Chapter 9 .

Infection by fungi or bacteria can either cause damage or complicate a preexisting ulcer. Nonpathogenic oral bacteria are frequently found in ulcer beds, while pathogenic organisms, which account for about 10% of infectious esophagitis, may invade the lamina propria and cause necrosis of overlying mucosa. Candidiasis, in its most advanced form, is characterized by adherent, gray-white **pseudomembranes** composed of densely matted fungal hyphae and inflammatory cells covering the esophageal mucosa.

The endoscopic appearance often provides a clue as to the infectious agent in viral esophagitis. Herpesviruses typically cause punched-out ulcers (Fig. 17-4A). Biopsy specimens demonstrate nuclear viral inclusions within a rim of degenerating epithelial cells at the margin of the ulcer (Fig. 17-4B). In contrast, CMV causes shallower ulcerations and characteristic nuclear and cytoplasmic inclusions within capillary endothelium and stromal cells (Fig. 17-4C). Although the histologic appearance is characteristic, immunohistochemical stains for virus-specific antigens are a sensitive and specific ancillary diagnostic tool.

Histologic features of esophageal **graft-versus-host disease** are similar to those in the skin and include basal epithelial cell apoptosis, mucosal atrophy, and submucosal fibrosis without significant acute inflammatory infiltrates. The microscopic appearances of esophageal involvement in bullous pemphigoid, epidermolysis bullosa, and Crohn disease are also similar to those in the skin (Chapter 25).

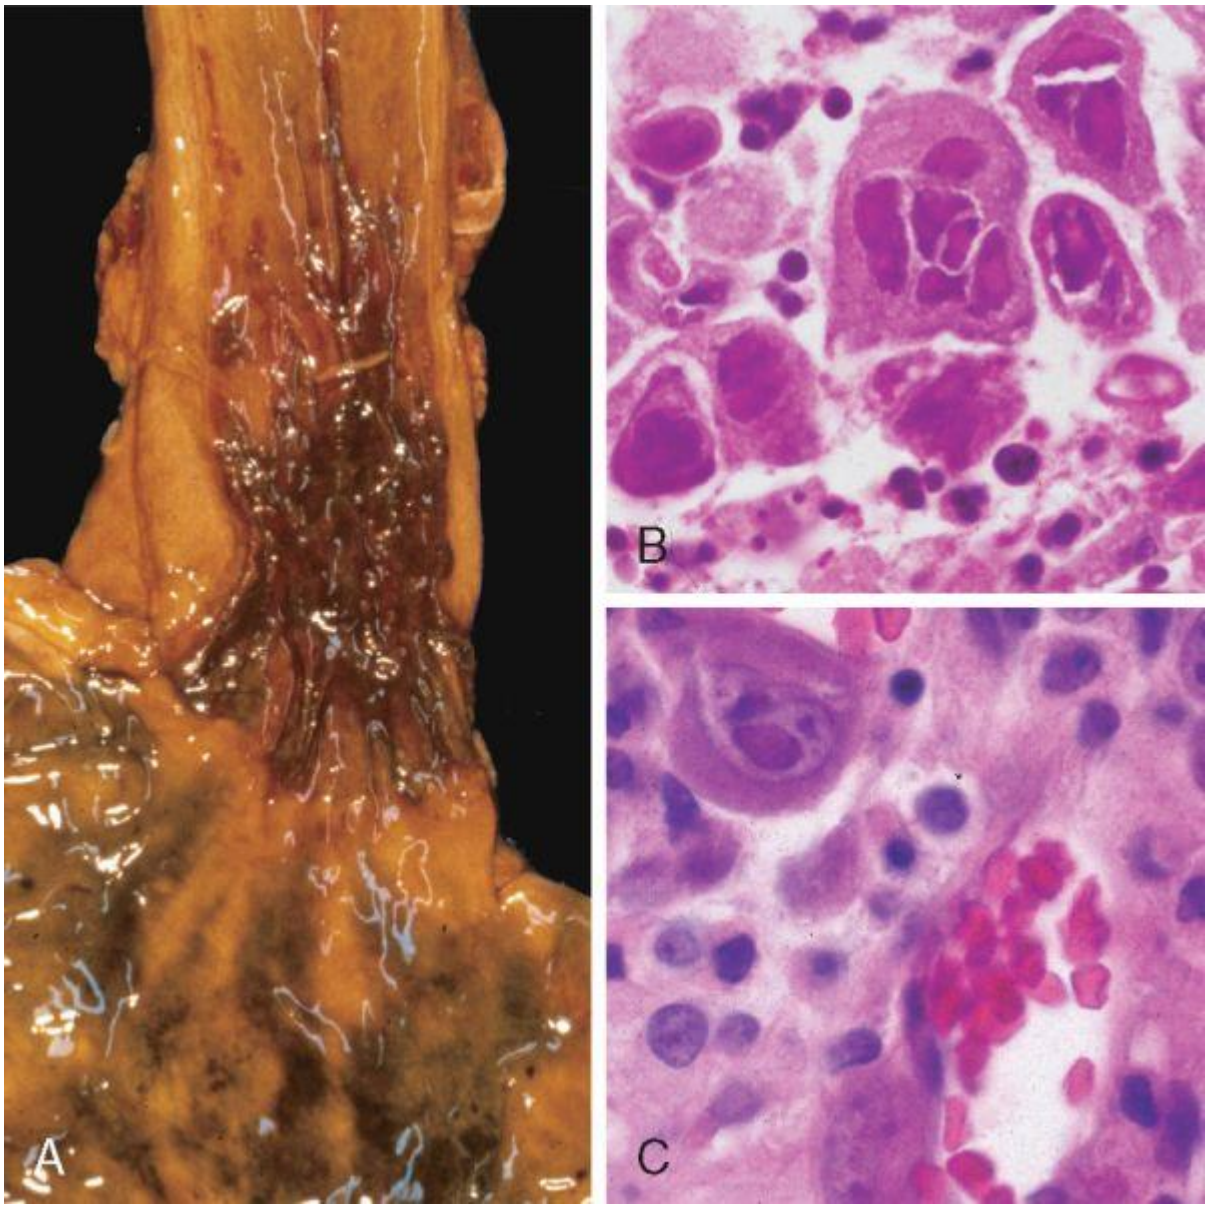

FIGURE 17-4 Viral esophagitis. **A**, Postmortem specimen with multiple herpetic ulcers in the distal esophagus. **B**, Multinucleate squamous cells containing Herpesvirus nuclear inclusions. **C**, Cytomegalovirus-infected endothelial cells with nuclear and cytoplasmic inclusions.

REFLUX ESOPHAGITIS

The stratified squamous epithelium of the esophagus is resistant to abrasion from foods but is sensitive to acid. Submucosal glands, which are most abundant in the proximal and distal esophagus, contribute to mucosal protection by secreting mucin and bicarbonate. More importantly, constant lower esophageal sphincter tone prevents reflux of acidic gastric contents, which are under positive pressure and would otherwise enter the esophagus. Reflux of gastric contents into the lower esophagus is the most frequent cause of esophagitis and the most common outpatient GI diagnosis in the United States.[6] The associated clinical condition is termed *gastroesophageal reflux disease (GERD).*

Pathogenesis.

Reflux of gastric juices is central to the development of mucosal injury in GERD. In severe cases, reflux of bile from the duodenum may exacerbate the damage. Conditions that decrease lower esophageal sphincter tone or increase abdominal pressure contribute to GERD and include alcohol and tobacco use, obesity, central nervous system depressants, pregnancy, hiatal hernia (discussed below), delayed gastric emptying, and increased gastric volume. In many cases, no definitive cause is identified.

Morphology. Simple **hyperemia**, evident to the endoscopist as redness, may be the only alteration. In mild GERD the mucosal histology is often unremarkable. With more significant disease, **eosinophils** are recruited into the squamous mucosa followed by neutrophils, which are usually associated with more severe injury (Fig. 17-5A). **Basal zone hyperplasia** exceeding 20% of the total epithelial thickness and elongation of lamina propria papillae, such that they extend into the upper third of the epithelium, may also be present.

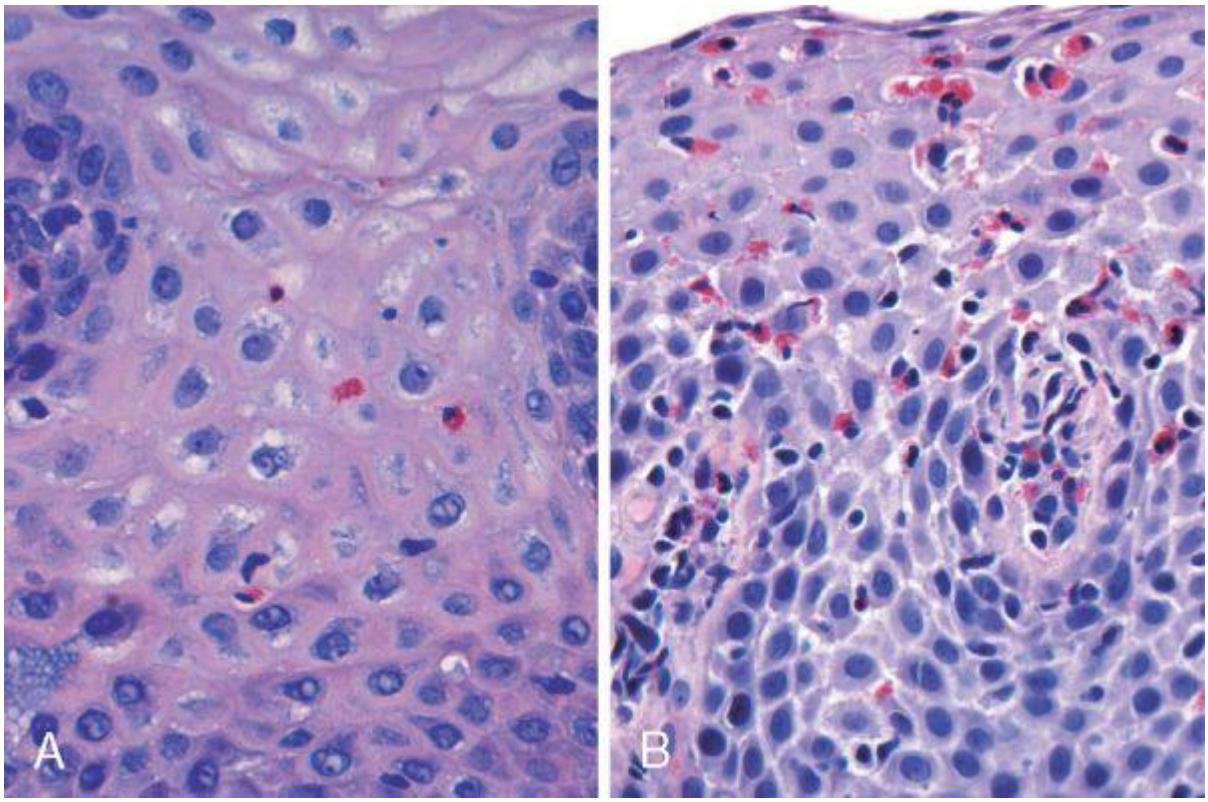

FIGURE 17-5 Esophagitis. **A**, Reflux esophagitis with scattered intraepithelial eosinophils. Although mild basal zone expansion can be appreciated, squamous cell maturation is relatively normal. **B**, Eosinophilic esophagitis is characterized by numerous intraepithelial eosinophils. Abnormal squamous maturation is also apparent.

Clinical Features.

GERD is most common in adults over age 40 but also occurs in infants and children. The most common clinical symptoms are dysphagia, heartburn, and, less frequently, noticeable regurgitation of sour-tasting gastric contents. Rarely, chronic GERD is punctuated by attacks of severe chest pain that may be mistaken for heart disease. Treatment with proton pump inhibitors or H_2 histamine receptor antagonists, which reduce gastric acidity, typically provides symptomatic relief. While the severity of symptoms is not closely related to the degree of histologic damage, the latter tends to increase with disease duration.

Complications of reflux esophagitis include esophageal ulceration, hematemesis, melena, stricture development, and Barrett esophagus.

Hiatal hernia is characterized by separation of the diaphragmatic crura and protrusion of the stomach into the thorax through the resulting gap. Congenital hiatal hernias are recognized in infants and children, but many are acquired in later life. Hiatal hernia is symptomatic in fewer than 10% of adults, and these cases are generally associated with other causes of LES incompetence. Symptoms, including heartburn and regurgitation of gastric juices, are similar to GERD.

EOSINOPHILIC ESOPHAGITIS

The incidence of eosinophilic esophagitis is increasing markedly.[7] Symptoms include food impaction and dysphagia in adults and feeding intolerance or GERD-like symptoms in children. The cardinal histologic feature is large numbers of intraepithelial eosinophils, particularly superficially (Fig. 17-5B). Their abundance can help to differentiate eosinophilic esophagitis from GERD, Crohn disease, and other causes of esophagitis. Clinical characteristics, particularly failure of high-dose proton pump inhibitor treatment and the absence of acid reflux, are also necessary for diagnosis. The majority of individuals with eosinophilic esophagitis are atopic and many have atopic dermatitis, allergic rhinitis, asthma, or modest peripheral eosinophilia. Treatments include dietary restrictions to prevent exposure to food allergens, such as cow's milk and soy products, and topical or systemic corticosteroids.

3.7.2.3 Barrett Esophagus

Barrett esophagus is a complication of chronic GERD that is characterized by *intestinal metaplasia within the esophageal squamous mucosa*. The incidence of Barrett esophagus is rising, and it is estimated to occur in as many as 10% of individuals with symptomatic GERD. Barrett esophagus is most common in white males and it typically presents between 40 and 60 years of age. The greatest concern in Barrett esophagus is that *it confers an increased risk of esophageal adenocarcinoma*. Molecular studies suggest that Barrett epithelium may be more similar to adenocarcinoma than to normal esophageal epithelium, consistent with the view that Barrett esophagus is a pre-malignant condition. In keeping with this, epithelial *dysplasia*, considered to be a pre-invasive lesion, is detected in 0.2% to 2.0% of persons with Barrett esophagus each year and is associated with prolonged symptoms and increased patient age. Although the vast majority of esophageal adenocarcinomas are associated with Barrett esophagus, it is important to remember that most individuals with Barrett esophagus do not develop esophageal tumors.

Morphology. Barrett esophagus can be recognized as one or several tongues or patches of red, velvety mucosa extending upward from the gastroesophageal junction. This metaplastic mucosa alternates with residual smooth, pale squamous (esophageal) mucosa and interfaces with light-brown columnar (gastric) mucosa distally (Fig. 17-6A , B). High-resolution endoscopes have increased the sensitivity of Barrett esophagus detection. This has led to subclassification of Barrett esophagus as long segment, in which 3 cm or more of esophagus is involved, or short segment, in which less than 3 cm is involved. It is not yet clear if the risk of dysplasia in short segment disease is less than in long segment Barrett esophagus.

Diagnosis of Barrett esophagus requires both endoscopic evidence of abnormal mucosa above the gastroesophageal junction and histologically documented intestinal metaplasia. **Goblet cells**, which have distinct mucous vacuoles that stain pale blue by H&E and impart the shape of a wine goblet to the remaining cytoplasm, define **intestinal metaplasia** and are necessary for diagnosis of Barrett esophagus (Fig. 17-6C). The requirement for intestinal metaplasia reflects the fact that this feature

correlates with neoplastic risk. Foveolar mucus cells, which do not have distinct mucous vacuoles are insufficient for diagnosis. The requirement for an endoscopic abnormality helps to prevent misdiagnosis if metaplastic goblet cells within the cardia are included in the biopsy.

When **dysplasia** is present, it is classified as low grade or high grade. Increased epithelial proliferation, often with atypical mitoses, nuclear hyperchromasia and stratification, irregularly clumped chromatin, increased nuclear-to-cytoplasmic ratio, and a failure of epithelial cells to mature as they migrate to the esophageal surface are present in both grades of dysplasia (Fig. 17-7A). Gland architecture is frequently abnormal and is characterized by budding, irregular shapes, and cellular crowding (Fig. 17-7B). High-grade dysplasia exhibits more severe cytologic and architectural changes. Intramucosal carcinoma is characterized by invasion of neoplastic epithelial cells into the lamina propria.

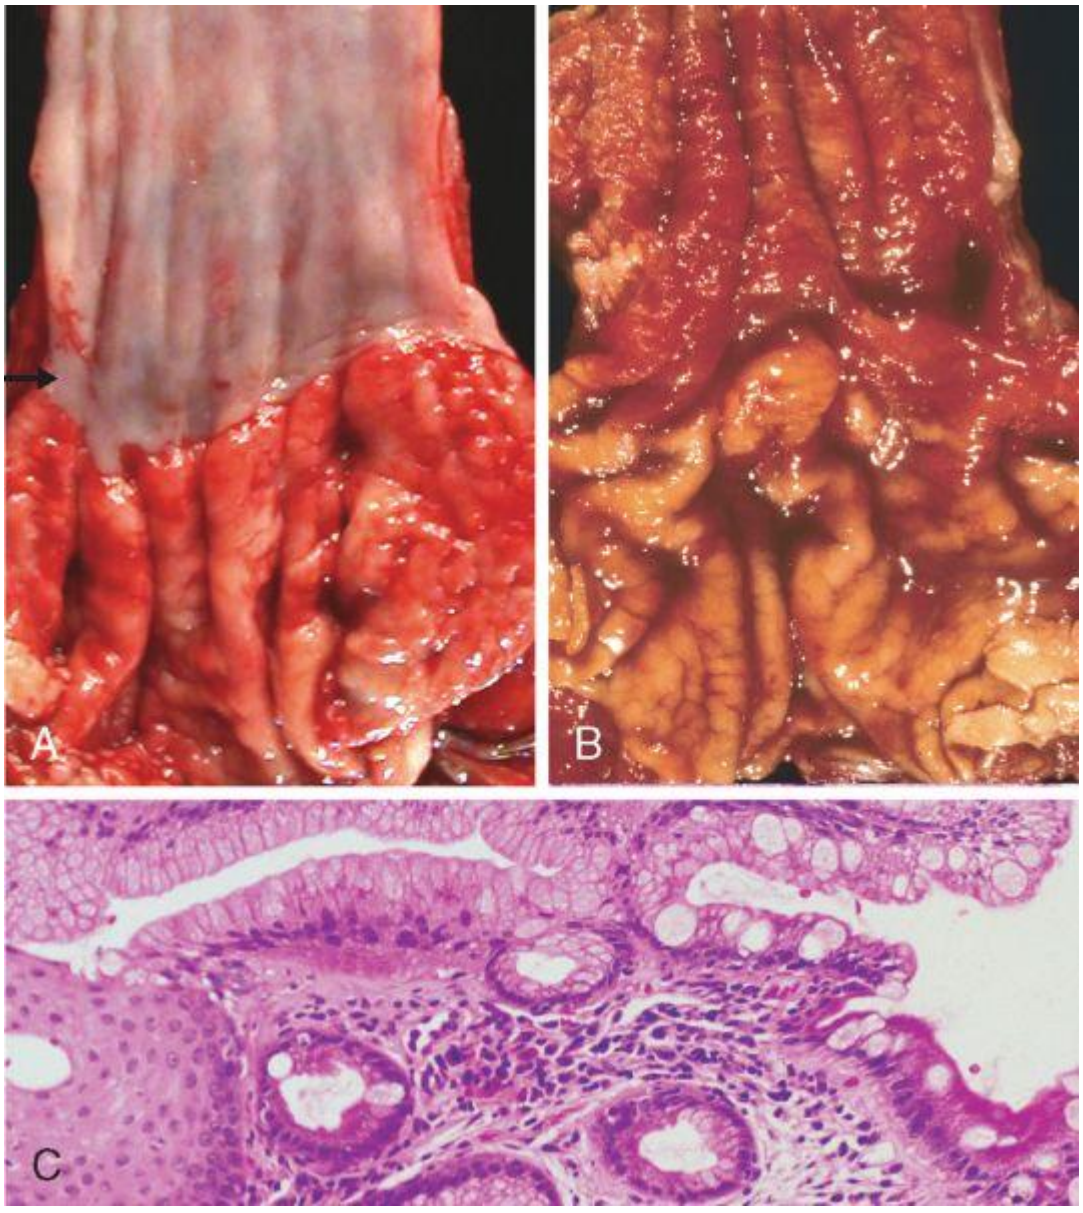

FIGURE 17-6 Barrett esophagus. **A**, Normal gastroesophageal junction. **B**, Barrett esophagus. Note the small islands of paler squamous mucosa within the Barrett mucosa. **C**, Histologic appearance of the gastroesophageal junction in Barrett esophagus. Note the transition

between esophageal squamous mucosa *(left)* and Barrett metaplasia, with abundant metaplastic goblet cells *(right)*.

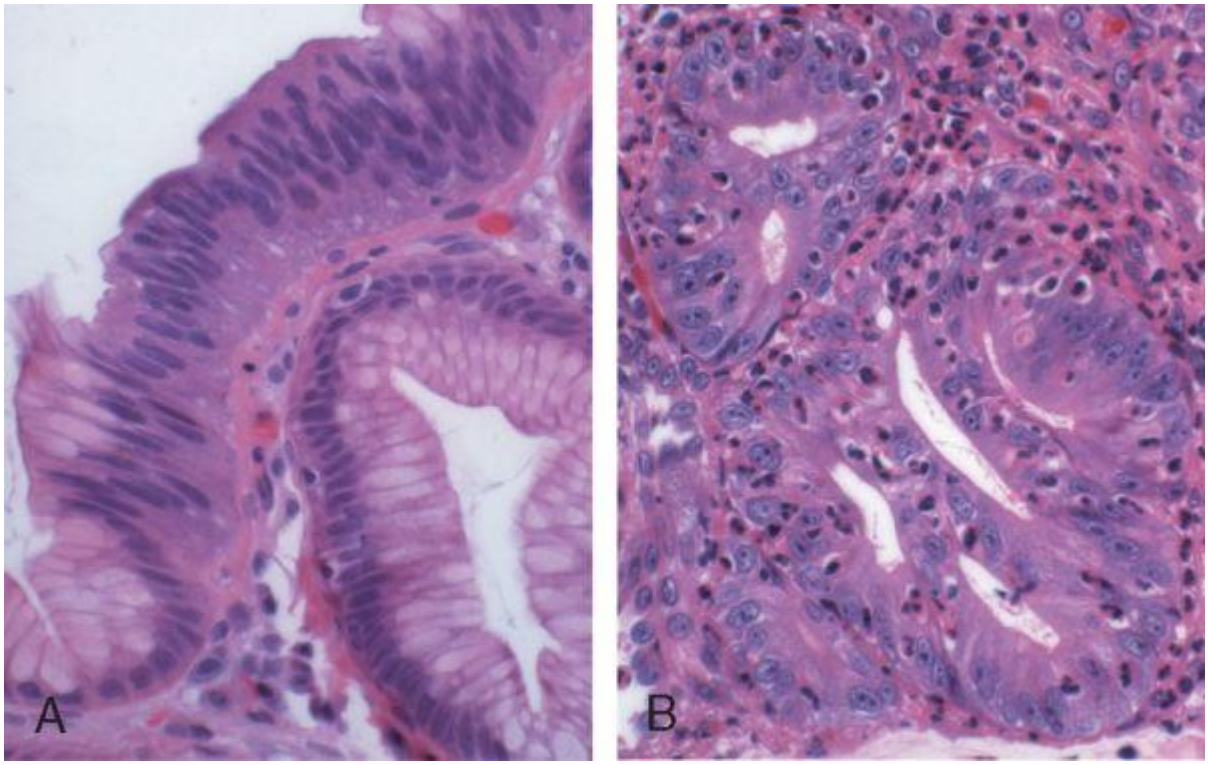

FIGURE 17-7 Dysplasia in Barrett esophagus. **A**, Abrupt transition from Barrett metaplasia to low-grade dysplasia. Note the nuclear stratification and hyperchromasia. **B**, Architectural irregularities, including gland-within-gland, or cribriform, profiles in high-grade dysplasia.

Clinical Features.

Barrett esophagus can only be identified thorough endoscopy and biopsy, which are usually prompted by GERD symptoms. Once diagnosed, the best course of management in Barrett esophagus is a matter of debate. However, most agree that periodic endoscopy with biopsy, for detection of dysplasia, has an important role. Nevertheless, uncertainties about the potential of dysplasia to regress, either spontaneously or in response to therapy, complicate clinical decisions when dysplasia is identified. In contrast, intramucosal carcinoma requires therapeutic intervention. Treatment options include surgical resection, or *esophagectomy*, as well as newer modalities such as photodynamic therapy, laser ablation, and endoscopic mucosectomy. Multifocal high-grade dysplasia, which carries a significant risk of progression to intramucosal or invasive carcinoma, is treated similarly to intramucosal carcinoma. Many physicians follow low-grade dysplasia or a single focus of high-grade dysplasia with endoscopy and biopsy at frequent intervals. However, management of esophageal dysplasia is evolving, and it is hoped that improved molecular understanding of neoplastic progression may allow development of chemopreventive approaches that reduce incidence of esophageal adenocarcinoma.[8]

ESOPHAGEAL VARICES

Instead of returning directly to the heart, venous blood from the GI tract is delivered to the liver via the portal vein before reaching the inferior vena cava. This circulatory pattern is responsible for the *first-pass effect* in which drugs and other materials absorbed in the intestines are processed by the liver before entering the systemic circulation. Diseases that impede this flow cause portal hypertension and can lead to the development of esophageal varices, an important cause of esophageal bleeding.

Pathogenesis.

Portal hypertension results in the development of collateral channels at sites where the portal and caval systems communicate. Although these collateral veins allow some drainage to occur, they lead to development of a congested subepithelial and submucosal venous plexus within the distal esophagus. These vessels, termed *varices*, develop in 90% of cirrhotic patients, most commonly in association with alcoholic liver disease. Worldwide, hepatic schistosomiasis is the second most common cause of varices. A more detailed consideration of portal hypertension is given in Chapter 18 .

Morphology. Varices can be detected by venogram (Fig. 17-8A) and appear as tortuous dilated veins lying primarily within the submucosa of the distal esophagus and proximal stomach. Venous channels directly beneath the esophageal epithelium may also become massively dilated. Varices may not be grossly obvious in surgical or postmortem specimens, because they collapse in the absence of blood flow (Fig. 17-8B) and, when they are not ruptured, the overlying mucosa is intact (Fig. 17-8C). Variceal rupture results in hemorrhage into the lumen or esophageal wall, in which case the overlying mucosa appears ulcerated and necrotic. If rupture has occurred in the past, venous thrombosis, inflammation, and evidence of prior therapy may also be present.

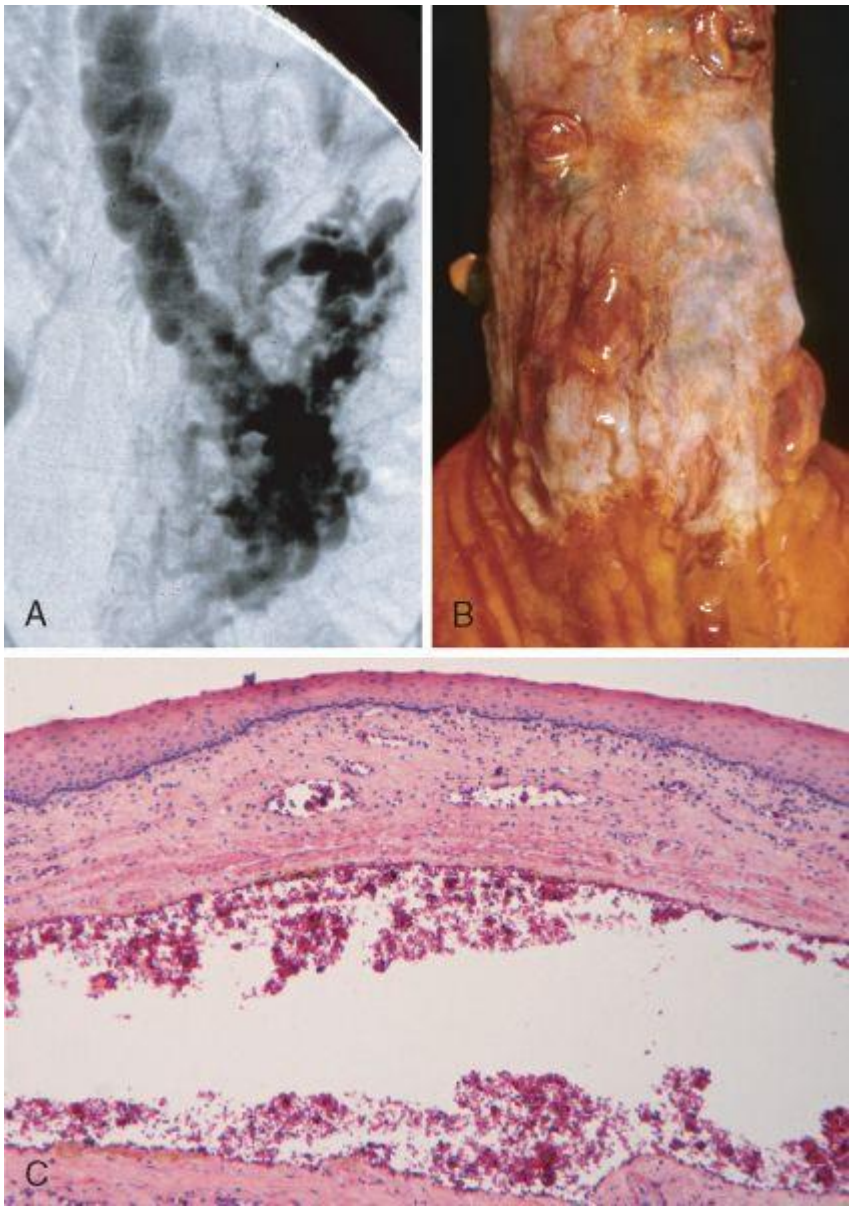

FIGURE 17-8 Esophageal varices. **A**, This angiogram shows several tortuous esophageal varices. **B**, Collapsed varices are present in this postmortem specimen corresponding to the angiogram in **A**. The polypoid areas represent previous sites of variceal hemorrhage that have been ligated with bands. **C**, Dilated varice beneath intact squamous mucosa.

Clinical Features.

While varices are often asymptomatic, they may rupture, causing massive hematemesis. The factors that lead to rupture are not well defined, but inflammatory erosion of thinned overlying mucosa, increased tension in progressively dilated veins, and increased vascular hydrostatic pressure associated with vomiting are likely to contribute. In any case, hemorrhage due to variceal rupture is a medical emergency that is treated by any of several methods: sclerotherapy by endoscopic injection of thrombotic agents; endoscopic balloon tamponade; or endoscopic rubber band ligation. Despite these interventions, as many as half of patients die from the first bleeding episode either as a direct consequence of hemorrhage or following hepatic coma triggered by hypovolemic shock. Among those

who survive, additional instances of hemorrhage occur in over 50% within 1 year. Each episode has a similar rate of mortality. Thus, over half of deaths among individuals with advanced cirrhosis result from variceal rupture. It must be remembered, however, that even when varices are present, they are only one of several causes of hematemesis.

3.7.2.4 Esophageal Tumors

Two morphologic variants comprise the majority of esophageal cancers: adenocarcinoma and squamous cell carcinoma. Worldwide, squamous cell carcinoma is more common, but in the United States and other Western countries adenocarcinoma is on the rise. The potential reasons for these increases are discussed below.

ADENOCARCINOMA

Adenocarcinoma of the esophagus typically arises in a background of Barrett esophagus and long-standing GERD. Risk of adenocarcinoma is greater in those with documented dysplasia and is further increased by tobacco use, obesity, and prior radiation therapy.[9] Conversely, risk of adenocarcinoma is reduced by diets rich in fresh fruits and vegetables. Some *Helicobacter pylori* serotypes are associated with a decreased risk of adenocarcinoma, perhaps by causing gastric atrophy and reducing acid reflux.

Esophageal adenocarcinoma occurs most frequently in Caucasians and shows a strong gender bias, being sevenfold more common in men. However, the incidence varies 60-fold worldwide, with rates being highest in certain developed Western countries, including the United States, the United Kingdom, Canada, Australia, the Netherlands, and Brazil and lowest in Korea, Thailand, Japan, and Ecuador. In countries where esophageal adenocarcinoma is more common, the incidence has increased markedly since 1970, more rapidly than almost any other cancer. As a result, esophageal adenocarcinoma, which represented less than 5% of esophageal cancers before 1970, now accounts for half of all esophageal cancers in the United States.

Pathogenesis.

Molecular studies suggest that the progression of Barrett esophagus to adenocarcinoma occurs over an extended period through the stepwise acquisition of genetic and epigenetic changes. This model is supported by the observation that epithelial clones identified in nondysplastic Barrett metaplasia persist and accumulate mutations during progression to dysplasia and invasive carcinoma. Chromosomal abnormalities and mutation or overexpression of p53 are present at early stages of esophageal adenocarcinoma. Additional genetic changes include amplification of *c-ERB-B2*, *cyclin D1*, and *cyclin E* genes; mutation of the retinoblastoma tumor suppressor gene; and allelic loss of the cyclindependent kinase inhibitor *p16/INK4a*. In other instances *p16/INK4a* is epigenetically silenced by hypermethylation. Increased epithelial expression of tumor necrosis factor (TNF)- and nuclear factor (NF)-κB–dependent genes suggests that inflammation may also contribute to neoplastic progression.

Morphology. Esophageal adenocarcinoma usually occurs in the distal third of the esophagus and may invade the adjacent gastric cardia (Fig. 17-9A). Initially appearing as flat or raised patches in otherwise intact mucosa, large masses of 5 cm or more in diameter may develop. Alternatively, tumors may infiltrate diffusely or ulcerate and invade deeply. Microscopically, Barrett esophagus is frequently present adjacent to the tumor. Tumors most commonly produce mucin and form glands (Fig. 17-10A), often with intestinal-type morphology; less frequently tumors are composed of diffusely infiltrative signet-ring cells (similar to those seen in diffuse gastric cancers) or, in rare cases, small poorly differentiated cells (similar to small-cell carcinoma of the lung).

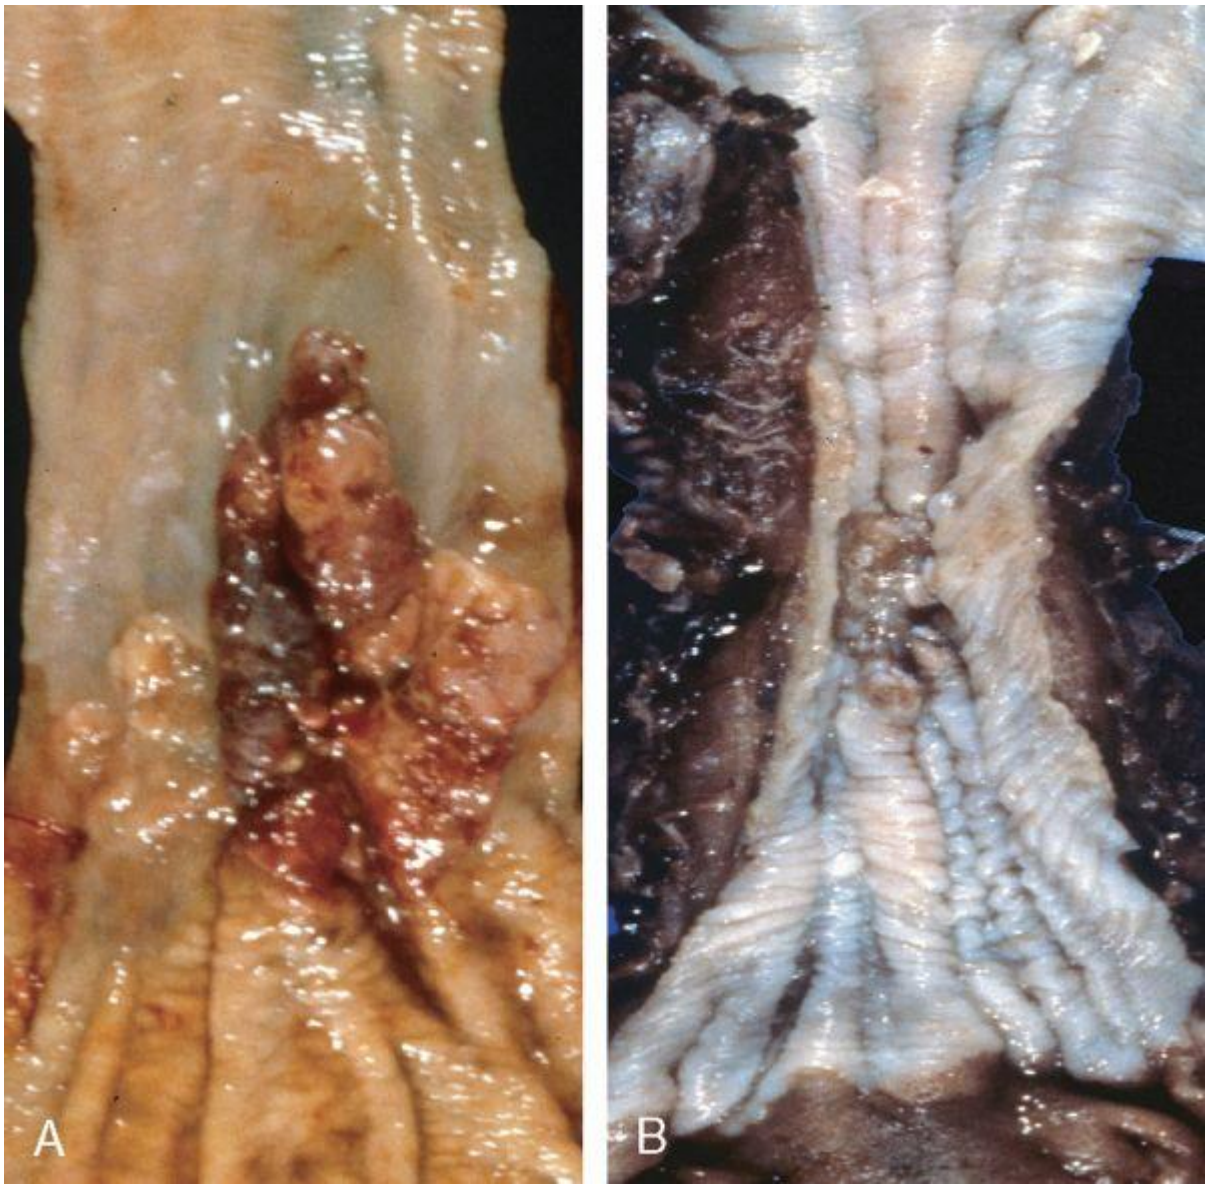

FIGURE 17-9 Esophageal cancer. **A**, Adenocarcinoma usually occurs distally and, as in this case, often involves the gastric cardia. **B**, Squamous cell carcinoma is most frequently found in the mid-esophagus, where it commonly causes strictures.

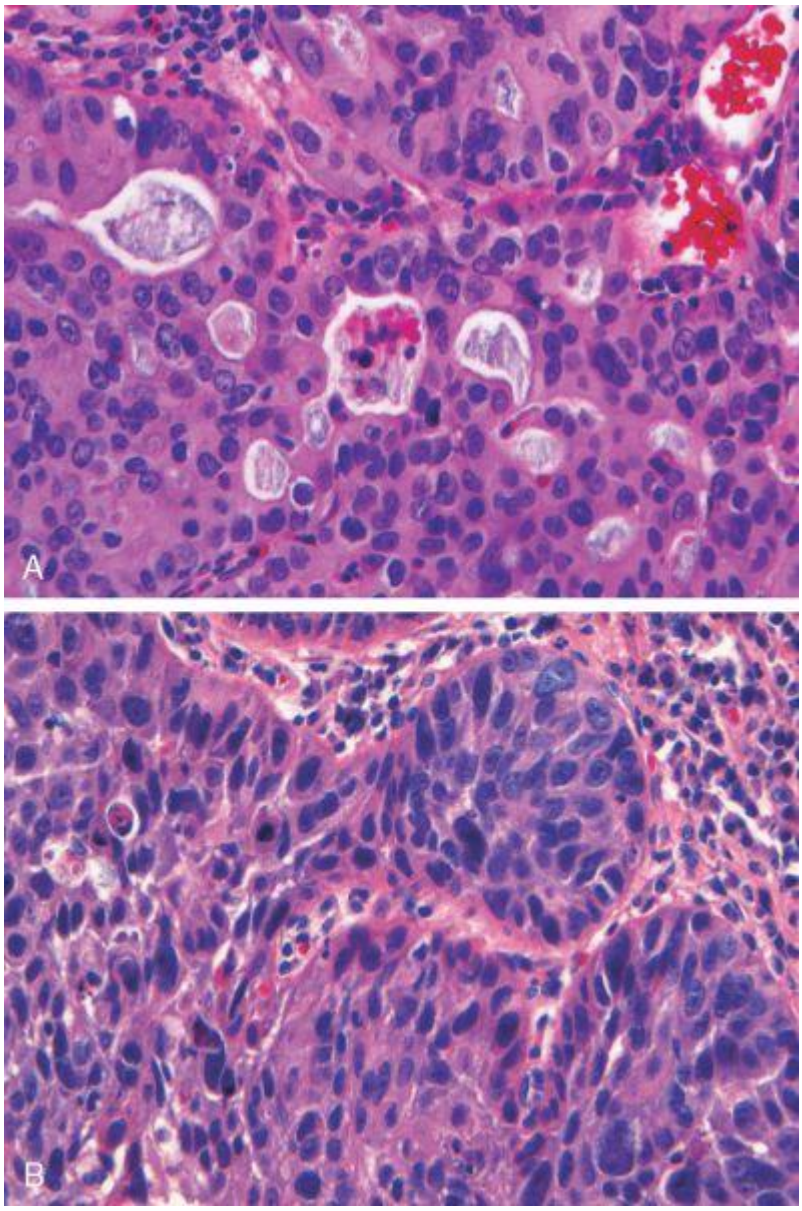

FIGURE 17-10 Esophageal cancer. **A**, Esophageal adenocarcinoma organized into back-to-back glands. **B**, Squamous cell carcinoma composed of nests of malignant cells that partially recapitulate the organization of squamous epithelium.

Clinical Features.

Although esophageal adenocarcinomas are occasionally discovered in evaluation of GERD or surveillance of Barrett esophagus, they more commonly present with pain or difficulty in swallowing, progressive weight loss, hematemesis, chest pain, or vomiting. By the time symptoms appear, the tumor has usually spread to submucosal lymphatic vessels. As a result of the advanced stage at diagnosis, overall 5-year survival is less than 25%. In contrast, 5-year survival approximates 80% in the few patients with adenocarcinoma limited to the mucosa or submucosa.

SQUAMOUS CELL CARCINOMA

In the United States, esophageal squamous cell carcinoma occurs in adults over age 45 and affects males four times more frequently than females.[10] Risk factors include alcohol and tobacco use, poverty, caustic esophageal injury, achalasia, tylosis, Plummer-Vinson syndrome, and frequent consumption of very hot beverages.[9] It is nearly sixfold more common in African-Americans than Caucasians, a striking risk disparity that reflects differences in rates of alcohol and tobacco use as well as other poorly understood factors.[11] Previous radiation therapy to the mediastinum also predisposes individuals to esophageal carcinoma, typically 10 or more years after exposure.[9]

Esophageal squamous cell carcinoma incidence varies up to 180-fold between and within countries, being more common in rural and underdeveloped areas. The regions with highest incidences are Iran, central China, Hong Kong, Brazil, and South Africa.

Pathogenesis.

The majority of esophageal squamous cell carcinomas in Europe and the United States are at least partially attributable to the use of alcohol and tobacco, which synergize to increase risk. However, esophageal squamous cell carcinoma is also common in some regions where alcohol and tobacco use is uncommon. Thus, nutritional deficiencies, as well as polycyclic hydrocarbons, nitrosamines, and other mutagenic compounds, such as those found in fungus-contaminated foods, must be considered. Human papillomavirus (HPV) infection has also been implicated in esophageal squamous cell carcinoma in high-risk areas but not in low-risk regions.[12] The molecular pathogenesis of esophageal squamous cell carcinoma remains incompletely defined, but loss of several tumor suppressor genes, including *p53* and *p16/INK4a*, is involved.

Morphology. In contrast to adenocarcinoma, half of squamous cell carcinomas occur in the middle third of the esophagus (see Fig. 17-9B). Squamous cell carcinoma begins as an in situ lesion termed **squamous dysplasia** (this lesion is referred to as intraepithelial neoplasia or carcinoma in situ at other sites). Early lesions appear as small, gray-white, plaque-like thickenings. Over months to years they grow into tumor masses that may be polypoid or exophytic and protrude into and obstruct the lumen. Other tumors are either ulcerated or diffusely infiltrative lesions that spread within the esophageal wall and cause thickening, rigidity, and luminal narrowing. These may invade surrounding structures including the respiratory tree, causing pneumonia; the aorta, causing catastrophic exsanguination; or the mediastinum and pericardium.

Most squamous cell carcinomas are moderately to well-differentiated (see Fig. 17-10B). Less common histologic variants include verrucous squamous cell carcinoma, spindle cell carcinoma, and basaloid squamous cell carcinoma. Regardless of histology, symptomatic tumors are generally very large at diagnosis and have already invaded the esophageal wall. The rich submucosal lymphatic network promotes circumferential and longitudinal spread, and intramural tumor nodules may be present several centimeters away from the principal mass. The sites of lymph node metastases vary with tumor location: cancers in the upper third of the esophagus favor cervical lymph nodes; those in the middle third favor mediastinal, paratracheal, and tracheobronchial nodes; and those in the lower third spread to gastric and celiac nodes.

Clinical Features.

The onset of esophageal squamous cell carcinoma is insidious and ultimately produces dysphagia, odynophagia (pain on swallowing), and obstruction. Patients subconsciously adjust to the progressively increasing obstruction by altering their diet from solid to liquid foods. Extreme weight loss and debilitation result from both impaired nutrition and effects of the tumor itself. Hemorrhage and sepsis

may accompany tumor ulceration. Occasionally, the first symptoms are caused by aspiration of food via a tracheoesophageal fistula.

Increased prevalence of endoscopic screening has led to earlier detection of esophageal squamous cell carcinoma. This is critical, because 5-year survival rates are 75% in individuals with superficial esophageal carcinoma but much lower in patients with more advanced tumors. Lymph node metastases, which are common, are associated with poor prognosis. The overall 5-year survival remains a dismal 9%.

UNCOMMON ESOPHAGEAL TUMORS

Other malignancies of the esophagus include unusual forms of adenocarcinoma, undifferentiated carcinoma, carcinoid tumor, melanoma, lymphoma, and sarcoma.

Benign tumors of the esophagus are generally mesenchymal in origin and arise within the esophageal wall. Tumors of smooth muscle origin, *leiomyomas*, are most common; fibromas, lipomas, hemangiomas, neurofibromas, and lymphangiomas also occur. Some benign tumors take the form of mucosal polyps. These are usually composed of fibrous and vascular tissue, or adipose tissue, and are known as *fibrovascular polyps* or *pedunculated lipomas*, respectively. *Squamous papillomas* are sessile lesions with a central core of connective tissue and a hyperplastic papilliform squamous mucosa. Uncommonly, papillomas are associated with HPV infection, in which case the term *condyloma* applies. In rare instances a mass of inflamed granulation tissue, growing either as an *inflammatory polyp* or an infiltrative mass in the wall of the esophagus, may resemble a malignant lesion. These benign lesions are called *inflammatory pseudotumors*.

3.7.3 Stomach

Disorders of the stomach are a frequent cause of clinical disease, with inflammatory and neoplastic lesions being particularly common. In the United States, diseases related to gastric acid account for nearly one third of all health care spending on GI disease. In addition, despite a decreasing incidence in certain locales such as the United States, gastric cancer remains a leading cause of death worldwide.

The stomach is divided into four major anatomic regions: the cardia, fundus, body, and antrum. The cardia and antrum are lined mainly by mucin-secreting foveolar cells that form small glands. The antral glands are similar but also contain endocrine cells, such as G cells, that release gastrin to stimulate luminal acid secretion by parietal cells within the gastric fundus and body. The well-developed glands of the body and fundus also contain chief cells that produce and secrete digestive enzymes such as pepsin.

3.7.3.1 Acute Gastritis

Acute gastritis is a transient mucosal inflammatory process that may be asymptomatic or cause variable degrees of epigastric pain, nausea, and vomiting. In more severe cases there may be mucosal erosion, ulceration, hemorrhage, hematemesis, melena, or, rarely, massive blood loss.

Pathogenesis.

The gastric lumen is strongly acidic with pH close to 1, more than a million times more acidic than the blood. This harsh environment contributes to digestion but also has the potential to damage the gastric mucosa. Multiple mechanisms have evolved to protect the gastric mucosa (Fig. 17-11). Mucin secreted by surface *foveolar cells* forms a thin layer of mucus that prevents large food particles from directly touching the epithelium. The mucus layer also promotes formation of an “unstirred” layer of fluid over the epithelium that protects the mucosa and has a neutral pH as a result of bicarbonate ion secretion by

surface epithelial cells. Finally, the rich vascular supply to the gastric mucosa delivers oxygen, bicarbonate, and nutrients while washing away acid that has back-diffused into the lamina propria. Acute or chronic gastritis can occur following disruption of any of these protective mechanisms. For example, reduced mucin synthesis in the elderly has been suggested as one factor that may explain their increased susceptibility to gastritis. Nonsteroidal anti-inflammatory drugs (NSAIDs) may interfere with cytoprotection normally provided by prostaglandins or reduce bicarbonate secretion, either of which increases the susceptibility of the gastric mucosa to injury. Similarly, the gastric injury that occurs in uremic patients and those infected with urease-secreting *H. pylori* may be due to inhibition of gastric bicarbonate transporters by ammonium ions. Ingestion of harsh chemicals, particularly acids or bases, either accidentally or as a suicide attempt, also results in severe gastric injury, predominantly as a result of direct injury to mucosal epithelial and stromal cells. Direct cellular injury is also implicated in gastritis due to excessive alcohol consumption, NSAIDs, radiation therapy, and chemotherapy. Since the entire gastric mucosal surface is replaced every 2 to 6 days, mitotic inhibitors, including those used in cancer chemotherapy, cause generalized mucosal damage due to insufficient epithelial regeneration. Finally, decreased oxygen delivery may explain increased incidence of acute gastritis at high altitudes.

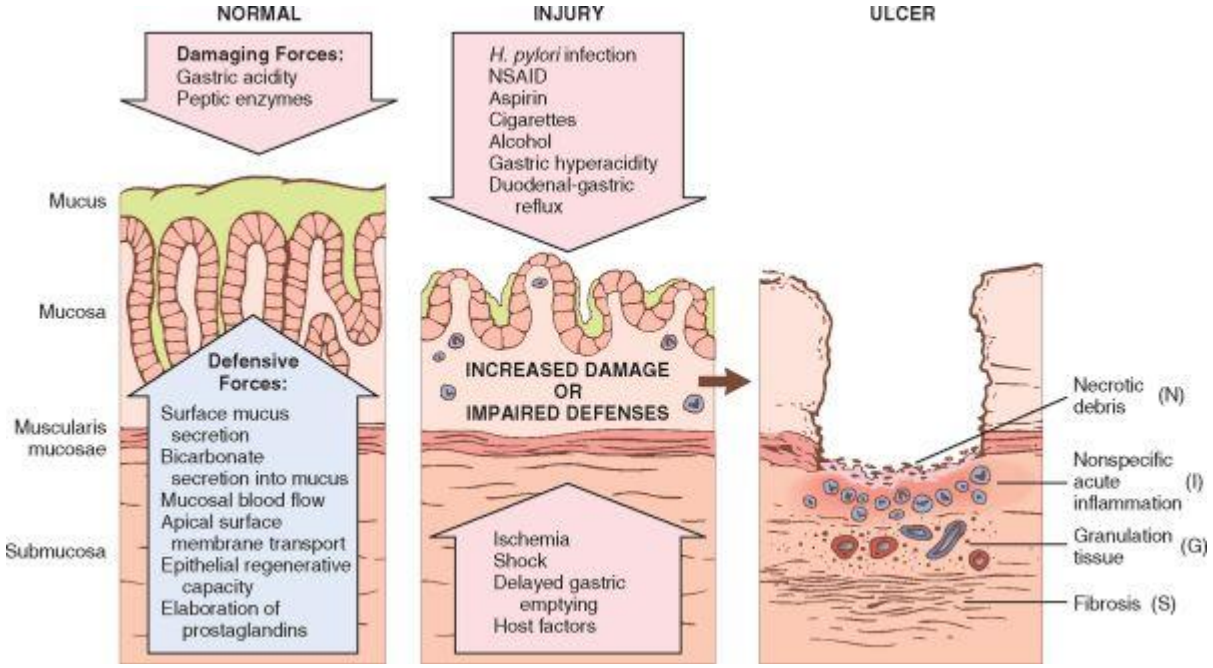

FIGURE 17-11 Mechanisms of gastric injury and protection. This diagram illustrates the progression from more mild forms of injury to ulceration that may occur with acute or chronic gastritis. Ulcers include layers of necrosis (N), inflammation (I), and granulation tissue (G), but a fibrotic scar (S), which takes time to develop, is only present in chronic lesions.

Morphology. Histologically, mild acute gastritis may be difficult to recognize, since the lamina propria shows only moderate edema and slight vascular congestion. The **surface epithelium is intact**, although scattered neutrophils may be present among the epithelial cells or within mucosal glands. In contrast, an abundance of lymphocytes or plasma cells suggests chronic disease. The presence of neutrophils above the basement membrane in direct contact with epithelial cells is abnormal in all parts of the GI tract and signifies **active inflammation**. This term is preferred over acute inflammation, since active inflammation may be present in both acute and chronic disease states. With more severe mucosal damage, erosions and hemorrhage develop. An **erosion** denotes loss of the

superficial epithelium, generating a defect in the mucosa that is limited to the lamina propria. It is accompanied by a pronounced neutrophilic infiltrate within the mucosa and a fibrin-containing purulent exudate in the lumen. Hemorrhage may occur and cause dark punctae in an otherwise hyperemic mucosa. Concurrent erosion and hemorrhage is termed **acute erosive hemorrhagic gastritis**. Large areas of the gastric surface may be denuded, although the involvement is typically superficial. When erosions extend deeply, they may progress to ulcers, as described below.

ACUTE GASTRIC ULCERATION

Focal, acutely developing gastric mucosal defects are a well-known complication of therapy with NSAIDs. They may also appear after severe physiologic stress. Some of these are given specific names, based on location and clinical associations. For example:

- *Stress ulcers* are most common in individuals with shock, sepsis, or severe trauma.
- Ulcers occurring in the proximal duodenum and associated with severe burns or trauma are called *Curling ulcers*.
- Gastric, duodenal, and esophageal ulcers arising in persons with intracranial disease are termed *Cushing ulcers* and carry a high incidence of perforation.

Pathogenesis.

The pathogenesis of acute ulceration is complex and incompletely understood. NSAID-induced ulcers are related to cyclooxygenase inhibition. This prevents synthesis of prostaglandins, which enhance bicarbonate secretion, inhibit acid secretion, promote mucin synthesis, and increase vascular perfusion. Lesions associated with intracranial injury are thought to be caused by direct stimulation of vagal nuclei, which causes hypersecretion of gastric acid. Systemic acidosis, a frequent finding in these settings, may also contribute to mucosal injury by lowering the intracellular pH of mucosal cells. Hypoxia and reduced blood flow caused by stress-induced splanchnic vasoconstriction also contribute to the pathogenesis of acute ulcers.

Morphology. Lesions described as acute gastric ulcers range in depth from shallow erosions caused by superficial epithelial damage to deeper lesions that penetrate the depth of the mucosa. Acute ulcers are rounded and less than 1 cm in diameter. The ulcer base is frequently stained brown to black by acid digestion of extravasated blood and may be associated with transmural inflammation and local serositis. Unlike peptic ulcers, which arise in the setting of chronic injury, acute stress ulcers are found anywhere in the stomach. The gastric rugal folds are essentially normal, and the margins and base of the ulcers are not indurated. While they may occur singly, more often there are multiple ulcers throughout the stomach and duodenum. Microscopically, acute stress ulcers are sharply demarcated, with essentially normal adjacent mucosa. Depending on the duration of the ulceration, there may be a suffusion of blood into the mucosa and submucosa and some inflammatory reaction. Conspicuously absent are the scarring and thickening of blood vessels that characterize chronic peptic ulcers. Healing with complete re-epithelialization occurs after the injurious factors are removed. The time required for healing varies from days to several weeks.

Clinical Features.

Most critically ill patients admitted to hospital intensive care units have histologic evidence of gastric mucosal damage. Bleeding from superficial gastric erosions or ulcers that may require transfusion develops in 1% to 4% of these patients. Other complications, including perforation, can also occur (Table 17-2). Prophylactic H_2 histamine receptor antagonists or proton pump inhibitors may blunt the

impact of stress ulceration, but the most important determinant of clinical outcome is the ability to correct the underlying conditions. The gastric mucosa can recover completely if the patient does not succumb to their primary disease.

TABLE 17-2 -- Complications of Gastric Ulcers

Bleeding
Occurs in 15% to 20% of patients
Most frequent complication
May be life-threatening
Accounts for 25% of ulcer deaths
May be the first indication of an ulcer
Perforation
Occurs in up to 5% of patients
Accounts for two thirds of ulcer deaths
Is rarely first indication of an ulcer
Obstruction
Mostly in chronic ulcers
Secondary to edema or scarring
Occurs in about 2% of patients
Most often associated with pyloric channel ulcers
May occur with duodenal ulcers
Causes incapacitating, crampy abdominal pain
Can rarely cause total obstruction and intractable vomiting

3.7.3.2 Chronic Gastritis

In contrast to acute gastritis, the symptoms associated with chronic gastritis are typically less severe but more persistent. Nausea and upper abdominal discomfort may occur, sometimes with vomiting, but hematemesis is uncommon. *The most common cause of chronic gastritis is infection with the bacillus Helicobacter pylori*. Before the acceptance of the central role of *H. pylori* infection in chronic gastritis, other chronic irritants, including psychologic stress, caffeine, alcohol, and tobacco use were considered the primary causes of gastritis. *Autoimmune gastritis*, the most common cause of *atrophic gastritis*, represents less than 10% of cases of chronic gastritis and is the most common form of chronic gastritis in patients without *H. pylori* infection. Less common etiologies include radiation injury, chronic bile reflux, mechanical injury, and involvement by systemic disease such as Crohn disease, amyloidosis, or graft-versus-host disease.

HELICOBACTER PYLORI GASTRITIS

The discovery of *H. pylori* has revolutionized our understanding of chronic gastritis.[13] *These spiral-shaped or curved bacilli are present in gastric biopsy specimens of almost all patients with duodenal ulcers and the majority of individuals with gastric ulcers or chronic gastritis*.[13] In a now-famous experiment, the Nobel laureate Barry Marshall ingested *H. pylori* cultures and developed mild gastritis.

While not a recommended approach to infectious disease investigation, this experiment did demonstrate the pathogenicity of *H. pylori*. Acute *H. pylori* infection does not produce sufficient symptoms to require medical attention in most cases; it is the chronic gastritis that ultimately causes the individual to seek treatment. *H. pylori* organisms are present in 90% of individuals with chronic gastritis affecting the antrum. In addition, *H. pylori* has important roles in other gastric and duodenal diseases. For example, the increased acid secretion that occurs in *H. pylori* gastritis may result in peptic ulcer disease, and *H. pylori* infection also confers increased risk of gastric cancer.

Epidemiology.

In the United States, *H. pylori* infection is associated with poverty, household crowding, limited education, African-American or Mexican-American ethnicity, residence in rural areas, and birth outside of the United States. Colonization rates exceed 70% in some groups and vary from less than 10% to more than 80% worldwide. In high-prevalence areas infection is often acquired in childhood and then persists for decades, explaining the direct correlation between colonization rate and patient age.

The mode of *H. pylori* transmission is not well defined, but humans are the only known host, making oral-oral, fecal-oral, and environmental spread the most likely routes of infection. The related organism *Helicobacter heilmannii* causes similar disease and has reservoirs in cats, dogs, pigs, and nonhuman primates. While the morphologic differences between *H. pylori* and *H. heilmannii* organisms are subtle, recognition of *H. heilmannii* infection can be important since it may prompt treatment of household pets to prevent re-infection of the human companion.

Pathogenesis.

H. pylori infection is the most common cause of chronic gastritis. The disease most often presents as a *predominantly antral gastritis with high acid production, despite hypogastrinemia*. The risk of duodenal ulcer is increased in these patients and, in most, gastritis is limited to the antrum with occasional involvement of the cardia. In a subset of patients the gastritis progresses to involve the gastric body and fundus. This pangastritis is associated with multifocal mucosal atrophy, reduced acid secretion, intestinal metaplasia, and increased risk of gastric adenocarcinoma.

H. pylori organisms have adapted to the ecologic niche provided by gastric mucus. Although *H. pylori* may invade the gastric mucosa, this is not evident histologically and the contribution of invasion to disease is not known. Four features are linked to *H. pylori* virulence:

- *Flagella*, which allow the bacteria to be motile in viscous mucus
- *Urease*, which generates ammonia from endogenous urea and thereby elevates local gastric pH
- *Adhesins* that enhance their bacterial adherence to surface foveolar cells
- *Toxins*, such as cytotoxin-associated gene A *(CagA)*, that may be involved in ulcer or cancer development by poorly defined mechanisms

Although the mechanisms by which *H. pylori* cause gastritis are incompletely defined, it is clear that infection results in increased acid production and disruption of normal gastric and duodenal protective mechanisms, as described earlier (see Fig. 17-11). *H. pylori* gastritis is, therefore, the result of an imbalance between gastroduodenal mucosal defenses and damaging forces that overcome those defenses.

Over time chronic antral *H. pylori* gastritis may progress to pangastritis, resulting in *multifocal atrophic gastritis*. The underlying mechanisms contributing to this progression are not clear, but interactions between the host and bacterium seem to be critical. For example, particular polymorphisms in the gene

encoding the pro-inflammatory cytokine interleukin-1β (IL-1β) correlate with the development of pangastritis after *H. pylori* infection. Polymorphisms in TNF and a variety of other genes associated with the inflammatory response also influence the clinical outcome in *H. pylori* infection.[14] Severity of disease may also be influenced by genetic variation among *H. pylori* strains. For example, the *CagA* gene, a marker for a pathogenicity island of approximately 20 genes, is present in 50% of *H. pylori* isolates overall but in 90% of *H. pylori* isolates found in populations with elevated gastric cancer risk.

Morphology. Gastric biopsy specimens generally demonstrate *H. pylori* in infected individuals. The organism is concentrated within the superficial mucus overlying epithelial cells in the surface and neck regions. The distribution can be irregular, with areas of heavy colonization adjacent to those with few organisms. In extreme cases, the organisms carpet the luminal surfaces of foveolar and mucous neck cells, and can even extend into the gastric pits. Organisms are most easily demonstrated with a variety of special stains (Fig. 17-12A). *H. pylori* shows tropism for gastric epithelia and is generally not found in association with gastric intestinal metaplasia or duodenal epithelium. However, *H. pylori* may be present in foci of pyloric metaplasia within chronically injured duodenum or gastric-type mucosa within Barrett esophagus.

Within the stomach, *H. pylori* are typically found in the antrum (Table 17-3). Although there is a good concordance between colonization of the antrum and cardia, infection of the cardia occurs at somewhat lower rates. *H. pylori* are uncommon in **oxyntic** (acid-producing) mucosa of the fundus and body except in heavy colonization. Thus, an antral biopsy is preferred for evaluation of *H. pylori* gastritis. When viewed endoscopically, *H. pylori*–infected antral mucosa is usually **erythematous** and has a coarse or even nodular appearance. The inflammatory infiltrate generally includes variable numbers of neutrophils within the lamina propria, including some that cross the basement membrane to assume an **intraepithelial** location (Fig. 17-12B) and accumulate in the lumen of gastric pits to create **pit abscesses**. In addition, the superficial lamina propria includes large numbers of plasma cells, often in clusters or sheets, and increased numbers of lymphocytes and macrophages. **Intraepithelial neutrophils** and **subepithelial plasma cells** are characteristic of *H. pylori* gastritis. When intense, inflammatory infiltrates may create thickened rugal folds, mimicking early infiltrative lesions. Long-standing *H. pylori* gastritis may extend to involve the body and fundus, and the mucosa can become **atrophic**. Lymphoid aggregates, some with germinal centers, are frequently present (Fig. 17-12C) and represent an induced form of **mucosa-associated lymphoid tissue**, or MALT, that has the potential to transform into lymphoma.

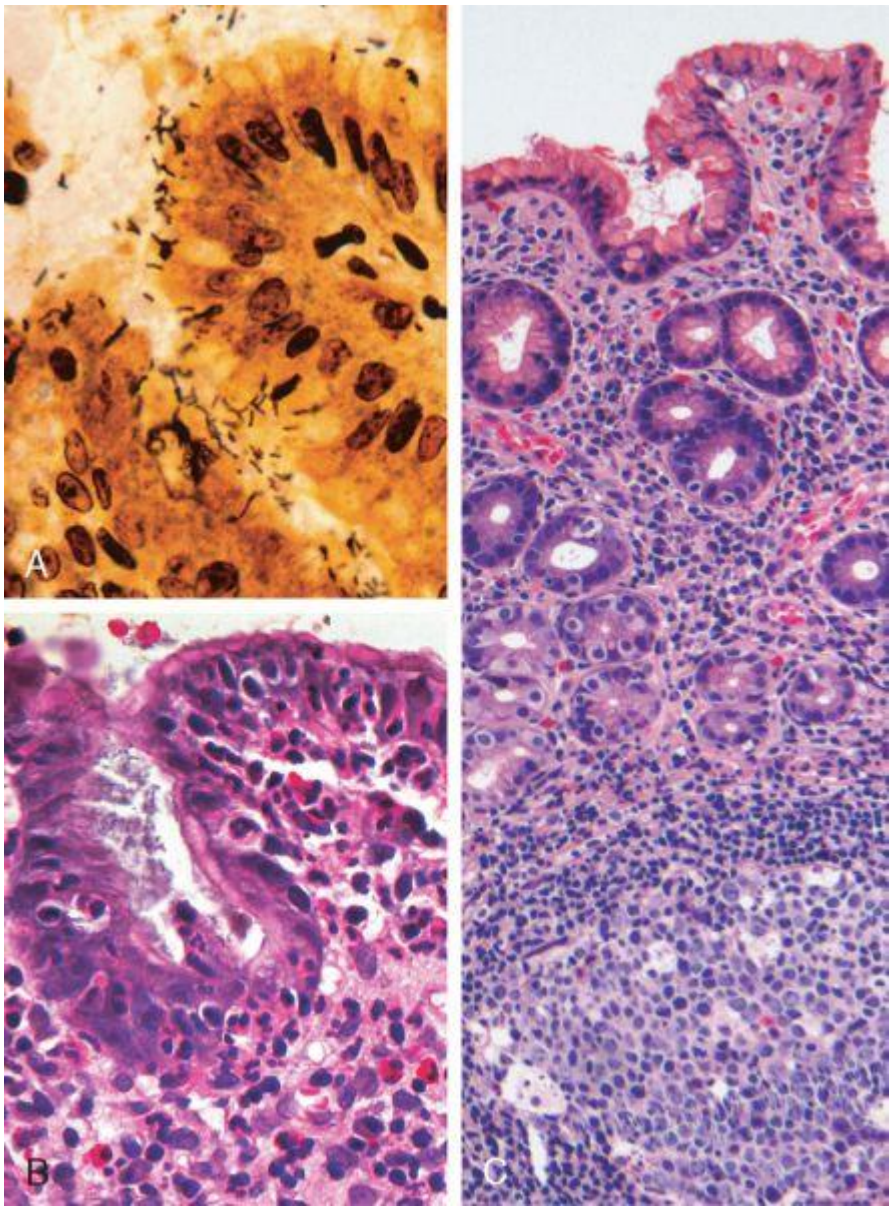

FIGURE 17-12 *Helicobacter pylori* gastritis. **A**, Spiral-shaped *H. pylori* are highlighted in this Warthin-Starry silver stain. Organisms are abundant within surface mucus. **B**, Intraepithelial and lamina propria neutrophils are prominent. **C**, Lymphoid aggregates with germinal centers and abundant subepithelial plasma cells within the superficial lamina propria are characteristic of *H. pylori* gastritis.

TABLE 17-3 -- Characteristics of *Helicobacter pylori*–Associated and Autoimmune Gastritis

	***H. pylori*–Associated**	**Autoimmune**
Location	Antrum	Body
Inflammatory infiltrate	Neutrophils, subepithelial plasma cells	Lymphocytes, macrophages
Acid production	Increased to slightly decreased	Decreased
Gastrin	Normal to decreased	Increased
Other lesions	Hyperplastic/inflammatory polyps	Neuroendocrine hyperplasia

Serology	Antibodies to *H. pylori*	Antibodies to parietal cells (H^+, K^+-ATPase, intrinsic factor)
Sequelae	Peptic ulcer, adenocarcinoma	Atrophy, pernicious anemia, adenocarcinoma, carcinoid tumor
Associations	Low socioeconomic status, poverty, residence in rural areas	Autoimmune disease; thyroiditis, diabetes mellitus, Graves disease

Clinical Features.

In addition to histologic identification of the organism, several diagnostic tests have been developed including a noninvasive serologic test for antibodies to *H. pylori*, fecal bacterial detection, and the urea breath test based on the generation of ammonia by the bacterial urease. Gastric biopsy specimens can also be analyzed by the rapid urease test, bacterial culture, or bacterial DNA detection by PCR.

Effective treatments for *H. pylori* infection include combinations of antibiotics and proton pump inhibitors. Individuals with *H. pylori* gastritis usually improve after treatment, although relapses can occur after incomplete eradication or re-infection. Prophylactic and therapeutic vaccine development is still at an early stage of development. Peptic ulcer disease, a complication of chronic *H. pylori* gastritis, is described later.

AUTOIMMUNE GASTRITIS

Autoimmune gastritis accounts for less than 10% of cases of chronic gastritis. In contrast to that caused by *H. pylori*, autoimmune gastritis typically spares the antrum and includes *hypergastrinemia* (see Table 17-3). Autoimmune gastritis is characterized by:

- Antibodies to parietal cells and intrinsic factor that can be detected in serum and gastric secretions
- Reduced serum pepsinogen I concentration
- Antral endocrine cell hyperplasia
- Vitamin B_{12} deficiency
- Defective gastric acid secretion *(achlorhydria)*

Pathogenesis.

Autoimmune gastritis is associated with loss of parietal cells, which are responsible for secretion of gastric acid and intrinsic factor. The absence of acid production stimulates gastrin release, resulting in hypergastrinemia and hyperplasia of antral gastrin-producing G cells. Lack of intrinsic factor disables ileal vitamin B_{12} absorption, leading to B_{12} deficiency and a slow-onset megaloblastic anemia *(pernicious anemia)*. The reduced serum pepsinogen I concentration results from chief cell destruction. In contrast, although *H. pylori* can cause hypochlorhydria, it is not associated with achlorhydria or pernicious anemia because the parietal and chief cell damage is not as severe as in autoimmune gastritis.

It was initially thought that the autoantibodies to parietal cell components, most prominently the H^+,K^+-ATPase, or proton pump, and intrinsic factor were involved in the pathogenesis of autoimmune gastritis. However, this is unlikely because neither secreted intrinsic factor nor the luminally oriented proton pump are accessible to circulating antibodies, and passive transfer of these antibodies does not produce gastritis in experimental animals. It is more likely that CD4+ T cells directed against parietal cell components, including the H^+,K^+-ATPase, are the principal agents of injury. This is supported by the observation that transfer of H^+,K^+-ATPasereactive CD4+ T cells into naive mice results in gastritis and production of H^+,K^+-ATPase autoantibodies. There is no evidence of an autoimmune reaction to chief cells, suggesting that these are lost through gastric gland destruction during autoimmune attack on

parietal cells. If autoimmune destruction is controlled by immunosuppression, the glands can repopulate, demonstrating that gastric stem cells survive and are able to differentiate into parietal and chief cells.

Morphology. Autoimmune gastritis is characterized by diffuse mucosal **damage of the oxyntic (acid-producing) mucosa** within the body and fundus. Damage to the antrum and cardia is typically absent or mild. With **diffuse atrophy**, the oxyntic mucosa of the body and fundus appears markedly thinned, and rugal folds are lost. If vitamin B_{12} deficiency is severe, nuclear enlargement (megaloblastic change) occurs within epithelial cells. Neutrophils may be present, but the inflammatory infiltrate is more often composed of lymphocytes, macrophages, and plasma cells. Lymphoid aggregates may be present. The superficial lamina propria plasma cells of *H. pylori* gastritis are typically absent, and the inflammatory reaction is most often deep and centered on the gastric glands (Fig. 17-13A). Loss of parietal and chief cells can be extensive. When atrophy is incomplete residual islands of oxyntic mucosa may give the appearance of multiple small polyps or nodules. Small surface elevations may be apparent, and these correlate with areas of **intestinal metaplasia**, characterized by the presence of goblet cells and columnar absorptive cells (Fig. 17-13B). The **antral endocrine cell hyperplasia** that develops in most patients can be difficult to appreciate on H&E-stained sections, since the endocrine cells, which are also referred to as enterochromaffin-like (ECL) cells, are not easily recognized. This hyperplasia parallels the degree of mucosal atrophy and is a physiologic response to decreased acid production. Over time, hypergastrinemia can stimulate endocrine cell hyperplasia in the fundus and body. Rarely, this may progress to form small, multicentric, low-grade neuroendocrine, or carcinoid, tumors.

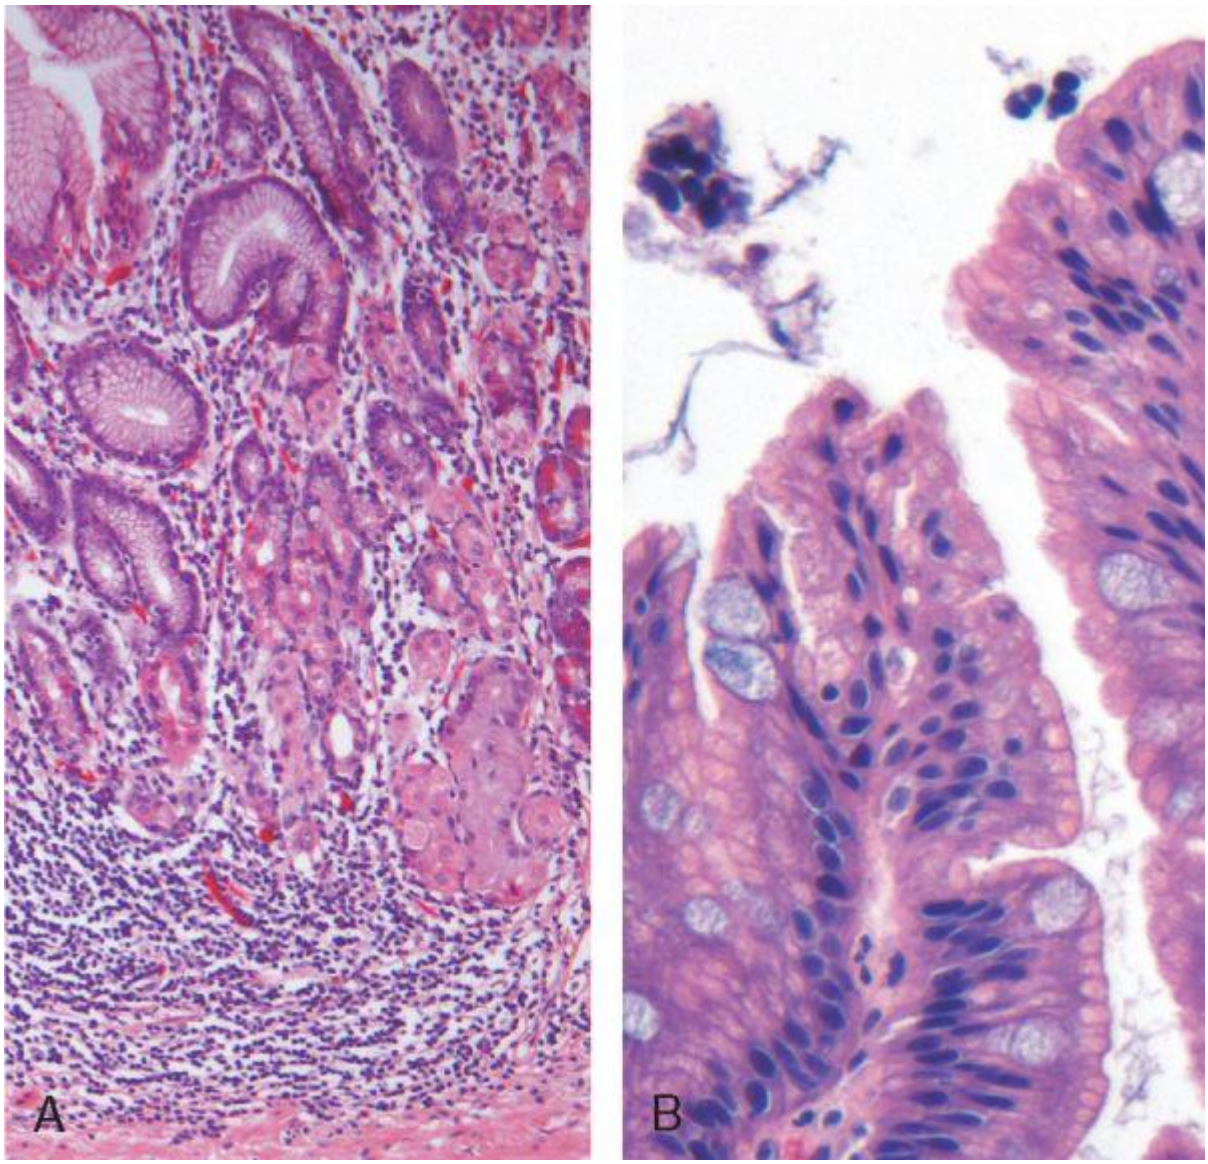

FIGURE 17-13 Autoimmune gastritis. **A**, Low-magnification image of gastric body demonstrating deep inflammatory infiltrates, primarily composed of lymphocytes, and glandular atrophy. **B**, Intestinal metaplasia, recognizable as the presence of goblet cells admixed with gastric foveolar epithelium.

Clinical Features.

Antibodies to parietal cells and to intrinsic factor are present early in the disease course. Progression to gastric atrophy probably occurs over 2 to 3 decades, and anemia is seen in only a few patients. Because of the slow onset and variable progression, patients are generally diagnosed only after being affected for many years; the median age at diagnosis is 60 years. Slightly more women than men are affected. Pernicious anemia and autoimmune gastritis are often associated with other autoimmune diseases including Hashimoto thyroiditis, insulin-dependent (type I) diabetes mellitus, Addison disease, primary ovarian failure, primary hypoparathyroidism, Graves disease, vitiligo, myasthenia gravis, and Lambert-Eaton syndrome. These associations, along with concordance in some monozygotic twins and clustering of disease in families, support a genetic predisposition. In general, about 20% of relatives of individuals with pernicious anemia also have autoimmune gastritis, although they may be asymptomatic. Despite

this strong genetic influence, autoimmune gastritis stands apart from other autoimmune diseases in that there is little evidence of linkage to specific HLA alleles.

Clinical presentation may be linked to symptoms of anemia.[15] In addition, vitamin B_{12} deficiency may cause *atrophic glossitis*, in which the tongue becomes smooth and beefy red, epithelial megaloblastosis, and malabsorptive diarrhea. Vitamin B_{12} deficiency may also cause peripheral neuropathy, spinal cord lesions, and cerebral dysfunction. Neuropathic changes include demyelination, axonal degeneration, and neuronal death. The most frequent manifestations of peripheral neuropathy are paresthesias and numbness. The spinal lesions may be associated with a mixture of loss of vibration and position sense, sensory ataxia with positive Romberg sign, limb weakness, spasticity, and extensor plantar responses. Cerebral manifestations range from mild personality changes and memory loss to psychosis. In contrast to anemia, neurologic changes are not reversed by vitamin B_{12} replacement therapy.

UNCOMMON FORMS OF GASTRITIS

Reactive Gastropathy.

This group of disorders is marked by foveolar hyperplasia, glandular regenerative changes, and mucosal edema. Neutrophils are not abundant. Causes of reactive gastropathy include chemical injury, NSAID use, bile reflux, and mucosal trauma secondary to prolapse. Notably, reactive gastropathy and bile reflux are common after gastric surgeries that bypass the pylorus. Gastric antral trauma induces a grossly characteristic lesion referred to as *gastric antral vascular ectasia* (GAVE). Endoscopy shows longitudinal stripes of edematous erythematous mucosa alternating with less severely injured mucosa that is sometimes referred to as *watermelon stomach*. Histologically, the antral mucosa shows reactive gastropathy with dilated capillaries containing fibrin thrombi.[16]

Eosinophilic Gastritis.

As indicated by the name, this form of gastritis is characterized by tissue damage associated with dense infiltrates of eosinophils in the mucosa and muscularis, usually in the antral or pyloric region. The lesion is often present in other areas of the GI tract as well and is associated with peripheral eosinophilia and increased serum IgE levels. Allergic reactions are one cause of eosinophilic gastritis. In children, the allergens include cow's milk and soy protein, while drugs are common allergens in children and adults. Eosinophilic gastritis can also occur in association with systemic collagen-vascular disease, such as systemic sclerosis and polymyositis. Parasitic infections and *H. pylori* infection are other causes of eosinophilic gastritis.

Lymphocytic Gastritis.

This disease preferentially affects women and produces nonspecific symptoms such as abdominal pain, anorexia, nausea, and vomiting. It is idiopathic, but approximately 40% of cases are associated with celiac disease, suggesting an immune-mediated pathogenesis. Lymphocytic gastritis is also referred to as *varioliform gastritis* based on the distinctive endoscopic appearance (thickened folds covered by small nodules with central aphthous ulceration).[17] The entire stomach is affected in most cases, but disease is occasionally limited to the body. Histologically there is a marked increase in the number of intraepithelial T lymphocytes, mostly CD8+ cells, within surface and pit regions.

Granulomatous Gastritis.

This descriptive term is applied to any gastritis that contains granulomas, or aggregates of epithelioid histiocytes (tissue macrophages). It encompasses a diverse group of diseases with widely varying clinical and pathologic features. Correlation with clinical, endoscopic, radiologic, and serologic data is generally necessary for diagnosis. In Western populations, gastric involvement by Crohn disease is the most common specific cause of granulomatous gastritis.[18] Sarcoidosis is the second most common

cause, followed by a variety of infections including mycobacteria, fungi, CMV, and *H. pylori*. In addition to the presence of histologically evident granulomas, narrowing and rigidity of the gastric antrum may occur secondary to transmural granulomatous inflammation.

3.7.3.3 Complications of Chronic Gastritis

PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD) is most often associated with *H. pylori*–induced hyperchlorhydric chronic gastritis, which is present in 85% to 100% of individuals with duodenal ulcers and in 65% with gastric ulcers. The presence of chronic gastritis can help to distinguish peptic ulcers from acute erosive gastritis or stress ulcers, since the mucosa adjacent to the ulcer is generally normal in the latter two conditions. PUD may occur in any portion of the GI tract exposed to acidic gastric juices, but is most common in the gastric antrum and first portion of the duodenum. PUD may also occur in the esophagus as a result of GERD or acid secretion by ectopic gastric mucosa. Gastric mucosa within a Meckel diverticulum can result in peptic ulceration of adjacent mucosa.

Epidemiology.

PUD is common and ranks fourth in both annual physician visits and costs among all GI diseases.[19] In the United States, the lifetime risk of developing an ulcer is approximately 10% for males and 4% for females; the latter are typically affected during or after menopause. PUD affects more than 300 million people and is responsible for treatment and ongoing care of over 3 million people, 190,000 hospitalizations, and 5000 deaths in the United States each year.[19]

Pathogenesis.

The imbalances of mucosal defenses and damaging forces that cause chronic gastritis are also responsible for PUD. Thus, PUD generally develops on a background of chronic gastritis. The reasons why some people develop only chronic gastritis while others develop PUD are poorly understood.

H. pylori infection and NSAID use are the primary underlying causes of PUD, and both compromise mucosal defense while causing mucosal damage. Although more than 70% of individuals with PUD are infected by *H. pylori*, fewer than 20% of *H. pylori*–infected individuals develop peptic ulcer. It is probable that host factors as well as variation among *H. pylori* strains determine the clinical outcomes.

The gastric hyperacidity that drives PUD may be caused by *H. pylori* infection, parietal cell hyperplasia, excessive secretory responses, or impaired inhibition of stimulatory mechanisms such as gastrin release. For example, *Zollinger-Ellison syndrome*, in which there are multiple peptic ulcerations in the stomach, duodenum, and even jejunum, is caused by uncontrolled release of gastrin by a tumor and the resulting massive acid production. More common cofactors in peptic ulcerogenesis include chronic NSAID use, which causes direct chemical irritation while suppressing prostaglandin synthesis necessary for mucosal protection; cigarette smoking, which impairs mucosal blood flow and healing; and high-dose corticosteroids that suppress prostaglandin synthesis and impair healing. Duodenal ulcers are more frequent in individuals with alcoholic cirrhosis, chronic obstructive pulmonary disease, chronic renal failure, and hyperparathyroidism. In the latter two conditions, hypercalcemia stimulates gastrin production and therefore increases acid secretion. Finally, self-imposed or exogenous psychologic stress may increase gastric acid production.

Morphology. Peptic ulcers are four times more common in the proximal duodenum than in the stomach. Duodenal ulcers usually occur within a few centimeters of the pyloric valve and involve the anterior duodenal wall. Gastric peptic ulcers are predominantly located along the lesser curvature near

the interface of the body and antrum.

Peptic ulcers are solitary in more than 80% of patients. Lesions less than 0.3 cm in diameter tend to be shallow while those over 0.6 cm are likely to be deeper ulcers. The classic peptic ulcer is a round to oval, **sharply punched-out defect** (Fig. 17-14A). The mucosal margin may overhang the base slightly, particularly on the upstream side, but is usually level with the surrounding mucosa. In contrast, **heaped-up margins are more characteristic of cancers**. The depth of ulcers may be limited by the thick gastric muscularis propria or by adherent pancreas, omental fat, or the liver. Hemorrhage and fibrin deposition are often present on the gastric serosa. **Perforation** into the peritoneal cavity is a surgical emergency that may be identified by the presence of free air under the diaphragm on upright radiographs of the abdomen.

The base of peptic ulcers is smooth and clean as a result of peptic digestion of exudate, and blood vessels may be evident. In active ulcers the base may have a thin layer of fibrinoid debris underlaid by a predominantly neutrophilic inflammatory infiltrate. Beneath this, active granulation tissue infiltrated with mononuclear leukocytes and a fibrous or collagenous scar forms the ulcer base (Fig. 17-14B). Vessel walls within the scarred area are typically thickened and are occasionally thrombosed. Ongoing bleeding within the ulcer base may cause life-threatening hemorrhage. Scarring may involve the entire thickness of the wall and pucker the surrounding mucosa into folds that radiate outward.

Size and location do not differentiate benign and malignant ulcers. However, the gross appearance of chronic peptic ulcers is virtually diagnostic. **Malignant transformation of peptic ulcers is very rare**, and reports of transformation probably represent cases wherein a lesion thought to be benign was actually an ulcerated carcinoma from the start.

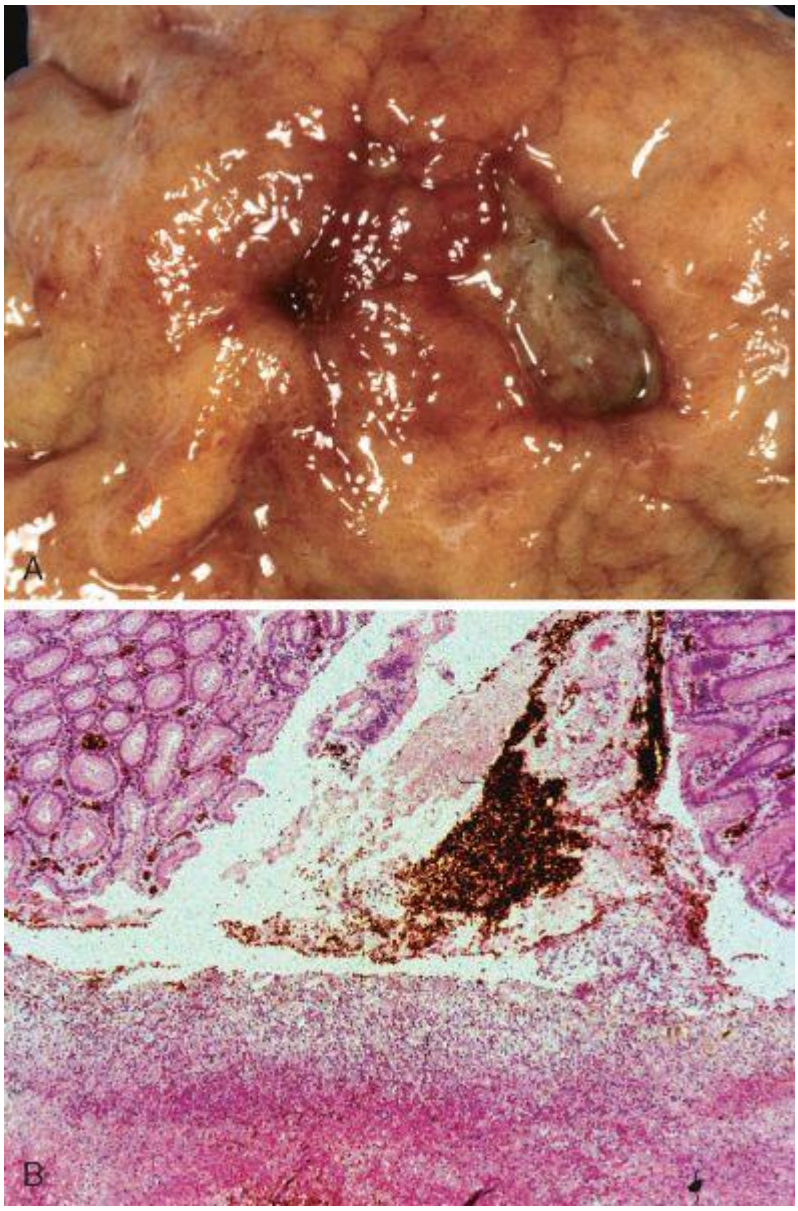

FIGURE 17-14 Acute gastric perforation in a patient presenting with free air under the diaphragm. **A**, Mucosal defect with clean edges. **B**, The necrotic ulcer base is composed of granulation tissue.

Clinical Features.

Peptic ulcers are notoriously chronic, recurring lesions with much greater morbidity than mortality. They may present in young adults but are most often diagnosed in middle-aged to older adults without obvious precipitating conditions. After a period of weeks to months of active disease, healing may occur with or without therapy, but the tendency to develop peptic ulcers remains. The majority of peptic ulcers come to clinical attention because of *epigastric burning or aching pain*, although a significant fraction present with complications such as *iron deficiency anemia*, *frank hemorrhage*, or *perforation*. The pain tends to occur 1 to 3 hours after meals during the day, is worse at night, and is relieved by alkali or food. Nausea, vomiting, bloating, belching, and significant weight loss are additional manifestations. With

penetrating ulcers the pain is occasionally referred to the back, the left upper quadrant, or the chest, where it may be misinterpreted as cardiac in origin.

Current therapies for PUD are aimed at *H. pylori* eradication and neutralization of gastric acid, primarily with proton pump inhibitors or H_2 histamine receptor antagonists.[20] A variety of surgical approaches were formerly used, including antrectomy to remove gastrin-producing cells and vagotomy to remove the acid-stimulatory effects mediated by the vagus nerve. Proton pump inhibitors and *H. pylori* eradication have markedly reduced the need for surgical intervention, which is primarily reserved for treatment of bleeding or perforated peptic ulcers.

MUCOSAL ATROPHY AND INTESTINAL METAPLASIA

Long-standing chronic gastritis that involves the body and fundus may ultimately lead to significant loss of parietal cell mass. This oxyntic atrophy may be associated with intestinal metaplasia, recognized by the presence of goblet cells, and is *strongly associated with increased risk of gastric adenocarcinoma*. The risk of adenocarcinoma is greatest in autoimmune gastritis. This may be because achlorhydria of gastric mucosal atrophy permits overgrowth of bacteria that produce carcinogenic nitrosamines. Intestinal metaplasia also occurs in chronic *H. pylori* gastritis and may regress after clearance of the organism.

DYSPLASIA

Chronic gastritis exposes the epithelium to inflammation-related free radical damage and proliferative stimuli. Over time this combination of stressors can lead to the accumulation of genetic alterations that result in carcinoma. Pre-invasive in situ lesions can be recognized histologically as *dysplasia*. The morphologic hallmarks of dysplasia are variations in epithelial size, shape, and orientation along with coarse chromatin texture, hyperchromasia, and nuclear enlargement. The distinction between dysplasia and *regenerative epithelial changes* induced by active inflammation can be a challenge for the pathologist, since increased epithelial proliferation and mitotic figures may be prominent in both. However, reactive epithelial cells mature as they reach the mucosal surface, while dysplastic lesions remain cytologically immature.

GASTRITIS CYSTICA

Gastritis cystica refers to an exuberant reactive epithelial proliferation associated with entrapment of epithelial-lined cysts. These may be found within the submucosa (gastritis cystica polyposa) or deeper layers of the gastric wall (gastritis cystica profunda). Because of the association with chronic gastritis and partial gastrectomy, it is presumed that gastritis cystica is trauma-induced, but the reasons for the development of epithelial cysts within deeper portions of the gastric wall are not clear. Regenerative epithelial changes can be prominent in the entrapped epithelium, and gastritis cystica can therefore mimic invasive adenocarcinoma.

3.7.3.4 Hypertrophic Gastropathies

Hypertrophic gastropathies are uncommon diseases characterized by giant cerebriform enlargement of the rugal folds due to epithelial hyperplasia without inflammation. As might be expected, the hypertrophic gastropathies are linked to excessive growth factor release. The two most well-understood examples are Ménétrier disease and Zollinger-Ellison syndrome, the morphologic features of which are compared with other gastric proliferations in Table 17-4 .

TABLE 17-4 -- Hypertrophic Gastropathies and Gastric Polyps

Parameter	Ménétrier Disease (adult)	Zollinger-Ellison Syndrome	Inflammatory and Hyperplastic Polyps	Gastritis Cystica	Fundic Gland Polyps	Gastric Adenomas
Mean patient age (yr)	30–60	50	50–60	Variable	50	50–60
Location	Body and fundus	Fundus	Antrum > body	Body	Body and fundus	Antrum > body
Predominant cell type	Mucous	Parietal > mucous, endocrine	Mucous	Mucous, cyst-lining	Parietal and chief	Dysplastic, intestinal
Inflammatory infiltrate	Limited, lymphocytes	Neutrophils	Neutrophils and lymphocytes	Neutrophils and lymphocytes	None	Variable
Symptoms	Hypoproteinemia, weight loss, diarrhea	Peptic ulcers	Chronic gastritis	Chronic gastritis	None, nausea	Chronic gastritis
Risk factors	None	Multiple endocrine neoplasia	Chronic gastritis, *H. pylori*	Trauma, prior surgery	PPIs, FAP	Chronic gastritis, atrophy, intestinal metaplasia
Association with adenocarcinoma	Yes	No	Occasional	No	No	Frequent

FAP, familial aderomatous polyposis; PPIs, proton pump inhibitors.

MÉNÉTRIER DISEASE

Ménétrier disease is a rare disorder caused by *excessive secretion of transforming growth factor* α (TGF-α)[21] The disease is characterized by diffuse hyperplasia of the foveolar epithelium of the body and fundus and hypoproteinemia due to protein-losing enteropathy. Secondary symptoms, such as weight loss, diarrhea, and peripheral edema, are commonly present. Symptoms and pathologic features of Ménétrier disease in children are similar to those in adults, but pediatric disease is usually self-limited and often follows respiratory infection. Risk of gastric adenocarcinoma is increased in adults with Ménétrier disease.

Morphology. Ménétrier disease is characterized by irregular enlargement of the gastric rugae. Some areas may appear polypoid. Enlarged rugae are present in the body and fundus (Fig. 17-15A), but the antrum is generally spared. Histologically, the most characteristic feature is **hyperplasia of foveolar mucous cells**. The glands are elongated with a corkscrew-like appearance and cystic dilation is common (Fig. 17-15B). Inflammation is usually only modest, although some cases show marked intraepithelial lymphocytosis. Diffuse or patchy glandular atrophy, evident as hypoplasia of parietal and chief cells, is typical.

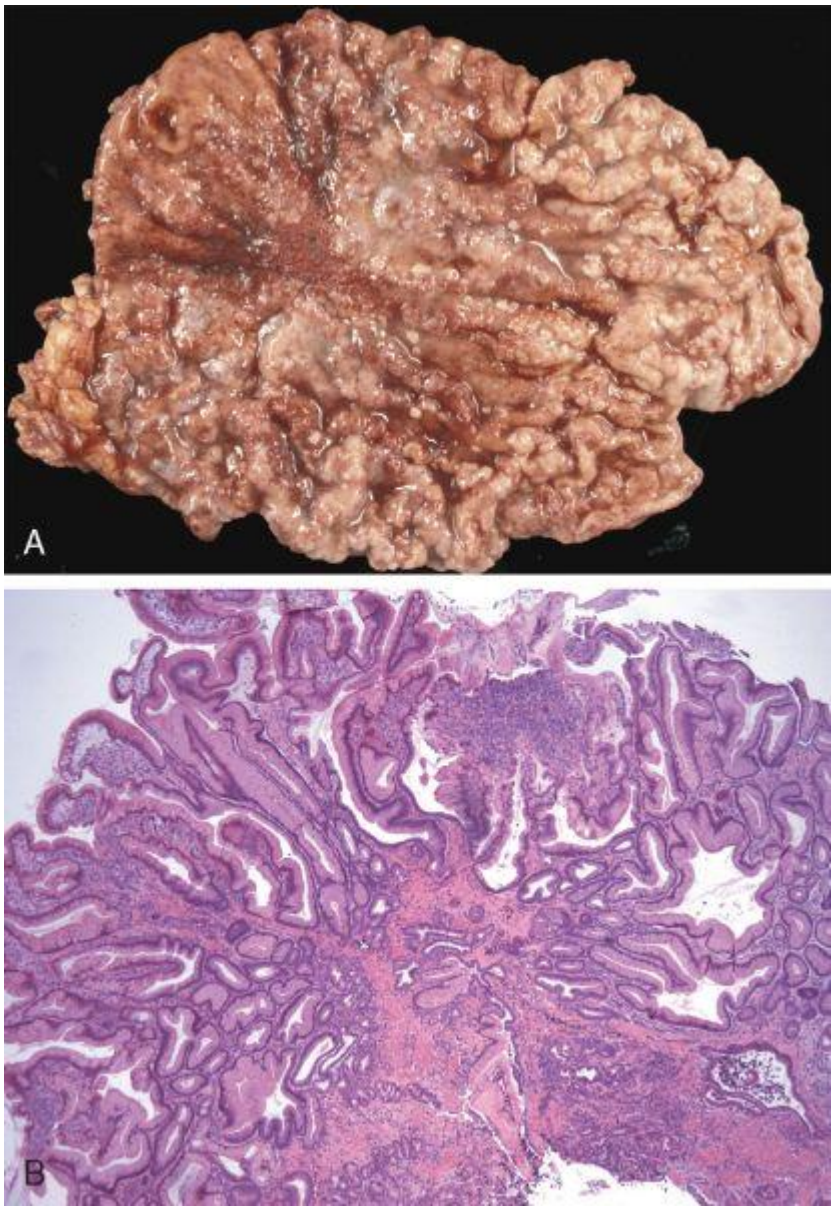

FIGURE 17-15 Ménétrier disease. **A**, Marked enlargement of rugal folds. **B**, Foveolar hyperplasia with elongated and focally dilated glands. *(Courtesy of Dr. M. Kay Washington, Vanderbilt University, Nashville, TN.)*

Treatment of Ménétrier disease is supportive, with intravenous albumin and parenteral nutritional supplementation. In severe cases gastrectomy may be performed. More recently, agents that block TGF-α–mediated activation of the epidermal growth factor receptor have shown promise.[22]

ZOLLINGER-ELLISON SYNDROME

Zollinger-Ellison syndrome is caused by gastrin-secreting tumors, gastrinomas, that are most commonly found in the small intestine or pancreas. Patients often present with duodenal ulcers or chronic diarrhea. Within the stomach, the most remarkable feature is a doubling of oxyntic mucosal thickness due to a fivefold *increase in the number of parietal cells*. Gastrin also induces hyperplasia of

mucous neck cells, mucin hyperproduction, and proliferation of endocrine cells within oxyntic mucosa. In some cases these endocrine cells can form small dysplastic nodules or, rarely, true carcinoid tumors.

Treatment of individuals with Zollinger-Ellison syndrome includes blockade of acid hypersecretion, which is accomplished in almost all patients with proton pump inhibitors or high-dose H_2 histamine receptor antagonists. Acid suppression allows peptic ulcers to heal and prevents gastric perforation, allowing treatment to focus on the gastrinoma, which becomes the main determinant of long-term survival.

Although they grow slowly, 60% to 90% of gastrinomas are malignant. Tumors are sporadic in 75% of patients. These tend to be solitary tumors and can be surgically resected. The remaining 25% of patients with gastrinomas have multiple endocrine neoplasia type I. These individuals often have multiple tumors or metastatic disease and may benefit from treatment with somatostatin analogues.[23] Clinical identification of tumors may be enhanced by somatostatin receptor scintigraphy and endoscopic ultrasonography.

3.7.3.5 Gastric Polyps & Tumors

Polyps, nodules or masses that project above the level of the surrounding mucosa, are identified in up to 5% of upper GI endoscopies. Polyps may develop as a result of epithelial or stromal cell hyperplasia, inflammation, ectopia, or neoplasia. Only the most common types of polyps will be discussed here (Peutz-Jeghers and juvenile polyps are discussed with intestinal polyps). This is followed by a presentation of gastric tumors, including *adenocarcinomas, lymphomas, carcinoid tumors, and stromal tumors*.

INFLAMMATORY AND HYPERPLASTIC POLYPS

Approximately 75% of all gastric polyps are *inflammatory* or *hyperplastic polyps*. They are most common in individuals between 50 and 60 years of age. These polyps usually develop in association with chronic gastritis, which initiates the injury and reactive hyperplasia that leads to polyp growth. Inflammatory or hyperplastic polyps are most common in individuals between 50 and 60 years of age. Among individuals with *H. pylori* gastritis, polyps may regress after bacterial eradication. Because the risk of dysplasia correlates with size, polyps larger than 1.5 cm should be resected and examined histologically.

Morphology. The majority of inflammatory or hyperplastic polyps are smaller than 1 cm in diameter and are frequently multiple, particularly in individuals with atrophic gastritis. These polyps are ovoid in shape and have a smooth surface, though superficial erosions are common. Microscopically, polyps have irregular, cystically dilated, and elongated foveolar glands (Fig. 17-16A). The lamina propria is typically edematous with variable degrees of acute and chronic inflammation, and surface ulceration may be present (Fig. 17-16B).

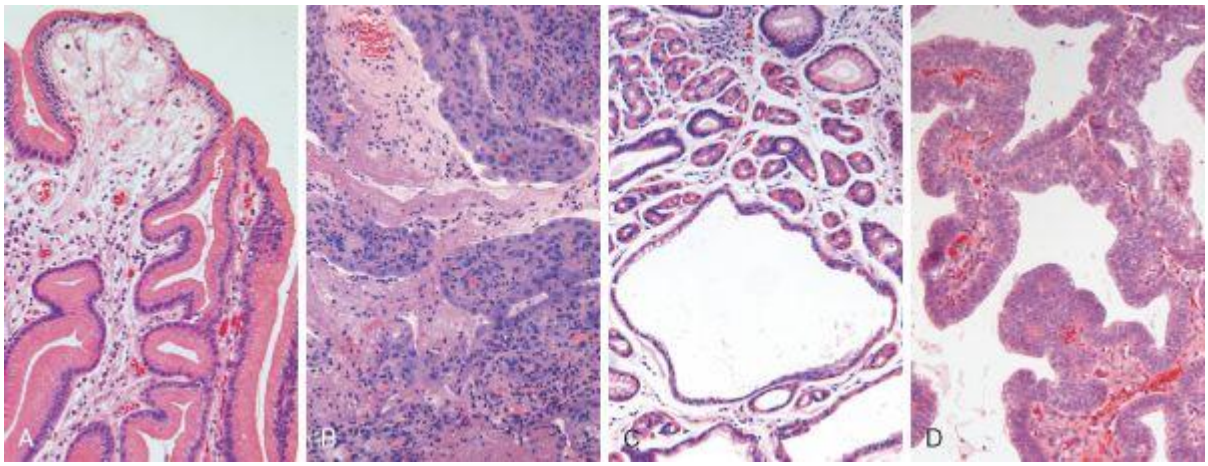

FIGURE 17-16 Gastric polyps. **A**, Hyperplastic polyp containing corkscrew-shaped foveolar glands. **B**, Hyperplastic polyp with ulceration. **C**, Fundic gland polyp composed of cystically dilated glands lined by parietal, chief, and foveolar cells. **D**, Gastric adenoma recognized by the presence of epithelial dysplasia.

FUNDIC GLAND POLYPS

Fundic gland polyps occur sporadically and in individuals with familial adenomatous polyposis (FAP). The prevalence of fundic gland polyps has increased markedly in recent years as a result of proton pump inhibitor therapy. This likely reflects increased gastrin secretion, in response to reduced gastric acidity, and the resulting glandular hyperplasia. These polyps are five times more common in women and are discovered at an average age of 50 years. Fundic gland polyps may be asymptomatic or associated with nausea, vomiting, or epigastric pain.

Morphology. Fundic gland polyps occur in the gastric body and fundus and are well-circumscribed lesions with a smooth surface. They may be single or multiple and are composed of cystically dilated, irregular glands lined by flattened parietal and chief cells. Inflammation is typically absent or minimal (Fig. 17-16C).

GASTRIC ADENOMA

Gastric adenomas represent as many as 10% of all gastric polyps (Table 17-4). Their incidence increases progressively with age,[24] and there is a marked variation in rate among different populations that parallels the incidence of gastric adenocarcinoma. Patients are usually between 50 and 60 years of age, and males are affected three times more often than females. Like fundic gland polyps, the incidence of adenomas is increased in individuals with FAP. *Similar to other forms of gastric dysplasia, adenomas almost always occur on a background of chronic gastritis with atrophy and intestinal metaplasia*. The risk of adenocarcinoma in gastric adenomas is related to the size of the lesion and is particularly elevated in lesions greater than 2 cm in diameter. Overall, carcinoma may be present in up to 30% of gastric adenomas.[24]

Morphology. Gastric adenomas are usually solitary lesions less than 2 cm in diameter, most commonly located in the antrum. The majority of adenomas are composed of intestinal-type columnar

epithelium. By definition, all GI adenomas have epithelial dysplasia (Fig. 17-16D) that can be classified as low or high grade. Both grades may include enlargement, elongation, and hyperchromasia of epithelial cell nuclei, epithelial crowding, and pseudostratification. High-grade dysplasia is characterized by more severe cytologic atypia and irregular architecture, including glandular budding and gland-within-gland, or cribriform, structures.[25]

GASTRIC ADENOCARCINOMA

Adenocarcinoma is the most common malignancy of the stomach, comprising over 90% of all gastric cancers. Early symptoms resemble those of chronic gastritis, including dyspepsia, dysphagia, and nausea. As a result, these tumors are often discovered at advanced stages, when symptoms such as weight loss, anorexia, altered bowel habits, anemia, and hemorrhage trigger further diagnostic evaluation.

Epidemiology.

Gastric cancer incidence varies markedly with geography. In Japan, Chile, Costa Rica, and Eastern Europe the incidence is up to 20-fold higher than in North America, northern Europe, Africa, and Southeast Asia. Mass endoscopic screening programs can be successful in regions where the incidence is high, such as Japan, where 35% of newly detected cases are *early gastric cancer*, tumors limited to the mucosa and submucosa. Unfortunately, mass screening programs are not cost-effective in regions where the incidence is low, and fewer than 20% of cases are detected at an early stage in North America and northern Europe.

In the United States, *gastric cancer rates dropped by over 85% during the twentieth century*.[26] Adenocarcinoma of the stomach was the most common cause of cancer death in the United States in 1930 and remains a leading cause of cancer death worldwide, but now accounts for fewer than 2.5% of cancer deaths in the United States. Similar declines have been reported in many other Western countries, suggesting that environmental and dietary factors are responsible.[26] Consistent with this conclusion, studies of migrants from high-risk to low-risk regions have shown that gastric cancer rates in second-generation immigrants are similar to those in their new country of residence.

The cause of the overall reduction in gastric cancer is unknown. One possible explanation is the decreased consumption of dietary carcinogens, such as N-nitroso compounds and benzo[*a*]pyrene, because of reduced use of salt and smoking for food preservation and the widespread availability of food refrigeration. Conversely, intake of green, leafy vegetables and citrus fruits, which contain antioxidants such as vitamin C, vitamin E, and beta-carotene, and is correlated with reduced risk of gastric cancers, may have increased as a result of improved food transportation networks.

Gastric cancer is more common in lower socioeconomic groups and in individuals with *multifocal mucosal atrophy and intestinal metaplasia*. PUD does not impart an increased risk of gastric cancer, but patients who have had *partial gastrectomies* for PUD have a slightly higher risk of developing cancer in the residual gastric stump as a result of hypochlorhydria, bile reflux, and chronic gastritis.

Although overall incidence of gastric adenocarcinoma is falling, *cancer of the gastric cardia is on the rise*. This is probably related to Barrett esophagus and may reflect the increasing incidence of chronic GERD and obesity.[10] Consistent with this presumed common pathogenesis, distal esophageal adenocarcinomas and gastric cardia adenocarcinomas are similar in morphology, clinical behavior, and therapeutic response.[27] [28] [29]

Pathogenesis.

While the majority of gastric cancers are not hereditary, the mutations identified in familial gastric cancer have provided important insights into mechanisms of carcinogenesis in sporadic cases. Germline mutations in *CDH1*, which encodes E-cadherin, a protein that contributes to epithelial intercellular adhesion, are associated with familial gastric cancers, which are usually of the diffuse type. Mutations in *CDH1* are present in about 50% of sporadic cases of diffuse gastric tumors, while E-cadherin expression is drastically decreased in the rest, often by methylation of the *CDH1* promoter. *Thus, the loss of E-cadherin function seems to be a key step in the development of diffuse gastric cancer*. Notably, *CDH1* mutations are also common in sporadic and familial lobular carcinoma of the breast, which also tends to infiltrate as single cells, and individuals with *BRCA2* mutations are at increased risk of developing diffuse gastric cancer.

In contrast to diffuse gastric tumors, there is an increased risk of intestinal-type gastric cancer in individuals with FAP, particularly in Japan. This implies an interaction between host genetic background and environmental factors, since gastric cancer risk is less markedly elevated in individuals with FAP residing in areas of low gastric cancer incidence. Mutations in β-catenin, a protein that binds to both E-cadherin and adenomatous polyposis coli (APC), as well as microsatellite instability and hypermethylation of several genes including *TGFβRII, BAX, IGFRII,* and *p16/INK4a* have also been described in sporadic intestinal-type gastric cancer.

Genetic variants of pro-inflammatory and immune response genes, including those that encode IL-1β, TNF, IL-10, IL-8, and Toll-like receptor 4 (TLR4), are associated with elevated risk of gastric cancer when accompanied by *H. pylori* infection, and *p53* mutations are present in the majority of sporadic gastric cancers of both histologic types. Thus, although specific sequences of events have not been defined, it is clear that chronic inflammation promotes neoplastic progression. Other associations between chronic inflammation and cancer were discussed in Chapter 7 .

Morphology. Gastric adenocarcinomas are classified according to their location in the stomach, and most importantly, according to gross and histologic morphology. Most gastric adenocarcinomas involve the gastric antrum; the lesser curvature is involved more often than the greater curvature.[28] Gastric tumors with an **intestinal** morphology tend to form bulky tumors (Fig. 17-17A) composed of glandular structures (Fig. 17-18A), while cancers with a **diffuse** infiltrative growth pattern (see Fig. 17-17B) are more often composed of signet-ring cells (see Fig. 17-18B). Although intestinal-type adenocarcinomas may penetrate the gastric wall, they typically grow along broad cohesive fronts to form either an exophytic mass or an ulcerated tumor. The neoplastic cells often contain apical mucin vacuoles, and abundant mucin may be present in gland lumens. In contrast, diffuse gastric cancer is generally composed of discohesive cells that do not form glands but instead have large mucin vacuoles that expand the cytoplasm and push the nucleus to the periphery, creating a **signet-ring cell** morphology. These cells permeate the mucosa and stomach wall individually or in small clusters, which makes tumor cells easy to confuse with inflammatory cells, such as macrophages, at low magnification. Extracellular mucin release in either type of gastric cancer can result in formation of large **mucin lakes** that dissect tissue planes.

A mass may be difficult to appreciate in diffuse gastric cancer, but these infiltrative tumors often evoke a **desmoplastic** reaction that stiffens the gastric wall and may provide a valuable diagnostic clue. When there are large areas of infitration, diffuse rugal flattening and a rigid, thickened wall may impart a **leather bottle** appearance termed **linitis plastica** (see Fig. 17-17B). Breast and lung cancers that metastasize to the stomach may also create a linitis plastica–like appearance.

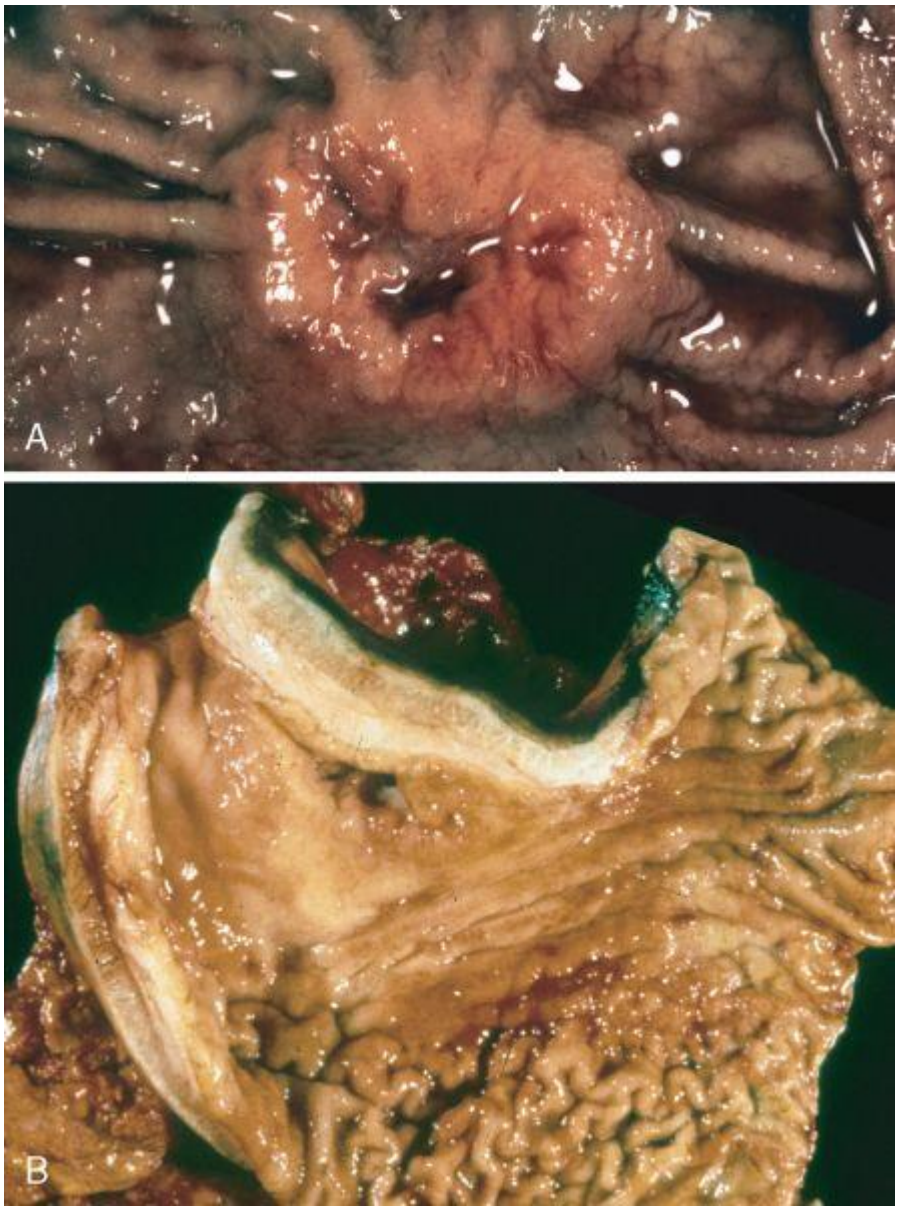

FIGURE 17-17 Gastric adenocarcinoma. **A**, Intestinal-type adenocarcinoma consisting of an elevated mass with heaped-up borders and central ulceration. Compare to the peptic ulcer in Figure 17-14A . **B**, Linitis plastica. The gastric wall is markedly thickened, and rugal folds are partially lost.

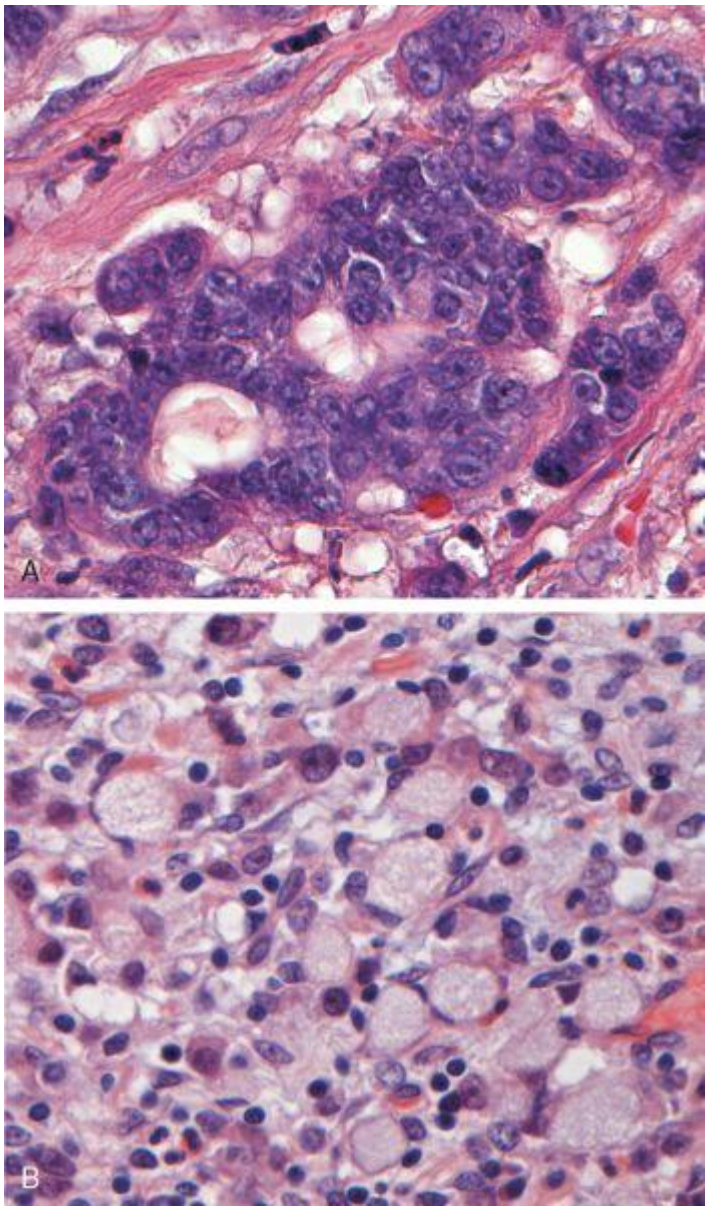

FIGURE 17-18 Gastric adenocarcinoma. **A**, Intestinal-type adenocarcinoma composed of columnar, gland-forming cells infiltrating through desmoplastic stroma. **B**, Signet-ring cells can be recognized by their large cytoplasmic mucin vacuoles and peripherally displaced, crescent-shaped nuclei.

Clinical Features.

Intestinal-type gastric cancer predominates in high-risk areas and develops from precursor lesions including flat dysplasia and adenomas. The mean age of presentation is 55 years, and the male-to-female ratio is 2 : 1. In contrast, the incidence of diffuse gastric cancer is relatively uniform across countries, there are no identified precursor lesions, and the disease occurs at similar frequencies in males and females. Notably, *the remarkable decrease in gastric cancer incidence applies only to the intestinal type*, which is most closely associated with atrophic gastritis and intestinal metaplasia. As a result, the incidences of intestinal and diffuse types of gastric cancers are now similar.

The depth of invasion and the extent of nodal and distant metastasis at the time of diagnosis remain the most powerful prognostic indicators for gastric cancer.[30] In advanced cases gastric carcinoma may first be detected as metastases to the supraclavicular sentinel lymph node, also called *Virchow's node*. Gastric tumors can also metastasize to the periumbilical region to form a subcutaneous nodule, termed a *Sister Mary Joseph nodule*, after the nurse who first noted this lesion as a marker of metastatic carcinoma. Local invasion into the duodenum, pancreas, and retroperitoneum is also characteristic. In such cases efforts are usually focused on chemotherapy or radiation therapy and palliative care. However, when possible, surgical resection remains the preferred treatment for gastric adenocarcinoma. After surgical resection, the 5-year survival rate of early gastric cancer can exceed 90%, even if lymph node metastases are present. In contrast, the 5-year survival rate for advanced gastric cancer remains below 20%.[28] Because of the advanced stage at which most gastric cancers are discovered in the United States, the overall 5-year survival is less than 30%.[28,][31]

LYMPHOMA

Although extra-nodal lymphomas can arise in virtually any tissue, they do so most commonly in the GI tract, particularly the stomach. In allogeneic bone marrow transplant and organ transplant recipients, the bowel is also the most frequent site for Epstein-Barr virus–positive B-cell lymphoproliferations,[32] because the deficits in T-cell function caused by oral immunosuppressive agents (e.g., cyclosporine) are greatest at intestinal sites of drug absorption. Nearly 5% of all gastric malignancies are primary lymphomas, the most common of which are indolent extra-nodal marginal zone B-cell lymphomas. In the gut these tumors are often referred to as lymphomas of *mucosa-associated lymphoid tissue (MALT)*, or *MALTomas*.[33] This entity and the second most common primary lymphoma of the gut, diffuse large B-cell lymphoma, are also discussed in Chapter 13 .

Pathogenesis.

Extra-nodal marginal zone B-cell lymphomas usually arise at sites of chronic inflammation. They can originate in the GI tract at sites of preexisting MALT, such as the Peyer's patches of the small intestine, but more commonly arise within tissues that are normally devoid of organized lymphoid tissue. The most common cause of “pro-lymphomatous” inflammation in the stomach is chronic *H. pylori* infection, which is found in association with most cases of gastric MALToma.[34] As with other low-grade lymphomas, MALTomas can transform into more aggressive tumors that are histologically identical to diffuse large B-cell lymphomas.

The most striking evidence linking *H. pylori* gastritis to MALToma is that eradication of the infection with antibiotics induces durable remissions with low rates of recurrence in most patients.[35] Histologic features that predict antibiotic treatment failures include transformation to large-cell lymphoma, tumor invasion to the muscularis propria or beyond, and lymph node involvement.

Three translocations are associated with gastric MALToma, the t(11;18)(q21;q21) and the less common t(1;14)(p22;q32) and t(14;18)(q32;q21). They are also highly predictive of response failure.[36,][37] The t(11;18)(q21;q21) translocation brings together the apoptosis inhibitor 2 *(API2)* gene on chromosome 11 with the “mutated in MALT lymphoma,” or *MLT*, gene on chromosome 18. This creates a chimeric *API2-MLT* fusion gene that encodes an API2-MLT fusion protein. The t(14;18)(q32;q21) and t(1;14)(p22;q32) translocations cause increased expression of intact MLT and BCL-10 proteins, respectively.

Although some details remain uncertain, each of the three translocations has the same net effect, the constitutive activation of NF-κB, a transcription factor that promotes B-cell growth and survival. Remarkably, antigen-dependent activation of NF-κB in normal B and T cells requires both BCL-10 and MLT, which work together in a pathway down-stream of the B- and T-cell antigen receptors. In

MALTomas that lack these translocations, *H. pylori*–induced inflammation may trigger NF-κB activation through the MLT/BCL-10 pathway. In these tumors elimination of the immune stimulus *(H. pylori)* down-regulates NF-κB, resulting in tumor regression. In contrast, NF-κB is constitutively active in tumors bearing translocations involving *MLT* or *BCL10*, and as a result the elimination of *H. pylori* has no effect. Additional genetic changes, such as inactivation of the tumor suppressor genes that encode p53 and p16, may lead to transformation of gastric MALToma into aggressive diffuse large B-cell lymphoma.[38]

Morphology. Histologically, gastric MALToma takes the form of a dense lymphocytic infiltrate in the lamina propria (Fig. 17-19A). Characteristically, the neoplastic lymphocytes infiltrate the gastric glands focally to create diagnostic **lymphoepithelial lesions** (Fig. 17-19A , inset). Reactive-appearing B-cell follicles may be present, and, in about 40% of tumors, plasmacytic differentiation is observed. Occasionally the tumor cells accumulate large amounts of pale cytoplasm, a feature referred to as **"monocytoid"** change.

Like other tumors of mature B cells, MALTomas express the B-cell markers CD19 and CD20. They do not express CD5 and CD10, and are positive for CD43 in about 25% of cases, an unusual feature that can be diagnostically helpful. In cases lacking lymphoepithelial lesions, monoclonality may be demonstrated by restricted expression of either κ or γ immunoglobulin light chain or by molecular detection of clonal IgH rearrangements. Molecular cytogenetic analysis (e.g., fluorescent in situ hybridization) is being used increasingly to identify tumors with translocations that predict resistance to therapy.

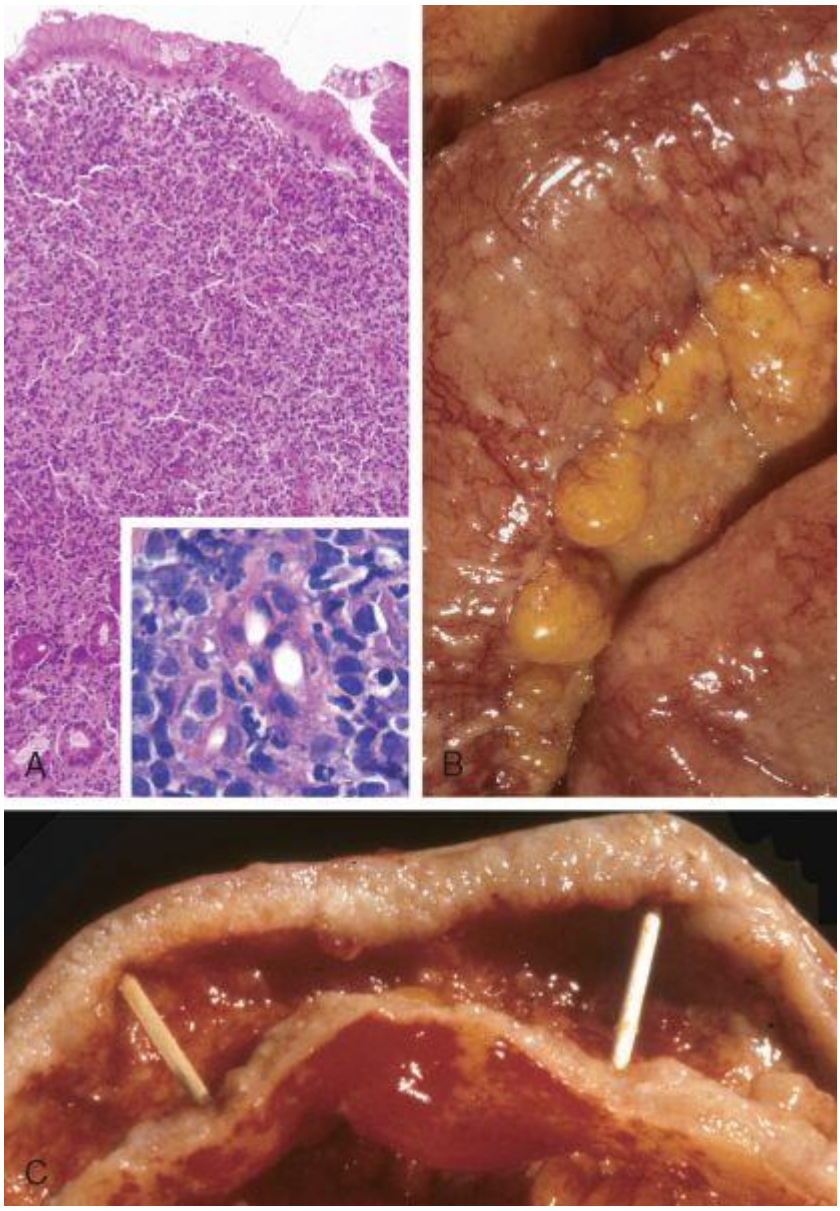

FIGURE 17-19 GI lymphoma. **A**, Gastric MALT lymphoma replacing much of the gastric epithelium. Inset shows lymphoepithelial lesions with neoplastic lymphocytes surrounding and infiltrating gastric glands. **B**, Disseminated lymphoma within the small intestine with numerous small serosal nodules. **C**, Large B-cell lymphoma infiltrating the small intestinal wall and producing diffuse thickening.

Clinical Features.

The most common presenting symptoms are dyspepsia and epigastric pain. Hematemesis, melena, and constitutional symptoms such as weight loss can also be present. Because gastric MALTomas and *H. pylori* gastritis often coexist and have overlapping clinical symptoms and endoscopic appearances, diagnostic difficulties sometimes arise, particularly in small biopsy specimens. GI lymphomas may also disseminate as discrete small nodules (Fig. 17-19B) or infiltrate the wall diffusely (Fig. 17-19C).

CARCINOID TUMOR

Carcinoid tumors arise from the diffuse components of the endocrine system. The majority are found in the GI tract, and more than 40% occur in the small intestine (Table 17-5).[39] The tracheobronchial tree and lungs are the next most commonly sites involved. Gastric carcinoids may be associated with endocrine cell hyperplasia, chronic atrophic gastritis, and Zollinger-Ellison syndrome. The term *carcinoid*, or "carcinoma-like," was applied because these tumors tend to have a more indolent clinical course than GI carcinomas. Carcinoid tumors are best considered to be *well-differentiated neuroendocrine carcinomas*. Carcinoids within the GI tract arise from the endocrine cells that release peptide and nonpeptide hormones to coordinate gut function.

TABLE 17-5 -- Features of Gastrointestinal Carcinoid Tumors

Feature	Esophagus	Stomach	Proximal Duodenum	Jejunum and Ileum	Appendix	Colorectum
Fraction of GI carcinoids	<1%	<10%	<10%	>40%	<25%	>25%
Mean patient age (yr)	Rare	55	50	65	All ages	60
Location	Distal	Body and fundus	Proximal third, peri-ampullary	Throughout	Tip	Rectum > cecum
Size	Limited data	1–2 cm, multiple; >2 cm, solitary	0.5–2 cm	<3.5 cm	0.2–1 cm	>5 cm (cecum); <1 cm (rectum)
Secretory product(s)	Limited data	Histamine, somatostatin, serotonin	Gastrin, somatostatin, cholecystokinin	Serotonin, substance P, polypeptide YY	Serotonin, polypeptide YY	Serotonin, polypeptide YY
Symptoms	Dysphagia, weight loss, reflux	Gastritis, ulcer, incidental	Peptic ulcer, biliary obstruction, abdominal pain	Asymptomatic, obstruction, metastatic disease	Asymptomatic, incidental	Abdominal pain, weight loss, incidental
Behavior	Limited data	Variable	Variable	Aggressive	Benign	Variable
Disease associations	None	Atrophic gastritis, MEN-I	Zollinger-Ellison syndrome, NF-1, sporadic	None	None	None

MEN-I, multiple endocrine neoplasia type I; NF-1, neurofibromatosis type I.

Morphology. Grossly, carcinoids are intramural or submucosal masses that create small polypoid lesions (Fig. 17-20A). The overlying mucosa may be intact or ulcerated, and the tumors may invade deeply to involve the mesentery. Carcinoids tend to be yellow or tan in color and are very firm as a consequence of an intense desmoplastic reaction, which may cause kinking of the bowel and obstruction. Histologically, carcinoid tumors are composed of islands, trabeculae, strands, glands, or sheets of uniform cells with scant, pink granular cytoplasm and a round to oval stippled nucleus (Fig. 17-20). In most tumors there is minimal pleomorphism, but anaplasia, mitotic activity, and necrosis may be present in rare cases. Immunohistochemical stains are typically positive for endocrine granule markers, such as synaptophysin and chromogranin A.

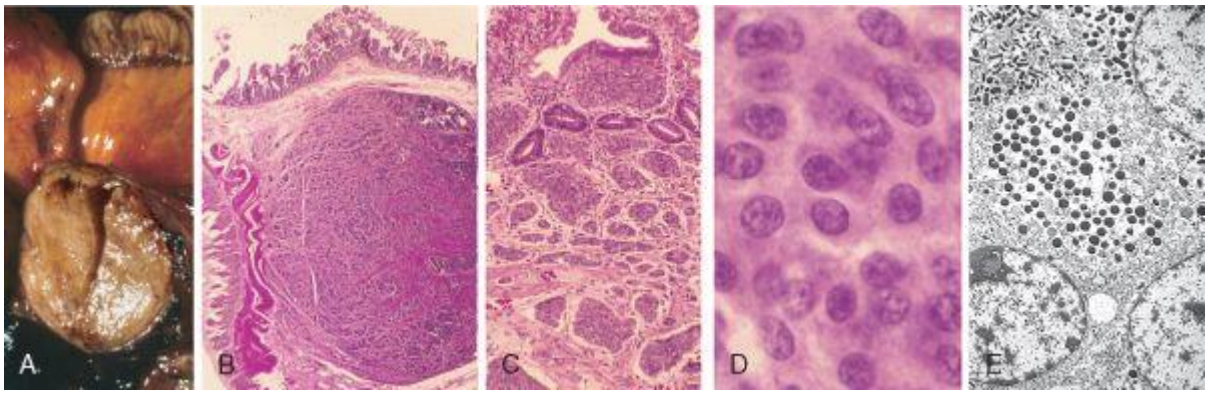

FIGURE 17-20 GI carcinoid tumor (neuroendocrine carcinoma). **A**, Gross cross-section of a submucosal tumor nodule. **B**, Microscopically the nodule is composed of tumor cells embedded in dense fibrous tissue. **C**, In other areas, the tumor has spread extensively within mucosal lymphatic channels. **D**, High magnification shows the bland cytology of carcinoid tumors. The chromatin texture, with fine and coarse clumps, is frequently described as a "salt and pepper" pattern. Despite their innocuous appearance, carcinoids can be extremely aggressive clinically. **E**, Electron microscopy reveals cytoplasmic dense core neurosecretory granules.

Clinical Features.

The peak incidence of carcinoid tumors is in the sixth decade, but they may appear at any age. Symptoms are determined by the hormones produced. For example, tumors that produce gastrin may cause Zollinger-Ellison syndrome, while ileal tumors may cause carcinoid syndrome, which is characterized by cutaneous flushing, sweating, bronchospasm, colicky abdominal pain, diarrhea, and right-sided cardiac valvular fibrosis. *Carcinoid syndrome* occurs in fewer than 10% of patients and is caused by vasoactive substances secreted by the tumor into the systemic circulation. When tumors are confined to the intestine, the vasoactive substances released are metabolized to inactive forms by the liver, a "first-pass" effect similar to that exerted on oral drugs. Carcinoid syndrome generally requires tumors to secrete hormones into a non-portal venous circulation and therefore is *strongly associated with metastatic disease*.

The most important prognostic factor for GI carcinoid tumors is location.

- *Foregut carcinoid tumors*, those found within the stomach, duodenum proximal to the ligament of Treitz, and esophagus, rarely metastasize and are generally cured by resection. This is particularly true for gastric carcinoid tumors that arise in association with atrophic gastritis, while gastric carcinoid tumors without predisposing factors are more aggressive.
- *Midgut carcinoid tumors* that arise in the jejunum and ileum are often multiple and tend to be aggressive. In these tumors, greater depth of local invasion, increased size, and presence of necrosis and mitosis are associated with poor outcome.
- *Hindgut carcinoids* arising in the appendix and colorectum are typically discovered incidentally. Those in the appendix occur at any age and are generally located at the tip. These tumors are rarely more than 2 cm in diameter and are almost uniformly benign. Rectal carcinoid tumors tend to produce polypeptide hormones and, when symptomatic, present with abdominal pain and weight loss. Metastasis of rectal carcinoid tumors is uncommon. In contrast, tumors of the proximal colon are uncommon but may grow to large size and metastasize.

GASTROINTESTINAL STROMAL TUMOR

A wide variety of mesenchymal neoplasms may arise in the stomach. Many are named according to the cell type they most resemble; for example, smooth muscle tumors are called *leiomyomas* or

leiomyosarcomas, nerve sheath tumors are termed *schwannomas*, and those resembling glomus bodies in the nailbeds and at other sites are termed *glomus tumors*. These are all rare and are discussed in greater detail in Chapter 26 . *GI stromal tumor (GIST)* is the most common mesenchymal tumor of the abdomen, and more than half of these tumors occur in the stomach. As will be discussed below, the term *stromal* reflects historical confusion about the origin of this tumor.

Epidemiology.

Overall, GISTs are slightly more common in males. The peak age of GIST diagnosis in the stomach is approximately 60 years, with fewer than 10% occurring in individuals under 40 years of age. Of the uncommon GISTs in children, some are related to the *Carney triad*, a nonhereditary syndrome seen primarily in young females that includes gastric GIST, paraganglioma, and pulmonary chondroma. There is also an increased incidence of GIST in individuals with neurofibromatosis type 1.[40]

Pathogenesis.

Approximately *75% to 80% of all GISTs have oncogenic, gain-of-function mutations of the gene encoding the tyrosine kinase c-KIT*, which is the receptor for stem cell factor. Approximately 8% of GISTs have mutations that activate a related tyrosine kinase, platelet-derived growth factor receptor α (PDGFRA).[41] In sporadic GISTs, *c-KIT* and *PDGFRA* gene mutations are mutually exclusive.[21] GISTs appear to arise from, or share a common stem cell with, the interstitial cells of Cajal, which are located in the muscularis propria and serve as pacemaker cells for gut peristalsis. Like GISTs, Cajal cells express c-KIT (also known as CD117) and CD34. Interestingly, familial GIST, which is rare, is associated with germline *c-KIT* or *PDGFRA* mutations; these patients, who develop multiple GISTs, may also have diffuse hyperplasia of Cajal cells.[42] Mutation of *c-KIT* or *PDGFRA* is an early event in sporadic GISTs and is detectable in lesions as small as 3 mm. The constitutively active c-KIT and PDGFRA receptor tyrosine kinases produce intracellular signals that activate the RAS and PI3K/AKT pathways and thereby promote tumor cell proliferation and survival.[21]

Morphology. Primary gastric GISTs can be quite large, as much as 30 cm in diameter. They usually form a solitary, well-circumscribed, fleshy mass (Fig. 17-21A) covered by ulcerated or intact mucosa (Fig. 17-21B), but can also project outward toward the serosa. Metastases may take the form of multiple serosal nodules throughout the peritoneal cavity or as one or more nodules in the liver; spread outside of the abdomen is uncommon. GISTs composed of thin elongated cells are classified as **spindle cell type** (Fig. 17-21C), whereas tumors dominated by epithelial-appearing cells are termed **epithelioid type**; mixtures of the two patterns also occur. The most useful diagnostic marker is c-KIT, which is immunohistochemically detectable in 95% of gastric GISTs.

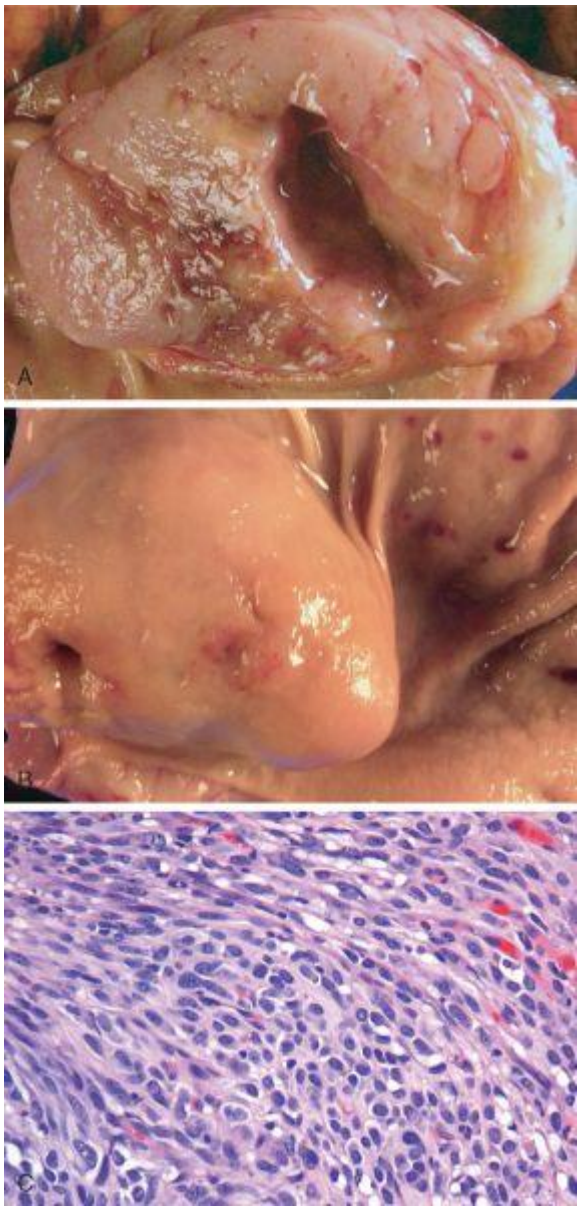

FIGURE 17-21 GI stromal tumor. **A**, On cross-section a whorled texture is evident within the white, fleshy tumor. **B**, The mass is covered by intact mucosa. **C**, Histologically the tumor is primarily composed of bundles, or fascicles, of spindle-shaped tumor cells. *(Courtesy of Dr. Christopher Weber, The University of Chicago, Chicago, IL.)*

Clinical Features.

Symptoms of GISTs at presentation may be related to mass effects. Mucosal ulceration can cause blood loss, and approximately half of individuals with GIST present with anemia or related symptoms. GISTs may also be discovered as an incidental finding during radiologic imaging, endoscopy, or abdominal surgery performed for other reasons. Complete surgical resection is the primary treatment for localized gastric GIST. The prognosis correlates with tumor size, mitotic index, and location, *with gastric GISTs being somewhat less aggressive than those arising in the small intestine*. Recurrence or metastasis is rare for gastric GISTs under 5 cm but common for mitotically active tumors larger than 10 cm.

Patients with unresectable, recurrent, or metastatic disease often respond to *imatinib*, a tyrosine kinase inhibitor that inhibits c-KIT and PDGFRA, and is also effective in suppressing BCR-ABL kinase activity in chronic myeloid leukemia (Chapter 13).[43] Development of resistance to imatinib is most often related to secondary *c-KIT* mutations that limit drug efficacy.

3.7.4 Small Intestine & Colon

The small intestine and colon account for the majority of GI tract length and are the sites of a broad array of diseases. Some of these relate to nutrient and water transport. Perturbation of these processes can cause malabsorption and diarrhea. The intestines are also the principal site where the immune system interfaces with a diverse array of antigens present in food and gut microbes. Indeed, intestinal bacteria outnumber eukaryotic cells in our bodies by tenfold. Thus, it is not surprising that the small intestine and colon are frequently involved by infectious and inflammatory processes. Finally, the colon is the most common site of GI neoplasia in Western populations.

3.7.4.1 Intestinal Obstruction

Obstruction of the GI tract may occur at any level, but the small intestine is most often involved because of its relatively narrow lumen. Collectively, *hernias, intestinal adhesions, intussusception, and volvulus* account for 80% of mechanical obstructions (Fig. 17-22), while tumors and infarction account for only about 10% to 15% of small bowel obstructions. The clinical manifestations of intestinal obstruction include abdominal pain and distention, vomiting, and constipation. Surgical intervention is usually required in cases of mechanical obstruction or severe infarction.

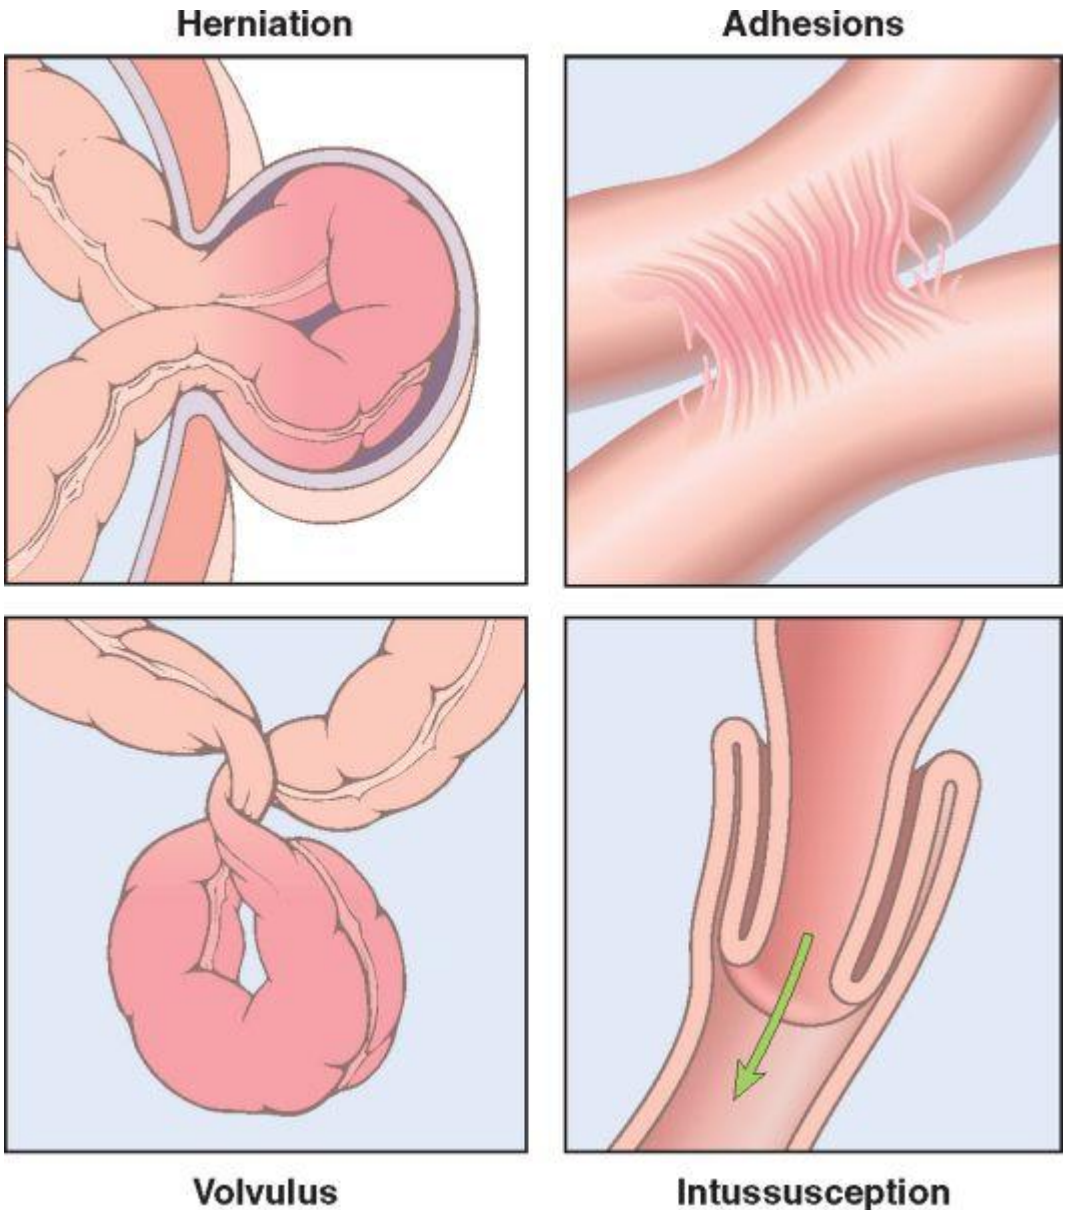

FIGURE 17-22 Intestinal obstruction. The four major causes of intestinal obstruction are (1) herniation of a segment in the umbilical or inguinal regions, (2) adhesion between loops of intestine, (3) volvulus, and (4) intussusception.

HERNIAS

Any weakness or defect in the wall of the peritoneal cavity may permit protrusion of a serosa-lined pouch of peritoneum called a *hernia sac.* Acquired hernias most commonly occur anteriorly, via the inguinal and femoral canals or umbilicus, or at sites of surgical scars. These are of concern because of visceral protrusion *(external herniation).* This is particularly true of inguinal hernias, which tend to have narrow orifices and large sacs. Small bowel loops are involved most often, but portions of omentum or large bowel also protrude, and any of these may become entrapped. Pressure at the neck of the pouch may impair venous drainage of the entrapped viscus. The resultant stasis and edema increase the bulk of the herniated loop, leading to permanent entrapment, or *incarceration,* and, over time, arterial and venous compromise *(strangulation)* develops that can result in infarction (Fig. 17-23A).

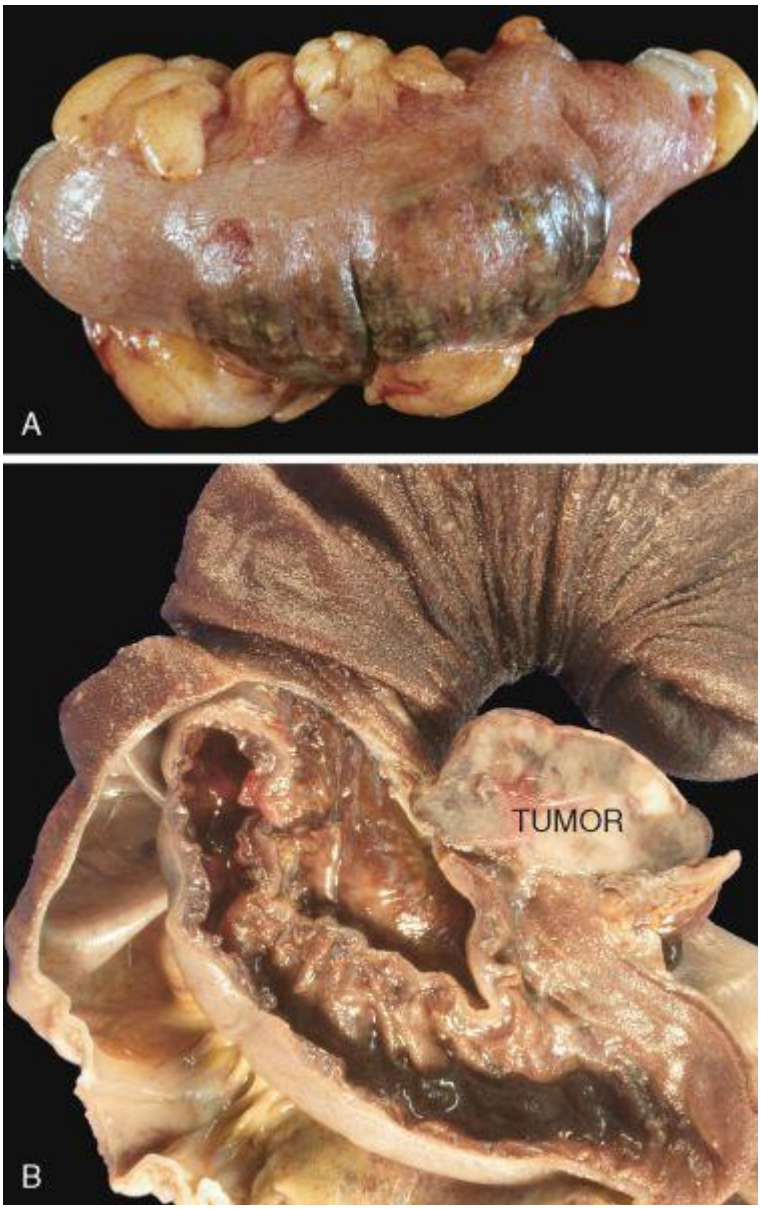

FIGURE 17-23 Intestinal obstruction. **A**, Portion of bowel incarcerated within an inguinal hernia. Note dusky serosa and hemorrhage that indicate ischemic damage. **B**, Intussusception caused by a tumor. The outermost layer of intestine with external serosa has been removed, leaving the mucosa of the second layer exposed. The serosa of the second layer is apposed to the serosa of the intussuscepted intestine. A tumor mass *(right, labelled* **tumor**) is present at the leading edge of the intussusception. Compare to Figure 17-22 . ***(B**, Courtesy of Dr. Christopher Weber, The University of Chicago, Chicago, IL.)*

ADHESIONS

Surgical procedures, infection, or other causes of peritoneal inflammation, such as endometriosis, may result in development of *adhesions* between bowel segments, the abdominal wall, and operative sites. These fibrous bridges can create closed loops through which other viscera may slide and become entrapped, resulting in *internal herniation*. Sequelae, including obstruction and strangulation, are much the same as with external hernias. Though rare, fibrous adhesions may be congenital, therefore, internal herniation must be considered even in the absence of a history of peritonitis or surgery.

VOLVULUS

Complete twisting of a loop of bowel about its mesenteric base of attachment is called *volvulus* and produces both luminal and vascular compromise. Thus, presentation includes features of obstruction and infarction. Volvulus occurs most often in large redundant loops of sigmoid colon, followed in frequency by the cecum, small bowel, stomach, or, rarely, transverse colon. Because it is rare, volvulus is often missed clinically.

INTUSSUSCEPTION

Intussusception occurs when a segment of the intestine, constricted by a wave of peristalsis, telescopes into the immediately distal segment. Once trapped, the invaginated segment is propelled by peristalsis and pulls the mesentery along. Untreated intussusception may progress to intestinal obstruction, compression of mesenteric vessels, and infarction.

When encountered in infants and children, there is usually no underlying anatomic defect and the patient is otherwise healthy, although some cases are associated with rotavirus infection. In older children and adults an intraluminal mass or tumor generally serves as the point of traction that causes intussusception (Fig. 17-23B). Barium enema may effectively reduce the intussusception in infants and young children, but surgical intervention is usually necessary in older patients.

3.7.4.2 Ischemic Bowel Disease

The majority of the GI tract is supplied by the celiac, superior mesenteric, and inferior mesenteric arteries. As they approach the intestinal wall the superior and inferior mesenteric arteries ramify into the mesenteric arcades. Interconnections between arcades, as well as collateral supplies from the proximal celiac and distal pudendal and iliac circulations, make it possible for the small intestine and colon to tolerate slowly progressive loss of the blood supply from one artery. In contrast, acute compromise of any major vessel can lead to infarction of several meters of intestine. Damage can range from *mucosal infarction*, extending no deeper than the muscularis mucosa; to *mural infarction* of mucosa and submucosa; to *transmural infarction* involving all three wall layers. While mucosal or mural infarctions are often secondary to acute or chronic *hypoperfusion*, transmural infarction is generally caused by acute vascular obstruction. Important causes of acute arterial obstruction include severe *atherosclerosis* (which is often prominent at the origin of mesenteric vessels), *aortic aneurysm*, *hypercoagulable states*, *oral contraceptive use*, and *embolization of cardiac vegetations or aortic atheromas*. Intestinal hypoperfusion can also be associated with *cardiac failure*, *shock*, *dehydration*, or *vasoconstrictive drugs*. Systemic *vasculitides*, such as polyarteritis nodosum, Henoch-Schönlein purpura, or Wegener granulomatosis, may also damage intestinal arteries. Mesenteric venous thrombosis, which can also lead to ischemic disease, is uncommon but can result from inherited or acquired hypercoagulable states, invasive neoplasms, cirrhosis, trauma, or abdominal masses that compress the portal drainage.

Pathogenesis.

Intestinal responses to ischemia occur in two phases. The initial *hypoxic injury* occurs at the onset of vascular compromise. While some damage occurs during this phase, the epithelial cells lining the intestine are relatively resistant to transient hypoxia. The second phase, *reperfusion injury*, is initiated by restoration of the blood supply and it is at this time that the greatest damage occurs. In severe cases this may trigger multiorgan failure. While the underlying mechanisms of reperfusion injury are incompletely understood, they involve free radical production, neutrophil infiltration, and release of inflammatory mediators, such as complement proteins and TNF (Chapter 1). Activation of intracellular signaling molecules and transcription factors, including hypoxia-inducible factor 1 (HIF-1) and NF-κB, also contribute to intestinal ischemia-reperfusion injury.[44,][45]

The severity of vascular compromise, the time frame during which it develops, and the vessels affected are the major variables in ischemic bowel disease. Two aspects of intestinal vascular anatomy also contribute to the distribution of ischemic damage.

- Intestinal segments at the end of their respective arterial supplies are particularly susceptible to ischemia. These *watershed zones* include the splenic flexure, where the superior and inferior mesenteric arterial circulations terminate, and, to a lesser extent, the sigmoid colon and rectum where inferior mesenteric, pudendal, and iliac arterial circulations end. Generalized hypotension or hypoxemia can therefore cause localized injury, and ischemic disease should be considered in the differential diagnosis of focal colitis of the splenic flexure or rectosigmoid colon.
- Intestinal capillaries run alongside the glands, from crypt to surface, before making a hairpin turn at the surface to empty into the post-capillary venules. This allows oxygenated blood to supply crypts but leaves the surface epithelium vulnerable to ischemic injury. This anatomy protects the crypts, which contain the epithelial stem cells that are necessary to repopulate the surface. Thus, surface epithelial atrophy, or even necrosis and sloughing, with normal or hyperproliferative crypts is a morphologic signature of ischemic intestinal disease.

Morphology. Despite the increased susceptibility of watershed zones, **mucosal and mural infarction** may involve any level of the gut from stomach to anus. The lesions may be continuous but are more often segmental and patchy (Fig. 17-24A). The mucosa is hemorrhagic and may be ulcerated and dark red or purple as a result of luminal hemorrhage (Fig. 17-24B). The bowel wall is also thickened by edema that may involve the mucosa or extend into the submucosa and muscularis propria. When severe, there is extensive mucosal and submucosal hemorrhage and necrosis, but serosal hemorrhage and serositis are generally absent.

Substantial portions of the bowel are generally involved in **transmural infarction** due to acute arterial obstruction. For reasons described above, the splenic flexure is the site at greatest risk. The demarcation between normal and ischemic bowel is sharply defined and the infarcted bowel is initially intensely congested and dusky to purple-red. Later, blood-tinged mucus or frank blood accumulates in the lumen and the wall becomes edematous, thickened, and rubbery. There is coagulative necrosis of the muscularis propria within 1 to 4 days, and perforation may occur. Serositis, with purulent exudates and fibrin deposition, may be prominent.

In mesenteric venous thrombosis arterial blood continues to flow for a time, resulting in a less abrupt transition from affected to normal bowel. However, propagation of the thrombus may lead to secondary involvement of the splanchnic bed. The ultimate result is similar to that produced by acute arterial obstruction because impaired venous drainage eventually prevents oxygenated arterial blood from entering the capillaries.

Microscopic examination of ischemic intestine demonstrates **atrophy or sloughing of surface epithelium** (Fig. 17-24C). In contrast, crypts may be hyperproliferative. Inflammatory infiltrates are initially absent in acute ischemia, but neutrophils are recruited within hours of reperfusion. Chronic ischemia is accompanied by fibrous scarring of the lamina propria (Fig. 17-24D) and, uncommonly, stricture formation. In acute phases of ischemic damage bacterial superinfection and enterotoxin release may induce pseudomembrane formation that can resemble *Clostridium difficile*–associated pseudomembranous colitis (discussed later).

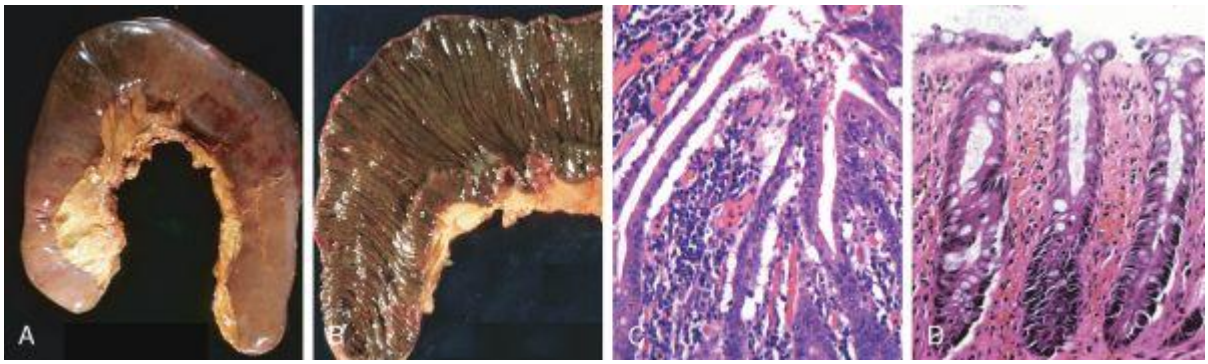

FIGURE 17-24 Ischemia. **A**, Jejunal resection with dusky serosa. **B**, Mucosa is stained with blood after hemorrhage. **C**, Characteristic attenuated villous epithelium in this case of acute jejunal ischemia. **D**, Chronic colonic ischemia with atrophic surface epithelium and fibrotic lamina propria.

Clinical Features.

Ischemic bowel disease tends to occur in older individuals with coexisting cardiac or vascular disease. Acute transmural infarction typically presents with sudden, severe abdominal pain and tenderness, sometimes accompanied by nausea, vomiting, bloody diarrhea, or grossly melanotic stool. Patients may progress to shock and vascular collapse within hours as a result of blood loss. Peristaltic sounds diminish or disappear, and muscular spasm creates board-like rigidity of the abdominal wall. Because these physical signs overlap with those of other abdominal emergencies, including acute appendicitis, perforated ulcer, and acute cholecystitis, the diagnosis of intestinal necrosis may be delayed or missed, with disastrous consequences. As the mucosal barrier breaks down, bacteria enter the circulation and sepsis can develop; mortality may exceed 50%. The overall progression of ischemic enteritis depends on the underlying cause and severity of injury.

- *Mucosal and mural infarctions* by themselves may not be fatal. However, these may progress to more extensive infarction if the vascular supply is not restored by correction of the insult or, in chronic disease, by development of adequate collateral supplies. The diagnosis of nonocclusive ischemic enteritis and colitis can be particularly difficult because there may be a confusing array of nonspecific abdominal symptoms, including intermittent bloody diarrhea and intestinal pseudo-obstruction.
- *Chronic ischemia* may masquerade as inflammatory bowel disease, with episodes of bloody diarrhea interspersed with periods of healing.
- *CMV infection* causes ischemic GI disease due to the viral tropism for and infection of endothelial cells. CMV infection, which can be a complication of immunosuppressive therapy, is discussed further in Chapter 8 .
- *Radiation enterocolitis* occurs when the GI tract is irradiated. In addition to epithelial damage, radiation-induced vascular injury may be significant and produce changes that are similar to ischemic disease. In addition to clinical history, the presence of bizarre “radiation fibroblasts” within the stroma may provide an important clue to the etiology. Acute radiation enteritis manifests as anorexia, abdominal cramps, and a malabsorptive diarrhea, while chronic radiation enteritis or colitis is often more indolent and may present as an inflammatory colitis.
- *Necrotizing enterocolitis* (NEC) is an acute disorder of the small and large intestines that can result in transmural necrosis. It is the most common acquired GI emergency of neonates, particularly those who are premature or of low birth weight, and occurs most often at the time of oral feeding. NEC is discussed in more detail in Chapter 10 , but is noted here because ischemic injury is generally considered to contribute to the pathogenesis.

3.7.4.3 Angiodysplasia

Angiodysplasia is characterized by malformed submucosal and mucosal blood vessels. It occurs *most often in the cecum or right colon*, usually after the sixth decade of life. Although the prevalence of angiodysplasia is less than 1% in the adult population, *it accounts for 20% of major episodes of lower intestinal bleeding; intestinal hemorrhage may be chronic and intermittent or acute and massive*.

The pathogenesis of angiodysplasia remains undefined but has been attributed to mechanical and congenital factors. Normal distention and contraction may intermittently occlude the submucosal veins that penetrate through the muscularis propria and can lead to focal dilation and tortuosity of overlying submucosal and mucosal vessels. Because the cecum has the largest diameter of any colonic segment, it develops the greatest wall tension. This may explain the preferential distribution of angiodysplastic lesions in the cecum and right colon. Degenerative vascular changes related to aging may also have some role. Finally, some data link angiodysplasia with aortic stenosis and Meckel diverticulum, suggesting the possibility of a developmental component.

Lesions of angiodysplasia are ectatic nests of tortuous veins, venules, and capillaries. The vascular channels may be separated from the intestinal lumen by only the vascular wall and a layer of attenuated epithelial cells; limited injury may therefore result in significant hemorrhage.

3.7.4.4 Malabsorption & Diarrhea

Malabsorption, which presents most commonly as *chronic diarrhea*, is characterized by defective absorption of fats, fat- and water-soluble vitamins, proteins, carbohydrates, electrolytes and minerals, and water. Chronic malabsorption can be accompanied by weight loss, anorexia, abdominal distention, borborygmi, and muscle wasting. A hallmark of malabsorption is *steatorrhea*, characterized by excessive fecal fat and bulky, frothy, greasy, yellow or clay-colored stools. *The chronic malabsorptive disorders most commonly encountered in the United States are pancreatic insufficiency, celiac disease, and Crohn disease* (Table 17-6). Intestinal graft-versus-host disease is an important cause of malabsorption and diarrhea after allogeneic bone marrow transplantation.

TABLE 17-6 -- Defects in Malabosorptive and Diarrheal Disease

Disease	Intraluminal Digestion	Terminal Digestion	Transepithelial Transport	Lymphatic Transport
Celiac disease		+	+	
Tropical sprue		+	+	
Chronic pancreatitis	+			
Cystic fibrosis	+			
Primary bile acid malabsorption	+		+	
Carcinoid syndrome			+	
Autoimmune enteropathy		+	+	
Disaccharidase deficiency		+		
Whipple disease				+
Abetalipoproteinemia			+	
Viral gastroenteritis		+	+	
Bacterial gastroenteritis		+	+	

Disease	Intraluminal Digestion	Terminal Digestion	Transepithelial Transport	Lymphatic Transport
Parasitic gastroenteritis		+	+	
Inflammatory bowel disease	+	+	+	

+ indicates that the process is abnormal in the disease indicated. Other processes are not affected.

Malabsorption results from disturbance in at least one of the four phases of nutrient absorption: (1) *intraluminal digestion*, in which proteins, carbohydrates, and fats are broken down into forms suitable for absorption; (2) *terminal digestion*, which involves the hydrolysis of carbohydrates and peptides by disaccharidases and peptidases, respectively, in the brush border of the small intestinal mucosa; (3) *transepithelial transport*, in which nutrients, fluid, and electrolytes are transported across and processed within the small intestinal epithelium; and (4) *lymphatic transport* of absorbed lipids.

In many malabsorptive disorders a defect in one of these processes predominates, but more than one usually contributes. As a result, malabsorption syndromes resemble each other more than they differ. General symptoms include *diarrhea* (from nutrient malabsorption and excessive intestinal secretion), *flatus, abdominal pain*, and *weight loss*. Inadequate absorption of vitamins and minerals can result in anemia and mucositis due to pyridoxine, folate, or vitamin B_{12} deficiency; bleeding, due to vitamin K deficiency; osteopenia and tetany due to calcium, magnesium, or vitamin D deficiencies; or peripheral neuropathy due to vitamin A or B_{12} deficiencies. A variety of endocrine and skin disturbances may also occur.

Diarrhea is defined as an increase in stool mass, frequency, or fluidity, typically greater than 200 g per day. In severe cases stool volume can exceed 14 L per day and, without fluid resuscitation, result in death. Painful, bloody, small-volume diarrhea is known as *dysentery*. Diarrhea can be classified according to four major categories:

- *Secretory diarrhea* is characterized by isotonic stool and persists during fasting.
- *Osmotic diarrhea*, such as that which occurs with lactase deficiency, is due to the excessive osmotic forces exerted by unabsorbed luminal solutes. The diarrhea fluid is over 50 mOsm more concentrated than plasma and abates with fasting.
- *Malabsorptive diarrhea* follows generalized failures of nutrient absorption and is associated with steatorrhea and is relieved by fasting.
- *Exudative diarrhea* is due to inflammatory disease and characterized by purulent, bloody stools that continue during fasting.

CYSTIC FIBROSIS

Cystic fibrosis is discussed in greater detail elsewhere (Chapter 10). Only the malabsorption associated with cystic fibrosis is considered here. Due to the absence of the epithelial cystic fibrosis transmembrane conductance regulator (CFTR), individuals with cystic fibrosis have defects in intestinal chloride ion secretion. This interferes with bicarbonate, sodium, and water secretion, ultimately resulting in defective luminal hydration. Formation of intraductal concretions can begin in utero, leading to duct obstruction, low-grade chronic autodigestion of the pancreas, and eventual *exocrine pancreatic insufficiency in more than 80% of patients*. The result is failure of the intraluminal phase of nutrient absorption, which can be effectively treated in most patients with oral enzyme supplementation.

CELIAC DISEASE

Celiac disease is also known as *celiac sprue* or *gluten-sensitive enteropathy*. It is an immune-mediated enteropathy triggered by the ingestion of gluten-containing cereals, such as wheat, rye, or barley, in genetically predisposed individuals. In countries where most people are Caucasians of European ancestry, celiac disease is a common disorder, with an estimated prevalence of 0.5% to 1%.

Pathogenesis.

Celiac disease is a unique intestinal immune disorder because the environmental precipitant, *gluten*, is known. Gluten is the major storage protein of wheat and similar grains, and the alcohol-soluble fraction of gluten, *gliadin*, contains most of the disease-producing components. Gluten is digested by luminal and brush-border enzymes into amino acids and peptides, including a 33–amino acid α-gliadin peptide that is resistant to degradation by gastric, pancreatic, and small intestinal proteases (Fig. 17-25). The network of immune reactions to gliadin that are thought to result in celiac disease is illustrated below. Some gliadin peptides induce epithelial cells to express IL-15, which in turn triggers activation and proliferation of CD8+ intraepithelial lymphocytes that are induced to express NKG2D, a natural killer cell marker. These lymphocytes become cytotoxic and kill enterocytes with surface MIC-A, an HLA class I–like protein expressed in response to stress. NKG2D is the receptor for MIC-A. Thus, unlike the CD4+ T cells, these NKG2D+ CD8+ T cells do not recognize gliadin. The resulting epithelial damage may contribute to the process by which other gliadin peptides cross the epithelium to be deamidated by tissue transglutaminase. Deamidated gliadin peptides are then able to interact with HLA-DQ2 or HLA-DQ8 on antigen-presenting cells and be presented to CD4+ T cells. These T cells produce cytokines that contribute to tissue damage and the characteristic mucosal pathology.

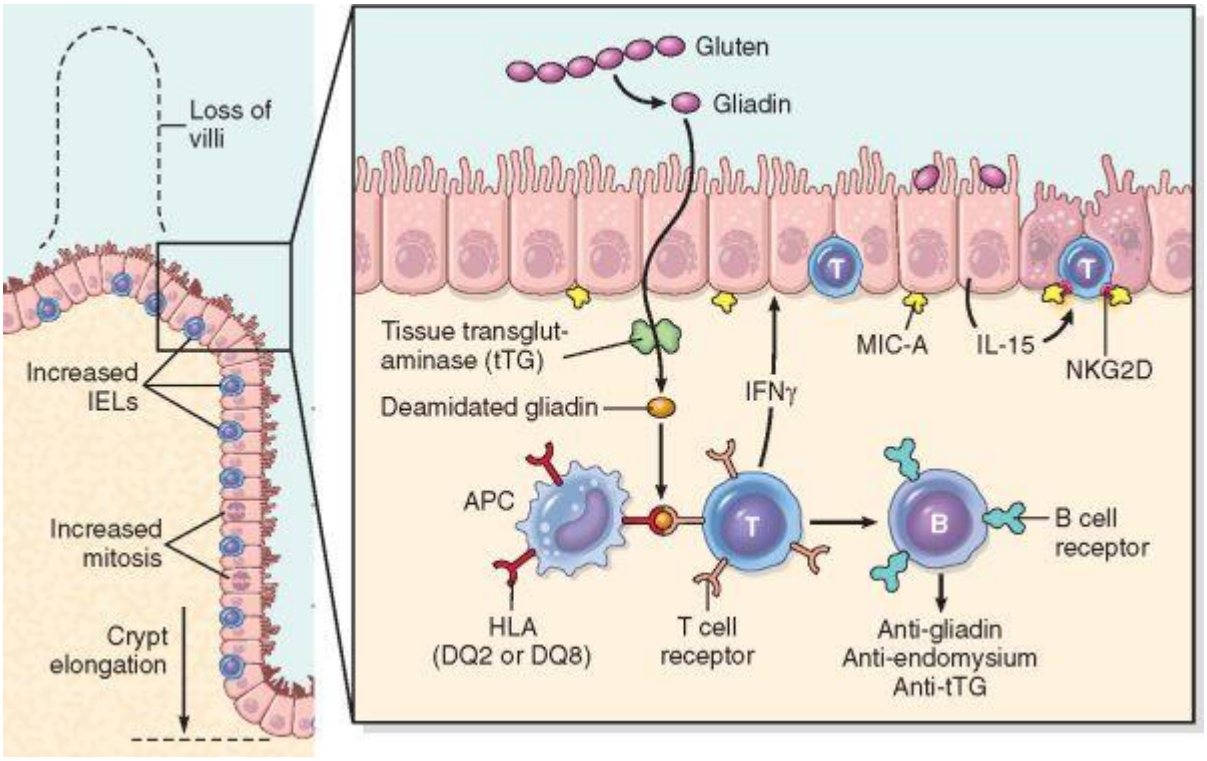

FIGURE 17-25 The left panel illustrates the morphologic alterations that may be present celiac disease, including villous atrophy, increased numbers of intraepithelial lymphocytes (IELs), and epithelial proliferation with crypt elongation (compare to Fig. 17-26). The right panel depicts a model for the pathogenesis of celiac disease. Note that both innate and adaptive immune mechanisms are involved in the tissue responses to gliadin.

While nearly all people eat grain and are exposed to gluten and gliadin, most do not develop celiac disease. Thus, host factors determine whether disease develops. Among these, HLA proteins seem to be critical, since almost all people with celiac disease carry the class II HLA-DQ2 or HLA-DQ8 allele. However, the HLA locus accounts for less than half of the genetic component of celiac disease. Remaining genetic factors may include polymorphisms of immune-regulatory genes, such as those encoding IL-2, IL-21, CCR3, and SH2B3,[46] and genes that determine epithelial polarity.[47,][48] There is also an association of celiac disease with other immune diseases including type 1 diabetes, thyroiditis, and Sjögren syndrome, as well as ataxia, autism, depression, some forms of epilepsy, IgA nephropathy, Down syndrome, and Turner syndrome.

Morphology. Biopsy specimens from the second portion of the duodenum or proximal jejunum, which are exposed to the highest concentrations of dietary gluten, are generally diagnostic in celiac disease. The histopathology is characterized by increased numbers of intraepithelial CD8+ T lymphocytes **(intraepithelial lymphocytosis)**, **crypt hyperplasia**, and **villous atrophy** (Fig. 17-26). This loss of mucosal and brush-border surface area probably accounts for the malabsorption. In addition, increased rates of epithelial turnover, reflected in increased crypt mitotic activity, may limit the ability of absorptive enterocytes to fully differentiate and contribute to defects in terminal digestion and transepithelial transport. Other features of fully developed celiac disease include increased numbers of plasma cells, mast cells, and eosinophils, especially within the upper part of the lamina propria. With increased frequency of serologic screening and early detection of disease-associated antibodies, it is now appreciated that an increase in the number of intraepithelial lymphocytes, particularly within the villus, is a marker of less advanced celiac disease.[49] However, intraepithelial lymphocytosis and villous atrophy are not specific for celiac disease and can be present in other diseases, including viral enteritis. The combination of histology and serology is most specific for diagnosis of celiac disease.

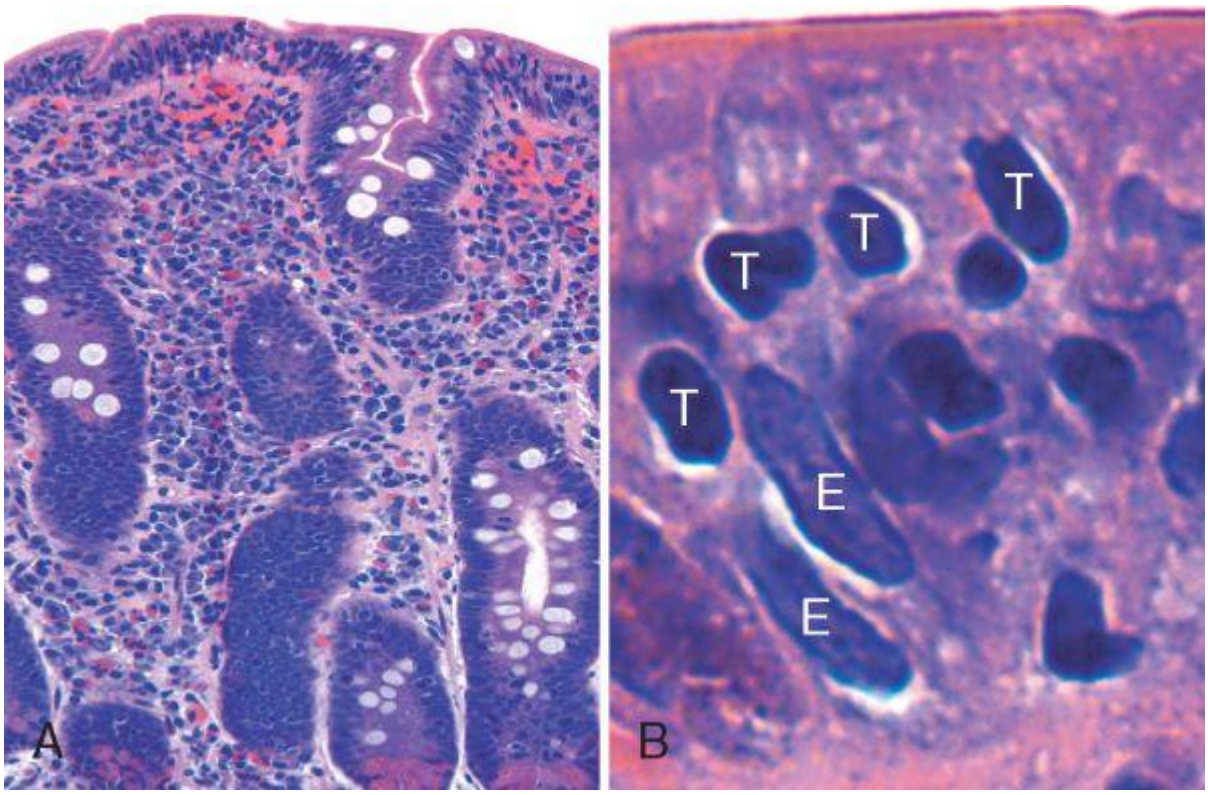

FIGURE 17-26 Celiac disease. **A**, Advanced cases of celiac disease show complete loss of villi, or total villous atrophy. Note the dense plasma cell infiltrates in the lamina propria. **B**, Infiltration of the surface epithelium by T lymphocytes, which can be recognized by their densely stained nuclei (labelled **T**). Compare to elongated, pale-staining epithelial nuclei (labelled **E**).

Clinical Features.

In adults, celiac disease presents most commonly between the ages of 30 and 60. However, many cases escape clinical attention for extended periods because of atypical presentations. Some patients may have *silent* celiac disease, defined as positive serology and villous atrophy without symptoms, or *latent* celiac disease, in which positive serology is not accompanied by villous atrophy. Symptomatic adult celiac disease is often associated with anemia, chronic diarrhea, bloating, or chronic fatigue. Although there is no gender preference, celiac disease is detected two- to threefold more commonly in women, perhaps because monthly menstrual bleeding increases the demand for iron and vitamins and accentuates the effects of impaired absorption.

Pediatric celiac disease, which affects males and females equally, may present with malabsorption or atypical symptoms affecting almost any organ.[50] In those with *classic symptoms*, disease typically begins between ages of 6 and 24 months, after introduction of gluten to the diet, and includes irritability, abdominal distention, anorexia, chronic diarrhea, failure to thrive, weight loss, or muscle wasting.[50] Children with *nonclassic symptoms* tend to present at older ages with complaints of abdominal pain, nausea, vomiting, bloating, or constipation. Common extra-intestinal complaints include arthritis or joint pain, seizure disorders, aphthous stomatitis, iron deficiency anemia, pubertal delay, and short stature.

A characteristic itchy, blistering skin lesion, *dermatitis herpetiformis*, can be present in as many as 10% of patients, and the incidence of *lymphocytic gastritis* and *lymphocytic colitis* is also increased.

Unfortunately, the only treatment currently available for celiac disease is a *gluten-free diet*, but, despite the challenges of adhering to this diet, it does result in symptomatic improvement for most patients. A gluten-free diet may also reduce the risk of long-term complications including anemia, female infertility, osteoporosis, and cancer.

Noninvasive serologic tests are generally performed prior to biopsy.[51] The most sensitive tests are the presence of IgA antibodies to tissue transglutaminase or IgA or IgG antibodies to deamidated gliadin. Anti-endomysial antibodies are highly specific but less sensitive than other antibodies. In cases with negative IgA tests, IgA deficiency, which is more common in celiac patients, should be ruled out. If IgA deficiency is present, titers of IgG antibodies to tissue transglutaminase and deamidated gliadin should be measured. The absence of HLA-DQ2 or HLA-DQ8 is useful for its high negative predictive value, but the presence of these alleles is not helpful in confirming the diagnosis.

Individuals with celiac disease have a higher than normal rate of malignancy. The most common celiac disease–associated cancer is *enteropathy-associated T-cell lymphoma*, an aggressive lymphoma of intraepithelial T lymphocytes. *Small intestinal adenocarcinoma* is also more frequent in individuals with celiac disease. Thus, when symptoms such as abdominal pain, diarrhea, and weight loss develop despite a strict gluten-free diet, cancer or *refractory sprue*, in which the response to a gluten-free diet is lost, must be considered. It is, however, important to remember that failure to adhere to a gluten-free diet is the most common cause of recurrent symptoms, and that most people with celiac disease do well with dietary restrictions and die of unrelated causes.

TROPICAL SPRUE

Tropical sprue is a malabsorption syndrome that occurs almost exclusively in people living in or visiting the tropics, including Puerto Rico, the Caribbean, northern South America, West Africa, India, and Southeast Asia. Inexplicably, it is uncommon in Jamaica. The disease is generally endemic, although epidemics have occurred.

Histologic changes of tropical sprue are similar to celiac disease, but total villous atrophy is uncommon, and tropical sprue tends to involve the distal small bowel. The latter probably explains the frequency of folate or vitamin B_{12} deficiencies with enlarged (megaloblastic) nuclei within epithelial cells that are reminiscent of those seen in pernicious anemia.

Malabsorption usually becomes apparent within days or a few weeks of an acute diarrheal enteric infection in visitors. Although no definite causal organism has been identified, overgrowth of aerobic enteric bacteria has been documented, and broad-spectrum antibiotics usually effect rapid recovery. Various infections, including *Cyclospora* or enterotoxigenic bacteria, have been suggested as etiologic factors.

AUTOIMMUNE ENTEROPATHY

Autoimmune enteropathy is an X-linked disorder characterized by severe persistent diarrhea and autoimmune disease that occurs most often in young children. A particularly severe familial form, termed *IPEX*, an acronym denoting immune dysregulation, polyendocrinopathy, enteropathy, and X-linkage, is due to a germline mutation in the *FOXP3* gene, which is located on the X chromosome.[52] FOXP3 is a transcription factor expressed in CD4+ regulatory T cells,[53] and individuals with IPEX and *FOXP3* mutations have defective T-regulatory function. Other defects in regulatory T cell function have also been linked to less severe forms of autoimmune enteropathy. Autoantibodies to enterocytes and goblet cells are common, and some patients may have antibodies to parietal or islet cells. Within the small intestine intraepithelial lymphocytes may be increased, but not to the extent seen in celiac disease,

and neutrophils are often present. Therapy includes immunosuppressive drugs such as cyclosporine and, in rare cases, bone marrow transplantation.[54]

LACTASE (DISACCHARIDASE) DEFICIENCY

The disaccharidases, including lactase, are located in the apical brush-border membrane of the villus absorptive epithelial cells. Because the defect is biochemical, biopsy histology is generally unremarkable. Lactase deficiency is of two types:

- *Congenital lactase deficiency*, caused by a mutation in the gene encoding lactase,[55] is an autosomal recessive disorder. The disease is rare and presents as explosive diarrhea with watery, frothy stools and abdominal distention upon milk ingestion. Symptoms abate when exposure to milk and milk products is terminated, thus removing the osmotically active but unabsorbable lactose from the lumen.
- *Acquired lactase deficiency* is caused by down-regulation of lactase gene expression and is particularly common among Native Americans, African-Americans, and Chinese populations. Disease presents after childhood, perhaps reflecting the fact that, before farming of dairy animals, lactase was unnecessary after children stopped drinking mothers' milk. Onset of acquired lactose deficiency is sometimes associated with enteric viral or bacterial infections. Symptoms, including abdominal fullness, diarrhea, and flatulence, due to fermentation of the unabsorbed sugars by colonic bacteria, are triggered by ingestion of lactose-containing dairy products.

ABETALIPOPROTEINEMIA

Abetalipoproteinemia is a rare autosomal recessive disease characterized by an inability to secrete triglyceride-rich lipoproteins. It is caused by a mutation in the *microsomal triglyceride transfer protein* (MTP) that catalyzes transport of triglycerides, cholesterol esters, and phospholipids. MTP-deficient enterocytes are unable to export lipoproteins and free fatty acids. As a result, monoglycerides cannot be assembled into chylomicrons and triglycerides accumulate within the epithelial cells. The malabsorption of abetalipoproteinemia is therefore a failure of transepithelial transport. Lipid vacuolization of small intestinal epithelial cells is evident under the light microscope and can be highlighted by special stains, such as oil red-O, particularly after a fatty meal.

Abetalipoproteinemia presents in infancy and the clinical picture is dominated by failure to thrive, diarrhea, and steatorrhea. Patients also have a complete absence of all plasma lipoproteins containing apolipoprotein B, although the gene that encodes apolipoprotein B itself is not affected. Failure to absorb essential fatty acids leads to deficiencies of fat-soluble vitamins as well as lipid membrane defects that can be recognized by the presence of acanthocytic red cells (burr cells) in peripheral blood smears.

3.7.4.5 Infectious Enterocolitis

Enterocolitis can present with a broad range of symptoms including diarrhea, abdominal pain, urgency, perianal discomfort, incontinence, and hemorrhage (Table 17-7). This global problem is responsible for more than 12,000 deaths per day among children in developing countries and half of all deaths before age 5 worldwide. Bacterial infections, such as enterotoxigenic *Escherichia coli*, are frequently responsible, but the most common pathogens vary with age, nutrition, and host immune status as well as environmental influences (Table 17-7). For example, epidemics of cholera are common in areas with poor sanitation, as a result of inadequate public health measures, or as a consequence of natural disasters or war. Pediatric infectious diarrhea, which may result in severe dehydration and metabolic acidosis, is commonly caused by enteric viruses.

TABLE 17-7 -- Features of Bacterial Enterocolitides

Infection Type	Geography	Reservoir	Transmission	Epidemiology	Affected GI Sites	Symptoms	Complications
Cholera	India, Africa	Shellfish	Fecal-oral, water	Sporadic, endemic, epidemic	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
***Campylobacter* spp.**	Developed countries	Chickens, sheep, pigs, cattle	Poultry, milk, other foods	Sporadic; children, travelers	Colon	Watery or bloody diarrhea	Arthritis, Guillain-Barré syndrome
Shigellosis	Developing countries	Humans	Fecal-oral, food, water	Children	Left colon, ileum	Bloody diarrhea	Reiter syndrome, hemolytic-uremic syndrome
Salmonellosis	Worldwide	Poultry, farm animals, reptiles	Meat, poultry, eggs, milk	Children, elderly	Colon and small intestine	Watery or bloody diarrhea	Sepsis, abscess
Enteric (typhoid) fever	India, Mexico, Phillipines	Humans	Fecal-oral, water	Children. adolescents, travelers	Small intestine	Bloody diarrhea, fever	Chronic infection, carrier state, encephalopathy, myocarditis
***Yersinia* spp.**	Northern and central Europe	Pigs	Pork, milk, water	Clustered cases	Ileum, appendix, right colon	Abdominal pain, fever, diarrhea	Autoimmune, e.g., Reiter syndrome
Escherichia coli							
Enterotoxigenic (ETEC)	Developing countries	Unknown	Food or fecal-oral	Infants, adolescents, travelers	Small intestine	Severe watery diarrhea	Dehydration, electrolyte imbalances
Enterohemorrhagic (EHEC)	Worldwide	Widespread, includes cattle	Beef, milk, produce	Sporadic and epidemic	Colon	Bloody diarrhea	Hemolytic-uremic syndrome
Enteroinvasive (EIEC)	Developing countries	Unknown	Cheese, other foods, water	Young children	Colon	Bloody diarrhea	Unknown
Enteroaggregative (EAEC)	Worldwide	Unknown	Unknown	Children, adults, travelers	Colon	Nonbloody diarrhea, afebrile	Poorly defined
Pseudomembranous colitis (*C. difficile*)	Developing countries	Humans, hospitals	Antibiotics allow emergence	Immunosuppressed, antibiotic-treated	Colon	Watery diarrhea, fever	Relapse
Whipple disease	Rural > urban	Unknown	Unknown	Rare	Small intestine	Malabsorption	Arthritis, CNS disease
Mycobacterial infection	Worldwide	Unknown	Unknown	Immunosuppressed	Small intestine	Malabsorption	Pneumonia, infection at other sites

CNS, central nervous system; GI, gastrointestinal.

CHOLERA

Vibrio cholerae are comma-shaped, Gram-negative bacteria that cause cholera, a disease that has been endemic in the Ganges Valley of India and Bangladesh for all of recorded history. Since 1817, seven great pandemics have spread along trade routes to large parts of Europe, Australia, and the Americas,[56] but, for unknown reasons these pandemics resolved and cholera retreated back to the Ganges Valley. Cholera also persists within the Gulf of Mexico.

V. cholerae is primarily transmitted by contaminated drinking water. However, it can also be present in food and causes sporadic cases of seafood-associated disease in North America. There is a marked seasonal variation in most climates due to rapid growth of *Vibrio* bacteria at warm temperatures; the only animal reservoirs are shellfish and plankton. Relatively few *V. cholerae* serotypes are pathogenic, but other species of *Vibrio* can also cause disease. For example, *V. parahaemolyticus* is the most common cause of seafood-associated gastroenteritis in North America.[57]

Pathogenesis.

Despite the severe diarrhea, *Vibrio* organisms are non-invasive and remain within the intestinal lumen. A *preformed enterotoxin*, cholera toxin, encoded by a virulence phage and released by the *Vibrio* organism, causes disease, but flagellar proteins, which are involved in motility and attachment, are necessary for efficient bacterial colonization. Hemagglutinin, a metalloproteinase, is important for bacterial detachment and shedding in the stool. The mechanism by which cholera toxin induces diarrhea is well understood (Fig. 17-27). Cholera toxin is composed of five B subunits and a single A subunit. The B subunit binds GM1 ganglioside on the surface of intestinal epithelial cells, and is carried by endocytosis to the endoplasmic reticulum, a process called *retrograde transport*.[58] Here, the A subunit is reduced by protein disulfide isomerase, and a fragment of the A subunit is unfolded and released. This peptide fragment is then transported into the cytosol using host cell machinery that moves misfolded proteins from the endoplasmic reticulum to the cytosol. Such unfolded proteins are normally disposed of via the proteasome, but the A subunit refolds to avoid degradation. The refolded A subunit peptide then interacts with cytosolic ADP ribosylation factors (ARFs) to ribosylate and activate the stimulatory G protein $G_{s\alpha}$. This stimulates adenylate cyclase and the resulting increases in intracellular cAMP open the cystic fibrosis transmembrane conductance regulator, CFTR, which releases chloride ions into the lumen. This causes secretion of bicarbonate, sodium, and water, leading to massive diarrhea. Chloride and sodium absorption are also inhibited by cAMP. Remarkably, mucosal biopsies show only minimal alterations.

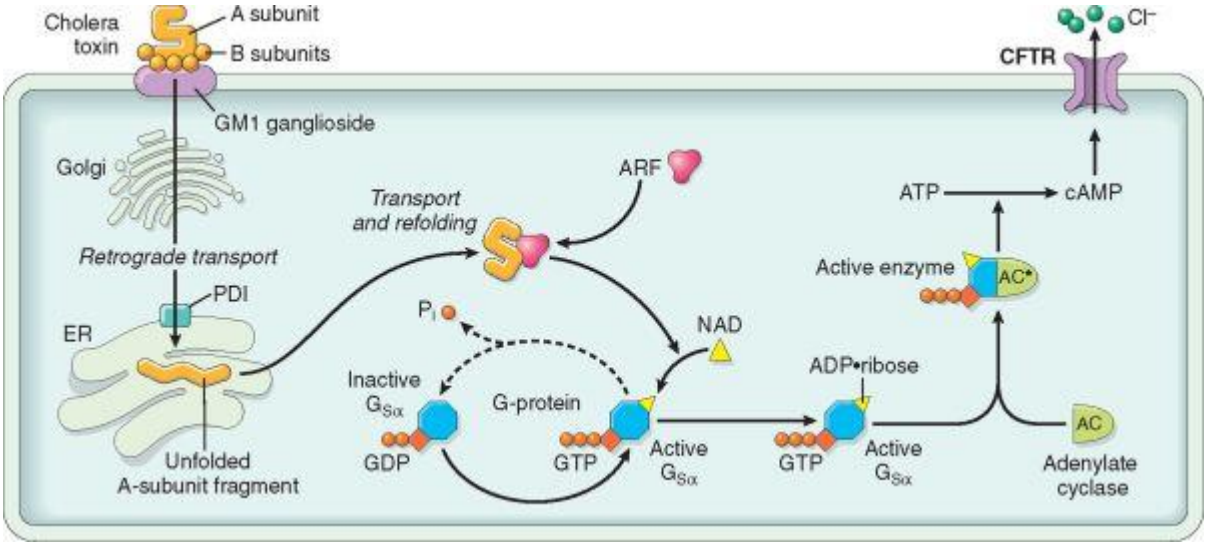

FIGURE 17-27 Mechanisms of cholera toxin transport and signaling. After retrograde toxin transport to the endoplasmic reticulum (ER), the A subunit is released by the action of protein disulfide isomerase (PDI) and is then able to access the epithelial cell cytoplasm. In concert with an ADP-ribosylation factor (ARF), the A subunit then ADP-ribosylates $G_{s\alpha}$, which locks it in the active, GTP-bound state. This leads to adenylate cyclase (AC) activation, and the cAMP produced opens CFTR to drive chloride secretion and diarrhea.

Clinical Features.

Most exposed individuals are asymptomatic or develop only mild diarrhea. In those with severe disease there is an abrupt onset of watery diarrhea and vomiting following an incubation period of 1 to 5 days. The voluminous stools resemble rice water and are sometimes described as having a fishy odor. The rate of diarrhea may reach 1 liter per hour, leading to dehydration, hypotension, muscular cramping, anuria, shock, loss of consciousness, and death. Most deaths occur within the first 24 hours after presentation. Although the mortality for severe cholera is about 50% without treatment, timely fluid replacement can save more than 99% of patients. Oral rehydration is often sufficient.[59] Because of an improved understanding of the host and *Vibrio* proteins involved, new therapies are being developed including CFTR inhibitors that block chloride secretion and prevent diarrhea.[60] Prophylactic vaccination is a long-term goal.[61]

CAMPYLOBACTER ENTEROCOLITIS

Campylobacter jejuni is the most common bacterial enteric pathogen in developed countries[57] and is an important cause of traveler's diarrhea. Most infections are associated with ingestion of improperly cooked chicken, but outbreaks can also be caused by unpasteurized milk or contaminated water.

Pathogenesis.

The pathogenesis of *Campylobacter* infection remains poorly defined, but four major virulence properties contribute: motility, adherence, toxin production, and invasion. Flagella allow *Campylobacter* to be motile. This facilitates adherance and colonization, which are necessary for mucosal invasion. Cytotoxins that cause epithelial damage and a cholera toxin–like enterotoxin are also released by some *C. jejuni* isolates. *Dysentery* is generally associated with invasion and only occurs with a small minority of *Campylobacter* strains. *Enteric fever* occurs when bacteria proliferate within the lamina propria and mesenteric lymph nodes.

Campylobacter infection can result in reactive arthritis, primarily in patients with HLA-B27. Other extra-intestinal complications, including erythema nodosum and Guillain-Barré syndrome, a flaccid paralysis caused by autoimmune-induced inflammation of peripheral nerves, are not HLA-linked.[62] Molecular mimicry has been implicated in the pathogenesis of Guillain-Barré syndrome, as serum antibodies to *C. jejuni* lipopolysaccharide cross-react with peripheral and central nervous system gangliosides. Moreover, 15% to 50% of individuals with Guillain-Barré syndrome have positive stool cultures or circulating antibodies to *Campylobacter*.[63] Fortunately, Guillain-Barré syndrome develops in 0.1% or less of those infected with *Campylobacter*.

Morphology. *Campylobacter* are comma-shaped, flagellated, Gram-negative organisms. Diagnosis is primarily by stool culture, since biopsy findings are nonspecific, and reveal **acute self-limited colitis** with features common to many forms of infectious colitis.[64] Mucosal and intraepithelial neutrophil infiltrates are prominent, particularly within the superficial mucosa (Fig. 17-28A); **cryptitis** (neutrophil infiltration of the crypts) and **crypt abscesses** (crypts with accumulations of luminal

neutrophils) may also be present. Importantly, crypt architecture is preserved (Fig. 17-28D), although this can be difficult to assess in cases with severe mucosal damage.

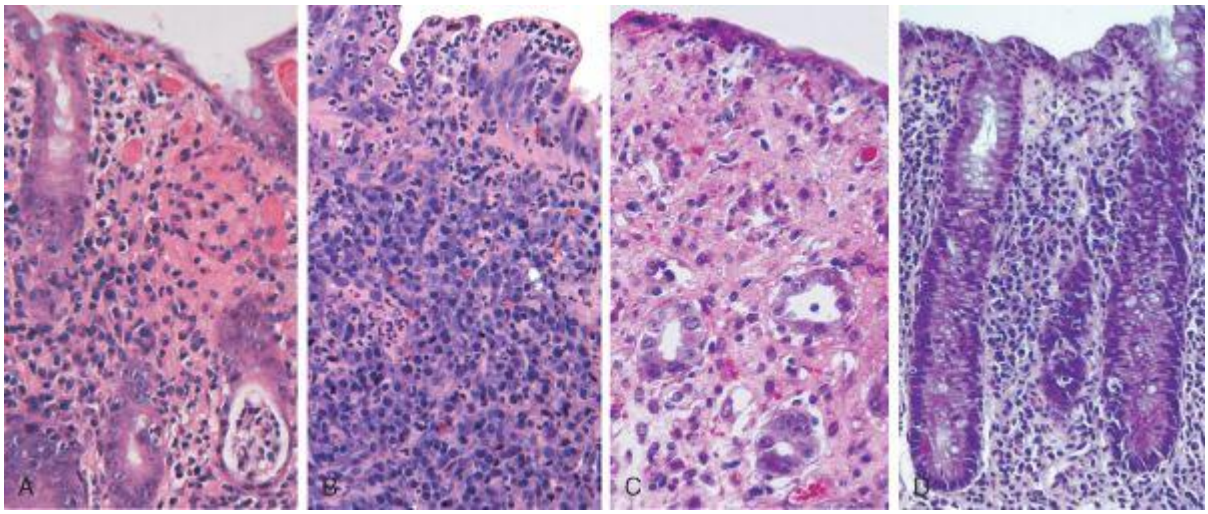

FIGURE 17-28 Bacterial enterocolitis. **A**, *Campylobacter jejuni* infection produces acute, self-limited colitis. Neutrophils can be seen within surface and crypt epithelium and a crypt abscess is present at the *lower right*. **B**, In *Yersinia* infection the surface epithelium can be eroded by neutrophils and the lamina propria is densely infiltrated by sheets of plasma cells admixed with lymphocytes and neutrophils. **C**, Enterohemorrhagic *E. coli* O157:H7 results in an ischemia-like morphology with surface atrophy and erosion. **D**, Enteroinvasive *E. coli* infection is a similar to other acute, self-limited colitides. Note the maintenance of normal crypt architecture and spacing, despite abundant intraepithelial neutrophils.

Clinical Features.

Ingestion of as few as 500 *C. jejuni* organisms can cause disease after an incubation period of up to 8 days. Watery diarrhea, either acute or following an influenza-like prodrome, is the primary symptom, and dysentery develops in 15% of patients. Patients may shed bacteria for 1 month or more after clinical resolution. Antibiotic therapy is generally not required.

SHIGELLOSIS

Shigella are Gram-negative bacilli that were initially isolated during the Japanese red diarrhea epidemic of 1897. Four major strains are now recognized. *Shigella* are unencapsulated, nonmotile, facultative anaerobes that belong to the Enterobacteriaceae and are closely related to *enteroinvasive E. coli*. Although humans are the only known reservoir, *Shigella* spp. remain one of the most common causes of bloody diarrhea. It is estimated that 165 million cases occur worldwide each year.[65] Given the *infective dose of fewer than several hundred organisms* and the presence of as many as 10^9 organisms in each gram of stool during acute disease, *Shigella* are highly transmissible by the fecal-oral route or via contaminated water and food.

In the United States and Europe, children in daycare centers, migrant workers, travelers to developing countries, and those in nursing homes are most commonly affected.[66,][67] Most *Shigella* infections and deaths occur in children under 5 years of age, and in countries where *Shigella* is endemic it is responsible for approximately 10% of all pediatric diarrheal disease and as many as 75% of diarrheal deaths.[65,][68]

Pathogenesis.

Shigella are resistant to the harsh acidic environment of the stomach, which translates into an extremely low infective dose. Once in the intestine, organisms are taken up by M, or microfold, epithelial cells, which are specialized for sampling and presentation of luminal antigens. *Shigella* proliferate intracellularly, escape into the lamina propria, and are phagocytosed by macrophages, in which they induce apoptosis. The ensuing inflammatory process damages surface epithelia and allows *Shigella* within the intestinal lumen to gain access to the colonocyte basolateral membrane, which is the only surface through which infection can occur in epithelial cells (other than M cells). All *Shigella* spp. carry virulence plasmids, some of which encode a type III secretion system capable of directly injecting bacterial proteins into the host cytoplasm. *S. dysenteriae* serotype 1 also release the Shiga toxin Stx, which inhibits eukaryotic protein synthesis resulting in host cell damage and death.[69]

Morphology. *Shigella* infections are most prominent in the left colon, but the ileum may also be involved, perhaps reflecting the abundance of M cells in the dome epithelium over the Peyer's patches. The mucosa is hemorrhagic and ulcerated, and pseudomembranes may be present. The histology of early cases is similar to other acute self-limited colitides, such as *Campylobacter* colitis, but because of the tropism for M cells, aphthous-appearing ulcers similar to those seen in Crohn disease may occur. The potential for confusion with chronic inflammatory bowel disease is significant, particularly if there is distortion of crypt architecture.

Clinical Features.

After an incubation period of as long as 4 days, *Shigella* causes self-limited disease characterized by about 6 days of diarrhea, fever, and abdominal pain. The initially watery diarrhea progresses to a dysenteric phase in approximately 50% of patients, and constitutional symptoms can persist for as long as 1 month. The subacute presentation that develops in a minority of adults is characterized by several weeks of waxing and waning diarrhea that can mimic new-onset ulcerative colitis.[68] While duration is typically shorter in children, severity is often much greater. Confirmation of *Shigella* infection requires stool culture.

Complications of *Shigella* infection are uncommon and include *Reiter syndrome*, a triad of sterile arthritis, urethritis, and conjunctivitis that preferentially affects HLA-B27-positive men between 20 and 40 years of age. Hemolytic-uremic syndrome, which is typically associated with *enterohemorrhagic E. coli* (EHEC), may also occur after infection with *S. dysenteriae* serotype 1 that secrete Shiga toxin [69] [70] [71]; only *Shigella* organisms that secrete the toxin are associated with hemolytic-uremic syndrome (Chapter 20). Antibiotic treatment shortens the clinical course and reduces the duration over which organisms are shed in the stool, but antidiarrheal medications are contraindicated because they can prolong symptoms and delay *Shigella* clearance.

SALMONELLOSIS

Salmonella, which are classified within the Enterobacteriaceae family of Gram-negative bacilli, are divided into *Salmonella typhi*, the causative agent of typhoid fever (discussed in the next section) and nontyphoid *Salmonella*. Nontyphoid *Salmonella* infection is usually due to *S. enteritidis;* more than 1 million cases occur each year in the United States, and the prevalence is even greater in other countries. Infection is most common in young children and the elderly, with peak incidence in summer and fall. Transmission is usually through contaminated food, particularly raw or undercooked meat, poultry, eggs, and milk.

Pathogenesis.

Very few viable *Salmonella* are necessary to cause infection, and the absence of gastric acid, as in individuals with atrophic gastritis or those on acid-suppressive therapy, further reduces the required inoculum. *Salmonella* possess *virulence genes that encode a type III secretion system* capable of transferring bacterial proteins into M cells and enterocytes. The transferred proteins activate host cell Rho GTPases, thereby triggering actin rearrangement and bacterial uptake that allow bacterial growth within phagosomes. In addition, *flagellin*, the core protein of bacterial flagellae, activates TLR5 on host cells and increases the local inflammatory response.[72] Similarly, bacterial *lipopolysaccharide* activates TLR4, although some *Salmonella* strains express a virulence factor that prevents TLR4 activation from occurring. *Salmonella* also secrete a molecule that induces epithelial release of the eicosanoid hepoxilin A3, thereby drawing neutrophils into the intestinal lumen and potentiating mucosal damage.[73] Mucosal T_H17 immune responses limit infection to the colon.

Morphology. The gross and microscopic features of *Salmonella* enteritis are non-specific and are similar to the acute self-limited colitis of *Campylobacter* and *Shigella*. Stool cultures are essential for diagnosis.

Clinical Features.

Salmonella infections are clinically indistinguishable from those caused by other enteric pathogens, and symptoms range from loose stools to cholera-like profuse diarrhea to dysentery. Fever often resolves within 2 days, but diarrhea can persist for a week and organisms can be shed in the stool for several weeks after resolution. Antibiotic therapy is not recommended in most cases, because it can prolong the carrier state or even cause relapse and does not typically shorten the duration of diarrhea.[74] Most *Salmonella* infections are self-limited, but deaths do occur. The risk of severe illness and complications is increased in patients with malignancies, immunosuppression, alcoholism, cardiovascular dysfunction, sickle cell disease, and hemolytic anemia.

TYPHOID FEVER

Typhoid fever, also referred to as *enteric fever*, is caused by *Salmonella typhi* and *Salmonella paratyphi*. It affects up to 30 million individuals worldwide each year. The majority of cases in endemic countries are due to *S. typhi*, while infection by *S. paratyphi* is more common among travelers,[75] perhaps because travelers tend to be vaccinated against *S. typhi* (there are no effective *S. paratyphi* vaccines). In endemic areas children and adolescents are affected most often, but there is no age preference in developed countries. Infection is strongly associated with travel to India, Mexico, the Philippines, Pakistan, El Salvador, and Haiti.[76] Like *Shigella*, humans are the sole reservoir for *S. typhi* and *S. paratyphi* and transmission occurs from person to person or via food or contaminated water. Gallbladder colonization with *S. typhi* or *S. paratyphi* may be associated with gallstones and the chronic carrier state.

Pathogenesis.

S. typhi are able to survive in gastric acid and, once in the small intestine, are taken up by and invade M cells. Organisms are then engulfed by mononuclear cells in the underlying lymphoid tissue. Unlike *S. enteritidis*, *S. typhi* can then disseminate via lymphatic and blood vessels. This causes reactive hyperplasia of phagocytes and lymphoid tissues throughout the body.

Morphology. Infection causes Peyer's patches in the terminal ileum to enlarge into sharply delineated, plateau-like elevations up to 8 cm in diameter. Draining mesenteric lymph nodes are also

enlarged. Neutrophils accumulate within the superficial lamina propria, and macrophages containing bacteria, red blood cells, and nuclear debris mix with lymphocytes and plasma cells in the lamina propria. Mucosal shedding creates **oval ulcers, oriented along the axis of the ileum**, that may perforate. The draining lymph nodes also harbor organisms and are enlarged due to phagocyte accumulation.

The spleen is enlarged and soft, with uniformly pale red pulp, obliterated follicular markings, and prominent phagocyte hyperplasia. The liver shows small, randomly scattered foci of parenchymal necrosis in which hepatocytes are replaced by macrophage aggregates, called **typhoid nodules**, that may also develop in the bone marrow and lymph nodes.

Clinical Features.

Patients experience anorexia, abdominal pain, bloating, nausea, vomiting, and bloody diarrhea followed by a short asymptomatic phase that gives way to bacteremia and fever with flu-like symptoms.[77] *Blood cultures are positive in more than 90% of affected individuals during the febrile phase*, which may prompt antibiotic treatment and prevent further disease progression.[76] In patients who do not receive treatment the febrile phase is followed by up to 2 weeks of sustained high fevers and abdominal tenderness that may mimic appendicitis. *Rose spots*, small erythematous maculopapular lesions, are seen on the chest and abdomen.[77] Symptoms abate after several weeks in those who survive, although relapse can occur.[77] Systemic dissemination may cause *extra-intestinal complications* including encephalopathy, meningitis, seizures, endocarditis, myocarditis, pneumonia, and cholecystitis. Patients with sickle cell disease are particularly susceptible to *Salmonella* osteomyelitis.

YERSINIA

Three *Yersinia* species are human pathogens. *Y. enterocolitica* and *Y. pseudotuberculosis* cause GI disease and are discussed here; *Y. pestis*, the agent of pulmonic and bubonic plague, is discussed in Chapter 8 . GI *Yersinia* infections are more common in Europe than North America and are most frequently linked to ingestion of pork, raw milk, and contaminated water. *Y. enterocolitica* is far more common than *Y. pseudotuberculosis*, and infections tend to cluster in the winter, possibly related to inadequately cooked foods served at holiday gatherings.

Pathogenesis.

Yersinia invade M cells and use bacterial adhesion proteins, *adhesins*, to bind to host cell β1 integrins. A pathogenicity island encodes an iron uptake system that mediates iron capture and transport; similar iron transport systems are also present in *E. coli*, *Klebsiella*, *Salmonella*, and enterobacteria. In *Yersinia*, iron enhances virulence and stimulates systemic dissemination, explaining why individuals with hemolytic anemia or hemochromatosis are more likely to develop sepsis and are at greater risk of death.[78]

Morphology. *Yersinia* infections preferentially involve the ileum, appendix, and right colon (Fig. 17-28B). The organisms multiply extracellularly in lymphoid tissue, resulting in regional **lymph node and Peyer's patch hyperplasia** and bowel wall thickening.[79] The mucosa overlying lymphoid tissue may become hemorrhagic, and aphthous-appearing ulcers may develop, along with neutrophil infiltrates (see Fig. 17-28B) and granulomas, increasing the potential for diagnostic confusion with Crohn disease.

Clinical Features.

People infected with *Yersinia* generally present with abdominal pain, but fever and diarrhea may also occur. Nausea, vomiting, and abdominal tenderness are common, and Peyer's patch invasion with subsequent involvement of regional lymphatics can mimic acute appendicitis in teenagers and young adults. Enteritis and colitis predominate in younger children. *Extra-intestinal symptoms of pharyngitis, arthralgia, and erythema nodosum* occur frequently. *Yersinia* can be detected in stool cultures on *Yersinia*-selective agar or, in cases with extra-intestinal disease, cultures of lymph nodes or blood.[80] Postinfectious complications, including sterile arthritis, Reiter syndrome, myocarditis, glomerulonephritis, and thyroiditis, have been reported.

ESCHERICHIA COLI

Escherichia coli are Gram-negative bacilli that colonize the healthy GI tract; most are nonpathogeneic, but a subset cause human disease. The latter are classified according to morphology, mechanism of pathogenesis, and in vitro behavior. Subgroups with major clinical relevance include enterotoxigenic *E. coli* (ETEC), enterohemorrhagic *E. coli* (EHEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli* (EAEC).

Enterotoxigenic *E. Coli.*

ETEC organisms are the principal cause of traveler's diarrhea and spread via contaminated food or water. Infection is common in underdeveloped regions, and children younger than 2 years of age are particularly susceptible. ETEC produce heat-labile toxin (LT) and heat-stable toxin (ST), and both induce chloride and water secretion while inhibiting intestinal fluid absorption. The LT toxin is similar to cholera toxin and activates adenylate cyclase, resulting in increased intracellular cAMP. This stimulates chloride secretion and, simultaneously, inhibits absorption. ST toxins, which have homology to the mammalian regulatory protein guanylin, bind to guanylate cyclase and increase intracellular cGMP with resulting effects on transport that are similar to those produced by LT. Like cholera, the histopathology induced by ETEC infection is limited. Clinical symptoms include secretory, noninflammatory diarrhea, dehydration, and, in severe cases, shock.

Enterohemorrhagic *E. Coli.*

EHEC are categorized as *E. coli* O157:H7 and non-O157:H7 serotypes. Large outbreaks of *E. coli* O157:H7 in developed countries have been associated with the consumption of inadequately cooked ground beef, sometimes from fast-food establishments. Contaminated milk and vegetables are also vehicles for infection. Both O157:H7 and non-O157:H7 serotypes produce Shiga-like toxins, and the morphology (see Fig. 17-28C) and clinical symptoms are thus similar to *S. dysenteriae*. O157:H7 strains of EHEC are more likely than non-O157:H7 serotypes to cause large outbreaks, bloody diarrhea, and hemolytic-uremic syndrome.

Enteroinvasive *E. Coli.*

EIEC organisms are bacteriologically similar to *Shigella* and are transmitted via food, water, or by person-to-person contact. While EIEC do not produce toxins, they invade epithelial cells and cause nonspecific features of acute self-limited colitis (see Fig. 17-28D). EIEC infections are most common among young children in developing countries and are occasionally associated with outbreaks in developed countries.

Enteroaggregative *E. Coli.*

EAEC organisms were identified on the basis of their unique pattern of adherence to epithelial cells. These organisms are now recognized as a cause of diarrhea in children and adults in developed as well as developing countries. These can also be a cause of traveler's diarrhea.[81] EAEC attach to enterocytes

via *adherence fimbriae* and are aided by *dispersin*, a bacterial surface protein that neutralizes the negative surface charge of lipopolysaccharide. While the bacteria do produce enterotoxins related to *Shigella* enterotoxin and ETEC ST toxin, histologic damage is minimal and the characteristic adherence lesions are only visible by electron microscopy.[82] EAEC organisms cause nonbloody diarrhea that may be prolonged in individuals with the acquired immunodeficiency syndrome (AIDS).

PSEUDOMEMBRANOUS COLITIS

Pseudomembranous colitis, generally caused by *Clostridium difficile*, is also known as antibiotic-associated colitis or antibiotic-associated diarrhea. The latter terms apply to diarrhea developing during or after a course of antibiotic therapy and may be due to *C. difficile* as well as *Salmonella*, *C. perfringens* type A, or *Staphylococcus aureus*. The latter two organisms produce enterotoxins and are common agents of food poisoning.

Pathogenesis.

It is likely that disruption of the normal colonic flora by antibiotics allows *C. difficile* overgrowth. Although almost any antibiotic may be responsible, third-generation cephalosporins are implicated most frequently. Immunosuppression is also a predisposing factor for *C. difficile* colitis. Toxins released by *C. difficile* cause the ribosylation of small GTPases, such as Rho, and lead to disruption of the epithelial cytoskeleton, tight junction barrier loss, cytokine release, and apoptosis.[83] The mechanisms by which these processes lead to the characteristic morphology of pseudomembranous colitis are incompletely understood.

Morphology. Fully developed *C. difficile*–associated colitis is accompanied by formation of **pseudomembranes** (Fig. 17-29A , B), made up of an adherent layer of inflammatory cells and debris at sites of colonic mucosal injury. While pseudomembranes are not specific and may occur in ischemia and necrotizing infections, the histopathology of *C. difficile*–associated colitis is striking. The surface epithelium is denuded, and the superficial lamina propria contains a dense infiltrate of neutrophils and occasional fibrin thrombi within capillaries. Superficially damaged crypts are distended by a mucopurulent exudate that forms an **eruption reminiscent of a volcano** (Fig. 17-29C). These exudates coalesce to form the pseudomembranes.

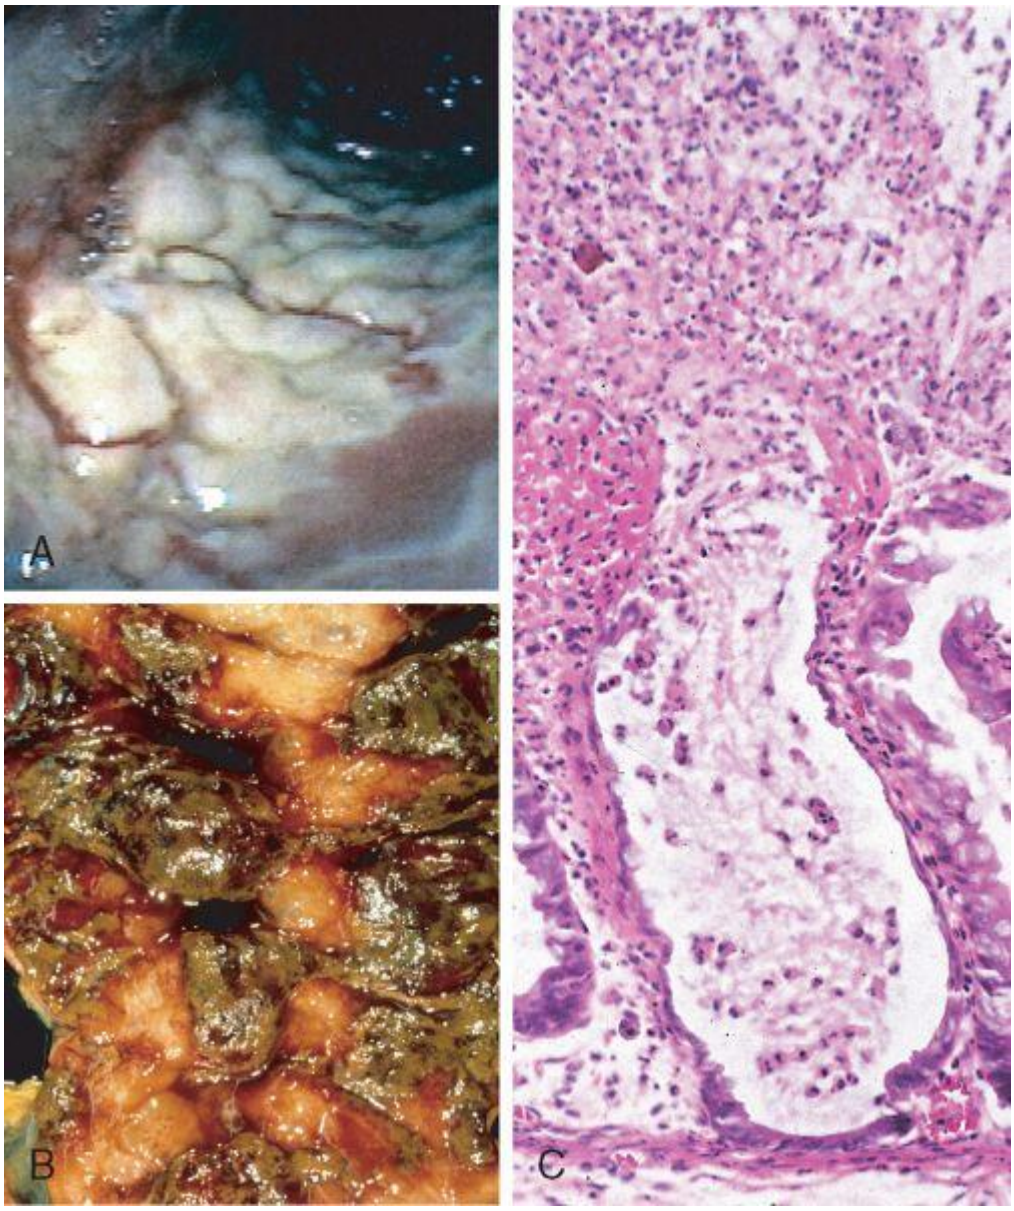

FIGURE 17-29 *Clostridium difficile* colitis. **A**, The colon is coated by tan pseudomembranes composed of neutrophils, dead epithelial cells, and inflammatory debris (endoscopic view). **B**, Pseudomembranes are easily appreciated on gross examination. **C**, Typical pattern of neutrophils emanating from a crypt is reminiscent of a volcanic eruption.

Clinical Features.

Risk factors for *C. difficile*–associated colitis include advanced age, hospitalization, and antibiotic treatment. The organism is particularly prevalent in hospitals; as many as 30% of hospitalized adults are colonized with *C. difficile* (a rate tenfold greater than the general population), but most colonized patients are free of disease. Individuals with *C. difficile*–associated colitis present with fever, leukocytosis, abdominal pain, cramps, hypoalbuminemia, watery diarrhea, and dehydration. Fecal leukocytes and occult blood may be present, but grossly bloody diarrhea is rare. Diagnosis of *C. difficile*–associated colitis is usually accomplished by detection of *C. difficile* toxin, rather than culture, and is supported by the characteristic histopathology. Metronidazole or vancomycin are generally

effective therapies, but antibiotic-resistant and hypervirulent *C. difficile* strains as well as recurrent disease are increasingly common.[84]

WHIPPLE DISEASE

Whipple disease is a rare, multivisceral chronic disease first described as intestinal lipodystrophy in 1907 by George Hoyt Whipple. A mere 27 years later the pathologist went on to win the Nobel Prize for his work on pernicious anemia. He was a contemporary, but not a relative, of Allen Oldfather Whipple, the surgeon who pioneered the pancreatoduodenectomy.

Pathogenesis.

Whipple's original case report described an individual with malabsorption, lymphadenopathy, and arthritis of undefined origin. Postmortem examination demonstrated the presence of foamy macrophages and large numbers of argyrophilic rods in the lymph nodes, providing evidence that the disease was infectious.[85] The Gram-positive actinomycete, named *Tropheryma whippelii*, that is responsible for Whipple disease was identified by PCR in 1992 and finally cultured in 2000.[86] Clinical symptoms occur because organism-laden macrophages accumulate within the small intestinal lamina propria and mesenteric lymph nodes, causing lymphatic obstruction. Thus, the *malabsorptive diarrhea* of Whipple disease is due to *impaired lymphatic transport*.

Morphology. The morphologic hallmark of Whipple disease is a dense accumulation of **distended, foamy macrophages** in the small intestinal lamina propria (Fig. 17-30A). The macrophages contain periodic acid–Schiff (PAS)-positive, diastase-resistant granules that represent lysosomes stuffed with partially digested bacteria (Fig. 17-30B). Intact rod-shaped bacilli can also be identified by electron microscopy (Fig. 17-30C). A similar infiltrate of foamy macrophages is present in intestinal tuberculosis (Fig. 17-30D), and in both diseases the organisms are PAS-positive. However, the acid-fast stain can be used to distinguish between these, since mycobacteria stain positively (Fig. 17-30E) while *T. whippelii* do not.

The **villous expansion** caused by the dense macrophage infiltrate imparts a shaggy gross appearance to the mucosal surface. Lymphatic dilatation and mucosal lipid deposition account for the common endoscopic detection of white to yellow mucosal plaques. In Whipple disease, bacteria-laden macrophages can accumulate within **mesenteric lymph nodes, synovial membranes of affected joints, cardiac valves, the brain**, and other sites.

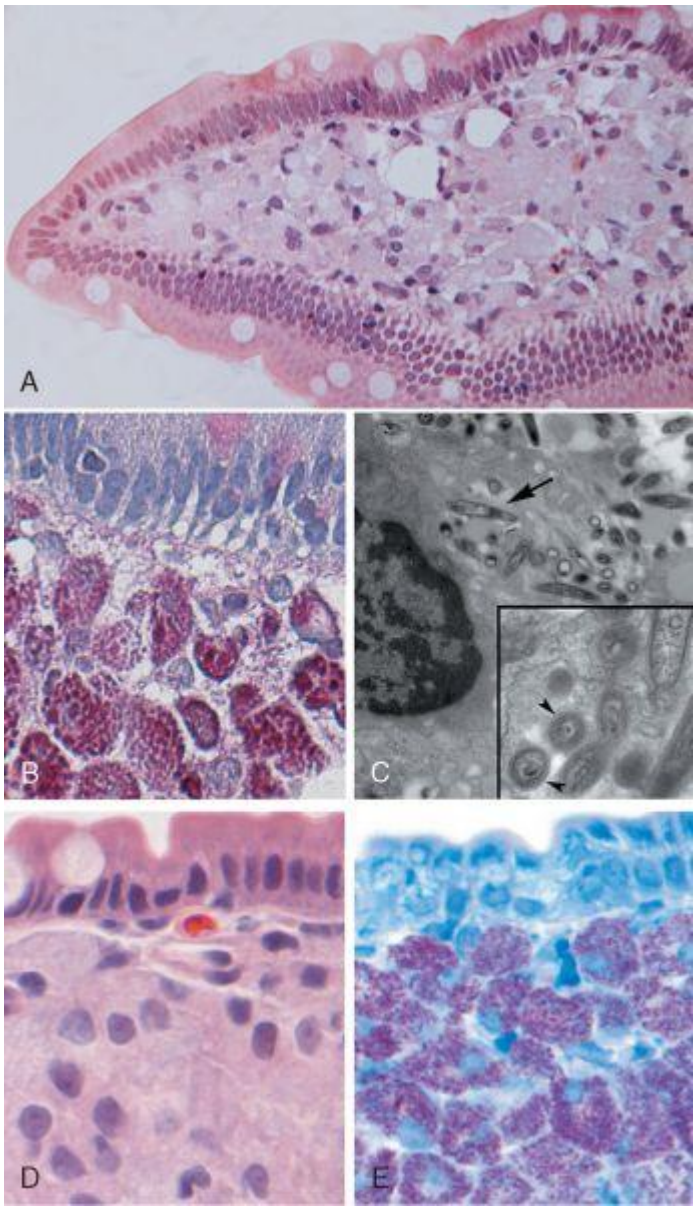

FIGURE 17-30 Whipple disease and mycobacterial infection. **A**, H&E staining shows effacement of normal lamina propria by a sheet of swollen macrophages. **B**, PAS stain highlights macrophage lysosomes full of bacilli. Note the positive staining of mucous vacuoles in the overlying goblet cells. **C**, An electron micrograph of one lamina propria macrophage shows these bacilli within the cell *(top)* and at higher magnification *(inset)*. **D**, The morphology of mycobacterial infection can be similar to Whipple disease, particularly in the immunocompromised host. Compare with **A**. **E**, Mycobacteria are positive with stains for acid-fast bacteria. ***(C**, Courtesy of George Kasnic and Dr. William Clapp, University of Florida, Gainesville, FL.)*

The clinical presentation of Whipple disease is usually a triad of *diarrhea, weight loss, and malabsorption*. Extraintestinal symptoms, which can exist for months or years before malabsorption, include arthritis, arthralgia, fever, lymphadenopathy, and neurologic, cardiac, or pulmonary disease.

Mycobacterial infections are considered in detail in Chapter 8 .

VIRAL GASTROENTERITIS

Symptomatic human infection is caused by several distinct groups of viruses. The most common are discussed here.

Norovirus.

This was previously known as *norwalk-like virus* and is a common cause of nonbacterial infectious gastroenteritis.[87] These are small icosahedral viruses with a single-stranded RNA genome that forms a genus within the Caliciviridae family. *Norovirus causes approximately half of all gastroenteritis outbreaks worldwide and is a common cause of sporadic gastroenteritis in developed countries*. Local outbreaks are usually related to contaminated food or water, but person-to-person transmission underlies most sporadic cases. Infections spread easily within schools, hospitals, nursing homes, and, most recently, cruise ships. Following a short incubation period, affected individuals develop nausea, vomiting, watery diarrhea, and abdominal pain. Biopsy morphology is nonspecific. When detected, abnormalities are most evident in the small intestine and include mild villous shortening, epithelial vacuolization, loss of the microvillus brush border, crypt hypertrophy, and lamina propria infiltration by lymphocytes (Fig. 17-31A). The disease is self-limited.

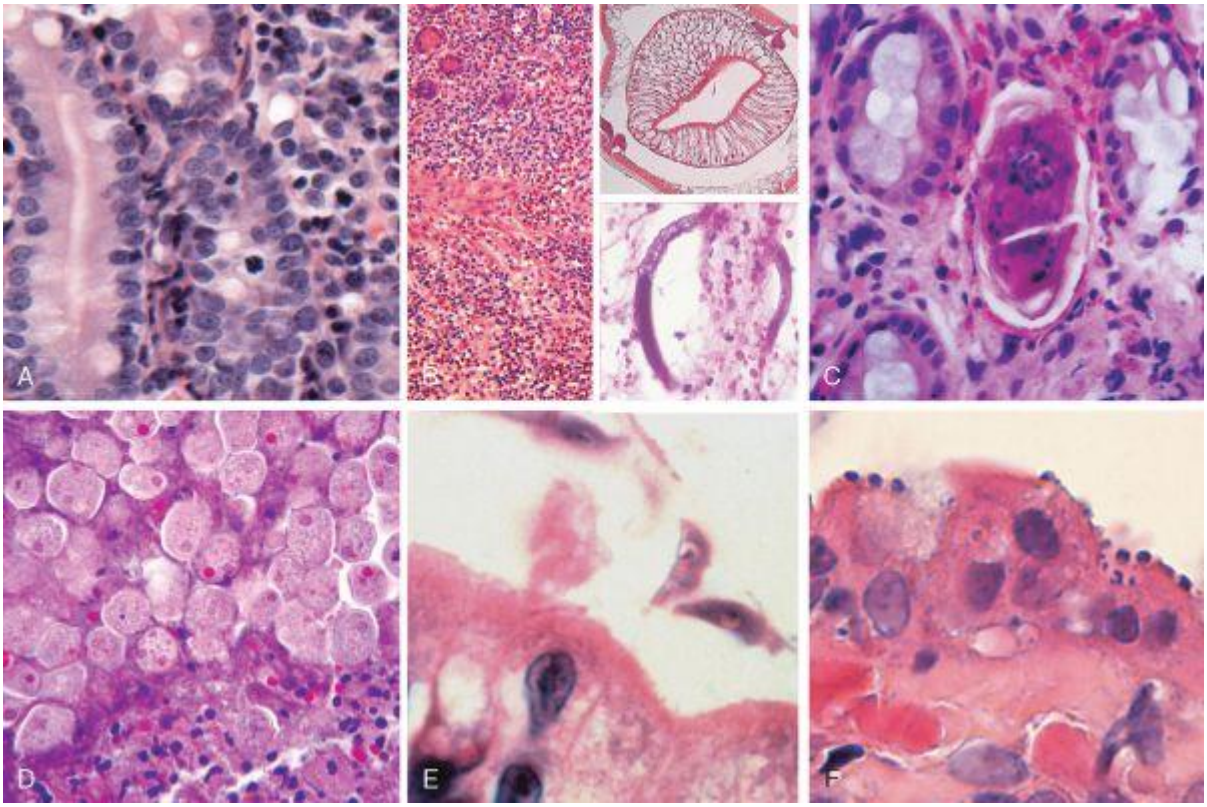

FIGURE 17-31 Infectious enteritis. **A**, Histologic features of viral enteritis include increased numbers of intraepithelial and lamina propria lymphocytes and crypt hypertrophy. **B**, Diffuse eosinophilic infiltrates in parasitic infection. This case was caused by *Ascaris (upper inset)*, but a similar tissue reaction could be caused by *Strongyloides (lower inset)*. **C**, Schistosomiasis can induce an inflammatory reaction to eggs trapped within the lamina propria. **D**, *Entamoeba histolytica* in a colon biopsy specimen. Note some organisms ingesting red blood cells. **E**, *Giardia lamblia*, which are present in the luminal space over nearly normal-appearing villi, are easily overlooked. **F**, *Cryptosporidia* organisms are seen as small blue spheres that appear to lay on top of the brush border but are actually enveloped by a thin layer of host cell cytoplasm.

Rotavirus.

This encapsulated virus with a segmented double-stranded RNA genome infects 140 million people and causes 1 million deaths each year, making rotavirus *the most common cause of severe childhood*

diarrhea and diarrheal mortality worldwide. Children between 6 and 24 months of age are most vulnerable. Protection in the first 6 months of life is probably due to the presence of antibodies to rotavirus in breast milk, while protection beyond 2 years is due to immunity that develops following the first infection.[88] Outbreaks in hospitals and daycare centers are common, and infection spreads easily; the estimated minimal infective inoculum is only 10 viral particles. *Rotavirus selectively infects and destroys mature enterocytes in the small intestine, and the villus surface is repopulated by immature secretory cells*. This results in loss of absorptive function and net secretion of water and electrolytes that is compounded by an osmotic diarrhea from incompletely absorbed nutrients. Like norovirus, rotavirus has a short incubation period followed by several days of vomiting and watery diarrhea. Vaccines are now available, and their use will probably change the epidemiology of rotavirus infection.

Adenovirus.

The second most common cause of pediatric diarrhea (after rotavirus), adenovirus also affects immunocompromised patients.[89] Small intestinal biopsy specimens can show epithelial degeneration but more often exhibit nonspecific villous atrophy and compensatory crypt hyperplasia. Viral nuclear inclusions are uncommon. Disease typically presents after an incubation period of 1 week with nonspecific symptoms that include diarrhea, vomiting, and abdominal pain. Fever and weight loss may also be present. Symptoms generally resolve within 10 days.

PARASITIC ENTEROCOLITIS

Although viruses and bacteria are the predominant enteric pathogens in the United States, parasitic disease and protozoal infections affect over one half of the world's population on a chronic or recurrent basis. The small intestine can harbor as many as 20 species of parasites, including nematodes, such as the roundworms *Ascaris* and *Strongyloides;* hookworms and pinworms; cestodes, including flatworms and tapeworms; trematodes, or flukes; and protozoa. Parasitic infections are covered in Chapter 8 , and we will briefly discuss only those that are common in the intestinal tract.

Ascaris lumbricoides.

This nematode infects over a billion individuals worldwide as a result of human fecal-oral contamination. Ingested eggs hatch in the intestine and larvae penetrate the intestinal mucosa, but disease is caused when larvae migrate from the splanchnic circulation to the systemic circulation and create hepatic abscess or *Ascaris* pneumonitis. In the latter case, larvae migrate up the trachea, are swallowed, and arrive again in the intestine to mature into adult worms. Adult worm masses induce an eosinophil-rich inflammatory reaction (Fig. 17-31B) that can physically obstruct the intestine or biliary tree. Diagnosis is usually made by detection of eggs in stool samples.

Strongyloides.

The larvae of *Strongyloides* live in fecally contaminated ground soil and can penetrate unbroken skin. They migrate through the lungs, where they induce inflammatory infiltrates, and then reside in the intestine while maturing into adult worms. Unlike other intestinal worms, which require an ova or larval stage outside the human, the eggs of *Strongyloides* can hatch within the intestine and release larvae that penetrate the mucosa, causing autoinfection (see Fig. 17-31B). Hence, *Strongyloides* infection can persist for life, and immunosuppressed individuals can develop overwhelming autoinfection. *Strongyloides* incite a strong tissue reaction and induce peripheral eosinophilia.

Necator duodenale and Ancylostoma duodenale.

These hookworms infect 1 billion people worldwide and cause significant morbidity. Infection is initiated by larval penetration through the skin and, after further development in the lungs the larvae

migrate up the trachea and are swallowed. Once in the duodenum the worms attach to the mucosa, suck blood, and reproduce. This causes multiple superficial erosions, focal hemorrhage, and inflammatory infiltrates and, in chronic infection, iron deficiency anemia. Diagnosis can be made by detection of the eggs in fecal smears.

Enterobius vermicularis.

Also known as pinworms, these parasites infect people in industrialized and developing countries; in the United States more than 60 million people have pinworms. Because they do not invade host tissue and live their entire life within the intestinal lumen, they rarely cause serious illness. Infection by *E. vermicularis*, or enterobiasis, is primarily by the fecal-oral route. Adult worms living in the intestine migrate to the anal orifice at night, where the female deposits eggs on the perirectal mucosa. The eggs cause intense irritation. Rectal and perineal pruritus ensues and leads to contamination of the fingers, which promotes human-to-human transmission. Both eggs and adult pinworms remain viable outside the body, and repeat infection is common. Diagnosis can be made by applying cellophane tape to the perianal skin and examining the tape for eggs under a microscope.

Trichuris trichiura.

Whipworms primarily infect young children. Similar to *E. vermicularis*, *Trichuris trichiura* does not penetrate the intestinal mucosa and rarely cause serious disease. Heavy infections, however, may cause bloody diarrhea and rectal prolapse.

Schistosomiasis.

This disease involving the intestines most commonly takes the form of adult worms residing within the mesenteric veins. Symptoms of intestinal schistosomiasis are caused by trapping of eggs within the mucosa and submucosa (Fig. 17-31C). The resulting immune reaction is often granulomatous and can cause bleeding and even obstruction. More details are presented in Chapter 8 .

Intestinal cestodes.

The three primary species of cestodes that affect humans are *Diphyllobothrium latum*, fish tapeworms; *Taenia solium*, pork tapeworms; and *Hymenolepsis nana*, dwarf tapeworms. They reside exclusively within the intestinal lumen and are transmitted by ingestion of raw or undercooked fish, meat, or pork that contain encysted larvae. Release of the larvae allows attachment to the intestinal mucosa through its head, or scolex. The worm derives its nutrients from the food stream and enlarges by formation of egg-filled segments termed *proglottids*. Humans are usually infected by a single worm, and, since the worm does not penetrate the intestinal mucosa, peripheral eosinophilia does not generally occur. Nevertheless, the parasite burden can be staggering, since adult worms can grow to many meters in length. Large numbers of proglottids or individual eggs are shed in the feces. Clinical symptoms include abdominal pain, diarrhea, and nausea. Diagnosis is established by stool examination.

Entamoeba histolytica.

This protozoan that causes amebiasis is spread by fecal-oral transmission. *E. histolytica* infects approximately 500 million people in developing countries such as India, Mexico, and Colombia, and causes 40 million cases of dysentery and liver abscess annually. *E. histolytica* cysts, which have a chitin wall and four nuclei, are resistant to gastric acid, a characteristic that allows them to pass through the stomach without harm. Cysts then colonize the epithelial surface of the colon and release *trophozoites*, ameboid forms that reproduce under anaerobic conditions.

Amebiasis is seen most frequently in the cecum and ascending colon, although the sigmoid colon, rectum, and appendix can also be involved. Dysentery develops when the amebae attach to the colonic epithelium, induce apoptosis, invade crypts, and burrow laterally into the lamina propria. This recruits neutrophils, causes tissue damage, and creates a *flask-shaped ulcer* with a narrow neck and broad base. Histologic diagnosis can be difficult, since amebae are similar to macrophages in size and general appearance (see Fig. 17-31D). Parasites may penetrate splanchnic vessels and embolize to the liver to produce abscesses in about 40% of patients with amebic dysentery. *Amebic liver abscesses*, which can exceed 10 cm in diameter, have a scant inflammatory reaction at their margins and a shaggy fibrin lining. The abscesses persist after the acute intestinal illness has passed and may, rarely, reach the lung and the heart by direct extension from the liver. Amebae may also spread via the bloodstream into the kidneys and brain.

Individuals with amebiasis may present with abdominal pain, bloody diarrhea, or weight loss. Occasionally, acute necrotizing colitis and megacolon occur, and both are associated with significant mortality. The parasites lack mitochondria or Krebs cycle enzymes and are thus obligate fermenters of glucose. Therefore, metronidazole, which inhibits the enzyme pyruvate oxidoreductase that is required for fermentation, is the most effective treatment.

Giardia lamblia.

These organisms, also referred to as *G. duodenalis* or *G. intestinalis*, were initially described by van Leeuwenhoek, the inventor of the microscope, who discovered the pathogen in his own stool. They are the *most common pathogenic parasitic infection in humans* and are spread by fecally contaminated water or food. Infection may occur after ingestion of as few as 10 cysts. Because cysts are resistant to chlorine, *Giardia* are endemic in unfiltered public water supplies. They are commonly present in rural streams, explaining infection in campers who use these as a water source. Infection may also occur by the fecal-oral route and, because the cysts are stable, they may be accidentally swallowed while swimming in contaminated water.

Giardia are flagellated protozoans that cause decreased expression of brush-border enzymes, including lactase; microvillous damage; and apoptosis of small intestinal epithelial cells. Secretory IgA and mucosal IL-6 responses are important for clearance of *Giardia* infections, and immunosuppressed, agammaglobulinemic, or malnourished individuals are often severely affected.[90] *Giardia* can evade immune clearance through continuous modification of the major surface antigen, variant surface protein, and can persist for months or years while causing intermittent symptoms.

Giardia trophozoites can be identified in duodenal biopsies by their characteristic pear shape with two nuclei of equal size, each of which contains a complete copy of the genome. Despite large numbers of trophozoites, which are sickle-shaped in profile and tightly bound to the brush border of villous enterocytes, there is no invasion and small intestinal morphology may be normal by light microscopy (see Fig. 17-31E). Villous blunting with increased numbers of intraepithelial lymphocytes and mixed lamina propria inflammatory infiltrates may be present in patients with heavy infections.

Giardiasis may be subclinical or accompanied by acute or chronic diarrhea, malabsorption, and weight loss.[90] Infection is usually documented by *immunofluorescent detection of cysts in stool samples*. Although oral antimicrobial therapy is effective, recurrence is common.

Cryptosporidium.

Like *Giardia, Cryptosporidia* are an important cause of diarrhea worldwide. Cryptosporidiosis was first discovered in the 1980s as an agent of *chronic diarrhea in AIDS patients* and is now recognized as a cause of acute, self-limited disease in immunologically normal hosts. Cryptosporidiosis causes traveler's

diarrhea as well as persistent diarrhea in residents of developing countries. The organisms are present worldwide, with the exception of Antarctica, perhaps because the oocysts are killed by freezing. The oocysts are resistant to chlorine and may, therefore, persist in treated, but unfiltered, water. *Contaminated drinking water continues to be the most common means of transmission*. The largest documented outbreak, a result of inadequate water purification, occurred in 1993 in Milwaukee, Wisconsin, and affected more than 400,000 people. Like giardiasis, cryptosporidiosis can be spread to water sport participants via contaminated water. Food-borne infection occurs less frequently.

Humans are infected by several different *Cryptosporidium* species, including *C. hominis* and *C. parvum*. All are able to go through an entire life cycle, with asexual and sexual reproductive phases, in a single host. The ingested encysted oocyte, of which 10 are sufficient to cause symptomatic infection, is activated by acid in the stomach to produce proteases that allow release of sporozoites from the oocysts. The sporozoites are motile and have a specialized organelle for attachment to the enterocyte brush border, where they induce actin polymerization. This drives extension of the epithelial cell membrane to engulf the parasite and form a vacuole within the microvilli. Sodium malabsorption, chloride secretion, and increased tight junction permeability are responsible for the nonbloody, watery diarrhea that ensues.

Mucosal histology is often only minimally altered, but persistent cryptosporidiosis in children is associated with villous atrophy. Heavy infection in immunosuppressed patients may be associated with villous atrophy, crypt hyperplasia, and variable inflammatory infiltrates. Although the sporozoite is intracellular, it appears, by light microscopy, to sit on top of the epithelial apical membrane (Fig. 17-31F). Organisms are typically most concentrated in the terminal ileum and proximal colon, but can be present throughout the gut, biliary tract, and even the respiratory tract of immunodeficient hosts. Diagnosis is based on finding oocysts in the stool.

3.7.4.6 Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is characterized by chronic, relapsing abdominal pain, bloating, and changes in bowel habits.[91] Despite very real symptoms, the gross and microscopic evaluation is normal in most IBS patients. Thus, the diagnosis depends on clinical symptoms.

Pathogenesis.

The pathogenesis of IBS remains poorly defined, although there is clearly an interplay between psychologic stressors, diet, and abnormal GI motility. Data showing disturbances of intestinal motility and enteric sensory function suggest that impairment of signaling in the brain-gut axis contributes to IBS. A small subgroup of IBS patients also relate onset to a bout of infectious gastroenteritis, suggesting an immune or neuroimmune contribution.

Clinical Features.

The peak prevalence of IBS is between 20 and 40 years of age, and there is a significant female predominance. Variability in diagnostic criteria makes it difficult to establish the incidence, but most authors report a *prevalence in developed countries of between 5% and 10%*. IBS is presently diagnosed using clinical criteria that require the occurrence of abdominal pain or discomfort at least 3 days per month over 3 months, improvement with defecation, and a change in stool frequency or form. Many patients also report fibromyalgia or other chronic pain disorders, visceral hypersensitivity, backache, headache, urinary symptoms, dyspareunia, lethargy, and depression. In those with diarrhea, microscopic colitis, celiac disease, giardiasis, lactose intolerance, small bowel bacterial overgrowth, bile salt malabsorption, *colon cancer*, and *inflammatory bowel disease must be excluded* (although IBS is common in inflammatory bowel disease patients). IBS is not associated with serious long-term sequelae, but affected patients may undergo unnecessary abdominal surgery due to chronic pain and their ability

to function socially may be compromised. The prognosis of IBS is most closely related to symptom duration, with longer duration correlating with reduced likelihood of improvement. Ongoing life stressors also reduce the chance of symptom resolution. Consistent with the uncertain mechanisms of disease, diverse treatments are used including psychotherapy, dietary fiber supplementation, tricyclic antidepressants, selective serotonin reuptake inhibitors, probiotics, and antibiotics. In addition, a chloride channel agonist may provide benefit in a subset of patients whose primary manifestation is constipation.

3.7.4.7 Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a chronic condition resulting from inappropriate mucosal immune activation. The two disorders that comprise IBD are *Crohn disease* and *ulcerative colitis*. Descriptions of ulcerative colitis and Crohn disease date back to antiquity and at least the sixteenth century, respectively, but it took modern bacteriologic techniques to exclude conventional infectious etiologies for these diseases.[92] As will be discussed below, however, commensal bacteria normally present in the intestinal lumen are probably involved in IBD pathogenesis.

The distinction between ulcerative colitis and Crohn disease is based, in large part, on the distribution of affected sites (Fig. 17-32) and the morphologic expression of disease (Table 17-8) at those sites. *Ulcerative colitis is a severe ulcerating inflammatory disease that is limited to the colon and rectum and extends only into the mucosa and submucosa. In contrast, Crohn disease, which has also been referred to as regional enteritis (because of frequent ileal involvement) may involve any area of the GI tract and is typically transmural*.

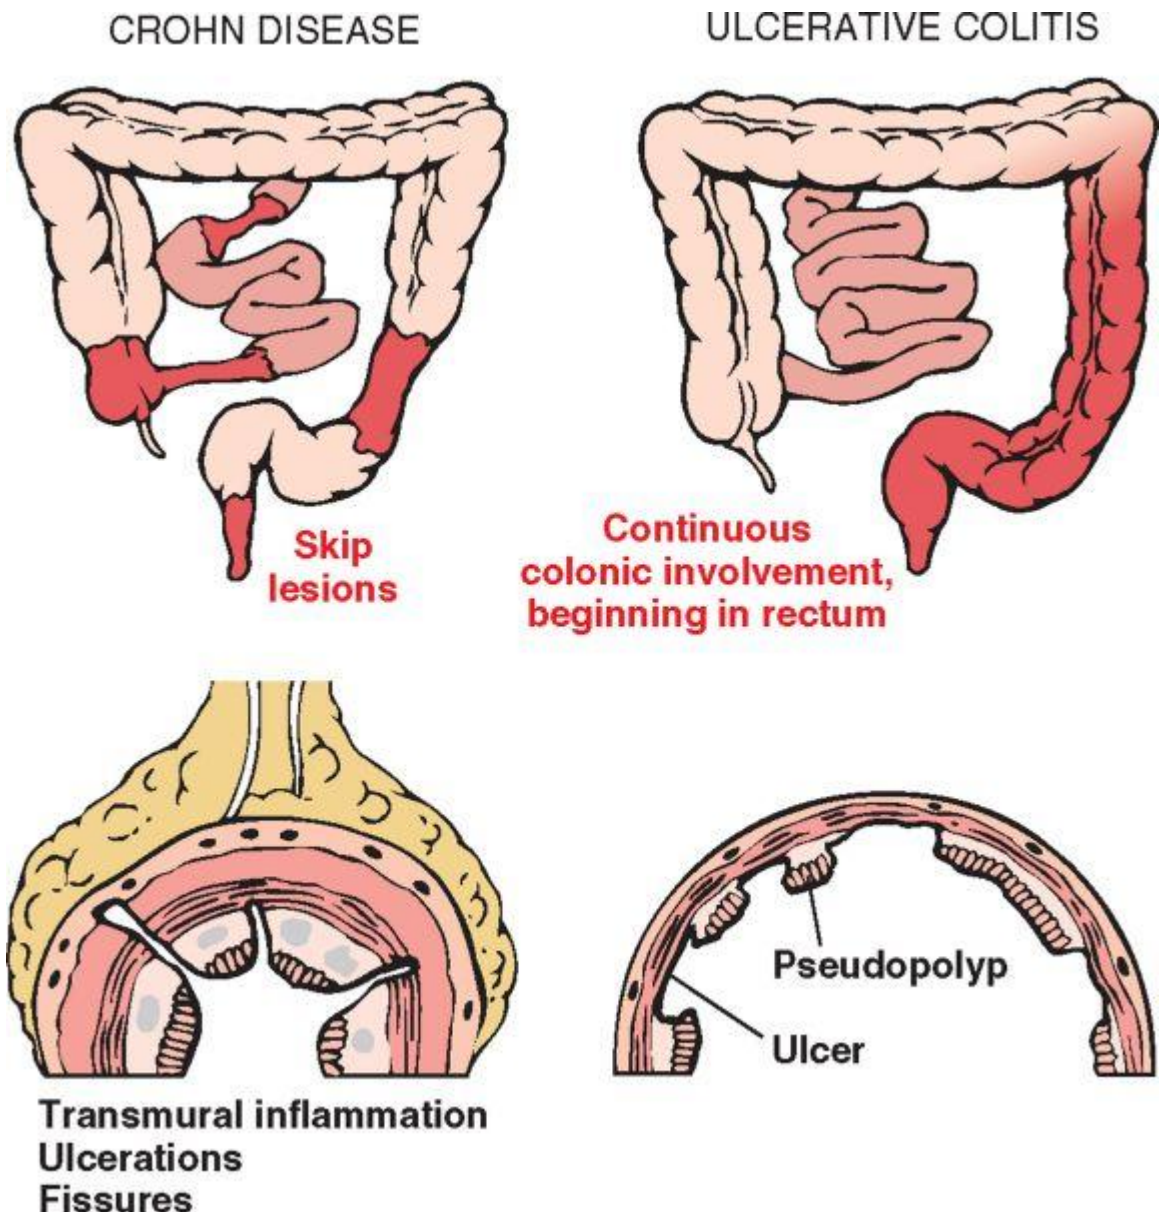

FIGURE 17-32 Distribution of lesions in inflammatory bowel disease. The distinction between Crohn disease and ulcerative colitis is primarily based on morphology.

TABLE 17-8 -- Features That Differ between Crohn Disease and Ulcerative Colitis

Feature	Crohn Disease	Ulcerative Colitis
MACROSCOPIC		
Bowel region	Ileum ± colon	Colon only
Distribution	Skip lesions	Diffuse
Stricture	Yes	Rare
Wall appearance	Thick	Thin
MICROSCOPIC		
Inflammation	Transmural	Limited to mucosa

Feature	Crohn Disease	Ulcerative Colitis
Pseudopolyps	Moderate	Marked
Ulcers	Deep, knife-like	Superficial, broad-based
Lymphoid reaction	Marked	Moderate
Fibrosis	Marked	Mild to none
Serositis	Marked	Mild to none
Granulomas	Yes (~35%)	No
Fistulae/sinuses	Yes	No
CLINICAL		
Perianal fistula	Yes (in colonic disease)	No
Fat/vitamin malabsorption	Yes	No
Malignant potential	With colonic involvement	Yes
Recurrence after surgery	Common	No
Toxic megacolon	No	Yes

Note: All features may not be present in a single case.

Epidemiology.

Both Crohn disease and ulcerative colitis are more common in females and frequently present in the teens and early 20s. In Western industrialized nations IBD is most common among Caucasians and, in the United States, occurs 3 to 5 times more often among eastern European (Ashkenazi) Jews. This is at least partly due to genetic factors, as discussed below. The geographic distribution of IBD is highly variable, but it is most common in North America, northern Europe, and Australia. However, IBD incidence worldwide is on the rise, and it is becoming more common in regions such as Africa, South America, and Asia, where the prevalence was historically low. The *hygiene hypothesis* suggests that this increasing incidence may be related to improved food storage conditions and decreased food contamination. This hypothesis suggests that reduced frequency of enteric infections has resulted in inadequate development of regulatory processes to limit mucosal immune responses, allowing pathogens that should cause self-limited disease to trigger overwhelming immune responses and chronic inflammatory disease in susceptible hosts. Although many details to support this hypothesis are lacking, the observation that helminth infection, which is endemic in regions where IBD incidence is low, can prevent IBD development in animal models and reduce disease in some patients lends support to this idea. The observation that an episode of acute infectious gastroenteritis may precede onset of IBD in some individuals is also consistent with the hygiene hypothesis.

Pathogenesis.

IBD is an *idiopathic disorder* and the responsible processes are only beginning to be understood. Although there is limited epidemiologic association of IBD with autoimmunity, neither Crohn disease nor ulcerative colitis is thought to be an autoimmune disease. Rather, *most investigators believe that the two diseases result from a combination of defects in host interactions with intestinal microbiota, intestinal epithelial dysfunction, and aberrant mucosal immune responses*. This view is supported by epidemiologic, genetic, and clinical studies as well as data from laboratory models of IBD (Fig. 17-33).

- ***Genetics*.** Genetic factors contribute to IBD.[93] Risk of disease is increased when there is an affected family member and, in Crohn disease, the concordance rate for monozygotic twins is approximately 50%. The same factors may also contribute to disease phenotype, because twins affected by Crohn disease tend to present within 2 years of each other and develop disease in similar regions of the GI tract. The concordance of monozygotic twins for ulcerative colitis is only 16%, suggesting that genetic factors are less dominant than in Crohn disease. Concordance for dizygotic twins is less than 10% for both Crohn disease and ulcerative colitis.
  Molecular linkage analyses of affected families have identified *NOD2* (nucleotide oligomerization binding domain 2) as a susceptibility gene in Crohn disease. Specific *NOD2* polymorphisms confer at least a four-fold increase in Crohn disease risk among Caucasians of European ancestry. *NOD2* encodes a protein that binds to intracellular bacterial peptidoglycans and subsequently activates NF-κB. It has been postulated that disease-associated *NOD2* variants are less effective at recognizing and combating luminal microbes, which are then able to enter the lamina propria and trigger inflammatory reactions. Other data suggest that *NOD2* may regulate immune responses to prevent excessive activation by luminal microbes. Whatever the mechanism by which *NOD2* polymorphisms contribute to Crohn disease pathogenesis, it should be remembered that fewer than 10% of individuals carrying *NOD2* mutations develop disease. Furthermore, *NOD2* mutations are uncommon in African and Asian Crohn disease patients. Thus, defective *NOD2* signaling is only one of many genetic factors that contribute to Crohn disease pathogenesis.
  More recently, the search for IBD-associated genes has used genome-wide association studies (GWAS) that assess single-nucleotide polymorphisms, as described in Chapter 5 .[94] The number of genes identified by GWAS is increasing rapidly (already numbering more than 30), but along with *NOD2*, two Crohn disease–related genes of particular interest are *ATG16L1* (autophagy-related 16-like), a part of the autophagosome pathway that is critical to host cell responses to intracellular bacteria and, perhaps, epithelial homeostasis, and *IRGM* (immunity-related GTPase M), which is also involved in autophagy and clearance of intracellular bacteria. *NOD2*, *ATG16L1*, and *IRGM* are expressed in multiple cell types, and their precise roles in Crohn disease pathogenesis have yet to be defined. However, like *NOD2*, *ATG16L1* and *IRGM* are related to recognition and response to intracellular pathogens, supporting the hypothesis that inappropriate immune reactions to luminal bacteria are an important component of IBD pathogenesis. None of these genes are associated with ulcerative colitis. However, some polymorphisms of the IL-23 receptor are protective in both Crohn disease and ulcerative colitis (discussed later).[95]
- ***Mucosal immune responses*.** Although the mechanisms by which mucosal immunity contributes to ulcerative colitis and Crohn disease pathogenesis are still being deciphered, immunosuppression remains the mainstay of IBD therapy. Polarization of helper T cells to the T_H1 type (see Chapter 6) is well-recognized in Crohn disease, and emerging data suggest that T_H17 T cells also contribute to disease pathogenesis. Consistent with this, certain polymorphisms of the IL-23 receptor confer protection from Crohn disease and ulcerative colitis.[95] IL-23 is involved in the development and maintenance of T_H17 cells, suggesting that the protective IL-23 receptor polymorphisms may attenuate pro-inflammatory T_H17 responses in Crohn disease and ulcerative colitis.
  Some data suggest that ulcerative colitis is a T_H2-mediated disease, and this is consistent with observations of increased mucosal IL-13 in ulcerative colitis patients. However, the protection afforded by IL-23 receptor polymorphisms and effectiveness of anti-TNF therapy in some ulcerative colitis patients seems to support roles for T_H1 and T_H17 cells. A recent report linking polymorphisms near the *IL-10* gene to ulcerative colitis, but not Crohn disease, further emphasizes the importance of immunoregulatory signals in IBD pathogenesis.[96] Overall it is likely that some combination of derangements that activate mucosal immunity and suppress immunoregulation contribute to the development of ulcerative colitis and Crohn disease. The relative roles of innate and adaptive arms of the immune system are presently the subject of intense scrutiny.
- ***Epithelial defects*.** A variety of epithelial defects have been described in both Crohn disease and ulcerative colitis. For example, defects in intestinal epithelial tight junction barrier function are present in Crohn disease patients and a subset of their healthy first-degree relatives.[97] In patients with Crohn disease and their relatives, this barrier dysfunction is associated with *NOD2* polymorphisms,[98] and experimental models demonstrate that barrier dysfunction can activate innate and adaptive mucosal immunity and sensitize subjects to disease.[99] Moreover, mutation of the organic cation transporter *SLC22A4* in Crohn disease suggests that defective transepithelial transport may also be related to IBD pathogenesis. Defects in the extracellular barrier formed by secreted mucin may also contribute.[100] Interestingly, polymorphisms in *ECM1* (extracellular matrix protein 1), which inhibits matrix metalloproteinase 9, are associated with ulcerative colitis but not Crohn disease.[101] While the pathogenic relevance of *ECM1* mutations is not understood, it is notable that inhibition of matrix metalloproteinase 9 reduces the severity of colitis in experimental models. Finally, the Paneth cell granules, which contain antibacterial peptides termed

defensins, are abnormal in Crohn disease patients carrying *ATG16L1* mutations,[102] suggesting that defective epithelial anti-microbial function contributes to IBD. Thus, while the details are incompletely defined and probably differ between Crohn disease and ulcerative colitis, deranged epithelial function is a critical component of IBD pathogenesis.

- ***Microbiota*.** The abundance of microbiota in the GI lumen is overwhelming, amounting to as much as 10^{12} organisms per milliliter in the colon and 50% of fecal mass. In total, these organisms greatly outnumber human cells in our bodies, meaning that, at a cellular level, we are only about 10% human. Although the composition of this dense microbial population tends to be stable within individuals over at least several years, it can be modified by diet and there is significant variation between individuals. In addition to the luminal microbiota, the more limited microbial population that inhabits the intestinal mucous layer may have the greatest impact on health. Despite growing evidence that intestinal microbiota contribute to IBD pathogenesis,[103] their precise role remains to be defined and is probably different in ulcerative colitis and Crohn disease. For example, antibodies against the bacterial protein flagellin are associated with *NOD2* polymorphisms as well as stricture formation, perforation, and small-bowel involvement in patients with Crohn disease, but are uncommon in ulcerative colitis patients. In addition, some antibiotics, e.g. metronidazole, can be helpful in management of Crohn disease, and broad-spectrum antibiotics can prevent disease in some experimental models of IBD.[104] Ongoing studies suggest that ill-defined mixtures containing probiotic, or beneficial, bacteria may combat disease in experimental models as well as some IBD patients, although the mechanisms responsible are not well understood.[105]

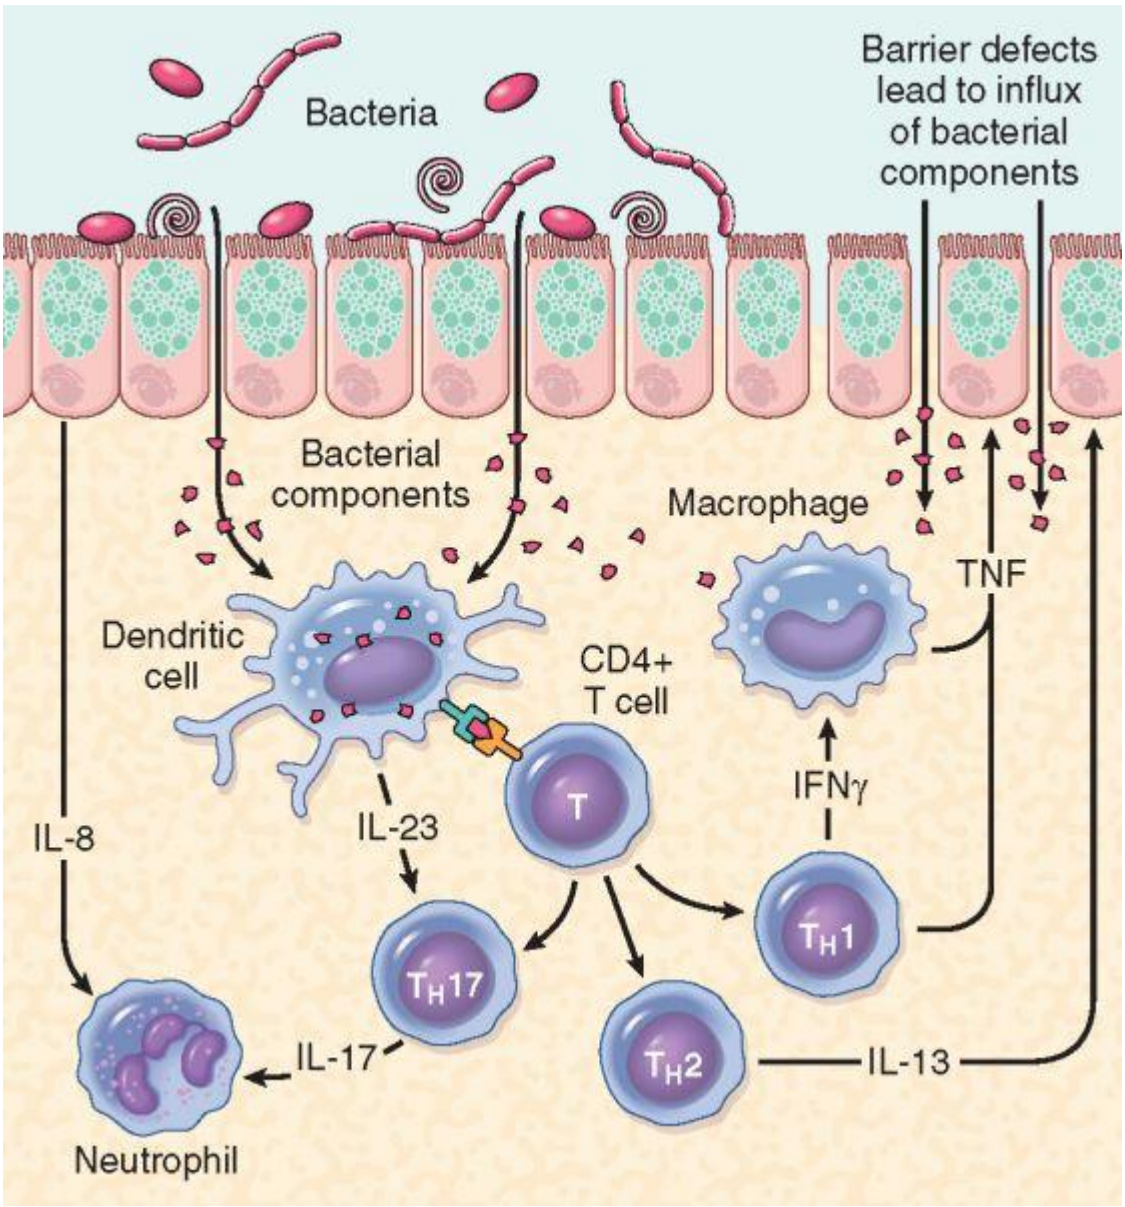

FIGURE 17-33 One model of IBD pathogenesis. Aspects of both Crohn disease and ulcerative colitis are shown.

One model that unifies the roles of intestinal microbiota, epithelial function, and mucosal immunity suggests a cycle by which transepithelial flux of luminal bacterial components activates innate and adaptive immune responses.[106] In a genetically susceptible host, the subsequent release of TNF and other immune-mediated signals direct epithelia to increase tight junction permeability, which causes further increases in the flux of luminal material. These events may establish a self-amplifying cycle in which a stimulus at any site may be sufficient to initiate IBD.[107] Although this model is helpful in advancing our understanding of IBD pathogenesis, it is important to recognize that a variety of factors are associated with disease for unknown reasons. For example, an episode of appendicitis is associated with reduced risk of developing ulcerative colitis. Tobacco also modifies IBD epidemiology, but, paradoxically, the risk of Crohn disease is increased by smoking while that of ulcerative colitis is reduced.

CROHN DISEASE

Crohn disease, an eponym based on the 1932 description by Crohn, Ginzburg, and Oppenheimer, has existed for centuries. Louis XIII of France (1601–1643) suffered relapsing bloody diarrhea, fever, rectal abscess, small intestinal and colonic ulcers, and fistulae beginning at age 20 years, most likely due to Crohn disease.

Morphology. Crohn disease may occur in any area of the GI tract, but the most common sites involved at presentation are the **terminal ileum, ileocecal valve**, and **cecum**. Disease is limited to the small intestine alone in about 40% of cases; the small intestine and colon are both involved in 30% of patients; and the remainder have only colonic involvement. The presence of multiple, separate, sharply delineated areas of disease, resulting in **skip lesions**, is characteristic of Crohn disease and may help in the differentiation from ulcerative colitis. Strictures are common (Fig. 17-34A).

The earliest Crohn disease lesion, the **aphthous ulcer**, may progress, and multiple lesions often coalesce into elongated, serpentine ulcers oriented along the axis of the bowel. Edema and loss of the normal mucosal texture are common. Sparing of interspersed mucosa, a result of the patchy distribution of Crohn disease, results in a coarsely textured, **cobblestone** appearance in which diseased tissue is depressed below the level of normal mucosa (Fig. 17-34B). **Fissures** frequently develop between mucosal folds and may extend deeply to become fistula tracts or sites of perforation (Fig. 17-34C). The intestinal wall is thickened and rubbery as a consequence of transmural edema, inflammation, submucosal fibrosis, and hypertrophy of the muscularis propria, all of which contribute to stricture formation. In cases with extensive transmural disease, mesenteric fat frequently extends around the serosal surface **(creeping fat)** (Fig. 17-34D).

The microscopic features of active Crohn disease include abundant neutrophils that infiltrate and damage crypt epithelium. Clusters of neutrophils within a crypt are referred to as **crypt abscesses** and are often associated with crypt destruction. Ulceration is common in Crohn disease, and there may be an abrupt transition between ulcerated and adjacent normal mucosa. Even in areas where gross examination suggests diffuse disease, microscopic pathology can appear patchy. Repeated cycles of crypt destruction and regeneration lead to **distortion of mucosal architecture**; the normally straight and parallel crypts take on bizarre branching shapes and unusual orientations to one another (Fig. 17-35A). Epithelial metaplasia, another consequence of chronic relapsing injury, often takes the form of

gastric antral-appearing glands, and is called pseudopyloric metaplasia. **Paneth cell metaplasia** may also occur in the left colon, where Paneth cells are normally absent. These architectural and metaplastic changes may persist even when active inflammation has resolved. Mucosal atrophy, with loss of crypts, may occur after years of disease. **Noncaseating granulomas** (Fig. 17-35B), a hallmark of Crohn disease, are found in approximately 35% of cases and may occur in areas of active disease or uninvolved regions in any layer of the intestinal wall (Fig. 17-35C). Granulomas may also be present in mesenteric lymph nodes. Cutaneous granulomas form nodules that are referred to as **metastatic Crohn disease**. The absence of granulomas does not preclude a diagnosis of Crohn disease.

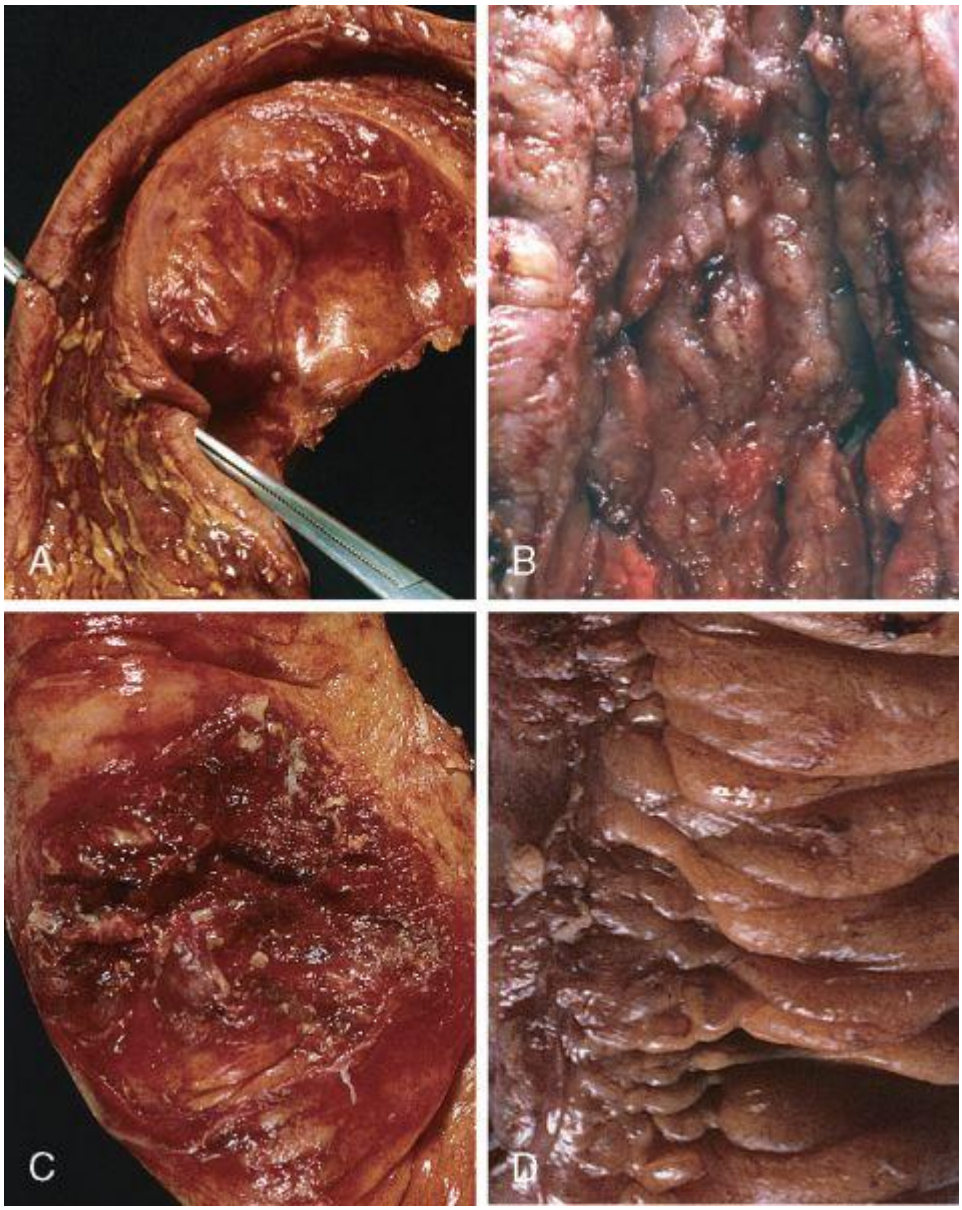

FIGURE 17-34 Gross pathology of Crohn disease. **A**, Small-intestinal stricture. **B**, Linear mucosal ulcers and thickened intestinal wall. **C**, Perforation and associated serositis. **D**, Creeping fat.

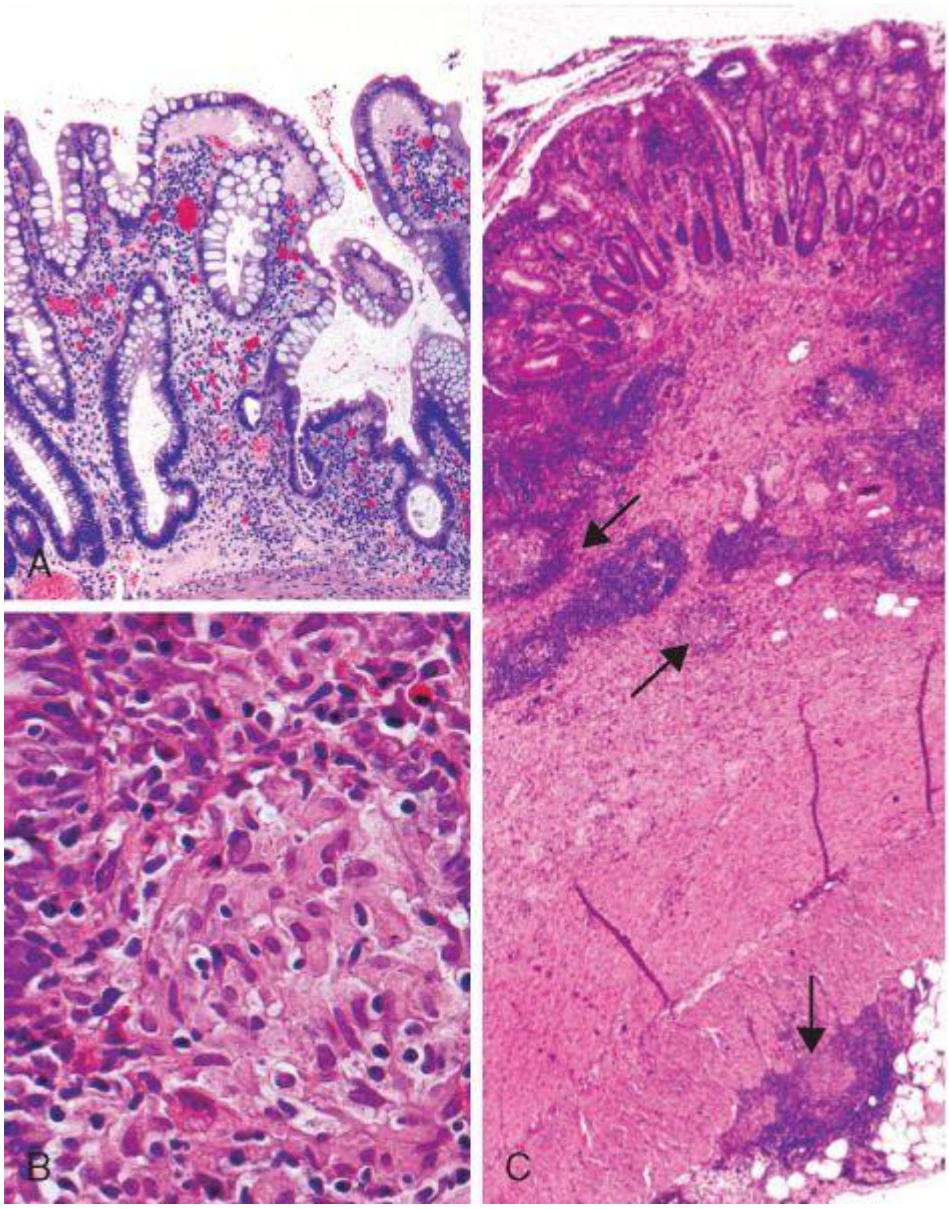

FIGURE 17-35 Microscopic pathology of Crohn disease. **A**, Haphazard crypt organization results from repeated injury and regeneration. **B**, Noncaseating granuloma. **C**, Transmural Crohn disease with submucosal and serosal granulomas (*arrows*).

Clinical Features.

The clinical manifestations of Crohn disease are extremely variable. In most patients *disease begins with intermittent attacks of relatively mild diarrhea, fever, and abdominal pain*. Approximately 20% of patients present acutely with right lower quadrant pain, fever, and bloody diarrhea that may mimic acute appendicitis or bowel perforation. Periods of active disease are typically interrupted by asymptomatic periods that last for weeks to many months. Disease re-activation can be associated with a variety of external triggers, including physical or emotional stress, specific dietary items, and cigarette smoking. The latter is a strong exogenous risk factor for development of Crohn disease and, in some cases, disease onset is associated with initiation of smoking. Unfortunately, smoking cessation does not result in disease remission.

Iron-deficiency anemia may develop in individuals with colonic disease, while extensive small bowel disease may result in serum protein loss and hypoalbuminemia, generalized nutrient malabsorption, or malabsorption of vitamin B_{12} and bile salts. Fibrosing strictures, particularly of the terminal ileum, are common and require surgical resection. Disease often recurs at the site of anastamosis, and as many as 40% of patients require additional resections within 10 years. Fistulae develop between loops of bowel and may also involve the urinary bladder, vagina, and abdominal or perianal skin. Perforations and peritoneal abscesses are common.

Extra-intestinal manifestations of Crohn disease include uveitis, migratory polyarthritis, sacroiliitis, ankylosing spondylitis, erythema nodosum, and clubbing of the fingertips, any of which may develop before intestinal disease is recognized. Pericholangitis and primary sclerosing cholangitis occur in Crohn disease but are more common in ulcerative colitis (see Chapter 18). As discussed below, risk of colonic adenocarcinoma is increased in patients with long-standing colonic disease.

ULCERATIVE COLITIS

Ulcerative colitis is closely related to Crohn disease. However, intestinal disease in ulcerative colitis is limited to the colon and rectum. Common extra-intestinal manifestations of ulcerative colitis overlap with those of Crohn disease and include migratory polyarthritis, sacroiliitis, ankylosing spondylitis, uveitis, skin lesions, pericholangitis, and primary sclerosing cholangitis (Chapter 18). Approximately 2.5% to 7.5% of individuals with ulcerative colitis also have primary sclerosis cholangitis. The long-term outlook for ulcerative colitis patients depends on the severity of active disease and disease duration.

Morphology. Grossly, ulcerative colitis always involves the rectum and extends proximally in a continuous fashion to involve part or all of the colon. Skip lesions are not seen (although focal appendiceal or cecal inflammation may occasionally be present in ulcerative colitis). Disease of the entire colon is termed **pancolitis** (Fig. 17-36A), while **left-sided disease** extends no farther than the transverse colon. Limited distal disease may be referred to descriptively as **ulcerative proctitis** or **ulcerative proctosigmoiditis**. The small intestine is normal, although mild mucosal inflammation of the distal ileum, **backwash ileitis**, may be present in severe cases of pancolitis.

Grossly, involved colonic mucosa may be slightly red and granular or have extensive, **broad-based ulcers**, and there can be an abrupt transition between diseased and uninvolved colon (Fig. 17-36B). Ulcers are aligned along the long axis of the colon but do not typically replicate the serpentine ulcers of Crohn disease. Isolated islands of regenerating mucosa often bulge into the lumen to create **pseudopolyps** (Fig. 17-36C), and the tips of these polyps may fuse to create **mucosal bridges** (Fig. 17-36D). Chronic disease may lead to **mucosal atrophy** with a flat and smooth mucosal surface that lacks normal folds. Unlike Crohn disease, **mural thickening is not present, the serosal surface is normal, and strictures do not occur**. However, inflammation and inflammatory mediators can damage the muscularis propria and disturb neuromuscular function leading to colonic dilation and **toxic megacolon**, which carries a significant risk of perforation.

Histologic features of mucosal disease in ulcerative colitis are similar to colonic Crohn disease and include inflammatory infiltrates, crypt abscesses (Fig. 17-37A), architectural crypt distortion, and epithelial metaplasia (Fig. 17-37B). However, **the inflammatory process is diffuse and generally limited to the mucosa** and superficial submucosa (Fig. 17-37C). In severe cases, extensive mucosal destruction may be accompanied by ulcers that extend more deeply into the submucosa, but the muscularis propria is rarely involved. Submucosal fibrosis, mucosal atrophy, and distorted mucosal architecture remain as residua of healed disease but histology may also revert to near normal after prolonged remission. **Granulomas are not present** in ulcerative colitis.

Clinical Features.

Ulcerative colitis is a relapsing disorder characterized by attacks of bloody diarrhea with stringy, mucoid material, lower abdominal pain, and cramps that are temporarily relieved by defecation. These symptoms may persist for days, weeks, or months before they subside, and, occasionally, the initial attack may be severe enough to constitute a medical or surgical emergency. More than half of patients have clinically mild disease, although almost all experience at least one relapse during a 10-year period, and up to 30% require colectomy within the first 3 years after presentation because of uncontrollable symptoms. Colectomy effectively cures intestinal disease in ulcerative colitis, but extra-intestinal manifestations may persist.

The factors that trigger ulcerative colitis are not known, but, as noted above, infectious enteritis precedes disease onset in some cases. In other cases the first attack is preceded by psychologic stress, which may also be linked to relapse during remission. The initial onset of symptoms has also been reported to occur shortly after smoking cessation in some patients, and smoking may partially relieve symptoms. Unfortunately, studies of nicotine as a therapeutic agent have been disappointing.

Indeterminate Colitis

There is extensive pathologic and clinical overlap between ulcerative colitis and Crohn disease (Table 17-8); definitive diagnosis is not possible in approximately 10% of IBD patients. These cases, termed *indeterminate colitis*, do not involve the small bowel and have colonic disease in a continuous pattern that would typically indicate ulcerative colitis. However, patchy histologic disease, fissures, a family history of Crohn disease, perianal lesions, onset after initiating use of cigarettes, or other features that are not typical of ulcerative colitis may prompt more detailed endoscopic, radiographic, and histologic examination. Serologic studies can be useful in these cases, because perinuclear anti-neutrophil cytoplasmic antibodies are positive in 75% of individuals with ulcerative colitis but only 11% with Crohn disease. In contrast, ulcerative colitis patients tend to lack antibodies to *Saccharomyces cerevisiae*, which are often present in those with Crohn disease. Even after extensive evaluation, IBD in approximately 10% of patients defies classification. In some of these cases features that develop over time (e.g., strictures or fistulae) ultimately establish the diagnosis; classification remains impossible in other patients. Because of extensive overlap in medical management of ulcerative colitis and Crohn disease, patients carrying a diagnosis of indeterminate colitis can be treated effectively. However, it is preferable to definitively categorize patients, when possible, as evolving medical therapies and surgical management differ in ulcerative colitis and Crohn disease.

Colitis-Associated Neoplasia

One of the most feared long-term complications of ulcerative colitis and colonic Crohn disease is the development of neoplasia. This begins as dysplasia, which, just as in Barrett esophagus and chronic gastritis, represents in situ transformation. The risk of dysplasia is related to several factors:

- Risk increases sharply 8 to 10 years after disease initiation.
- Patients with pancolitis are at greater risk than those with only left-sided disease.
- Greater frequency and severity of active inflammation (characterized by the presence of neutrophils) may increase risk.

The role of inflammation in promoting dysplasia is emphasized by the observation that anti-TNF antibody treatment can suppress the development of colitis-associated cancers in experimental animals.

To facilitate early detection of neoplasia, patients are typically enrolled in surveillance programs approximately 8 years after diagnosis of IBD. The major exception to this is patients with primary sclerosing cholangitis, who have an even greater risk of dysplasia and are generally enrolled for surveillance at the time of diagnosis. Surveillance requires regular and extensive mucosal biopsy, making it a costly practice. Research efforts have therefore included a search for molecular markers of dysplasia in nondysplastic mucosa. Genomic instability in rectal mucosa has the potential to be such a marker, but biopsy surveillance remains the best tool currently available.

In many cases dysplasia occurs in flat areas of mucosa that are not grossly recognized as abnormal. Thus, advanced endoscopic imaging techniques including chromoendoscopy and confocal endoscopy are beginning to be used experimentally to increase sensitivity of detection. IBD-associated dysplasia is classified histologically as low grade or high grade (Fig. 17-38A , B) and may be multifocal. High-

grade dysplasia may be associated with invasive carcinoma at the same site (Fig. 17-38C) or elsewhere in the colon and, therefore typically prompts colectomy. Low-grade dysplasia may be treated with colectomy or followed closely, depending on a variety of factors including patient age and the number of dysplastic foci present. Colonic adenomas (discussed below) also occur in IBD patients, and in some cases these may be difficult to differentiate from a polypoid focus of IBD-associated dysplasia.[108]

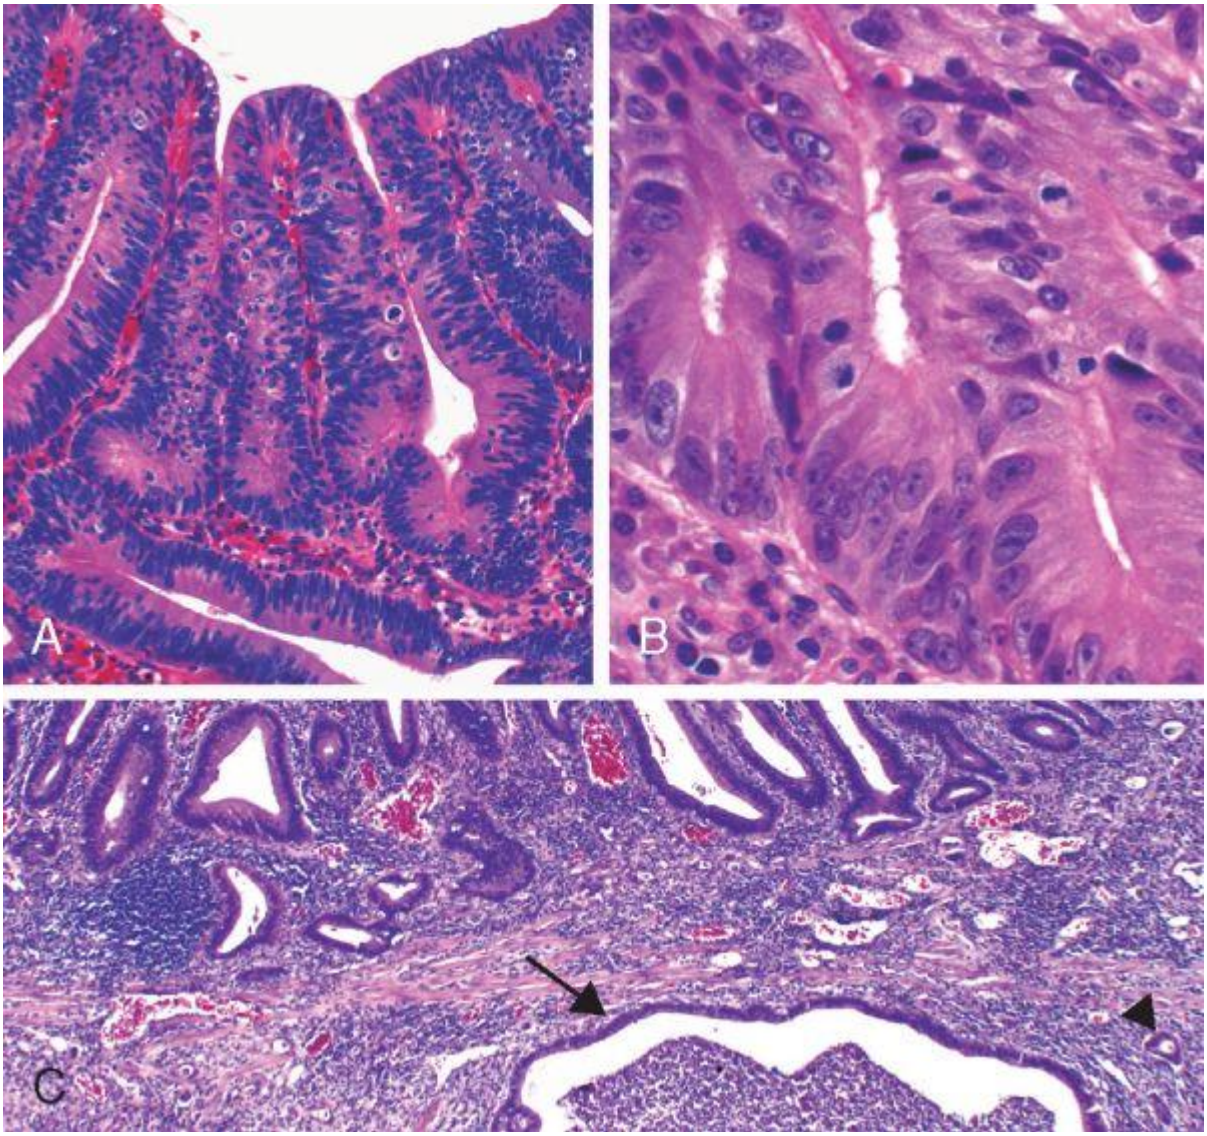

FIGURE 17-38 Colitis-associated dysplasia. **A**, Dysplasia with extensive nuclear stratification and marked nuclear hyperchromasia. **B**, Cribriform glandular arrangement in high-grade dysplasia. **C**, Colectomy specimen with high-grade dysplasia on the surface and underlying invasive adenocarcinoma. A large cystic, neutrophil-filled space lined by invasive adenocarcinoma is apparent at the bottom right (*arrow*) beneath the muscularis mucosa, and is surrounded by small invasive glands (*arrowhead*).

3.7.4.8 Other Causes of Chronic Colitis

DIVERSION COLITIS

Surgical treatment of ulcerative colitis, Hirschsprung disease, and other intestinal disorders sometimes requires creation of a temporary or permanent ostomy and a blind distal segment of colon, such as a Hartmann's pouch, from which the normal fecal flow is diverted. Colitis can develop within the diverted segment, particularly in ulcerative colitis patients. Besides mucosal erythema and friability, the most

striking feature of *diversion colitis* is the development of numerous mucosal lymphoid follicles (Fig. 17-39A). Increased numbers of lamina propria lymphocytes, monocytes, macrophages, and plasma cells may also be present. In severe cases the histopathology may resemble IBD and include crypt abscesses, mucosal architectural distortion, or, rarely, granulomas. The pathogenic mechanisms responsible for diversion colitis are not well understood, but changes in the luminal microbiota and diversion of the fecal stream that provides nutrients to colonic epithelial cells have been proposed. Consistent with this, enemas containing short-chain fatty acids, a product of bacterial digestion in the colon and an important energy source for colonic epithelial cells, can promote mucosal recovery in some cases. The ultimate cure is reanastomosis of the diverted segment.

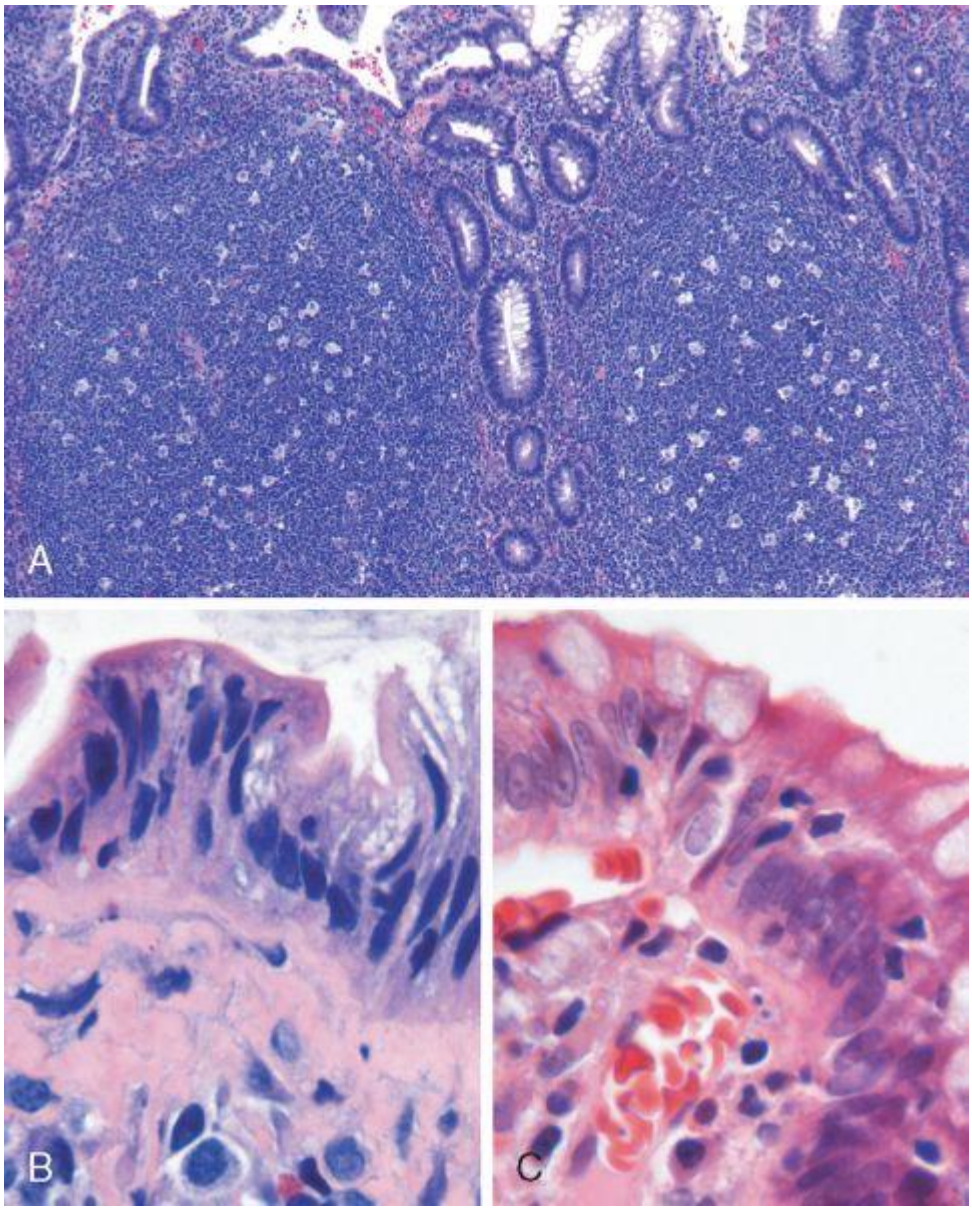

FIGURE 17-39 Uncommon causes of colitis. **A**, Diversion colitis in a Hartmann's pouch. Note the large lymphoid aggregates with germinal centers. **B**, Collagenous colitis with intraepithelial lymphocytes and a dense subepithelial collagen band. **C**, Lymphocytic colitis.

MICROSCOPIC COLITIS

Microscopic colitis encompases two entities, *collagenous colitis* and *lymphocytic colitis*. These idiopathic diseases both present with chronic, nonbloody, watery diarrhea without weight loss. Radiologic and endoscopic studies are typically normal. Collagenous colitis, which occurs primarily in middle-aged and older women, is characterized by the presence of a dense subepithelial collagen layer, increased numbers of intraepithelial lymphocytes, and a mixed inflammatory infiltrate within the lamina propria (Fig. 17-39B). Lymphocytic colitis is histologically similar, but the subepithelial collagen layer is of normal thickness and the increase in intraepithelial lymphocytes may be greater, frequently exceeding one T lymphocyte per five colonocytes (Fig. 17-39C). Lymphocytic colitis shows a strong association with celiac disease and autoimmune diseases, including thyroiditis, arthritis, and autoimmune or lymphocytic gastritis.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease occurs following allogeneic bone marrow transplantation. The small bowel and colon are involved in most cases. Although graft-versus-host disease is secondary to donor T cells targeting antigens on the recipient's GI epithelial cells, the lamina propria lymphocytic infiltrate is typically sparse. Epithelial apoptosis, particularly of crypt cells, is the most common histologic finding. Rarely, total gland destruction occurs, although endocrine cells may persist. Intestinal graft-versus-host disease often presents as a watery diarrhea.

3.7.4.9 Sigmoid Diverticulitis

In general, diverticular disease refers to acquired pseudo-diverticular outpouchings of the colonic mucosa and submucosa. Such *colonic diverticula* are rare in persons under age 30, but the prevalence approaches 50% in Western adult populations over age 60. Diverticulae are generally multiple and the condition is referred to as *diverticulosis*. This disease is much less common in Japan and nonindustrialized tropical countries, probably because of dietary differences.

Pathogenesis.

Colonic diverticula result from the unique structure of the colonic muscularis propria and elevated intraluminal pressure in the sigmoid colon. Where nerves, arterial vasa recta, and their connective tissue sheaths penetrate the inner circular muscle coat, focal discontinuities in the muscle wall are created. In other parts of the intestine these gaps are reinforced by the external longitudinal layer of the muscularis propria, but, in the colon, this muscle layer is gathered into the three bands termed *taeniae coli*. Increased intraluminal pressure is probably due to exaggerated peristaltic contractions, with spasmodic sequestration of bowel segments, and may be enhanced by diets low in fiber, which reduce stool bulk, particularly in the sigmoid colon.

Morphology. Anatomically, colonic diverticula are small, flask-like outpouchings, usually 0.5 to 1 cm in diameter, that occur in a regular distribution alongside the taeniae coli (Fig. 17-40A). These are most common in the sigmoid colon, but more extensive areas may be affected in severe cases. Because diverticulae are compressible, easily emptied of fecal contents, and often surrounded by the fat-containing **epiploic appendices** on the surface of the colon, they may be missed on casual inspection. Colonic diverticula have a thin wall composed of a flattened or atrophic mucosa, compressed submucosa, and attenuated or, most often, totally absent muscularis propria (Fig. 17-40B , C). Hypertrophy of the circular layer of the muscularis propria in the affected bowel segment is common. Obstruction of diverticulae leads to inflammatory changes, producing **diverticulitis** and peri-diverticulitis. Because the wall of the diverticulum is supported only by the muscularis mucosa and a thin layer of subserosal adipose tissue, inflammation and increased pressure within an obstructed diverticulum can lead to **perforation**. With or without perforation, diverticulitis may cause

segmental diverticular disease–associated colitis, fibrotic thickening in and around the colonic wall, or stricture formation. Perforation can result in pericolonic abscesses, sinus tracts, and, occasionally, peritonitis.

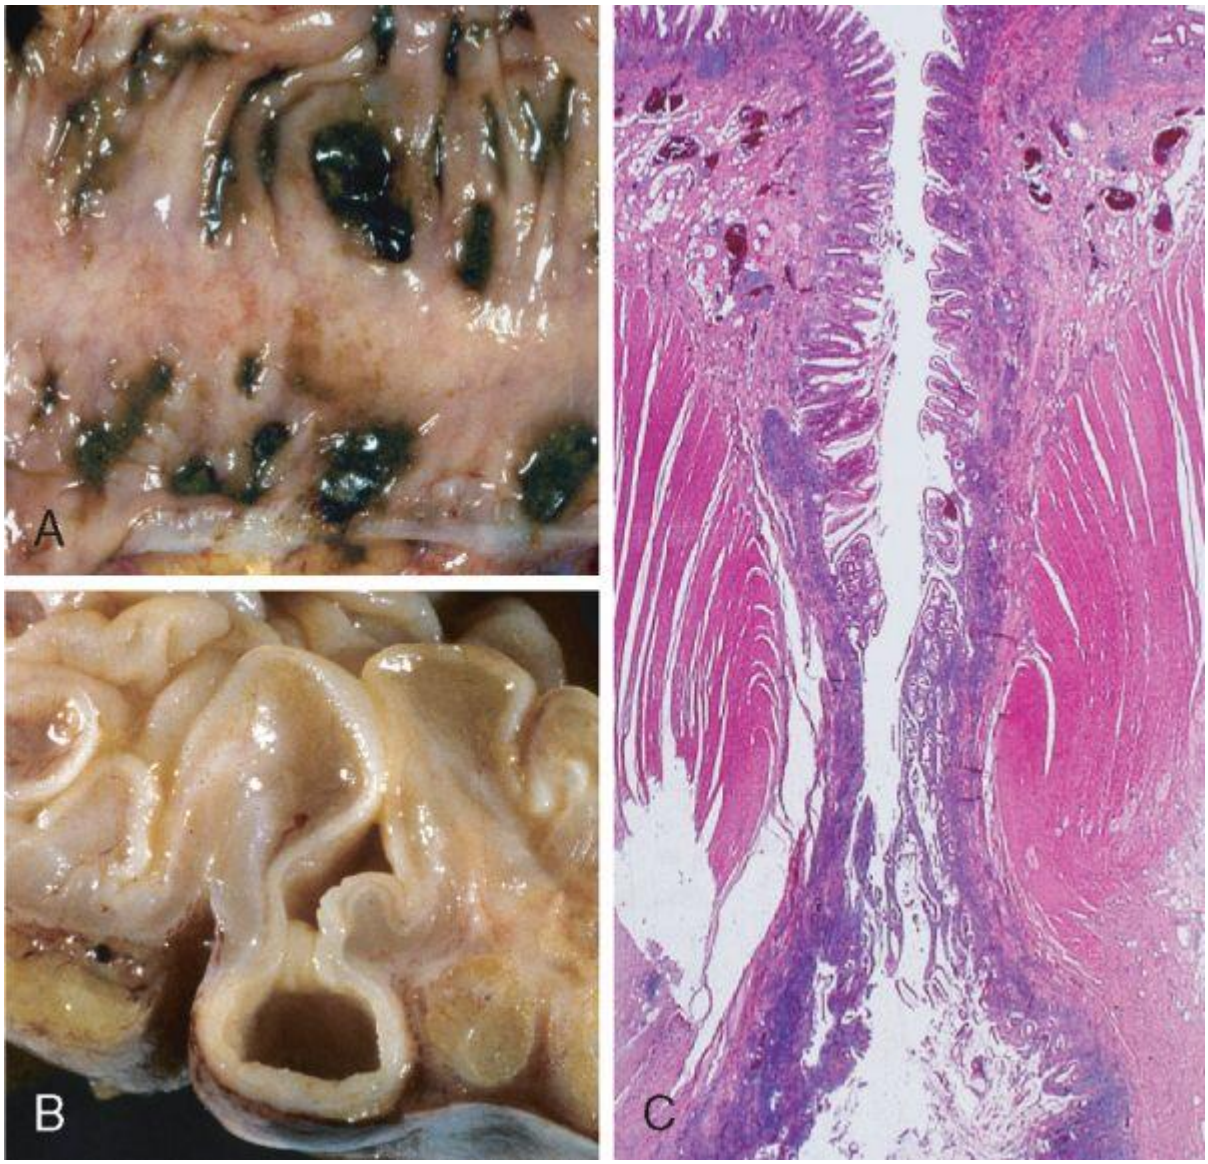

FIGURE 17-40 Sigmoid diverticular disease. **A**, Stool-filled diverticula are regularly arranged. **B**, Cross-section showing the outpouching of mucosa beneath the muscularis propria. **C**, Low-power photomicrograph of a sigmoid diverticulum showing protrusion of the mucosa and submucosa through the muscularis propria.

Clinical Features.

Most individuals with diverticular disease remain asymptomatic throughout their lives, and the lesions are most often discovered incidentally. About 20% of those affected develop manifestations of disease including intermittent cramping, continuous lower abdominal discomfort, constipation, distention, and a sensation of never being able to completely empty the rectum. Patients sometimes experience alternating constipation and diarrhea. Occasionally there may be minimal chronic or intermittent blood loss, or, in extremely rare cases, massive hemorrhage. Longitudinal studies have shown that diverticulae

can regress early in their development or, more commonly, become more numerous and prominent over time. Whether a high-fiber diet prevents such progression or protects against diverticulitis is unclear, but diets supplemented with fiber may provide symptomatic improvement. Even when diverticulitis occurs, it most often resolves spontaneously and relatively few patients require surgical intervention.

3.7.4.10 Polyps

Polyps are most common in the colon but may occur in the esophagus, stomach, or small intestine. Most, if not all, polyps begin as small elevations of the mucosa. These are referred to as *sessile*, a term borrowed from botanists who use it to describe flowers and leaves that grow directly from the stem without a stalk. As sessile polyps enlarge, several processes, including proliferation of cells adjacent to the mass and the effects of traction on the luminal protrusion, may combine to create a stalk. Polyps with stalks are termed *pedunculated*. In general, intestinal polyps can be classified as non-neoplastic or neoplastic in nature. The most common neoplastic polyp is the adenoma, which has the potential to progress to cancer. The non-neoplastic polyps can be further classified as inflammatory, hamartomatous, or hyperplastic.

INFLAMMATORY POLYPS

The polyp that forms as part of the *solitary rectal ulcer syndrome* is an example of a purely inflammatory lesion. Patients present with a clinical triad of rectal bleeding, mucus discharge, and an inflammatory lesion of the anterior rectal wall. The underlying cause is impaired relaxation of the anorectal sphincter that creates a sharp angle at the anterior rectal shelf and leads to recurrent abrasion and ulceration of the overlying rectal mucosa. An inflammatory polyp may ultimately form as a result of chronic cycles of injury and healing. Entrapment of this polyp in the fecal stream leads to mucosal prolapse. Thus, the distinctive histologic features are those of a typical inflammatory polyp with superimposed mucosal prolapse and include lamina propria fibromuscular hyperplasia, mixed inflammatory infiltrates, erosion, and epithelial hyperplasia (Fig. 17-41).

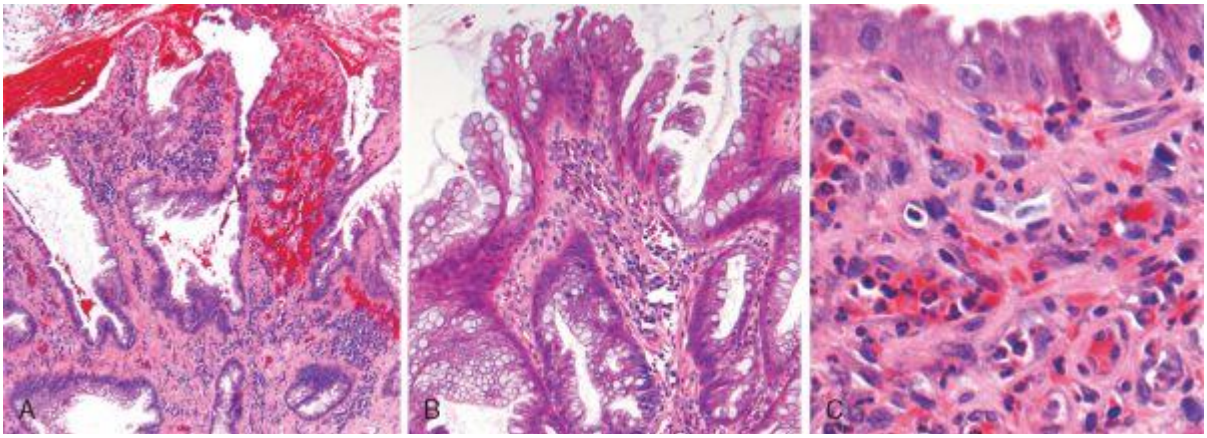

FIGURE 17-41 Solitary rectal ulcer syndrome. **A**, The dilated glands, proliferative epithelium, superficial erosions, and inflammatory infiltrate are typical of an inflamatory polyp. However, the smooth muscle hyperplasia within the lamina propria suggests that mucosal prolapse has also occurred. **B**, Epithelial hyperplasia. **C**, Granulation tissue-like capillary proliferation within the lamina propria caused by repeated erosion and re-epithelialization.

HAMARTOMATOUS POLYPS

Hamartomatous polyps occur sporadically and in the context of various genetically determined or acquired syndromes (Table 17-9). Recall that hamartomas are tumor-like growths composed of mature tissues that are normally present at the site in which they develop. Although hamartomatous polyposis syndromes are rare, they are important to recognize because of associated intestinal and extra-intestinal manifestations and the possibility that other family members are affected.

TABLE 17-9 -- Gastrointestinal Polyposis Syndromes

Syndrome	Mean Age at Presentation (yr)	Mutated Gene	Gastrointestinal Lesions	Selected Extra-Gastrointestinal Manifestations
Peutz-Jeghers syndrome	10–15	*LKB1/STK11*	Arborizing polyps; Small intestine > colon > stomach; colonic adenocarcinoma	Skin macules; increased risk of thyroid, breast, lung, pancreas, gonadal, and bladder cancers
Juvenile polyposis	<5	*SMAD4, BMPR1A*	Juvenile polyps; risk of gastric, small intestinal, colonic, and pancreatic adenocarcinoma	Pulmonary arteriovenous malformations, digital clubbing
