Robbins & Cotran Pathologic Basis of Disease, 8e [Vishal]

Table Of Contents

1. Front 13
   1.1 Cover 13
   1.2 About This Book 183
   1.3 Frontmatter 183
   1.4 Copyright 185
   1.5 Dedication 186
   1.6 Contributors 186
   1.7 Preface: The Golden Jubilee Edition 188
   1.8 Acknowledgments 190
2. I. General Pathology 192
   2.1 1. Cellular Responses to Stress & Toxic Insults: Adaptation, Injury & Death 192
      2.1.1 Introduction to Pathology 192
      2.1.2 Overview: Cellular Responses to Stress & Noxious Stimuli 193
      2.1.3 Adaptations of Cellular Growth & Differentiation 196
      2.1.4 Overview of Cell Injury & Cell Death 204
      2.1.5 Causes of Cell Injury 204
      2.1.6 Morphologic Alterations in Cell Injury 206
      2.1.7 Mechanisms of Cell Injury 216
      2.1.8 Clinico-Pathologic Correlations: Selected Examples of Cell Injury & Necrosis 228
      2.1.9 Apoptosis 231
      2.1.10 Autophagy 243
      2.1.11 Intracellular Accumulations 244
      2.1.12 Pathologic Calcification 253
      2.1.13 Cellular Aging 255
      2.1.14 References 258
   2.2 2. Acute & Chronic Inflammation 260
      2.2.1 Overview of Inflammation 260
      2.2.2 Historical Highlights 261
      2.2.3 Acute Inflammation 262
      2.2.4 Mediators of Inflammation 281
      2.2.5 Outcomes of Acute Inflammation 297
      2.2.6 Morphologic Patterns of Acute Inflammation 298
      2.2.7 Summary of Acute Inflammation 301
      2.2.8 Chronic Inflammation 302
      2.2.9 Systemic Effects of Inflammation 311
      2.2.10 Consequences of Defective or Excessive Inflammation 312
      2.2.11 References 312
   2.3 3. Tissue Renewal, Regeneration & Repair 314
      2.3.1 Control of Normal Cell Proliferation & Tissue Growth 314
      2.3.2 Cell Cycle & the Regulation of Cell Replication 326
      2.3.3 Mechanisms of Tissue & Organ Regeneration 336

2.3.4 Extracellular Matrix & Cell-Matrix Interactions ... 338
2.3.5 Healing by Repair, Scar Formation & Fibrosis ... 345
2.3.6 References ... 360
2.4 4. Hemodynamic Disorders, Thromboembolic Disease & Shock ... 362
2.4.1 Edema ... 362
2.4.2 Hyperemia & Congestion ... 367
2.4.3 Hemorrhage ... 368
2.4.4 Hemostasis & Thrombosis ... 369
2.4.5 Embolism ... 387
2.4.6 Infarction ... 391
2.4.7 Shock ... 395
2.4.8 References ... 400
2.5 5. Genetic Disorders ... 401
2.5.1 Human Genetic Architecture ... 401
2.5.2 Genes & Human Diseases ... 404
2.5.3 Mendelian Disorders ... 409
2.5.4 Complex Multigenic Disorders ... 441
2.5.5 Chromosomal Disorders ... 441
2.5.6 Single-Gene Disorders with Nonclassic Inheritance ... 455
2.5.7 Molecular Diagnosis of Genetic Diseases ... 465
2.5.8 References ... 478
2.6 6. Diseases of the Immune System ... 480
2.6.1 The Normal Immune Response ... 480
2.6.2 Hypersensitivity & Autoimmune Disorders ... 503
2.6.3 Rejection of Tissue Transplants ... 556
2.6.4 Immunodeficiency Syndromes ... 562
2.6.5 Amyloidosis ... 592
2.6.6 References ... 602
2.7 7. Neoplasia ... 606
2.7.1 Nomenclature ... 606
2.7.2 Characteristics of Benign & Malignant Neoplasms ... 611
2.7.3 Epidemiology ... 630
2.7.4 Molecular Basis of Cancer ... 639
2.7.5 Molecular Basis of Multistep Carcinogenesis ... 691
2.7.6 Carcinogenic Agents & Their Cellular Interactions ... 692
2.7.7 Host Defense against Tumors: Tumor Immunity ... 705
2.7.8 Clinical Aspects of Neoplasia ... 711
2.7.9 References ... 724
2.8 8. Infectious Diseases ... 729
2.8.1 General Principles of Microbial Pathogenesis ... 729
2.8.2 Viral Infections ... 758
2.8.3 Bacterial Infections ... 775
2.8.4 Fungal Infections ... 826

2.8.5 Parasitic Infections ... 833
2.8.6 References ... 855
2.9 9. Environmental & Nutritional Diseases ... 858
2.9.1 The Global Burden of Disease ... 858
2.9.2 Health Effects of Climate Change ... 860
2.9.3 Toxicity of Chemical & Physical Agents ... 862
2.9.4 Environmental Pollution ... 864
2.9.5 Occupational Health Risks: Industrial & Agricultural Exposures ... 873
2.9.6 Effects of Tobacco ... 875
2.9.7 Effects of Alcohol ... 881
2.9.8 Injury by Therapeutic Drugs & Drugs of Abuse ... 885
2.9.9 Injury by Physical Agents ... 895
2.9.10 Nutritional Diseases ... 909
2.9.11 References ... 937
2.10 10. Diseases of Infancy & Childhood ... 939
2.10.1 Congenital Anomalies ... 939
2.10.2 Disorders of Prematurity ... 951
2.10.3 Perinatal Infections ... 960
2.10.4 Fetal Hydrops ... 961
2.10.5 Inborn Errors of Metabolism & Other Genetic Disorders ... 968
2.10.6 Sudden Infant Death Syndrome (SIDS) ... 984
2.10.7 Tumors & Tumor-like Lesions of Infancy & Childhood ... 987
2.10.8 References ... 1004
3. II. Systemic Pathology: Diseases of Organ Systems ... 1007
3.1 11. Blood Vessels ... 1007
3.1.1 The Structure & Function of Blood Vessels ... 1007
3.1.2 Vessel Development, Growth & Remodeling ... 1009
3.1.3 Congenital Anomalies ... 1009
3.1.4 Vascular Wall Cells & Their Response to Injury ... 1010
3.1.5 Hypertensive Vascular Disease ... 1014
3.1.6 Arteriosclerosis ... 1019
3.1.7 Atherosclerosis ... 1020
3.1.8 Aneurysms & Dissection ... 1035
3.1.9 Vasculitis ... 1043
3.1.10 Raynaud Phenomenon ... 1055
3.1.11 Veins & Lymphatics ... 1056
3.1.12 Tumors ... 1059
3.1.13 Pathology of Vascular Interventions ... 1068
3.1.14 References ... 1071
3.2 12. The Heart ... 1073
3.2.1 Cardiac Structure & Specializations ... 1073
3.2.2 Effects of Aging on the Heart ... 1076
3.2.3 Heart Disease: Overview of Pathophysiology ... 1077

3.2.4 Heart Failure ... 1077
3.2.5 Congenital Heart Disease ... 1085
3.2.6 Ischemic Heart Disease ... 1099
3.2.7 Hypertensive Heart Disease ... 1123
3.2.8 Valvular Heart Disease ... 1126
3.2.9 Cardiomyopathies ... 1142
3.2.10 Pericardial Disease ... 1159
3.2.11 Tumors of the Heart ... 1164
3.2.12 Cardiac Transplantation ... 1167
3.2.13 References ... 1168
3.3 13. Diseases of White Blood Cells, Lymph Nodes, Spleen & Thymus ... 1171
3.3.1 Development & Maintenance of Hematopoietic Tissues ... 1171
3.3.2 Disorders of White Cells ... 1174
3.3.2.1 Leukopenia ... 1175
3.3.2.2 Reactive (Inflammatory) Proliferations of White Cells & Lymph Nodes ... 1176
3.3.2.3 Neoplastic Proliferations of White Cells ... 1182
3.3.3 Spleen ... 1249
3.3.3.1 Splenomegaly ... 1251
3.3.3.2 Neoplasms ... 1254
3.3.3.3 Congenital Anomalies ... 1254
3.3.3.4 Rupture ... 1254
3.3.4 Thymus ... 1254
3.3.4.1 Developmental Disorders ... 1255
3.3.4.2 Thymic Hyperplasia ... 1255
3.3.4.3 Thymomas ... 1255
3.3.5 References ... 1257
3.4 14. Red Blood Cell & Bleeding Disorders ... 1259
3.4.1 Anemias ... 1259
3.4.2 Polycythemia ... 1312
3.4.3 Bleeding Disorders: Hemorrhagic Diatheses ... 1313
3.4.4 References ... 1327
3.5 15. The Lung ... 1328
3.5.1 Congenital Anomalies ... 1328
3.5.2 Atelectasis (Collapse) ... 1332
3.5.3 Pulmonary Edema ... 1334
3.5.4 Acute Lung Injury & Acute Respiratory Distress Syndrome (Diffuse Alveolar Damage) ... 1335
3.5.5 Obstructive versus Restrictive Pulmonary Diseases ... 1340
3.5.6 Obstructive Pulmonary Diseases ... 1340
3.5.7 Chronic Diffuse Interstitial (Restrictive) Diseases ... 1359
3.5.8 Diseases of Vascular Origin ... 1384
3.5.9 Pulmonary Infections ... 1395
3.5.10 Lung Transplantation ... 1413
3.5.11 Tumors ... 1415

3.5.12 Pleura 1435
3.5.13 References 1442
3.6 16. Head & Neck 1446
3.6.1 Oral Cavity 1446
3.6.1.1 Teeth & Supporting Structures 1447
3.6.1.2 Inflammatory/Reactive Tumor-like Lesions 1449
3.6.1.3 Infections 1453
3.6.1.4 Oral Manifestations of Systemic Disease 1454
3.6.1.5 Tumors & Precancerous Lesions 1455
3.6.1.6 Odontogenic Cysts & Tumors 1461
3.6.2 Upper Airways 1463
3.6.2.1 Nose 1463
3.6.2.2 Nasopharynx 1466
3.6.2.3 Tumors of the Nose, Sinuses & Nasopharynx 1467
3.6.2.4 Larynx 1470
3.6.3 Ears 1473
3.6.3.1 Inflammatory Lesions 1473
3.6.3.2 Otosclerosis 1473
3.6.3.3 Tumors 1474
3.6.4 Neck 1474
3.6.4.1 Branchial Cyst (Cervical Lymphoepithelial Cyst) 1474
3.6.4.2 Thyroglossal Duct Cyst 1474
3.6.4.3 Paraganglioma (Carotid Body Tumor) 1475
3.6.5 Salivary Glands 1477
3.6.5.1 Xerostomia 1477
3.6.5.2 Inflammation (Sialadenitis) 1477
3.6.5.3 Neoplasms 1478
3.6.6 References 1484
3.7 17. The Gastrointestinal Tract 1486
3.7.1 Congenital Abnormalities 1486
3.7.1.1 Atresia, Fistulae & Duplications 1486
3.7.1.2 Diaphragmatic Hernia, Omphalocele & Gastroschisis 1487
3.7.1.3 Ectopia 1488
3.7.1.4 Meckel Diverticulum 1488
3.7.1.5 Pyloric Stenosis 1489
3.7.1.6 Hirschsprung Disease 1489
3.7.2 Esophagus 1491
3.7.2.1 Esophageal Obstruction 1492
3.7.2.2 Esophagitis 1493
3.7.2.3 Barrett Esophagus 1497
3.7.2.4 Esophageal Tumors 1502
3.7.3 Stomach 1506
3.7.3.1 Acute Gastritis 1506

3.7.3.2 Chronic Gastritis 1509
3.7.3.3 Complications of Chronic Gastritis 1517
3.7.3.4 Hypertrophic Gastropathies 1520
3.7.3.5 Gastric Polyps & Tumors 1523
3.7.4 Small Intestine & Colon 1536
3.7.4.1 Intestinal Obstruction 1536
3.7.4.2 Ischemic Bowel Disease 1539
3.7.4.3 Angiodysplasia 1542
3.7.4.4 Malabsorption & Diarrhea 1542
3.7.4.5 Infectious Enterocolitis 1548
3.7.4.6 Irritable Bowel Syndrome 1565
3.7.4.7 Inflammatory Bowel Disease 1566
3.7.4.8 Other Causes of Chronic Colitis 1578
3.7.4.9 Sigmoid Diverticulitis 1580
3.7.4.10 Polyps 1582
3.7.4.11 Familial Syndromes 1593
3.7.4.12 Adenocarcinoma 1595
3.7.4.13 Tumors of the Anal Canal 1602
3.7.4.14 Hemorrhoids 1603
3.7.4.15 Acute Appendicitis 1604
3.7.4.16 Tumors of the Appendix 1605
3.7.5 Peritoneal Cavity 1605
3.7.5.1 Inflammatory Disease 1605
3.7.5.2 Tumors 1606
3.7.6 References 1607
3.8 18. Liver & Biliary Tract 1610
3.8.1 The Liver 1610
3.8.1.1 General Features of Hepatic Disease 1612
3.8.1.2 Infectious Disorders 1627
3.8.1.3 Autoimmune Hepatitis 1647
3.8.1.4 Drug- & Toxin-Induced Liver Disease 1649
3.8.1.5 Metabolic Liver Disease 1655
3.8.1.6 Intrahepatic Biliary Tract Disease 1667
3.8.1.7 Circulatory Disorders 1675
3.8.1.8 Hepatic Complications of Organ or Bone Marrow Transplantation 1683
3.8.1.9 Hepatic Disease Associated with Pregnancy 1684
3.8.1.10 Nodules & Tumors 1686
3.8.2 The Biliary Tract 1698
3.8.2.1 Congenital Anomalies 1698
3.8.2.2 Disorders of the Gallbladder 1699
3.8.2.3 Disorders of the Extrahepatic Bile Ducts 1708
3.8.2.4 Tumors 1709
3.8.3 References 1712

3.9 19. The Pancreas ... 1714
3.9.1 Congenital Anomalies ... 1714
3.9.2 Pancreatitis ... 1717
3.9.3 Non-Neoplastic Cysts ... 1726
3.9.4 Neoplasms ... 1727
3.9.5 References ... 1735
3.10 20. The Kidney ... 1737
3.10.1 Clinical Manifestations of Renal Diseases ... 1737
3.10.2 Glomerular Diseases ... 1740
3.10.3 Tubular & Interstitial Diseases ... 1789
3.10.4 Vascular Diseases ... 1816
3.10.5 Congenital Anomalies ... 1829
3.10.6 Cystic Diseases of the Kidney ... 1831
3.10.7 Urinary Tract Obstruction (Obstructive Uropathy) ... 1839
3.10.8 Urolithiasis (Renal Calculi, Stones) ... 1843
3.10.9 Tumors of the Kidney ... 1845
3.10.10 References ... 1853
3.11 21. The Lower Urinary Tract & Male Genital System ... 1856
3.11.1 The Lower Urinary Tract ... 1856
3.11.1.1 Ureters ... 1856
3.11.1.2 Urinary Bladder ... 1860
3.11.1.3 Urethra ... 1878
3.11.2 The Male Genital Tract ... 1880
3.11.2.1 Penis ... 1880
3.11.2.2 Testis & Epididymis ... 1887
3.11.2.3 Prostate ... 1904
3.11.3 References ... 1922
3.12 22. The Female Genital Tract ... 1926
3.12.1 Development ... 1926
3.12.2 Anatomy ... 1927
3.12.3 Infections of the Female Genital Tract ... 1929
3.12.4 Vulva ... 1933
3.12.4.1 Bartholin Cyst ... 1934
3.12.4.2 Non-Neoplastic Epithelial Disorders ... 1934
3.12.4.3 Benign Exophytic Lesions ... 1936
3.12.4.4 Squamous Neoplastic Lesions ... 1937
3.12.4.5 Glandular Neoplastic Lesions ... 1940
3.12.4.6 Malignant Melanoma ... 1943
3.12.5 Vagina ... 1943
3.12.5.1 Developmental Anomalies ... 1943
3.12.5.2 Premalignant & Malignant Neoplasms ... 1944
3.12.6 Cervix ... 1946
3.12.6.1 Inflammations ... 1946

3.12.6.2 Endocervical Polyps 1946
3.12.6.3 Premalignant & Malignant Neoplasms 1947
3.12.7 Body of Uterus & Endometrium 1957
3.12.7.1 Endometrial Histology in the Menstrual Cycle 1957
3.12.7.2 Functional Endometrial Disorders (Dysfunctional Uterine Bleeding) 1959
3.12.7.3 Inflammation 1962
3.12.7.4 Endometriosis & Adenomyosis 1962
3.12.7.5 Endometrial Polyps 1965
3.12.7.6 Endometrial Hyperplasia 1965
3.12.7.7 Malignant Tumors of the Endometrium 1968
3.12.7.8 Tumors of the Endometrium with Stromal Differentiation 1974
3.12.7.9 Tumors of the Myometrium 1975
3.12.8 Fallopian Tubes 1978
3.12.8.1 Inflammations 1978
3.12.8.2 Tumors & Cysts 1978
3.12.9 Ovaries 1978
3.12.9.1 Non-Neoplastic & Functional Cysts 1978
3.12.9.2 Ovarian Tumors 1981
3.12.10 Gestational & Placental Disorders 2003
3.12.10.1 Disorders of Early Pregnancy 2005
3.12.10.2 Disorders of Late Pregnancy 2006
3.12.10.3 Gestational Trophoblastic Disease 2012
3.12.11 References 2019
3.13 23. The Breast 2022
3.13.1 The Female Breast 2022
3.13.1.1 Disorders of Development 2025
3.13.1.2 Clinical Presentations of Breast Disease 2025
3.13.1.3 Inflammatory Disorders 2029
3.13.1.4 Benign Epithelial Lesions 2032
3.13.1.5 Carcinoma of the Breast 2040
3.13.2 The Male Breast 2071
3.13.2.1 Gynecomastia 2071
3.13.2.2 Carcinoma 2072
3.13.3 References 2073
3.14 24. The Endocrine System 2075
3.14.1 Pituitary Gland 2075
3.14.1.1 Clinical Manifestations of Pituitary Disease 2077
3.14.1.2 Pituitary Adenomas & Hyperpituitarism 2078
3.14.1.3 Hypopituitarism 2086
3.14.1.4 Posterior Pituitary Syndromes 2088
3.14.1.5 Hypothalamic Suprasellar Tumors 2088
3.14.2 Thyroid Gland 2089
3.14.2.1 Hyperthyroidism 2091

3.14.2.2 Hypothyroidism 2094
3.14.2.3 Thyroiditis 2097
3.14.2.4 Graves Disease 2102
3.14.2.5 Diffuse & Multinodular Goiters 2105
3.14.2.6 Neoplasms of the Thyroid 2108
3.14.2.7 Congenital Anomalies 2125
3.14.3 Parathyroid Glands 2125
3.14.3.1 Hyperparathyroidism 2126
3.14.3.2 Hypoparathyroidism 2131
3.14.3.3 Pseudohypoparathyroidism 2132
3.14.4 The Endocrine Pancreas 2132
3.14.4.1 Diabetes Mellitus 2133
3.14.4.2 Pancreatic Endocrine Neoplasms 2162
3.14.5 Adrenal Glands 2166
3.14.5.1 Adrenal Cortex 2166
3.14.5.2 Adrenal Medulla 2189
3.14.6 Multiple Endocrine Neoplasia Syndromes 2195
3.14.7 Pineal Gland 2197
3.14.7.1 Pinealomas 2197
3.14.8 References 2197
3.15 25. The Skin 2199
3.15.1 The Skin: More Than a Mechanical Barrier 2199
3.15.2 Disorders of Pigmentation & Melanocytes 2203
3.15.3 Benign Epithelial Tumors 2214
3.15.4 Premalignant & Malignant Epidermal Tumors 2219
3.15.5 Tumors of the Dermis 2225
3.15.6 Tumors of Cellular Migrants to the Skin 2227
3.15.7 Disorders of Epidermal Maturation 2230
3.15.8 Acute Inflammatory Dermatoses 2231
3.15.9 Chronic Inflammatory Dermatoses 2236
3.15.10 Blistering (Bullous) Diseases 2239
3.15.11 Disorders of Epidermal Appendages 2248
3.15.12 Panniculitis 2250
3.15.13 Infection 2251
3.15.14 References 2256
3.16 26. Bones, Joints & Soft-Tissue Tumors 2259
3.16.1 Bones 2259
3.16.1.1 Bone Modeling, Remodeling & Peak Bone Mass 2264
3.16.1.2 Bone Growth & Development 2264
3.16.1.3 Developmental Abnormalities in Bone Cells, Matrix & Structure 2266
3.16.1.4 Fractures 2285
3.16.1.5 Osteonecrosis (Avascular Necrosis) 2287
3.16.1.6 Infections: Osteomyelitis 2289

3.16.1.7 Bone Tumors & Tumor-Like Lesions ... 2292
3.16.1.8 Miscellaneous Tumors ... 2314
3.16.2 Joints ... 2320
3.16.2.1 Arthritis ... 2320
3.16.2.2 Tumors & Tumor-Like Lesions ... 2341
3.16.3 Soft-Tissue Tumors & Tumor-Like Lesions ... 2344
3.16.3.1 Pathogenesis & General Features ... 2345
3.16.3.2 Fatty Tumors ... 2347
3.16.3.3 Fibrous Tumors & Tumor-Like Lesions ... 2349
3.16.3.4 Fibrohistiocytic Tumors ... 2355
3.16.3.5 Tumors of Skeletal Muscle ... 2356
3.16.3.6 Tumors of Smooth Muscle ... 2358
3.16.3.7 Synovial Sarcoma ... 2359
3.16.4 References ... 2360
3.17 27. Peripheral Nerve & Skeletal Muscle ... 2362
3.17.1 General Reactions of the Motor Unit ... 2362
3.17.2 Diseases of Peripheral Nerve ... 2368
3.17.3 Diseases of Skeletal Muscle ... 2377
3.17.4 References ... 2393
3.18 28. The Central Nervous System ... 2394
3.18.1 Cellular Pathology of the Central Nervous System ... 2394
3.18.2 Cerebral Edema, Hydrocephalus & Raised Intracranial Pressure & Herniation ... 2398
3.18.3 Malformations & Developmental Diseases ... 2402
3.18.4 Perinatal Brain Injury ... 2408
3.18.5 Trauma ... 2409
3.18.6 Cerebrovascular Diseases ... 2416
3.18.7 Infections ... 2430
3.18.8 Transmissible Spongiform Encephalopathies (Prion Diseases) ... 2447
3.18.9 Demyelinating Diseases ... 2451
3.18.10 Degenerative Diseases ... 2457
3.18.11 Genetic Metabolic Diseases ... 2478
3.18.12 Toxic & Acquired Metabolic Diseases ... 2483
3.18.13 Tumors ... 2487
3.18.14 Metastatic Tumors, Paraneoplastic Syndromes, Peripheral Nerve Sheath Tumors, Familial Tumor Syndromes ... 2504

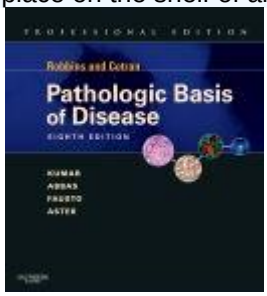
1.2 About This Book

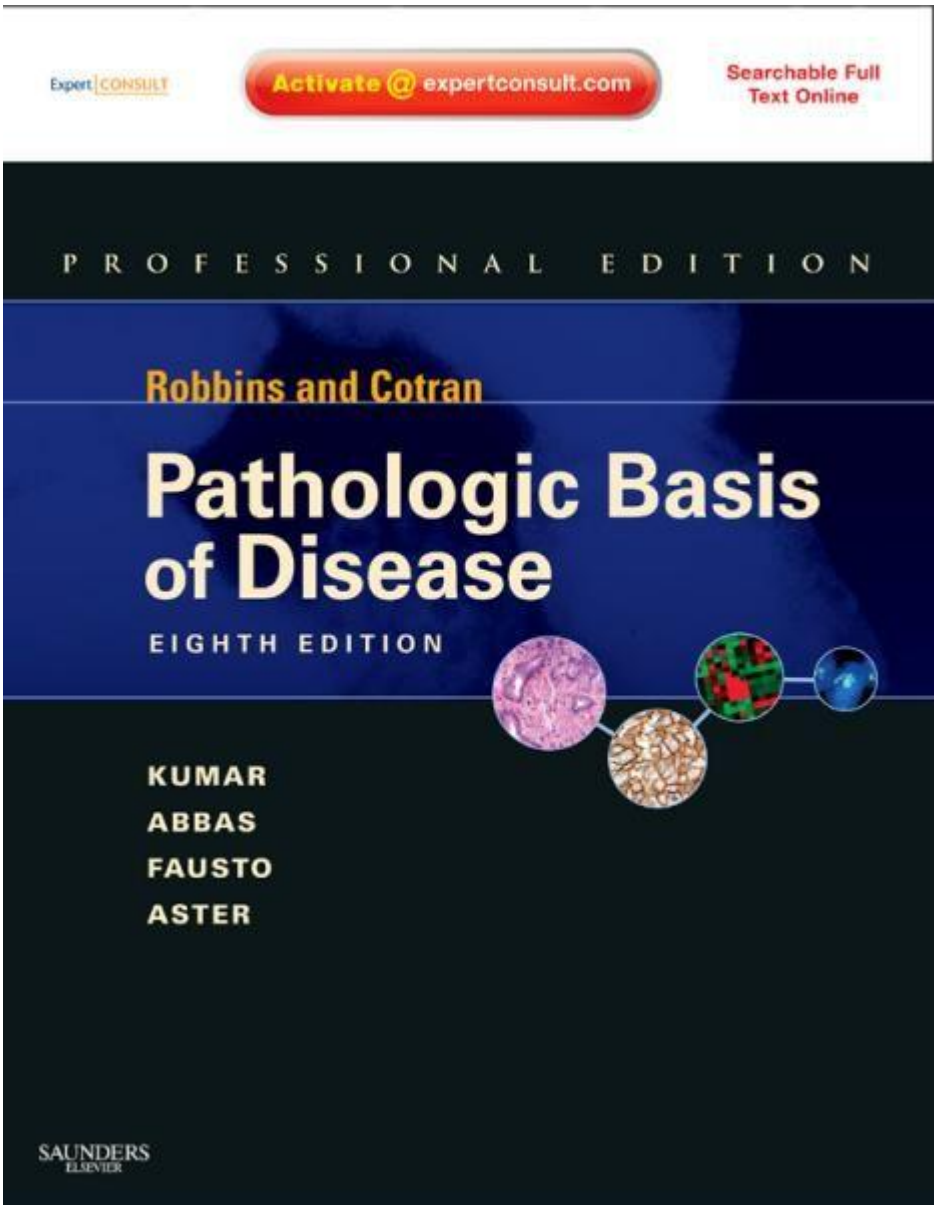
"Remarkably up to date...Provides the reader with a current understanding of disease mechanisms and deserves a place on the shelf of any health care professional, irrespective of specialty or level of training." - JAMA



One of the best-selling medical textbooks of all time, *Robbins and Cotran Pathologic Basis of Disease* is the one book that nearly all medical students purchase, and is also widely used by physicians worldwide. A "who's who" of pathology experts delivers the most dependable, current, and complete coverage of today's essential pathology knowledge. At the same time, masterful editing and a practical organization make mastering every concept remarkably easy. The result remains the ideal source for an optimal understanding of pathology.

1.3 Frontmatter

Eighth Edition



VINAY KUMAR, MBBS, MD FRCPath
Alice Hogge and Arthur Baer Professor, Chairman, Department of Pathology
Executive Vice Dean, Division of Biologic Sciences and, The Pritzker School of Medicine, The University of Chicago, Chicago, Illinois
ABUL K. ABBAS, MBBS
Professor and Chairman, Department of Pathology, University of California, San Francisco, San Francisco, California
NELSON FAUSTO, MD
Professor and Chairman, Department of Pathology, University of Washington School of Medicine, Seattle, Washington
JON C. ASTER, MD, PhD
Professor of Pathology, Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts

1.7 Preface: The Golden Jubilee Edition

As we launch the 8th edition of *Pathologic Basis of Disease* we pause to look back 50 years ago, when the first edition of this book, entitled "Pathology with Clinical Correlations" was published. (For those who may not know, the first three editions were published under this name and so the current "8th edition" is really the 11th edition of this book.)

In the preface of the first edition, Stanley Robbins wrote:

- "But the study of morphology is only one facet of pathology. Pathology contributes much to clinical medicine. The pathologist is interested not only in the recognition of structural alterations, but also in their significance, i.e., the effects of these changes on cellular and tissue function and ultimately the effect of these changes on the patient. It is not a discipline isolated from the living patient, but rather a basic approach to a better understanding of disease and therefore a foundation of sound clinical medicine."
- "The why's and how's are as important as the what's."

In today's vocabulary, what Robbins said in 1957 was that pathology is the study of the mechanism of diseases and morphology is a tool (the only one available at that time) to gain insight into pathogenesis and clinical correlations. Over the past 50 years, this focus has not changed and it remains the guiding principle for the current edition. The main difference is that now we have many more tools to supplement morphology, including molecular biology, genetics, and informatics, to name a few. Indeed, it might be said that this book presents the molecular basis of human disease with clinical correlations. This edition, like all previous ones, has been extensively revised, and some areas have been completely rewritten. A few examples of significant changes are as follows:

- Chapter 1 has been completely reorganized to include the entire spectrum of cellular responses to injury, from adaptations and sublethal injury to cell death.
- Chapter 3 , covering tissue repair and wound healing, has been extensively revised to include new and exciting information on stem cell biology, growth factor signaling, and the mechanisms that underlie fibrosis.
- Chapter 5 includes a completely rewritten section on molecular diagnosis that reflects rapid advances in DNA sequencing technology. The principles of genome-wide analysis, now becoming a powerful tool in the

study of complex human diseases like cancer and diabetes, have also been added.

- Chapter 9 has been completely revised and reorganized in view of the increasing importance of environmental factors in human diseases.
- Chapter 17 has been completely rewritten and highlights new insights into the pathogenesis of inflammatory bowel disease and gastrointestinal cancers.
- Chapter 22 , covering diseases of the female genital tract, includes discussion of the molecular basis of cancer, endometriosis, and preeclampsia.
- In addition to the revision and reorganization of the text, many new photographs and schematics have been added and a large number of the older "gems" have been enhanced by digital technology. Thus, we hope that even the veterans of *Robbins Pathology* will find the illustrations and figures sparkling and fresh.

Wherever appropriate, we have blended new discoveries into the discussion of pathogenesis and pathophysiology, while never losing sight that the "state of the art" has little value if it does not enhance the understanding of disease mechanisms. As in the past, we have not avoided discussions of "unsolved" problems because of our belief that many who read the text might be encouraged to embark on a path of discovery.

Despite the changes highlighted above, our goals remain the same as those articulated by Robbins and Cotran over the past many years.

- To integrate into the discussion of pathologic processes and disorders the newest established information available—morphologic as well as molecular.
- To organize information into logical and uniform presentations, facilitating readability, comprehension, and learning.
- To maintain the book at a reasonable size and yet provide adequate discussion of the significant lesions, processes, and disorders. Indeed, we have reduced the girth and the weight of this book by trimming out about 80 pages (making it less useful for weight lifting).
- To place great emphasis on clarity of writing and proper use of language in the recognition that struggling to comprehend is time-consuming and wearisome and gets in the way of the learning process.
- To make this first and foremost a student text—used by students throughout all years of medical school and into their residencies—but, at the same time, to provide sufficient detail and depth to meet the needs of more advanced readers.

We have been repeatedly told by readers that up-todatedness is a special feature that makes this book very valuable. We have strived to remain current by providing new information and references from recent literature, many published in 2008 and some from the early part of 2009. However, older classics have also been retained to provide original source material for advanced readers.

We are now into the digital age and so the text will be available online to those who own the print version. Such access gives the reader the ability to search across the entire text, bookmark passages, add personal notes, and use PubMed to view references, and has many other exciting features. In addition, also available online are case studies, previously available separately as the Interactive Case Study Companion developed by one of us (VK) in collaboration with Herb Hagler, PhD, and Nancy Schneider, MD, PhD, at the University of Texas Southwestern Medical School in Dallas. The cases are designed to enhance and reinforce learning by challenging students to apply their knowledge to solve clinical cases. A virtual microscope feature enables the viewing of selected images at various magnifications.

This edition is also marked by the addition of a new coauthor, Jon Aster. All four of us have reviewed, critiqued, and edited each chapter to ensure the uniformity of style and flow that have been the hallmarks of the book. Together, we hope that we have succeeded in equipping the readers with the

scientific basis for the practice of medicine and in whetting their appetite for learning beyond what can be offered in any textbook.

VK,
AKA,
NF,
JCA

1.8 Acknowledgments

The authors are grateful to a large number of individuals who have contributed in many ways toward the completion of this textbook.

First and foremost, all four of us offer thanks to our contributing authors for their commitment to this textbook. Many are veterans of previous editions; others are new to the eighth edition. All are acknowledged in the table of contents. Their names lend authority to this book, for which we are grateful.

Many colleagues have enhanced the text by reading various chapters and providing helpful critiques in their area of expertise. They include Drs. Michelle LeBeau, Jerry Krishnan, Julian Solway, Elyssa Gordon, Ankit Desai, Sue Cohen, Megan McNerney, Peter Pytel, and Tony Chang (at the University of Chicago); Dr. Serdar Bulun (at Northwestern University, Chicago); Drs. Steven Deeks, Sanjay Kakar, Zoltan Laszik, Scott Oakes, Jay Debnath, and Michael Nystrom (at the University of California San Francisco); Dr. Lundy Braun at Brown University and Dr. Peter Byers at the University of Washington; Drs. Frank Bunn, Jeffery Kutok, Helmut Rennke, Fred Wang, Max Loda, and Mark Fleming (at Harvard Medical School); and Dr. Richard Aster (at the Milwaukee Blood Center and Medical College of Wisconsin). Special thanks are due to Dr. Raminder Kumar for updating clinical information and extensive proof-reading of many chapters. Many colleagues provided photographic gems from their collections. They are individually acknowledged in the text.

Our administrative staff needs special mention since they maintain order in the chaotic lives of the authors and have willingly chipped in when needed for multiple tasks relating to the text. At the University of Chicago, they include Ms. Valerie Driscoll and Garcia Wilson; at The University of California at San Francisco, Ms. Ana Narvaez; at the University of Washington, Seattle, Greg Lawrence, Joscelyn Rompogren, Stephanie Meleady-Brown, and Jane Norris; at the Brigham and Women's Hospital, Deborah Kutok and Muriel Goutas. Ms. Beverly Shackelford at the University of Texas Southwestern Medical School at Dallas, who has helped one of us (VK) for 26 years, deserves a gold star since she coordinated the submission of all manuscripts, proofread many of them, and maintained liaison with the contributors and publisher. Without her dedication to this book and her meticulous attention to detail, our task would have been much more difficult. Almost all of the graphic art in this book was created by Mr. James Perkins, Assistant Professor of Medical Illustration at Rochester Institute of Technology. His ability to convert complex ideas into simple and aesthetically pleasing sketches has considerably enhanced this book.

Many individuals associated with our publisher, Elsevier (under the imprint of W.B. Saunders), need our special thanks. Outstanding among them is Ellen Sklar, Production Editor, supervising the production of this book. Her understanding of the needs of the authors and the complexity of publishing a textbook went a long way in making our lives less complicated. Mr. William Schmitt, Publishing Director of Medical Textbooks, has always been our cheerleader and is now a dear friend. Our thanks also go to Managing Editor Rebecca Gruliow and Design Manager Ellen Zanolle at Elsevier. Undoubtedly there are many other “heroes” who may have been left out unwittingly—to them we say “thank you” and tender apologies for not acknowledging you individually.

Efforts of this magnitude take a heavy toll on the families of the authors. We thank our spouses, Raminder Kumar, Ann Abbas, Ann DeLancey, and Erin Malone for their patience, love, and support of this venture, and for their tolerance of our absences.

Finally, Vinay Kumar, Abul Abbas, and Nelson Fausto wish to express their deep appreciation to Jon Aster for joining the team. Jon has proved his excellence as a contributor for many years, and now he adds luster to the entire book. Despite differences in our vantage points, opinions, and individual styles, our common vision shared with the late Drs. Stanley Robbins and Ramzi Cotran, has made this an exciting and rewarding partnership.

JCA

2. I. General Pathology

2.1 1. Cellular Responses to Stress & Toxic Insults: Adaptation, Injury & Death

2.1.1 Introduction to Pathology

Pathology is the study *(logos)* of disease *(pathos)*. More specifically, it is devoted to the study of the structural, biochemical, and functional changes in cells, tissues, and organs that underlie disease. By the use of molecular, microbiologic, immunologic, and morphologic techniques, pathology attempts to explain the whys and wherefores of the signs and symptoms manifested by patients while providing a rational basis for clinical care and therapy. It thus serves as the bridge between the basic sciences and clinical medicine, and is the scientific foundation for all of medicine.

Traditionally the study of pathology is divided into general pathology and systemic pathology. The former is concerned with the reactions of cells and tissues to abnormal stimuli and to inherited defects, which are the main causes of disease. The latter examines the alterations in specialized organs and tissues that are responsible for disorders that involve these organs. In this book we first cover the principles of general pathology and then proceed to specific disease processes as they affect particular organs or systems.

The four aspects of a disease process that form the core of pathology are its cause *(etiology)*, the mechanisms of its development *(pathogenesis)*, the biochemical and structural alterations induced in the cells and organs of the body *(molecular and morphologic changes)*, and the functional consequences of these changes *(clinical manifestations)*.

Etiology or Cause.

The concept that certain abnormal symptoms or diseases are "caused" is as ancient as recorded history. For the Arcadians (2500 BC), if someone became ill it was the patient's own fault (for having sinned) or the effects of outside agents, such as bad smells, cold, evil spirits, or gods.[1] We now recognize that there are two major classes of etiologic factors: genetic (e.g., inherited mutations and disease-associated gene variants, or polymorphisms) and acquired (e.g., infectious, nutritional, chemical, physical). The idea that one etiologic agent is the cause of one disease—developed from the study of infections and single-gene disorders—is not applicable to the majority of diseases. In fact, most of our common afflictions, such as atherosclerosis and cancer, are multifactorial and arise from the effects of various external triggers on a genetically susceptible individual. The relative contribution of inherited susceptibility and external influences varies in different diseases.

Pathogenesis.

Pathogenesis refers to the sequence of events in the response of cells or tissues to the etiologic agent, from the initial stimulus to the ultimate expression of the disease. The study of pathogenesis remains one of the main domains of pathology. Even when the initial cause is known (e.g., infection or mutation), it is many steps removed from the expression of the disease. For example, to understand cystic fibrosis is to know not only the defective gene and gene product, but also the biochemical and morphologic events leading to the formation of cysts and fibrosis in the lungs, pancreas, and other organs. Indeed, as we shall see throughout the book, the molecular revolution has already identified mutant genes underlying a great number of diseases, and the entire human genome has been mapped. Nevertheless, the functions of the encoded proteins and how mutations induce disease—the pathogenesis—are still often obscure. Technologic advances are making it increasingly feasible to link specific molecular abnormalities to disease manifestations and to use this knowledge to design new

therapeutic approaches. For these reasons, the study of pathogenesis has never been more exciting scientifically or more relevant to medicine.

Molecular and Morphologic Changes.

Morphologic changes refer to the structural alterations in cells or tissues that are either characteristic of a disease or diagnostic of an etiologic process. The practice of diagnostic pathology is devoted to identifying the nature and progression of disease by studying morphologic changes in tissues and chemical alterations in patients. More recently the limitations of morphology for diagnosing diseases have become increasingly evident, and the field of diagnostic pathology has expanded to encompass molecular biologic and immunologic approaches for analyzing disease states. Nowhere is this more striking than in the study of tumors; breast cancers that look morphologically identical may have widely different courses, therapeutic responses, and prognosis. Molecular analysis by techniques such as DNA microarrays (Chapter 5) has begun to reveal genetic differences that predict the behavior of the tumors as well as their responsiveness to different therapies. Increasingly, such techniques are being used to extend and even supplant traditional morphologic analyses.

Functional Derangements and Clinical Manifestations.

The end results of genetic, biochemical, and structural changes in cells and tissues are functional abnormalities, which lead to the clinical manifestations (symptoms and signs) of disease, as well as its progress (clinical course and outcome).

Virtually all forms of disease start with molecular or structural alterations in cells, a concept first put forth in the nineteenth century by Rudolf Virchow, known as the father of modern pathology. We therefore begin our consideration of pathology with the study of the causes, mechanisms, and morphologic and biochemical correlates of *cell injury*. Injury to cells and to extracellular matrix ultimately leads to *tissue and organ injury*, which determine the morphologic and clinical patterns of disease.

2.1.2 Overview: Cellular Responses to Stress & Noxious Stimuli

The normal cell is confined to a fairly narrow range of function and structure by its state of metabolism, differentiation, and specialization; by constraints of neighboring cells; and by the availability of metabolic substrates. It is nevertheless able to handle physiologic demands, maintaining a steady state called *homeostasis*. *Adaptations* are reversible functional and structural responses to more severe physiologic stresses and some pathologic stimuli, during which new but altered steady states are achieved, allowing the cell to survive and continue to function (Fig. 1-1 and Table 1-1). The adaptive response may consist of an increase in the size of cells (hypertrophy) and functional activity, an increase in their number (hyperplasia), a decrease in the size and metabolic activity of cells (atrophy), or a change in the phenotype of cells (metaplasia). When the stress is eliminated the cell can recover to its original state without having suffered any harmful consequences.

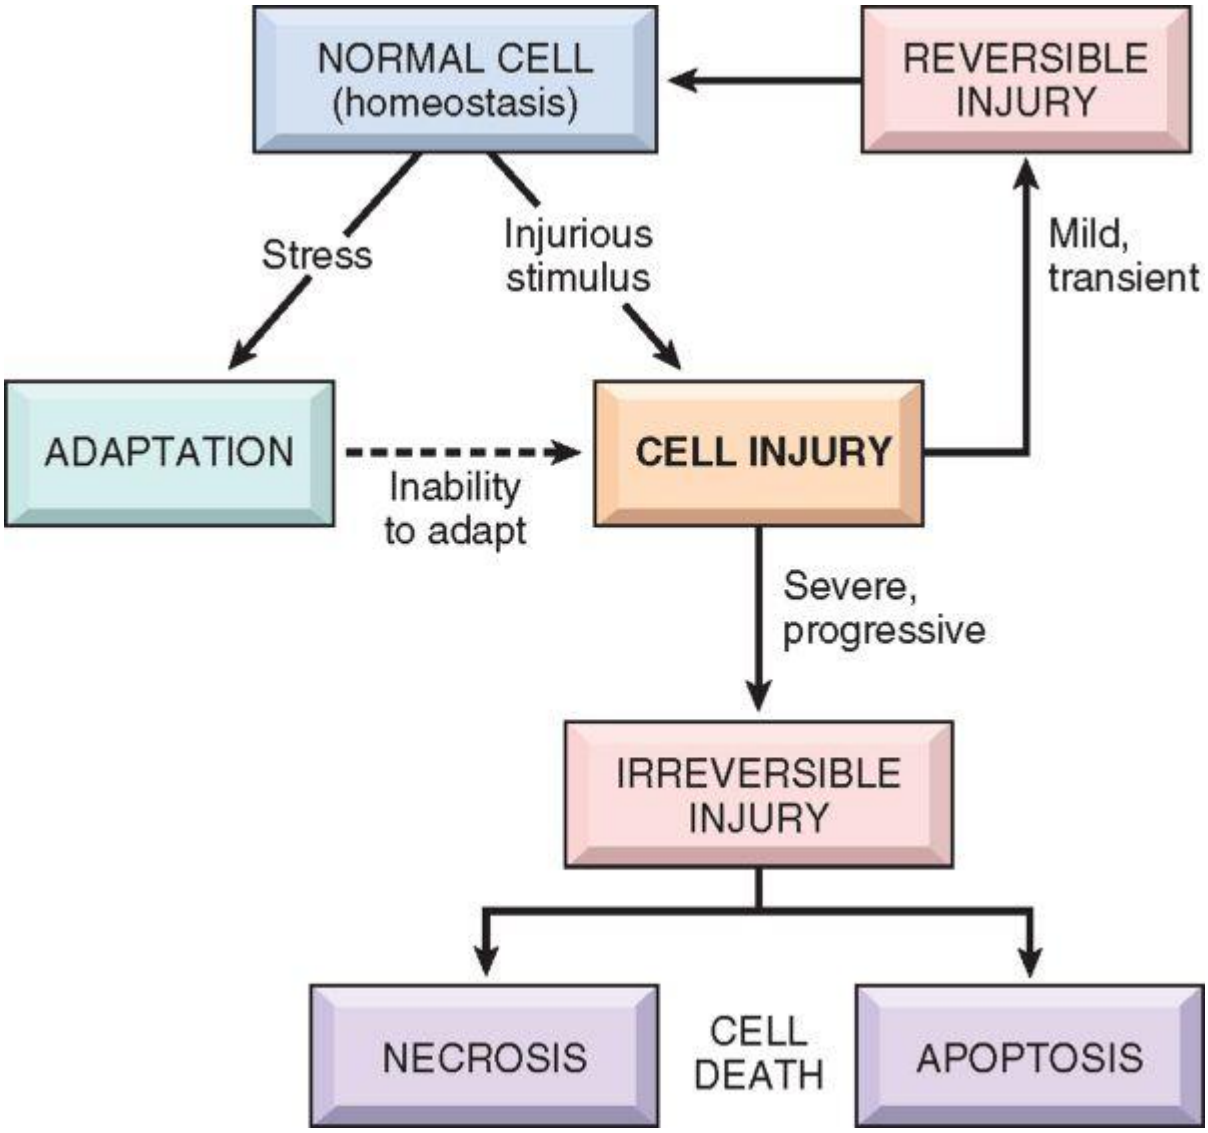

FIGURE 1-1 Stages of the cellular response to stress and injurious stimuli.

TABLE 1-1 -- Cellular Responses to Injury

Nature of Injurious Stimulus	Cellular Response
ALTERED PHYSIOLOGICAL STIMULI; SOME NONLETHAL INJURIOUS STIMULI	**CELLULAR ADAPTATIONS**
• Increased demand, increased stimulation (e.g., by growth factors, hormones) • Decreased nutrients, decreased stimulation • Chronic irritation (physical or chemical)	• Hyperplasia, hypertrophy • Atrophy • Metaplasia
REDUCED OXYGEN SUPPLY; CHEMICAL INJURY; MICROBIAL INFECTION	**CELL INJURY**
• Acute and transient • Progressive and severe (including DNA damage)	• Acute reversible injury Cellular swelling fatty change • Irreversible injury → cell death Necrosis

Nature of Injurious Stimulus	Cellular Response
	Apoptosis
METABOLIC ALTERATIONS, GENETIC OR ACQUIRED; CHRONIC INJURY	**INTRACELLULAR ACCUMULATIONS; CALCIFICATION**
CUMULATIVE SUBLETHAL INJURY OVER LONG LIFE SPAN	**CELLULAR AGING**

If the limits of adaptive responses are exceeded or if cells are exposed to injurious agents or stress, deprived of essential nutrients, or become compromised by mutations that affect essential cellular constituents, a sequence of events follows that is termed *cell injury* (see Fig. 1-1) Cell injury is *reversible* up to a certain point, but if the stimulus persists or is severe enough from the beginning, the cell suffers *irreversible injury* and ultimately *cell death. Adaptation, reversible injury*, and *cell death* may be stages of progressive impairment following different types of insults. For instance, in response to increased hemodynamic loads, the heart muscle becomes enlarged, a form of adaptation, and can even undergo injury. If the blood supply to the myocardium is compromised or inadequate, the muscle first suffers reversible injury, manifested by certain cytoplasmic changes (described later). Eventually, the cells suffer irreversible injury and die (Fig. 1-2).

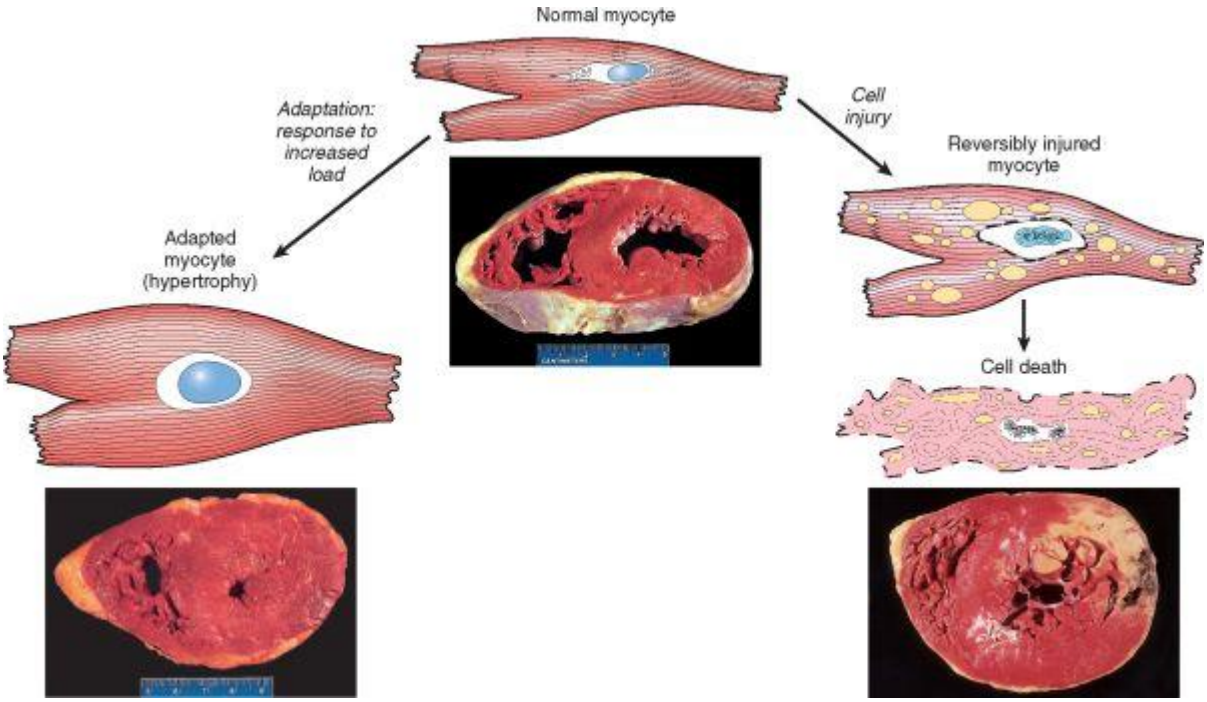

FIGURE 1-2 The relationship between normal, adapted, reversibly injured, and dead myocardial cells. The cellular adaptation is myocardial hypertrophy *(lower left)*, caused by increased blood flow requiring greater mechanical effort by myocardial cells. This adaptation leads to thickening of the left ventricular wall to over 2 cm (normal, 1–1.5 cm). In reversibly injured myocardium (illustrated schematically, *right*) there are generally only functional effects, without any readily apparent gross or even microscopic changes. In the specimen showing necrosis, a form of cell death *(lower right)*, the light area in the posterolateral left ventricle represents an acute myocardial infarction caused by reduced blood flow (ischemia). All three transverse sections of the heart have been stained with triphenyltetrazolium chloride, an enzyme substrate that colors viable myocardium magenta. Failure to stain is due to enzyme loss following cell death.

Cell death, the end result of progressive cell injury, is one of the most crucial events in the evolution of disease in any tissue or organ. It results from diverse causes, including ischemia (reduced blood flow), infection, and toxins. Cell death is also a normal and essential process in embryogenesis, the

development of organs, and the maintenance of homeostasis. There are two principal pathways of cell death, *necrosis* and *apoptosis*. Nutrient deprivation triggers an adaptive cellular response called *autophagy* that may also culminate in cell death. We will return to a detailed discussion of these pathways of cell death later in the chapter.

Stresses of different types may induce changes in cells and tissues other than typical adaptations, cell injury, and death (see Table 1-1). Metabolic derangements in cells and sublethal, chronic injury may be associated with *intracellular accumulations* of a number of substances, including proteins, lipids, and carbohydrates. Calcium is often deposited at sites of cell death, resulting in *pathologic calcification*. Finally, the normal process of *aging* itself is accompanied by characteristic morphologic and functional changes in cells.

In this chapter we discuss first how cells adapt to stresses, and then the causes, mechanisms, and consequences of the various forms of acute cell damage, including reversible cell injury, and cell death. We conclude with three other processes that affect cells and tissues: intracellular accumulations, pathologic calcification, and cell aging.

2.1.3 Adaptations of Cellular Growth & Differentiation

Adaptations are reversible changes in the size, number, phenotype, metabolic activity, or functions of cells in response to changes in their environment. Such adaptations may take several distinct forms.

HYPERTROPHY

Hypertrophy refers to an increase in the size of cells, resulting in an increase in the size of the organ. The hypertrophied organ has no new cells, just larger cells. The increased size of the cells is due to the synthesis of more structural components of the cells. Cells capable of division may respond to stress by undergoing both hyperplasia (described below) and hypertrophy, whereas in *nondividing cells* (e.g., myocardial fibers) increased tissue mass is due to hypertrophy. In many organs hypertrophy and hyperplasia may coexist and contribute to increased size.

Hypertrophy can be *physiologic* or *pathologic* and is caused by increased functional demand or by stimulation by hormones and growth factors. The striated muscle cells in the heart and skeletal muscles have only a limited capacity for division, and respond to increased metabolic demands mainly by undergoing hypertrophy. *The most common stimulus for hypertrophy of muscle is increased workload*. For example, the bulging muscles of bodybuilders engaged in “pumping iron” result from an increase in size of the individual muscle fibers in response to increased demand. In the heart, the stimulus for hypertrophy is usually chronic hemodynamic overload, resulting from either hypertension or faulty valves (see Fig. 1-2). In both tissue types the muscle cells synthesize more proteins and the number of myofilaments increases. This increases the amount of force each myocyte can generate, and thus increases the strength and work capacity of the muscle as a whole.

The massive physiologic growth of the uterus during pregnancy is a good example of hormone-induced increase in the size of an organ that results mainly from hypertrophy of muscle fibers (Fig. 1-3). The cellular enlargement is stimulated by estrogenic hormones acting on smooth muscle estrogen receptors, eventually resulting in increased synthesis of smooth muscle proteins and an increase in cell size.

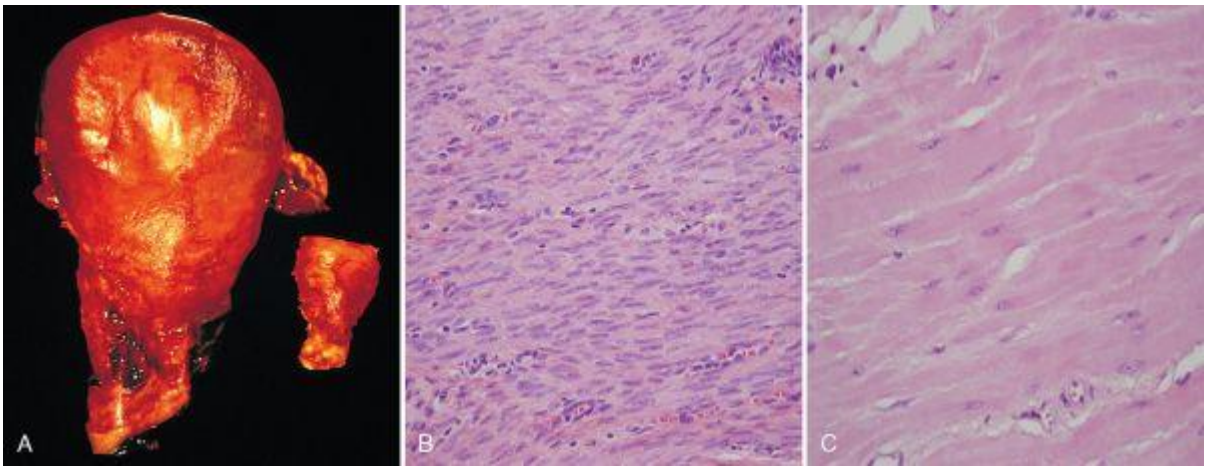

FIGURE 1-3 Physiologic hypertrophy of the uterus during pregnancy. **A**, Gross appearance of a normal uterus *(right)* and a gravid uterus (removed for postpartum bleeding) *(left)*. **B**, Small spindle-shaped uterine smooth muscle cells from a normal uterus, compared with **C**, large plump cells from the gravid uterus, at the same magnification.

Although the traditional view of cardiac and skeletal muscle is that in adults these tissues are incapable of proliferation and, therefore, their enlargement is entirely a result of hypertrophy, there is now accumulating evidence that even these cell types are capable of some proliferation as well as repopulation from precursors, in addition to hypertrophy (Chapter 3).[2]

Mechanisms of Hypertrophy

Hypertrophy is the result of increased production of cellular proteins. Much of our understanding of hypertrophy is based on studies of the heart. Hypertrophy can be induced by the linked actions of mechanical sensors (that are triggered by increased work load), growth factors (including TGF-β, insulin-like growth factor-1 [IGF-1], fibroblast growth factor), and vasoactive agents (such as α-adrenergic agonists, endothelin-1, and angiotensin II). Indeed, mechanical sensors themselves induce production of growth factors and agonists (Fig. 1-4). [3] [4] [5] These stimuli work coordinately to increase the synthesis of muscle proteins that are responsible for the hypertrophy. The two main biochemical pathways involved in muscle hypertrophy seem to be the phosphoinositide 3-kinase/Akt pathway (postulated to be most important in physiologic, e.g., exercise-induced, hypertrophy) and signaling downstream of G protein-coupled receptors (induced by many growth factors and vasoactive agents, and thought to be more important in pathologic hypertrophy). Hypertrophy may also be associated with a switch of contractile proteins from adult to fetal or neonatal forms. For example, during muscle hypertrophy the α isoform of myosin heavy chain is replaced by the β isoform, which has a slower, more energetically economical contraction. In addition, some genes that are expressed only during early development are re-expressed in hypertrophic cells, and the products of these genes participate in the cellular response to stress. For example, the gene for atrial natriuretic factor (ANF) is expressed in both the atrium and the ventricle in the embryonic heart, but it is down-regulated after birth. Cardiac hypertrophy, however, is associated with reinduction of ANF gene expression. ANF is a peptide hormone that causes salt secretion by the kidney, decreases blood volume and pressure, and therefore serves to reduce hemodynamic load.

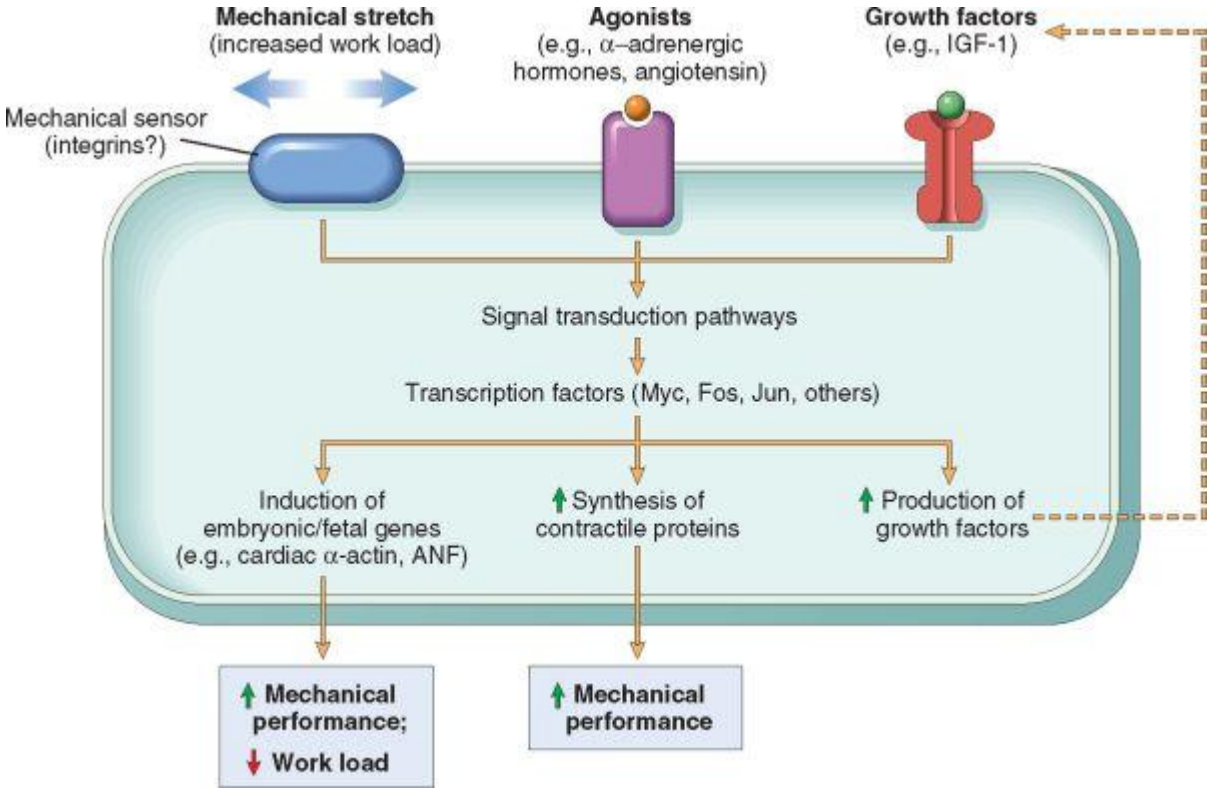

FIGURE 1-4 Biochemical mechanisms of myocardial hypertrophy. The major known signaling pathways and their functional effects are shown. Mechanical sensors appear to be the major triggers for physiologic hypertrophy, and agonists and growth factors may be more important in pathologic states. ANF, atrial natriuretic factor; IGF-1, insulin-like growth factor.

Whatever the exact cause and mechanism of cardiac hypertrophy, it eventually reaches a limit beyond which enlargement of muscle mass is no longer able to compensate for the increased burden. At this stage several regressive changes occur in the myocardial fibers, of which the most important are lysis and loss of myofibrillar contractile elements. In extreme cases myocyte death can occur by either apoptosis or necrosis.[5,][6] The net result of these changes is cardiac failure, a sequence of events that illustrates how *an adaptation to stress can progress to functionally significant cell injury if the stress is not relieved*.

Although hypertrophy usually refers to increase in size of cells or tissues, sometimes a subcellular organelle may undergo selective hypertrophy. For instance, individuals treated with drugs such as barbiturates show hypertrophy of the smooth endoplamic reticulum (ER) in hepatocytes, which is an adaptive response that increases the amount of enzymes (cytochrome P-450 mixed function oxidases) available to detoxify the drugs. Over time, the patients respond less to the drug because of this adaptation. Adaptation to one drug may result in an increased capacity to metabolize other drugs. For instance, alcohol intake causes hypertrophy of the smooth ER and may lead to reduced levels of available barbiturates that are being taken at the same time. Although P-450-mediated modification is often thought of as "detoxification," many compounds are rendered *more* injurious by this process. In addition, the products formed by this oxidative metabolism include reactive oxygen species, which can injure the cell. Normal genetic variations (polymorphisms) influence the activity of P-450, and thus the sensitivity of different individuals to various drugs.[7]

HYPERPLASIA

Hyperplasia is an increase in the number of cells in an organ or tissue, usually resulting in increased mass of the organ or tissue. Although hyperplasia and hypertrophy are distinct processes, frequently they occur together, and they may be triggered by the same external stimulus. Hyperplasia takes place if the cell population is capable of dividing, and thus increasing the number of cells. Hyperplasia can be physiologic or pathologic.

Physiologic Hyperplasia

Physiologic hyperplasia can be divided into: (1) *hormonal hyperplasia*, which increases the functional capacity of a tissue when needed, and (2) *compensatory hyperplasia*, which increases tissue mass after damage or partial resection. Hormonal hyperplasia is well illustrated by the proliferation of the glandular epithelium of the female breast at puberty and during pregnancy, usually accompanied by enlargement (hypertrophy) of the glandular epithelial cells. The classical illustration of compensatory hyperplasia comes from the myth of Prometheus, which shows that the ancient Greeks recognized the capacity of the liver to regenerate. As punishment for having stolen the secret of fire from the gods, Prometheus was chained to a mountain, and his liver was devoured daily by an eagle, only to regenerate anew every night.[1] In individuals who donate one lobe of the liver for transplantation, the remaining cells proliferate so that the organ soon grows back to its original size. Experimental models of partial hepatectomy have been very useful for defining the mechanisms that stimulate regeneration of the liver[7] (Chapter 3).

Pathologic Hyperplasia

Most forms of pathologic hyperplasia are caused by *excesses of hormones or growth factors* acting on target cells. Endometrial hyperplasia is an example of abnormal hormone-induced hyperplasia. Normally, after a menstrual period there is a rapid burst of proliferative activity in the epithelium that is stimulated by pituitary hormones and ovarian estrogen. It is brought to a halt by the rising levels of progesterone, usually about 10 to 14 days before the end of the menstrual period. In some instances, however, the balance between estrogen and progesterone is disturbed. This results in absolute or relative increases in the amount of estrogen, with consequent hyperplasia of the endometrial glands. This form of pathologic hyperplasia is a common cause of abnormal menstrual bleeding. Benign prostatic hyperplasia is another common example of pathologic hyperplasia induced by responses to hormones, in this case, androgens. Although these forms of hyperplasia are abnormal, the process remains controlled because there are no mutations in genes that regulate cell division, and the hyperplasia regresses if the hormonal stimulation is eliminated. As is discussed in Chapter 7 , in cancer the growth control mechanisms become dysregulated or ineffective because of genetic aberrations, resulting in unrestrained proliferation. *Thus, hyperplasia is distinct from cancer, but pathologic hyperplasia constitutes a fertile soil in which cancerous proliferation may eventually arise*. For instance, patients with hyperplasia of the endometrium are at increased risk for developing endometrial cancer (Chapter 22).

Hyperplasia is a characteristic response to certain *viral infections*, such as papillomaviruses, which cause skin warts and several mucosal lesions composed of masses of hyperplastic epithelium. Here, growth factors produced by viral genes or by infected cells may stimulate cellular proliferation (Chapter 7).

Mechanisms of Hyperplasia

Hyperplasia is the result of growth factor–driven proliferation of mature cells and, in some cases, by increased output of new cells from tissue stem cells. For instance, after partial hepatectomy growth factors are produced in the liver that engage receptors on the surviving cells and activate signaling pathways that stimulate cell proliferation. But if the proliferative capacity of the liver cells is

compromised, as in some forms of hepatitis causing cell injury, hepatocytes can instead regenerate from intrahepatic stem cells.[8] The roles of growth factors and stem cells in cellular replication and tissue hyperplasia are discussed in more detail in Chapter 3 .

ATROPHY

Atrophy is reduced size of an organ or tissue resulting from a decrease in cell size and number. Atrophy can be physiologic or pathologic. *Physiologic atrophy* is common during normal development. Some embryonic structures, such as the notochord and thyroglossal duct, undergo atrophy during fetal development. The uterus decreases in size shortly after parturition, and this is a form of physiologic atrophy.

Pathologic atrophy depends on the underlying cause and can be local or generalized. The common causes of atrophy are the following:

- *Decreased workload (atrophy of disuse)*. When a fractured bone is immobilized in a plaster cast or when a patient is restricted to complete bedrest, skeletal muscle atrophy rapidly ensues. The initial decrease in cell size is reversible once activity is resumed. With more prolonged disuse, skeletal muscle fibers decrease in number (due to apoptosis) as well as in size; this atrophy can be accompanied by increased bone resorption, leading to osteoporosis of disuse.
- *Loss of innervation (denervation atrophy)*. The normal metabolism and function of skeletal muscle are dependent on its nerve supply. Damage to the nerves leads to atrophy of the muscle fibers supplied by those nerves (Chapter 27).
- *Diminished blood supply*. A decrease in blood supply (ischemia) to a tissue as a result of slowly developing arterial occlusive disease results in atrophy of the tissue. In late adult life, the brain may undergo progressive atrophy, mainly because of reduced blood supply as a result of atherosclerosis (Fig. 1-5). This is called *senile atrophy*; it also affects the heart.
- *Inadequate nutrition*. Profound protein-calorie malnutrition (marasmus) is associated with the use of skeletal muscle as a source of energy after other reserves such as adipose stores have been depleted. This results in marked muscle wasting *(cachexia*; Chapter 9). Cachexia is also seen in patients with chronic inflammatory diseases and cancer. In the former, chronic overproduction of the inflammatory cytokine tumor necrosis factor (TNF) is thought to be responsible for appetite suppression and lipid depletion, culminating in muscle atrophy.
- *Loss of endocrine stimulation*. Many hormone-responsive tissues, such as the breast and reproductive organs, are dependent on endocrine stimulation for normal metabolism and function. The loss of estrogen stimulation after menopause results in physiologic atrophy of the endometrium, vaginal epithelium, and breast.
- *Pressure*. Tissue compression for any length of time can cause atrophy. An enlarging benign tumor can cause atrophy in the surrounding uninvolved tissues. Atrophy in this setting is probably the result of ischemic changes caused by compromise of the blood supply by the pressure exerted by the expanding mass.

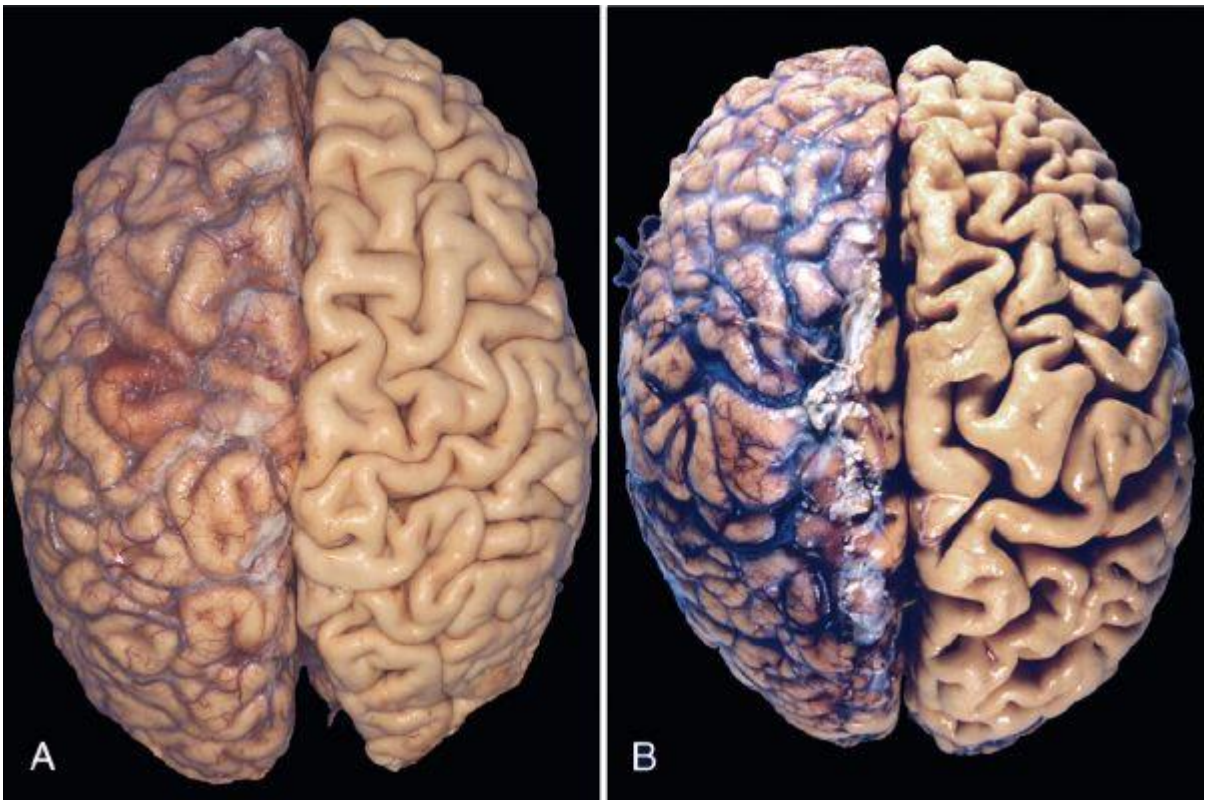

FIGURE 1-5 Atrophy. **A**, Normal brain of a young adult. **B**, Atrophy of the brain in an 82-year-old male with atherosclerotic cerebrovascular disease, resulting in reduced blood supply. Note that loss of brain substance narrows the gyri and widens the sulci. The meninges have been stripped from the right half of each specimen to reveal the surface of the brain.

The fundamental cellular changes associated with atrophy are identical in all of these settings. The initial response is a decrease in cell size and organelles, which may reduce the metabolic needs of the cell sufficiently to permit its survival. In atrophic muscle, the cells contain fewer mitochondria and myofilaments and a reduced amount of rough ER. By bringing into balance the cell's metabolic demand and the lower levels of blood supply, nutrition, or trophic stimulation, a new equilibrium is achieved. *Early in the process atrophic cells may have diminished function, but they are not dead*. However, atrophy caused by gradually reduced blood supply may progress to the point at which cells are irreversibly injured and die, often by apoptosis. Cell death by apoptosis also contributes to the atrophy of endocrine organs after hormone withdrawal.

Mechanisms of Atrophy

Atrophy results from decreased protein synthesis and increased protein degradation in cells. Protein synthesis decreases because of reduced metabolic activity. The degradation of cellular proteins occurs mainly by the *ubiquitin-proteasome pathway*. Nutrient deficiency and disuse may activate ubiquitin ligases, which attach the small peptide ubiquitin to cellular proteins and target these proteins for degradation in *proteasomes*.[3,][9,][10] This pathway is also thought to be responsible for the accelerated proteolysis seen in a variety of catabolic conditions, including cancer cachexia.

In many situations, atrophy is also accompanied by increased *autophagy*, with resulting increases in the number of *autophagic vacuoles*. Autophagy ("self eating") is the process in which the starved cell eats its own components in an attempt to find nutrients and survive. Autophagic vacuoles are membrane-

bound vacuoles that contain fragments of cell components. The vacuoles ultimately fuse with lysosomes, and their contents are digested by lysosomal enzymes. Some of the cell debris within the autophagic vacuoles may resist digestion and persist as membrane-bound *residual bodies* that may remain as a sarcophagus in the cytoplasm. An example of such residual bodies is the *lipofuscin granules*, discussed later in the chapter. When present in sufficient amounts, they impart a brown discoloration to the tissue *(brown atrophy)*. Autophagy is associated with various types of cell injury, and we will discuss it in more detail later.

METAPLASIA

Metaplasia is a reversible change in which one differentiated cell type (epithelial or mesenchymal) is replaced by another cell type. It may represent an adaptive substitution of cells that are sensitive to stress by cell types better able to withstand the adverse environment.

The most common epithelial metaplasia is *columnar* to *squamous* (Fig. 1-6), as occurs in the respiratory tract in response to chronic irritation. In the habitual cigarette smoker, the normal ciliated columnar epithelial cells of the trachea and bronchi are often replaced by stratified squamous epithelial cells. Stones in the excretory ducts of the salivary glands, pancreas, or bile ducts may also cause replacement of the normal secretory columnar epithelium by stratified squamous epithelium. A deficiency of vitamin A (retinoic acid) induces squamous metaplasia in the respiratory epithelium (Chapter 9). In all these instances the more rugged stratified squamous epithelium is able to survive under circumstances in which the more fragile specialized columnar epithelium might have succumbed. However, the change to metaplastic squamous cells comes with a price. In the respiratory tract, for example, although the epithelial lining becomes tough, important mechanisms of protection against infection—mucus secretion and the ciliary action of the columnar epithelium—are lost. Thus, epithelial metaplasia is a double-edged sword and, in most circumstances, represents an undesirable change. Moreover, *the influences that predispose to metaplasia, if persistent, may initiate malignant transformation in metaplastic epithelium*. Thus, a common form of cancer in the respiratory tract is composed of squamous cells, which arise in areas of metaplasia of the normal columnar epithelium into squamous epithelium.

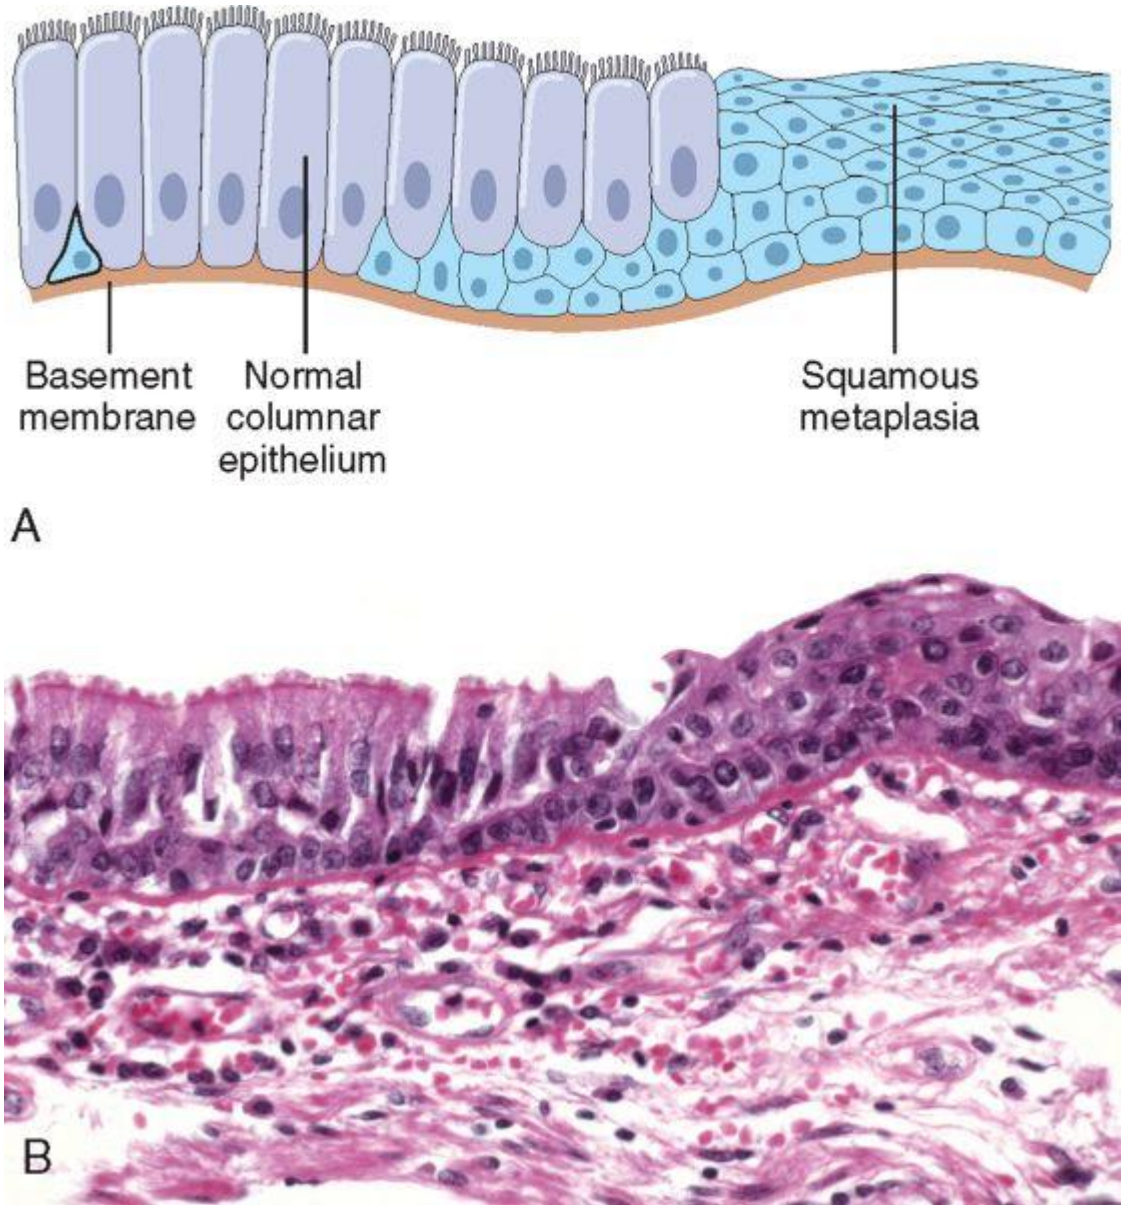

FIGURE 1-6 Metaplasia of columnar to squamous epithelium. **A**, Schematic diagram. **B**, Metaplasia of columnar epithelium *(left)* to squamous epithelium *(right)* in a bronchus.

Metaplasia from squamous to columnar type may also occur, as in *Barrett esophagus*, in which the esophageal squamous epithelium is replaced by intestinal-like columnar cells under the influence of refluxed gastric acid. Cancers may arise in these areas; these are typically glandular (adeno)carcinomas (Chapter 17).

Connective tissue metaplasia is the formation of cartilage, bone, or adipose tissue (mesenchymal tissues) in tissues that normally do not contain these elements. For example, bone formation in muscle, designated *myositis ossificans*, occasionally occurs after intramuscular hemorrhage. This type of metaplasia is less clearly seen as an adaptive response, and may be a result of cell or tissue injury.

Mechanisms of Metaplasia

Metaplasia does not result from a change in the phenotype of an already differentiated cell type; instead it is *the result of a reprogramming of stem cells that are known to exist in normal tissues, or of undifferentiated mesenchymal cells present in connective tissue*. In a metaplastic change, these precursor cells differentiate along a new pathway. The differentiation of stem cells to a particular lineage is brought about by signals generated by cytokines, growth factors, and extracellular matrix components in the cells' environment.[11,][12] These external stimuli promote the expression of genes that drive cells toward a specific differentiation pathway. In the case of vitamin A deficiency or excess, it is known that retinoic acid regulates gene transcription directly through nuclear retinoid receptors (Chapter 9), which can influence the differentiation of progenitors derived from tissue stem cells. How other external stimuli cause metaplasia is unknown, but it is clear that they too somehow alter the activity of transcription factors that regulate differentiation.

2.1.4 Overview of Cell Injury & Cell Death

As stated at the beginning of the chapter, cell injury results when cells are stressed so severely that they are no longer able to adapt or when cells are exposed to inherently damaging agents or suffer from intrinsic abnormalities. Injury may progress through a reversible stage and culminate in cell death (see Fig. 1-1).

- *Reversible cell injury*. In early stages or mild forms of injury, the functional and morphologic changes are reversible if the damaging stimulus is removed. The hallmarks of reversible injury are reduced oxidative phosphorylation with resultant depletion of energy stores in the form of adenosine triphosphate (ATP), and cellular swelling caused by changes in ion concentrations and water influx. In addition, various intracellular organelles, such as mitochondria and the cytoskeleton, may also show alterations.
- *Cell death*. With continuing damage the injury becomes irreversible, at which time the cell cannot recover and it dies. *There are two principal types of cell death, necrosis and apoptosis, which differ in their morphology, mechanisms, and roles in physiology and disease*. [13] [14] [15] When damage to membranes is severe, lysosomal enzymes enter the cytoplasm and digest the cell, and cellular contents leak out, resulting in *necrosis*. In situations when the cell's DNA or proteins are damaged beyond repair, the cell kills itself by *apoptosis*, a form of cell death that is characterized by nuclear dissolution, fragmentation of the cell without complete loss of membrane integrity, and rapid removal of the cellular debris. *Whereas necrosis is always a pathologic process, apoptosis serves many normal functions and is not necessarily associated with cell injury*. Cell death is also sometimes the end result of *autophagy*. Although it is easier to understand these pathways of cell death by discussing them separately, there may be many connections between them. Both apoptosis and necrosis may be seen in response to the same insult, such as ischemia, perhaps at different stages. Apoptosis can progress to necrosis, and cell death during autophagy may show many of the biochemical characteristics of apoptosis.

In the following sections we discuss the causes, morphologic features, and mechanisms of cell injury and its common end point, necrosis, with selected illustrative examples. We conclude with a discussion of the unique pattern of cell death represented by apoptosis, and then a brief description of the process of autophagy and how it may progress to cell death.

2.1.5 Causes of Cell Injury

The causes of cell injury range from the external gross physical violence of an automobile accident to subtle internal abnormalities, such as a genetic mutation causing lack of a vital enzyme that impairs normal metabolic function. Most injurious stimuli can be grouped into the following broad categories.

Oxygen Deprivation.

Hypoxia is a deficiency of oxygen, which causes cell injury by reducing aerobic oxidative respiration. Hypoxia is an extremely important and common cause of cell injury and cell death. *Causes of hypoxia* include reduced blood flow (celled *ischemia*), inadequate oxygenation of the blood due to cardiorespiratory failure, and decreased oxygen-carrying capacity of the blood, as in anemia or carbon

monoxide poisoning (producing a stable carbon monoxyhemoglobin that blocks oxygen carriage) or after severe blood loss. Depending on the severity of the hypoxic state, cells may adapt, undergo injury, or die. For example, if an artery is narrowed, the tissue supplied by that vessel may initially shrink in size (atrophy), whereas more severe or sudden hypoxia induces injury and cell death.

Physical Agents.

Physical agents capable of causing cell injury include mechanical trauma, extremes of temperature (burns and deep cold), sudden changes in atmospheric pressure, radiation, and electric shock (Chapter 9).

Chemical Agents and Drugs.

The list of chemicals that may produce cell injury defies compilation. Simple chemicals such as glucose or salt in hypertonic concentrations may cause cell injury directly or by deranging electrolyte balance in cells. Even oxygen at high concentrations is toxic. Trace amounts of *poisons*, such as arsenic, cyanide, or mercuric salts, may destroy sufficient numbers of cells within minutes or hours to cause death. Other potentially injurious substances are our daily companions: environmental and air pollutants, insecticides, and herbicides; industrial and occupational hazards, such as carbon monoxide and asbestos; recreational drugs such as alcohol; and the ever-increasing variety of therapeutic drugs.

Infectious Agents.

These agents range from the submicroscopic viruses to the large tapeworms. In between are the rickettsiae, bacteria, fungi, and higher forms of parasites. The ways by which these biologic agents cause injury are diverse and are discussed in Chapter 8 .

Immunologic Reactions.

The immune system serves an essential function in defense against infectious pathogens, but immune reactions may also cause cell injury. Injurious reactions to endogenous self-antigens are responsible for several autoimmune diseases (Chapter 6). Immune reactions to many external agents, such as microbes and environmental substances, are also important causes of cell and tissue injury (Chapters 2 and 6 .

Genetic Derangements.

As described in Chapter 5 , genetic abnormalities may result in a defect as severe as the congenital malformations associated with Down syndrome, caused by a chromosomal anomaly, or as subtle as the decreased life span of red blood cells caused by a single amino acid substitution in hemoglobin in sickle cell anemia. Genetic defects may cause cell injury because of deficiency of functional proteins, such as enzyme defects in inborn errors of metabolism, or accumulation of damaged DNA or misfolded proteins, both of which trigger cell death when they are beyond repair. Variations in the genetic makeup can also influence the susceptibility of cells to injury by chemicals and other environmental insults.

Nutritional Imbalances.

Nutritional imbalances continue to be major causes of cell injury. Protein-calorie deficiencies cause an appalling number of deaths, chiefly among underprivileged populations. Deficiencies of specific vitamins are found throughout the world (Chapter 9). Nutritional problems can be self-imposed, as in anorexia nervosa (self-induced starvation). Ironically, nutritional excesses have also become important causes of cell injury. Excess of cholesterol predisposes to atherosclerosis; obesity is associated with increased incidence of several important diseases, such as diabetes and cancer. Atherosclerosis is virtually endemic in the United States, and obesity is rampant. In addition to the problems of

undernutrition and overnutrition, the composition of the diet makes a significant contribution to a number of diseases.

2.1.6 Morphologic Alterations in Cell Injury

It is useful to describe the basic alterations that occur in damaged cells before we discuss the biochemical mechanisms that bring about these changes. All stresses and noxious influences exert their effects first at the molecular or biochemical level. There is a time lag between the stress and the morphologic changes of cell injury or death; the duration of this delay may vary with the sensitivity of the methods used to detect these changes (Fig. 1-7). With histochemical or ultrastructural techniques, changes may be seen in minutes to hours after injury; however, it may take considerably longer (hours to days) before changes can be seen by light microscopy or on gross examination. As would be expected, the morphologic manifestations of necrosis take more time to develop than those of reversible damage. For example, in ischemia of the myocardium, cell swelling is a reversible morphologic change that may occur in a matter of minutes, and may progress to irreversibility within an hour or two. Unmistakable light microscopic changes of cell death, however, may not be seen until 4 to 12 hours after total ischemia.

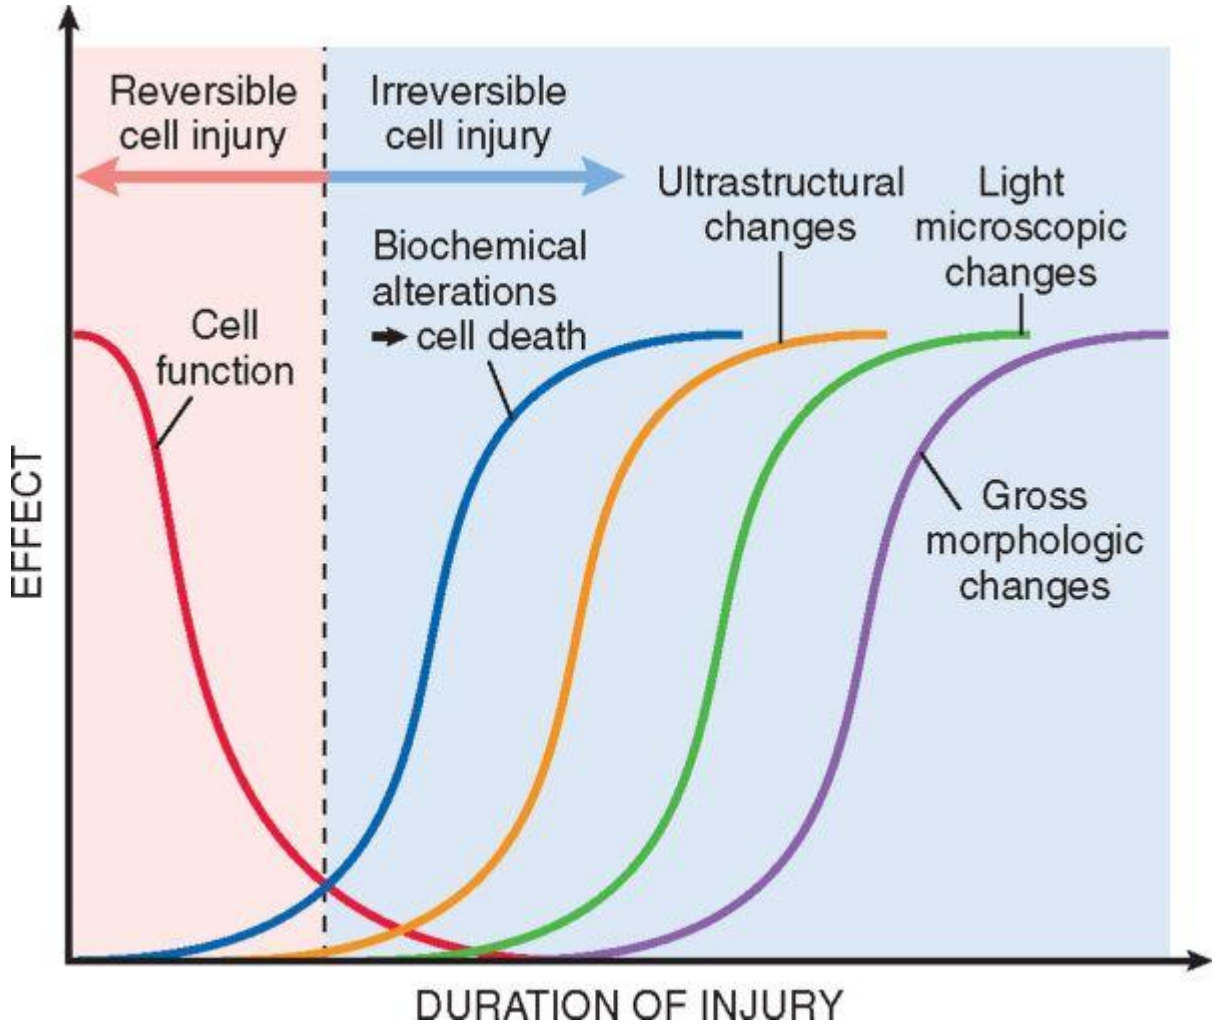

FIGURE 1-7 Sequential development of biochemical and morphologic changes in cell injury. Cells may become rapidly nonfunctional after the onset of injury, although they are still viable, with potentially reversible damage; a longer duration of injury may eventually lead to irreversible injury and cell death. Note that irreversible biochemical alterations may cause cell death, and typically this precedes ultrastructural,

light microscopic, and grossly visible morphologic changes.

The sequential morphologic changes in cell injury progressing to cell death are illustrated in Figure 1-8 . Reversible injury is characterized by generalized swelling of the cell and its organelles; blebbing of the plasma membrane; detachment of ribosomes from the ER; and clumping of nuclear chromatin. These morphologic changes are associated with decreased generation of ATP, loss of cell membrane integrity, defects in protein synthesis, cytoskeletal damage, and DNA damage. Within limits, the cell can repair these derangements and, if the injurious stimulus abates, will return to normalcy. Persistent or excessive injury, however, causes cells to pass the rather nebulous "point of no return" into irreversible injury and *cell death*. Different injurious stimuli may induce death by necrosis or apoptosis (Fig. 1-8 and Table 1-2). Severe mitochondrial damage with depletion of ATP and rupture of lysosomal and plasma membranes are typically associated with necrosis. Necrosis is the principal outcome in many commonly encountered injuries, such as those following ischemia, exposure to toxins, various infections, and trauma. Apoptosis has many unique features, and we will describe it later in the chapter.

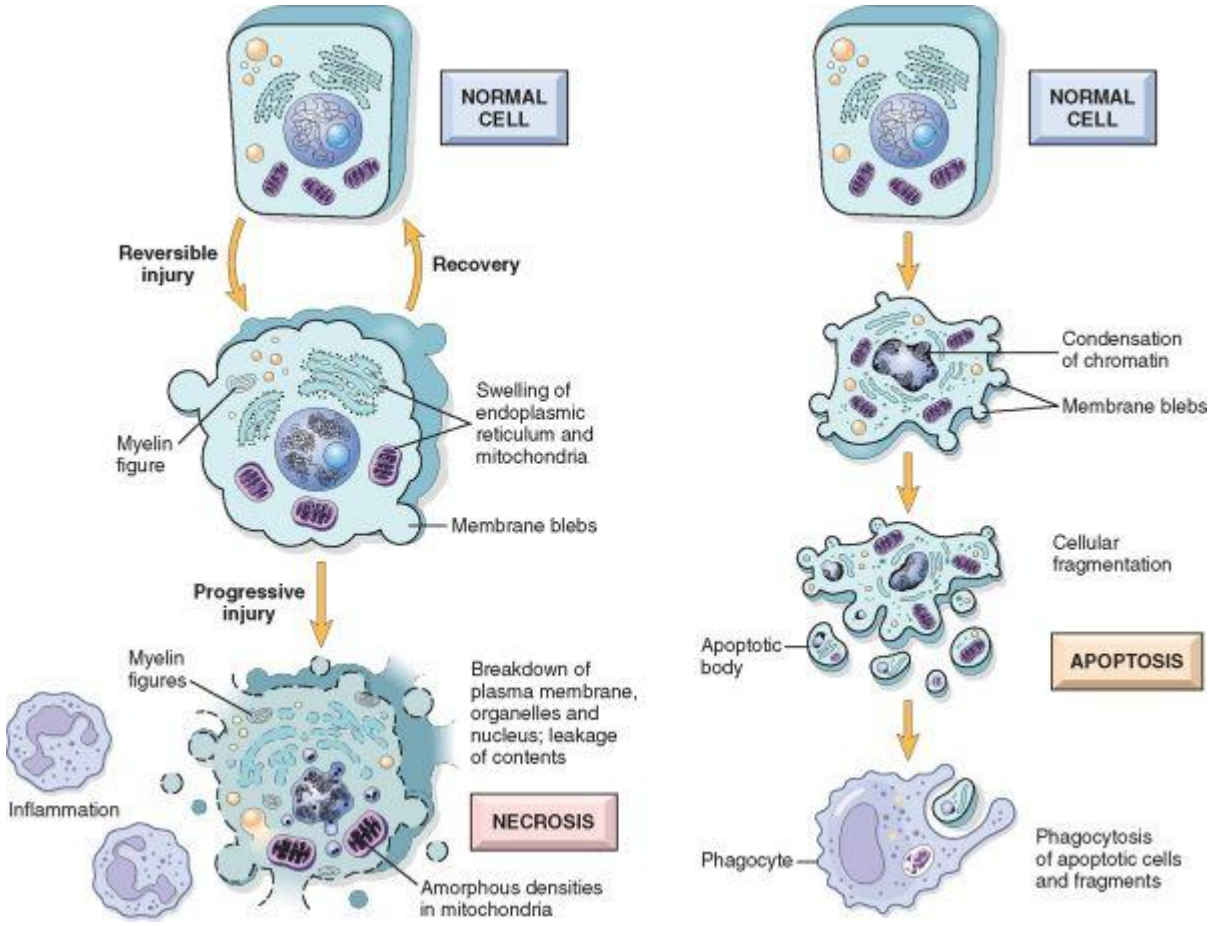

FIGURE 1-8 Schematic illustration of the morphologic changes in cell injury culminating in necrosis or apoptosis.

TABLE 1-2 -- Features of Necrosis and Apoptosis

Feature	Necrosis	Apoptosis

Feature	Necrosis	Apoptosis
Cell size	Enlarged (swelling)	Reduced (shrinkage)
Nucleus	Pyknosis → karyorrhexis → karyolysis	Fragmentation into nucleosome-size fragments
Plasma membrane	Disrupted	Intact; altered structure, especially orientation of lipids
Cellular contents	Enzymatic digestion; may leak out of cell	Intact; may be released in apoptotic bodies
Adjacent inflammation	Frequent	No
Physiologic or pathologic role	Invariably pathologic (culmination of irreversible cell injury)	Often physiologic, means of eliminating unwanted cells; may be pathologic after some forms of cell injury, especially DNA damage

REVERSIBLE INJURY

Two features of reversible cell injury can be recognized under the light microscope: *cellular swelling* and *fatty change*. Cellular swelling appears whenever cells are incapable of maintaining ionic and fluid homeostasis and is the result of failure of energy-dependent ion pumps in the plasma membrane. Fatty change occurs in hypoxic injury and various forms of toxic or metabolic injury. It is manifested by the appearance of lipid vacuoles in the cytoplasm. It is seen mainly in cells involved in and dependent on fat metabolism, such as hepatocytes and myocardial cells. The mechanisms of fatty change are discussed later in the chapter.

Morphology. Cellular swelling is the first manifestation of almost all forms of injury to cells (Fig. 1-9B). It is a difficult morphologic change to appreciate with the light microscope; it may be more apparent at the level of the whole organ. When it affects many cells, it causes some pallor, increased turgor, and increase in weight of the organ. On microscopic examination, small clear vacuoles may be seen within the cytoplasm; these represent distended and pinched-off segments of the ER. This pattern of nonlethal injury is sometimes called hydropic change or vacuolar degeneration. Swelling of cells is reversible. Cells may also show increased eosinophilic staining, which becomes much more pronounced with progression to necrosis (described below).

The ultrastructural changes of reversible cell injury (Fig. 1-10B) include:

1. **Plasma membrane alterations**, such as blebbing, blunting, and loss of microvilli
2. **Mitochondrial changes**, including swelling and the appearance of small amorphous densities
3. **Dilation** of the **ER**, with detachment of polysomes; intracytoplasmic myelin figures may be present (see later)
4. **Nuclear alterations**, with disaggregation of granular and fibrillar elements.

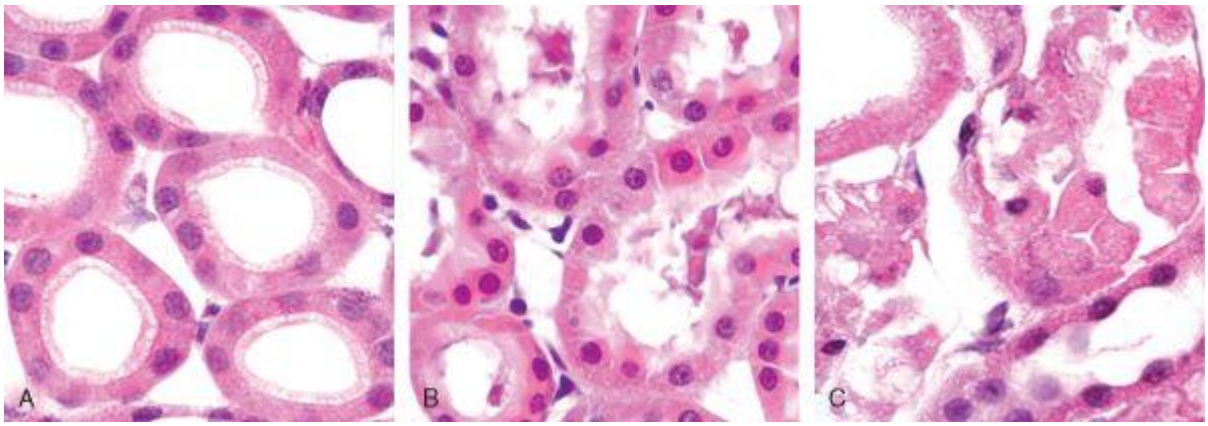

FIGURE 1-9 Morphologic changes in reversible cell injury and necrosis. **A**, Normal kidney tubules with viable epithelial cells. **B**, Early (reversible) ischemic injury showing surface blebs, increased eosinophilia of cytoplasm, and swelling of occasional cells. **C**, Necrosis (irreversible injury) of epithelial cells, with loss of nuclei, fragmentation of cells, and leakage of contents. The ultrastructural features of these stages of cell injury are shown in Figure 1-10 . *(Courtesy of Drs. Neal Pinckard and M.A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, TX.)*

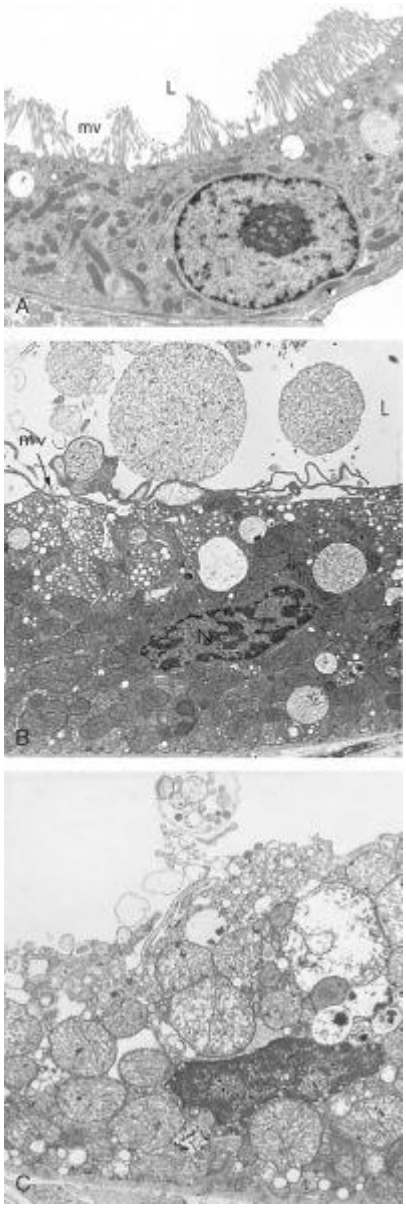

FIGURE 1-10 Ultrastructural features of reversible and irreversible cell injury (necrosis) in a rabbit kidney. **A**, Electron micrograph of a normal epithelial cell of the proximal kidney tubule. Note abundant microvilli (mv) lining the luminal surface (L). **B**, Epithelial cell of the proximal tubule showing early cell injury resulting from reperfusion following ischemia. The microvilli are lost and have been incorporated in apical cytoplasm; blebs have formed and are extruded in the lumen. Mitochondria would have been swollen during ischemia; with reperfusion, they rapidly undergo condensation and become electron-dense. **C**, Proximal tubular cell showing late injury, expected to be irreversible. Note the markedly swollen mitochondria containing electron-dense deposits, expected to contain precipitated calcium and proteins. Higher magnification micrographs of the cell would show disrupted plasma membrane and swelling and fragmentation of organelles. *(**A**, Courtesy of Dr. Brigitte Kaisslin, Institute of Anatomy, University of Zurich, Switzerland. **B, C**, Courtesy of Dr. M.A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, TX.)*

NECROSIS

The morphologic appearance of necrosis is the result of *denaturation of intracellular proteins and enzymatic digestion of the lethally injured cell* (cells placed immediately in fixative are dead but not necrotic). Necrotic cells are unable to maintain membrane integrity and their contents often leak out, a

process that may elicit inflammation in the surrounding tissue. The enzymes that digest the necrotic cell are derived from the lysosomes of the dying cells themselves and from the lysosomes of leukocytes that are called in as part of the inflammatory reaction. Digestion of cellular contents and the host response may take hours to develop, and so there would be no detectable changes in cells if, for example, a myocardial infarct caused sudden death. The only circumstantial evidence might be occlusion of a coronary artery. The earliest histologic evidence of myocardial necrosis does not become apparent until 4 to 12 hours later. However, because of the loss of plasma membrane integrity, cardiac-specific enzymes and proteins are rapidly released from necrotic muscle and can be detected in the blood as early as 2 hours after myocardial cell necrosis.

Morphology. Necrotic cells show **increased eosinophilia** in hematoxylin and eosin (H & E) stains, attributable in part to the loss of cytoplasmic RNA (which binds the blue dye, hematoxylin) and in part to denatured cytoplasmic proteins (which bind the red dye, eosin). The necrotic cell may have a more glassy homogeneous appearance than do normal cells, mainly as a result of the loss of glycogen particles (Fig. 1-9C). When enzymes have digested the cytoplasmic organelles, the cytoplasm becomes vacuolated and appears moth-eaten. Dead cells may be replaced by large, whorled phospholipid masses called **myelin figures** that are derived from damaged cell membranes. These phospholipid precipitates are then either phagocytosed by other cells or further degraded into fatty acids; calcification of such fatty acid residues results in the generation of calcium soaps. Thus, the dead cells may ultimately become calcified. By electron microscopy, necrotic cells are characterized by discontinuities in plasma and organelle membranes, marked dilation of mitochondria with the appearance of large amorphous densities, intracytoplasmic myelin figures, amorphous debris, and aggregates of fluffy material probably representing denatured protein (see Fig. 1-10C).

Nuclear changes appear in one of three patterns, all due to nonspecific breakdown of DNA (see Fig. 1-9C). The basophilia of the chromatin may fade **(karyolysis)**, a change that presumably reflects loss of DNA because of enzymatic degradation by endonucleases. A second pattern (which is also seen in apoptotic cell death) is **pyknosis**, characterized by nuclear shrinkage and increased basophilia. Here the chromatin condenses into a solid, shrunken basophilic mass. In the third pattern, known as **karyorrhexis**, the pyknotic nucleus undergoes fragmentation. With the passage of time (a day or two), the nucleus in the necrotic cell totally disappears.

Patterns of Tissue Necrosis

The discussion of necrosis has focused so far on changes in individual cells. When large numbers of cells die the tissue or organ is said to be necrotic; thus, a myocardial infarct is necrosis of a portion of the heart caused by death of many myocardial cells. Necrosis of tissues has several morphologically distinct patterns, which are important to recognize because they may provide clues about the underlying cause. Although the terms that describe these patterns are somewhat outmoded, they are used often and their implications are understood by pathologists and clinicians.

Morphology. Coagulative necrosis is a form of necrosis in which the architecture of dead tissues is preserved for a span of at least some days (Fig. 1-11). The affected tissues exhibit a firm texture. Presumably, the injury denatures not only structural proteins but also enzymes and so blocks the proteolysis of the dead cells; as a result, eosinophilic, anucleate cells may persist for days or weeks. Ultimately the necrotic cells are removed by phagocytosis of the cellular debris by infiltrating leukocytes and by digestion of the dead cells by the action of lysosomal enzymes of the leukocytes. Ischemia caused by obstruction in a vessel may lead to coagulative necrosis of the supplied tissue in all organs except the brain. A localized area of coagulative necrosis is called an **infarct**.

Liquefactive necrosis, in contrast to coagulative necrosis, is characterized by digestion of the dead cells, resulting in transformation of the tissue into a liquid viscous mass. It is seen in focal bacterial or, occasionally, fungal infections, because microbes stimulate the accumulation of leukocytes and the liberation of enzymes from these cells. The necrotic material is frequently creamy yellow because of the presence of dead leukocytes and is called **pus**. For unknown reasons, hypoxic death of cells within the central nervous system often manifests as liquefactive necrosis (Fig. 1-12).

Gangrenous necrosis is not a specific pattern of cell death, but the term is commonly used in clinical practice. It is usually applied to a limb, generally the lower leg, that has lost its blood supply and has undergone necrosis (typically coagulative necrosis) involving multiple tissue planes. When bacterial infection is superimposed there is more liquefactive necrosis because of the actions of degradative enzymes in the bacteria and the attracted leukocytes (giving rise to so-called **wet gangrene**).

Caseous necrosis is encountered most often in foci of tuberculous infection (Chapter 8). The term "caseous" (cheeselike) is derived from the friable white appearance of the area of necrosis (Fig. 1-13). On microscopic examination, the necrotic area appears as a collection of fragmented or lysed cells and amorphous granular debris enclosed within a distinctive inflammatory border; this appearance is characteristic of a focus of inflammation known as a **granuloma** (Chapter 2).

Fat necrosis is a term that is well fixed in medical parlance but does not in reality denote a specific pattern of necrosis. Rather, it refers to focal areas of fat destruction, typically resulting from release of activated pancreatic lipases into the substance of the pancreas and the peritoneal cavity. This occurs in the calamitous abdominal emergency known as acute pancreatitis (Chapter 19). In this disorder pancreatic enzymes leak out of acinar cells and liquefy the membranes of fat cells in the peritoneum. The released lipases split the triglyceride esters contained within fat cells. The fatty acids, so derived, combine with calcium to produce grossly visible chalky-white areas (fat saponification), which enable the surgeon and the pathologist to identify the lesions (Fig. 1-14). On histologic examination the necrosis takes the form of foci of shadowy outlines of necrotic fat cells, with basophilic calcium deposits, surrounded by an inflammatory reaction.

Fibrinoid necrosis is a special form of necrosis usually seen in immune reactions involving blood vessels. This pattern of necrosis typically occurs when complexes of antigens and antibodies are deposited in the walls of arteries. Deposits of these "immune complexes," together with fibrin that has leaked out of vessels, result in a bright pink and amorphous appearance in H&E stains, called "fibrinoid" (fibrin-like) by pathologists (Fig. 1-15). The immunologically mediated vasculitis syndromes in which this type of necrosis is seen are described in Chapter 6 .

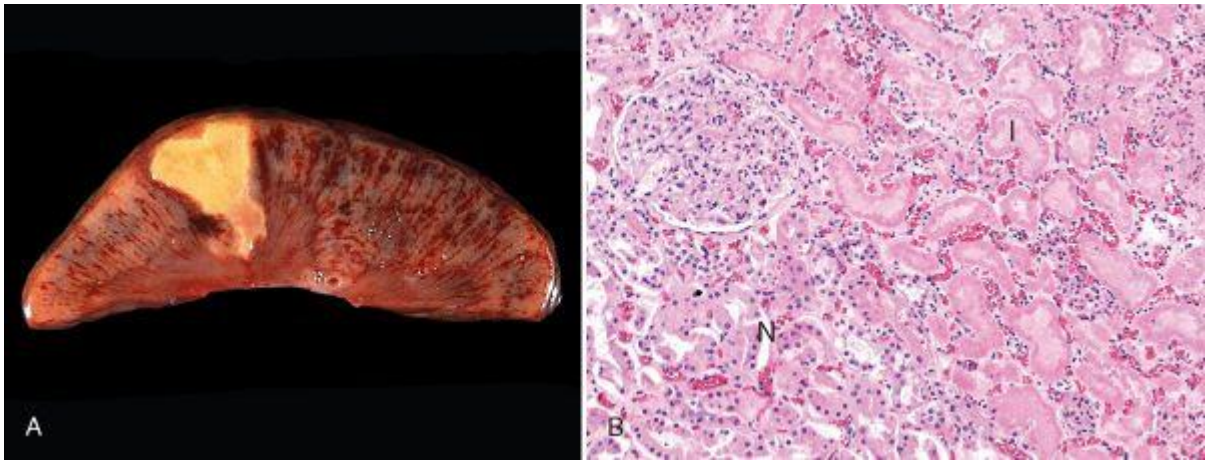

FIGURE 1-11 Coagulative necrosis. **A**, A wedge-shaped kidney infarct (yellow). **B**, Microscopic view of the edge of the infarct, with normal kidney (N) and necrotic cells in the infarct (I) showing preserved cellular outlines with loss of nuclei and an inflammatory infiltrate (which is difficult to discern at this magnification).

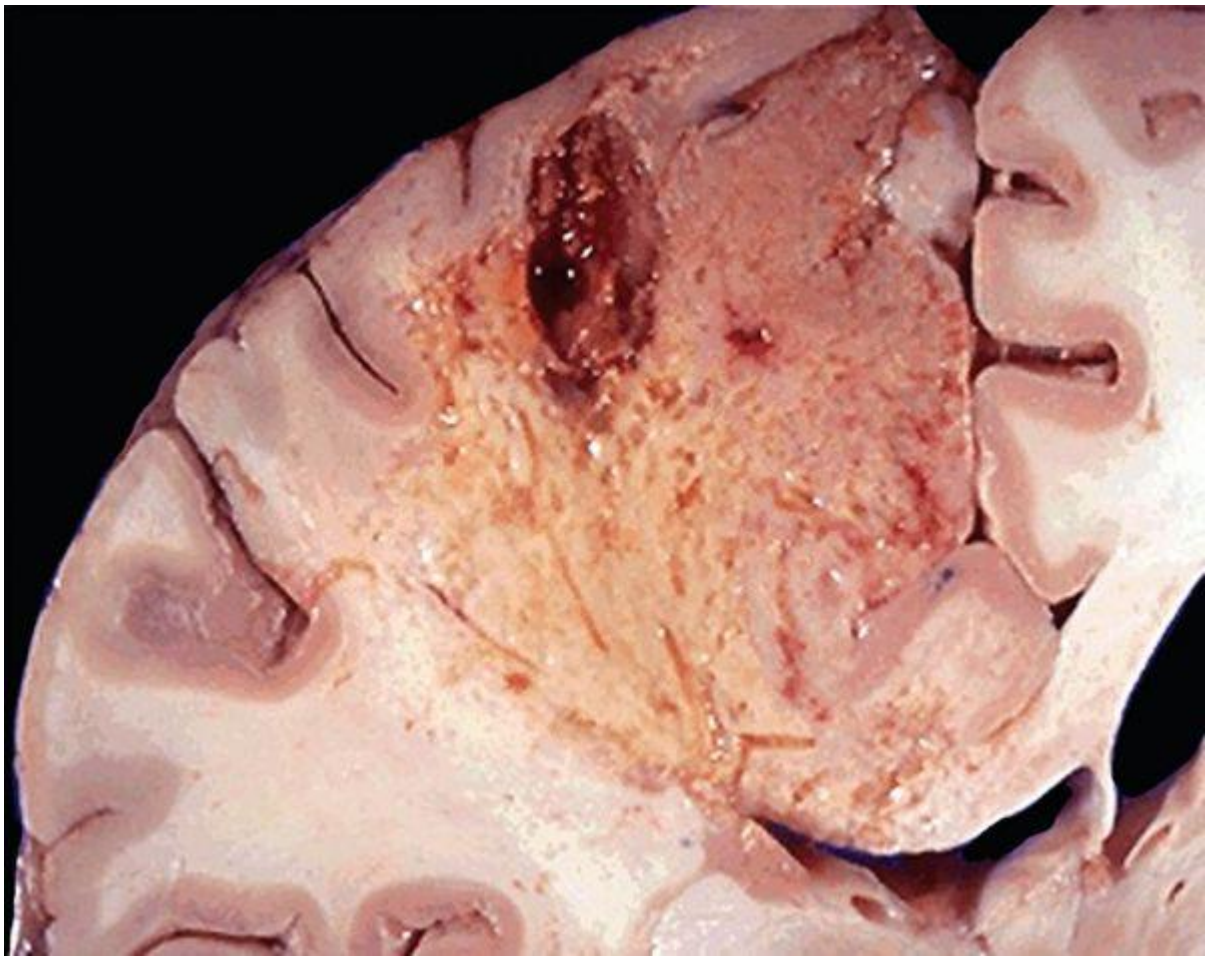

FIGURE 1-12 Liquefactive necrosis. An infarct in the brain, showing dissolution of the tissue.

FIGURE 1-13 Caseous necrosis. Tuberculosis of the lung, with a large area of caseous necrosis containing yellow-white and cheesy debris.

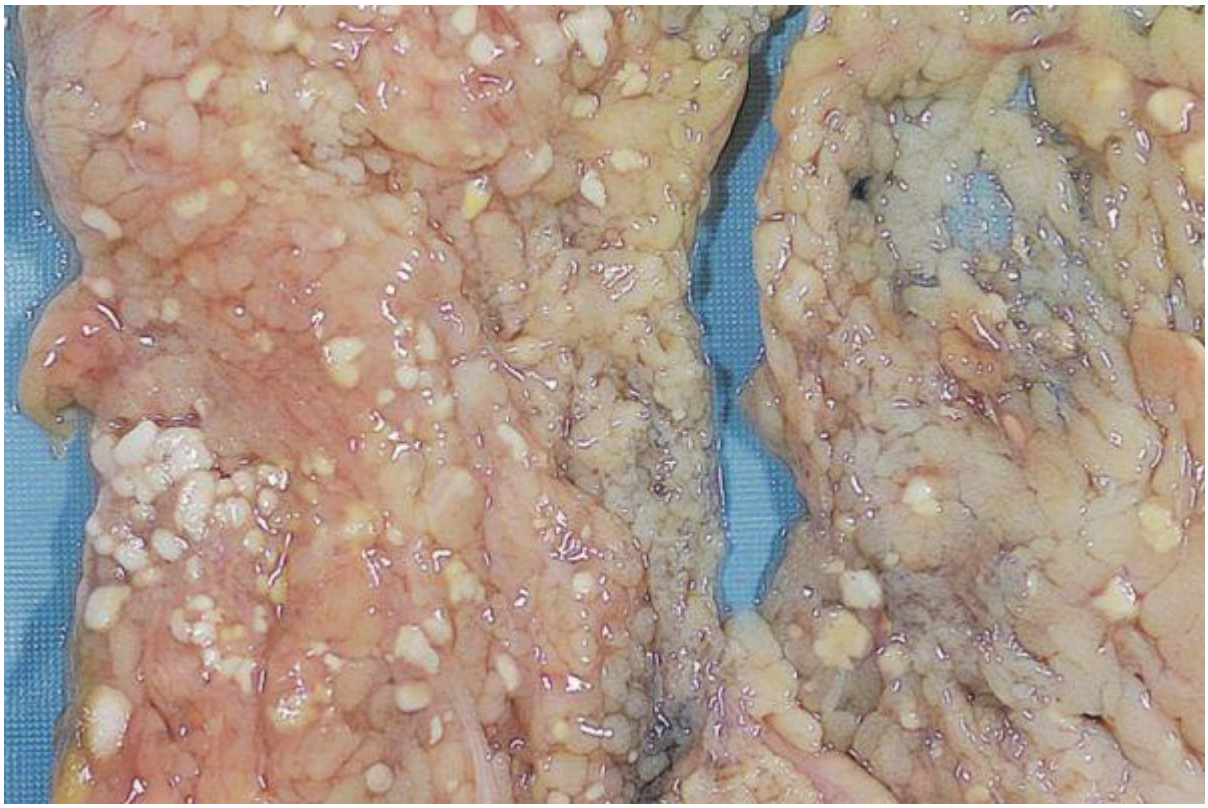

FIGURE 1-14 Fat necrosis. The areas of white chalky deposits represent foci of fat necrosis with calcium soap formation (saponification) at sites of lipid breakdown in the mesentery.

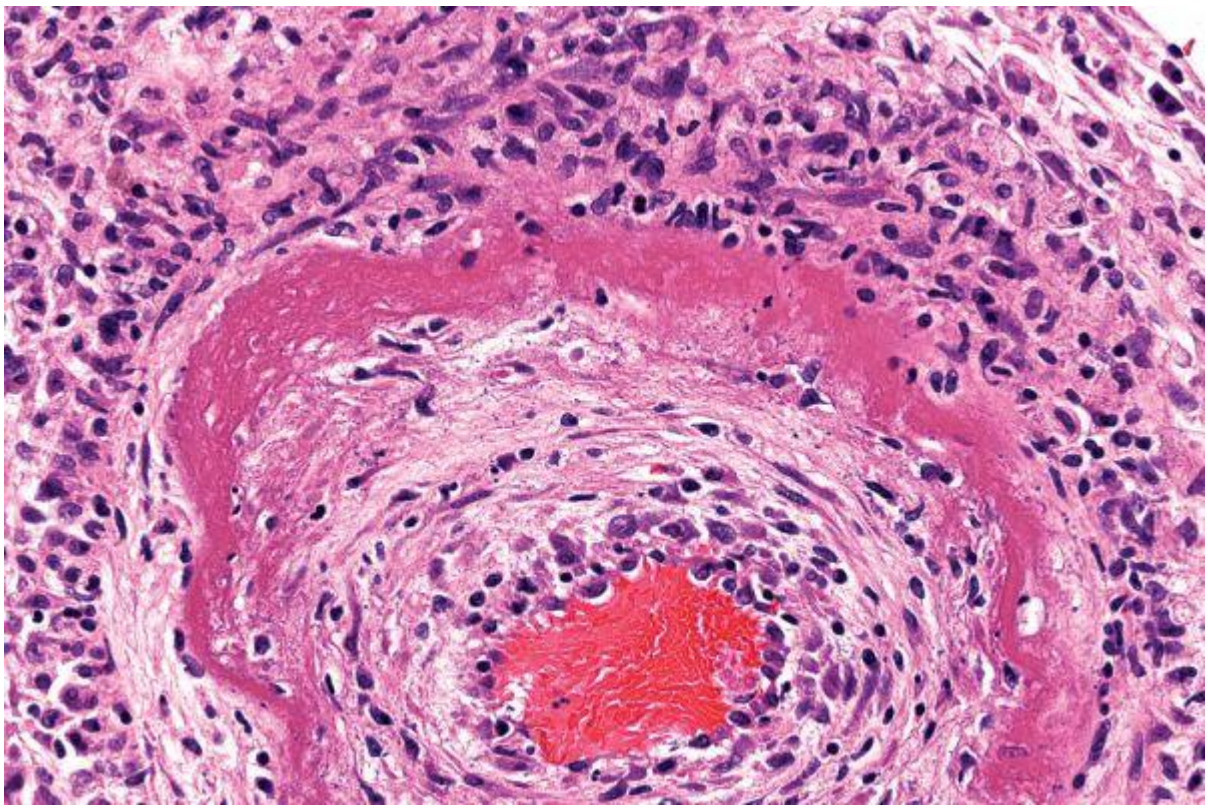

FIGURE 1-15 Fibrinoid necrosis in an artery. The wall of the artery shows a circumferential bright pink area of necrosis with inflammation (neutrophils with dark nuclei).

Ultimately, in the living patient most necrotic cells and their contents disappear by phagocytosis of the debris and enzymatic digestion by leukocytes. If necrotic cells and cellular debris are not promptly destroyed and reabsorbed, they tend to attract calcium salts and other minerals and to become calcified. This phenomenon, called *dystrophic calcification*, is considered later in the chapter.

2.1.7 Mechanisms of Cell Injury

The discussion of the cellular pathology of cell injury and necrosis sets the stage for a consideration of the mechanisms and biochemical pathways of cell injury. The mechanisms responsible for cell injury are complex. There are, however, several principles that are relevant to most forms of cell injury:

- *The cellular response to injurious stimuli depends on the nature of the injury, its duration, and its severity*. Small doses of a chemical toxin or brief periods of ischemia may induce reversible injury, whereas large doses of the same toxin or more prolonged ischemia might result either in instantaneous cell death or in slow, irreversible injury leading in time to cell death.
- *The consequences of cell injury depend on the type, state, and adaptability of the injured cell*. The cell's nutritional and hormonal status and its metabolic needs are important in its response to injury. How vulnerable is a cell, for example, to loss of blood supply and hypoxia? When the striated muscle cell in the leg is deprived of its blood supply, it can be placed at rest and preserved; not so the striated muscle of the heart. Exposure of two individuals to identical concentrations of a toxin, such as carbon tetrachloride, may produce no effect in one and cell death in the other. This may be due to genetic variations affecting the amount and activity of hepatic enzymes that convert carbon tetrachloride (CCl_4) to toxic by-products (Chapter 9). With the complete mapping of the human genome, there is great interest in identifying genetic polymorphisms that affect the responses of different individuals to injurious agents.
- *Cell injury results from different biochemical mechanisms acting on several essential cellular components* (Fig. 1-16). These mechanisms are described individually below. The cellular components that are most frequently damaged by injurious stimuli include mitochondria, cell membranes, the machinery of protein synthesis and packaging, and the DNA in nuclei.
- Any injurious stimulus may simultaneously trigger multiple interconnected mechanisms that damage cells. This is one reason why it is difficult to ascribe cell injury in a particular situation to a single or even dominant biochemical derangement.

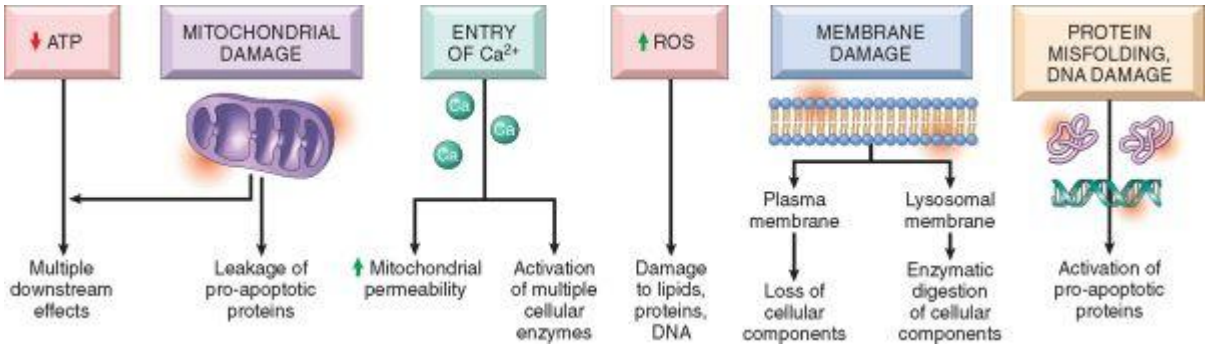

FIGURE 1-16 The principal mechanisms of cell injury, and their biochemical and functional effects, are shown. These are described in detail in the text.

In the following section we describe the biochemical mechanisms that may be activated by different injurious stimuli and contribute to cell injury.[16] Our focus here is on reversible injury and necrosis, and the special cases of apoptosis and autophagy are best discussed separately.

DEPLETION OF ATP

ATP depletion and decreased ATP synthesis are frequently associated with both hypoxic and chemical (toxic) injury (Fig. 1-17). ATP is produced in two ways. The major pathway in mammalian cells is oxidative phosphorylation of adenosine diphosphate, in a reaction that results in reduction of oxygen by the electron transfer system of mitochondria. The second is the glycolytic pathway, which can generate ATP in the absence of oxygen using glucose derived either from body fluids or from the hydrolysis of glycogen. *The major causes of ATP depletion are reduced supply of oxygen and nutrients, mitochondrial damage, and the actions of some toxins (e.g., cyanide).* Tissues with a greater glycolytic capacity (e.g., the liver) are able to survive loss of oxygen and decreased oxidative phosphorylation better than are tissues with limited capacity for glycolysis (e.g., the brain).

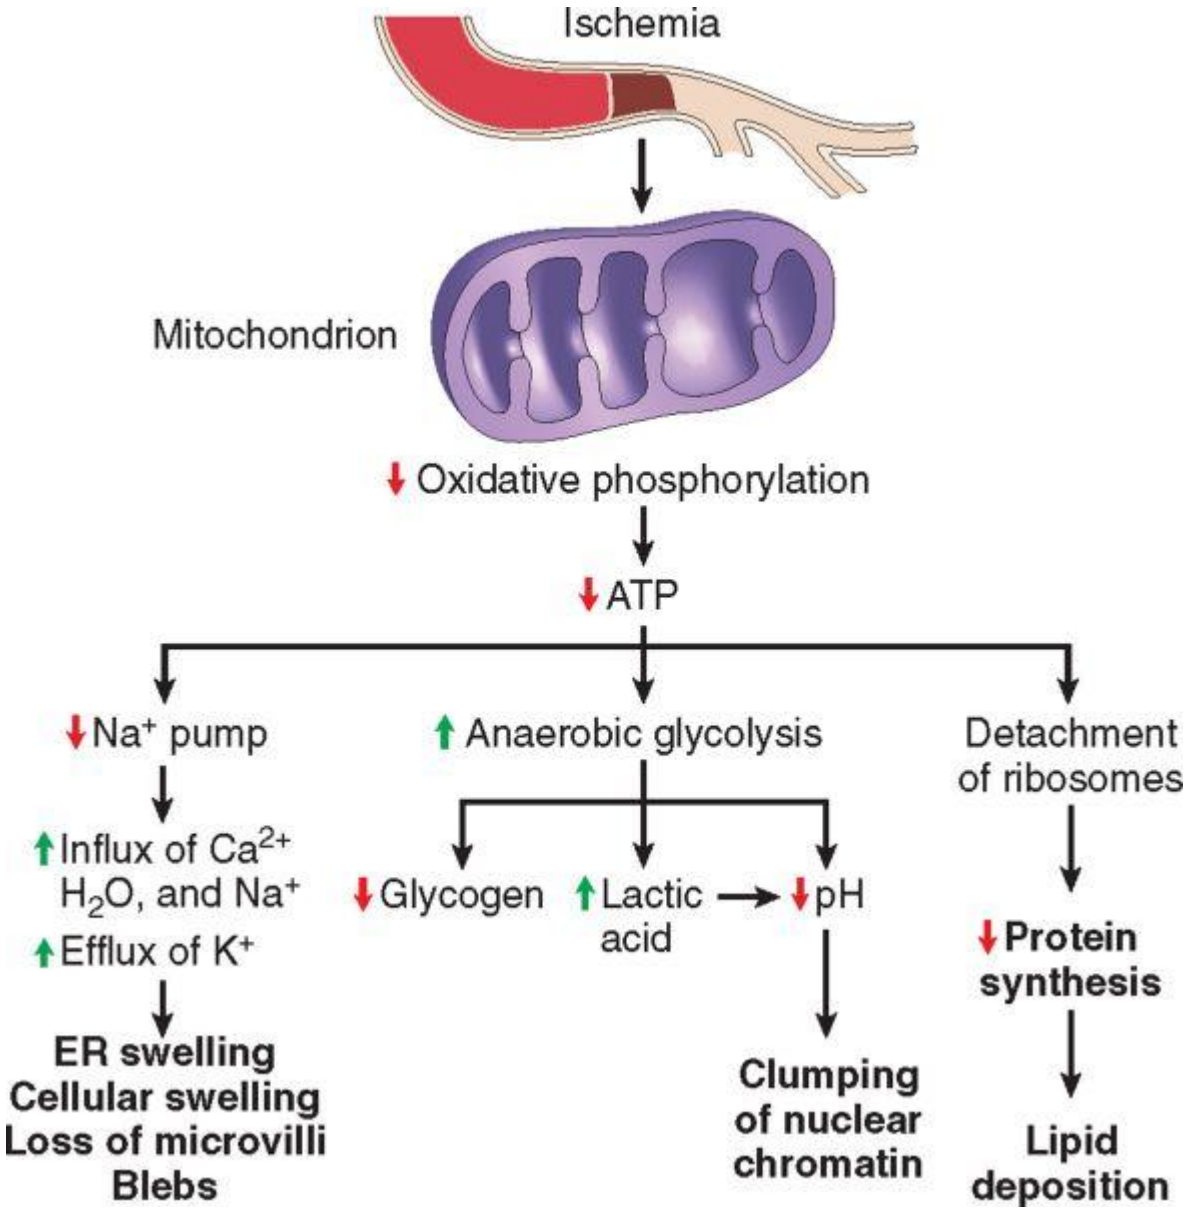

FIGURE 1-17 Functional and morphologic consequences of decreased intracellular ATP during cell injury. The morphologic changes shown here are indicative of reversible cell injury. Further depletion of ATP results in cell death, typically by necrosis. ER, endoplasmic reticulum.

High-energy phosphate in the form of ATP is required for virtually all synthetic and degradative processes within the cell. These include membrane transport, protein synthesis, lipogenesis, and the deacylation-reacylation reactions necessary for phospholipid turnover. *Depletion of ATP to 5% to 10% of normal levels has widespread effects on many critical cellular systems*:

- The activity of the *plasma membrane energy-dependent sodium pump* (ouabain-sensitive Na^+, K^+-ATPase) is reduced. Failure of this active transport system causes sodium to enter and accumulate inside cells and potassium to diffuse out. The net gain of solute is accompanied by isosmotic gain of water, causing *cell swelling*, and dilation of the ER.
- *Cellular energy metabolism is altered*. If the supply of oxygen to cells is reduced, as in ischemia, oxidative phosphorylation ceases, resulting in a decrease in cellular ATP and associated increase in adenosine monophosphate. These changes stimulate phosphofructokinase and phosphorylase activities, leading to an increased rate of *anaerobic glycolysis*, which is designed to maintain the cell's energy sources by generating ATP through metabolism of glucose derived from glycogen. As a consequence *glycogen stores are rapidly depleted*. Anaerobic glycolysis results in the accumulation of *lactic acid* and inorganic phosphates from the hydrolysis of phosphate esters. This reduces the intracellular pH, resulting in decreased activity of many cellular enzymes.
- Failure of the Ca^{2+} pump leads to influx of Ca^{2+}, with damaging effects on numerous cellular components, described below.
- With prolonged or worsening depletion of ATP, structural disruption of the protein synthetic apparatus occurs, manifested as detachment of ribosomes from the rough ER and dissociation of polysomes, with a consequent *reduction in protein synthesis*.
- In cells deprived of oxygen or glucose, proteins may become misfolded, and misfolded proteins trigger a cellular reaction called the *unfolded protein response* that may culminate in cell injury and even death. This process is described later in the chapter.
- Ultimately, there is irreversible damage to mitochondrial and lysosomal membranes, and the cell undergoes *necrosis*.

MITOCHONDRIAL DAMAGE

Mitochondria are the cell's suppliers of life-sustaining energy in the form of ATP, but they are also critical players in cell injury and death.[17] Mitochondria can be damaged by increases of cytosolic Ca^{2+}, reactive oxygen species (discussed below), and oxygen deprivation, and so they are sensitive to virtually all types of injurious stimuli, including hypoxia and toxins. In addition, mutations in mitochondrial genes are the cause of some inherited diseases (Chapter 5).

There are two major *consequences of mitochondrial damage*.

- Mitochondrial damage often results in the formation of a high-conductance channel in the mitochondrial membrane, called the *mitochondrial permeability transition pore* (Fig. 1-18).[18] The opening of this conductance channel leads to the loss of mitochondrial membrane potential, resulting in failure of oxidative phosphorylation and progressive depletion of ATP, culminating in necrosis of the cell. One of the structural components of the mitochondrial permeability transition pore is the protein cyclophilin D, which is a target of the immunosuppressive drug cyclosporine (used to prevent graft rejection). In some experimental models of ischemia, cyclosporine reduces injury by preventing opening of the mitochondrial permeability transition pore—an interesting example of molecularly targeted therapy for cell injury (although its clinical value is not established).

- The mitochondria also sequester between their outer and inner membranes several proteins that are capable of activating apoptotic pathways; these include cytochrome *c* and proteins that indirectly activate apoptosisinducing enzymes called caspases. Increased permeability of the outer mitochondrial membrane may result in leakage of these proteins into the cytosol, and death by apoptosis (discussed later).

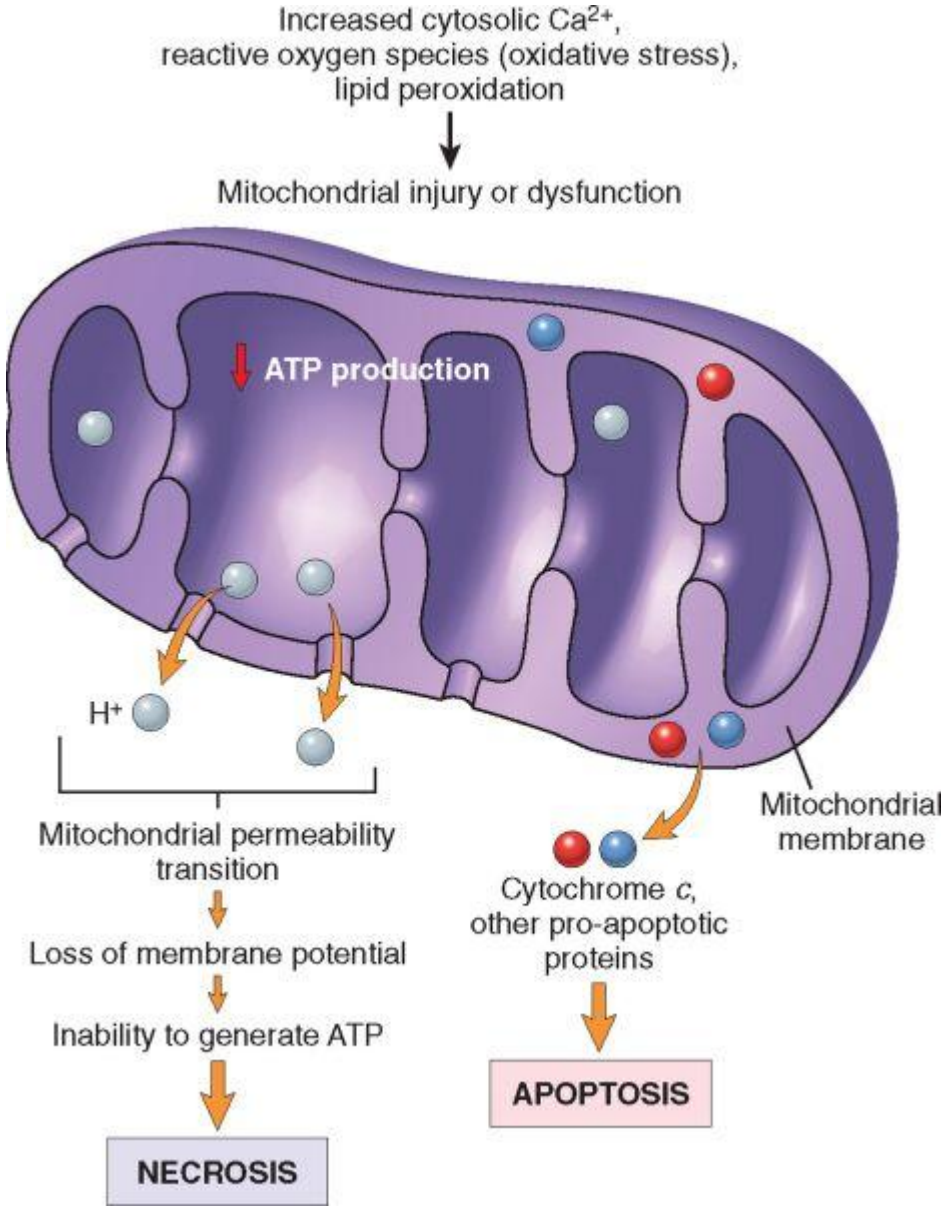

FIGURE 1-18 Consequences of mitochondrial dysfunction, culminating in cell death by necrosis or apoptosis.

INFLUX OF CALCIUM AND LOSS OF CALCIUM HOMEOSTASIS

The finding that depleting calcium protects cells from injury induced by a variety of harmful stimuli indicates that calcium ions are important mediators of cell injury.[19] Cytosolic free calcium is normally maintained at very low concentrations (-0.1 μmol) compared with extracellular levels of 1.3 mmol, and most intracellular calcium is sequestered in mitochondria and the ER. Ischemia and certain toxins cause an increase in cytosolic calcium concentration, initially because of release of Ca^{2+} from intracellular stores, and later resulting from increased influx across the plasma membrane (Fig. 1-19). Increased intracellular Ca^{2+} causes cell injury by several mechanisms.

- The accumulation of Ca^{2+} in mitochondria results in opening of the mitochondrial permeability transition pore and, as described above, failure of ATP generation.
- Increased cytosolic Ca^{2+} activates a number of enzymes, with potentially deleterious cellular effects. These enzymes include *phospholipases* (which cause membrane damage), *proteases* (which break down both membrane and cytoskeletal proteins), *endonucleases* (which are responsible for DNA and chromatin fragmentation), and *ATPases* (thereby hastening ATP depletion).
- Increased intracellular Ca^{2+} levels also result in the induction of apoptosis, by direct activation of caspases and by increasing mitochondrial permeability.[20]

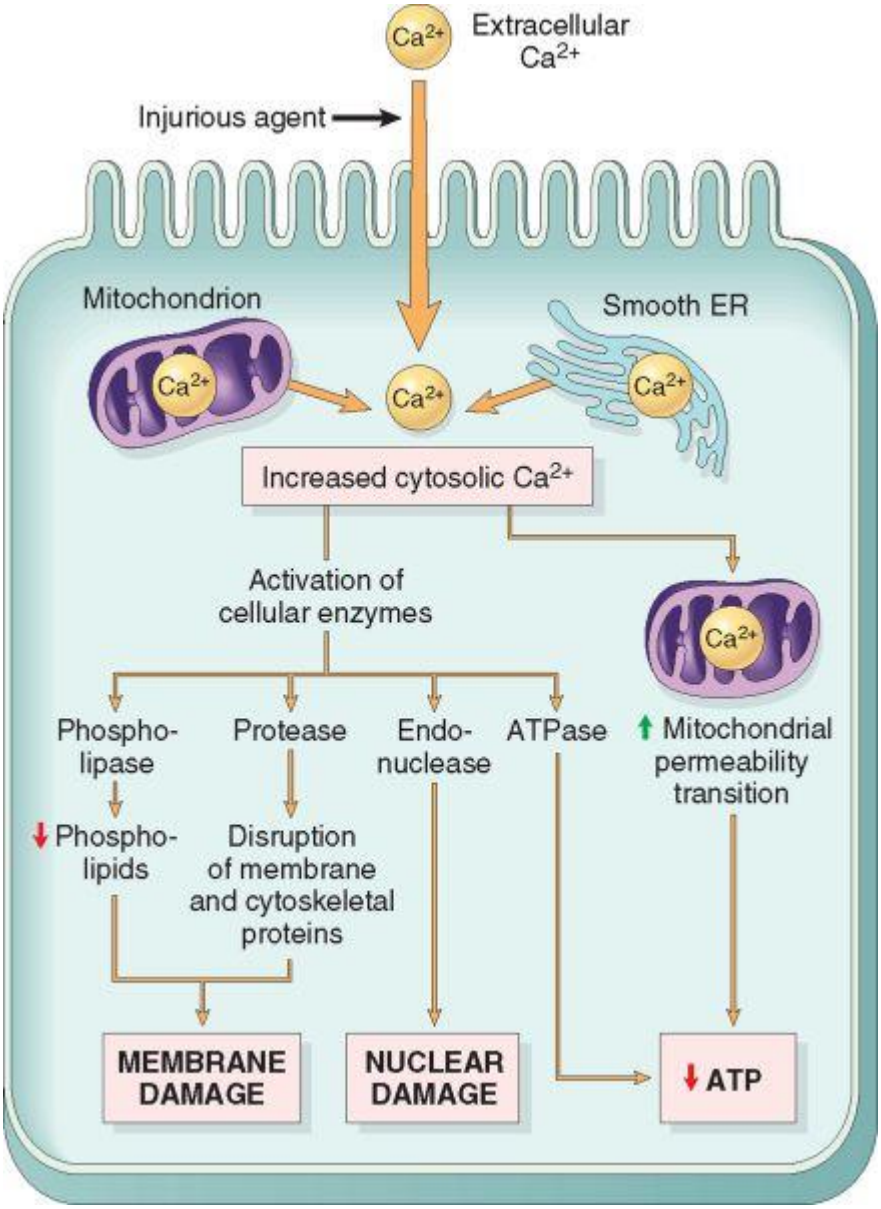

FIGURE 1-19 The role of increased cytosolic calcium in cell injury. ER, endoplasmic reticulum.

ACCUMULATION OF OXYGEN-DERIVED FREE RADICALS (OXIDATIVE STRESS)

Cell injury induced by free radicals, particularly reactive oxygen species, is an important mechanism of cell damage in many pathologic conditions, such as chemical and radiation injury, ischemia-reperfusion

injury (induced by restoration of blood flow in ischemic tissue), cellular aging, and microbial killing by phagocytes.[21] *Free radicals* are chemical species that have a single unpaired electron in an outer orbit. Energy created by this unstable configuration is released through reactions with adjacent molecules, such as inorganic or organic chemicals—proteins, lipids, carbohydrates, nucleic acids—many of which are key components of cell membranes and nuclei. Moreover, free radicals initiate autocatalytic reactions, whereby molecules with which they react are themselves converted into free radicals, thus propagating the chain of damage. *Reactive oxygen species (ROS)* are a type of oxygen-derived free radical whose role in cell injury is well established. ROS are produced normally in cells during mitochondrial respiration and energy generation, but they are degraded and removed by cellular defense systems. Thus, cells are able to maintain a steady state in which free radicals may be present transiently at low concentrations but do not cause damage. When the production of ROS increases or the scavenging systems are ineffective, the result is an excess of these free radicals, leading to a condition called *oxidative stress*. Oxidative stress has been implicated in a wide variety of pathologic processes, including cell injury, cancer, aging, and some degenerative diseases such as Alzheimer disease. ROS are also produced in large amounts by leukocytes, particularly neutrophils and macrophages, as mediators for destroying microbes, dead tissue, and other unwanted substances. Therefore, injury caused by these reactive compounds often accompanies inflammatory reactions, during which leukocytes are recruited and activated (Chapter 2).

In the following section we discuss the generation and removal of ROS, and how they contribute to cell injury. The properties of some of the most important free radicals are summarized in Table 1-3 .

TABLE 1-3 -- Properties of the Principal Free Radicals Involved in Cell Injury

Properties	$O_2^{\cdot-}$	H_2O_2	$^{\cdot}OH$	$ONOO^-$
MECHANISMS OF PRODUCTION	Incomplete reduction of O_2 during oxidative phosphorylation; by phagocyte oxidase in leukocytes	Generated by SOD from O_2^- and by oxidases in peroxisomes	Generated from H_2O by hydrolysis, e.g., by radiation; from H_2O_2 by Fenton reaction; from $O_2^{\cdot-}$	Produced by interaction of $O_2^{\cdot-}$ and NO generated by NO synthase in many cell types (endothelial cells, leukocytes, neurons, others)
MECHANISMS OF INACTIVATION	Conversion to H_2O_2 and O_2 by SOD	Conversion to H_2O and O_2 by catalase (peroxisomes), glutathione peroxidase (cytosol, mitochondria)	Conversion to H_2O by glutathione peroxidase	Conversion to HNO_2 by peroxiredoxins (cytosol, mitochondria)
PATHOLOGIC EFFECTS	Stimulates production of degradative enzymes in leukocytes and other cells; may directly	Can be converted to	Most reactive oxygen-derived free radical; principal ROS responsible for damaging lipids,	Damages lipids, proteins, DNA

Properties		H_2O_2	H	$ONOO^-$
	damage lipids, proteins, DNA; acts close to site of production	H and OCl^-, which destroy microbes and cells; can act distant from site of production	proteins, and DNA	

HNO_2, nitrite; H_2O_2, hydrogen peroxide; NO, nitric oxide; , superoxide anion; OCl^-, hypochlorite; H, hydroxyl radical; $ONOO^-$, peroxynitrite; ROS, reactive oxygen species; SOD, superoxide dismutase.

Generation of Free Radicals.

Free radicals may be generated within cells in several ways (Fig. 1-20):

- *The reduction-oxidation reactions that occur during normal metabolic processes*. During normal respiration, molecular O_2 is reduced by the transfer of four electrons to H_2 to generate two water molecules. This conversion is catalyzed by oxidative enzymes in the ER, cytosol, mitochondria, peroxisomes, and lysosomes. During this process small amounts of partially reduced intermediates are produced in which different numbers of electrons have been transferred from O_2, these include superoxide anion (, one electron), hydrogen peroxide (H_2O_2, two electrons), and hydroxyl ions (H, three electrons).

- *Absorption of radiant energy* (e.g., ultraviolet light, x-rays). For example, ionizing radiation can hydrolyze water into  H and hydrogen (H) free radicals.
- Rapid bursts of ROS are produced in activated leukocytes during *inflammation*. This occurs by a precisely controlled reaction in a plasma membrane multiprotein complex that uses NADPH oxidase for the redox reaction (Chapter 2). In addition, some intracellular oxidases (such as xanthine oxidase) generate .
- *Enzymatic metabolism of exogenous chemicals or drugs* can generate free radicals that are not ROS but have similar effects (e.g., CCl_4 can generate CCl_3, described later in the chapter).
- *Transition metals* such as iron and copper donate or accept free electrons during intracellular reactions and catalyze free radical formation, as in the Fenton reaction ($H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH + OH^-$). Because most of the intracellular free iron is in the ferric (Fe^{3+}) state, it must be reduced to the ferrous (Fe^{2+}) form to participate in the Fenton reaction. This reduction can be enhanced by  , and thus sources of iron and may cooperate in oxidative cell damage.
- *Nitric oxide* (NO), an important chemical mediator generated by endothelial cells, macrophages, neurons, and other cell types (Chapter 2), can act as a free radical and can also be converted to highly reactive peroxynitrite anion ($ONOO^-$) as well as NO_2 and NO_3^-.[22]

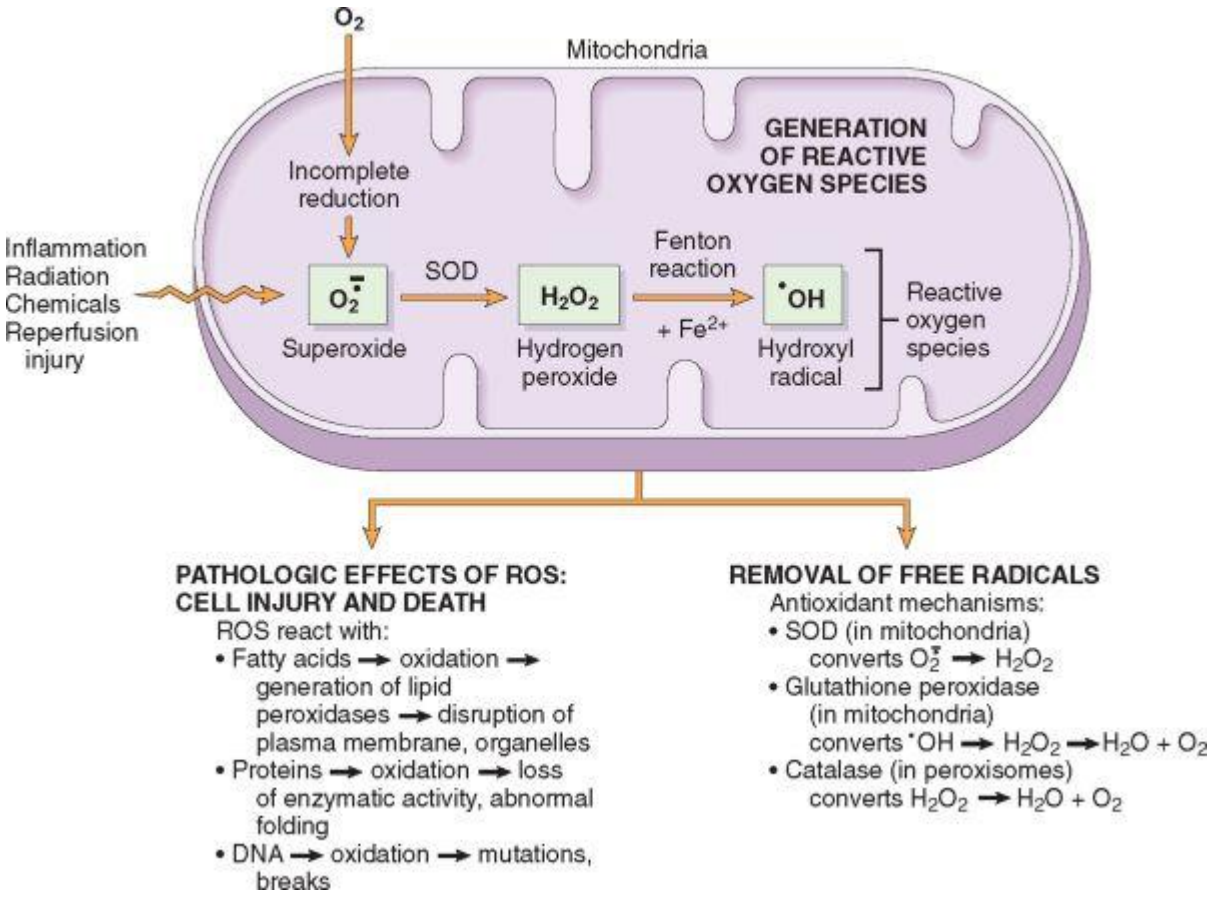

FIGURE 1-20 The role of reactive oxygen species (ROS) in cell injury. O_2 is converted to superoxide ($O_2^{\cdot-}$) by oxidative enzymes in the endoplasmic reticulum (ER), mitochondria, plasma membrane, peroxisomes, and cytosol. $O_2^{\cdot-}$ is converted to H_2O_2 by dismutation and thence to $^{\cdot}OH$ by the Cu^{2+}/Fe^{2+}-catalyzed Fenton reaction. H_2O_2 is also derived directly from oxidases in peroxisomes (not shown). Resultant free radical damage to lipids (by peroxidation), proteins, and DNA leads to injury to numerous cellular components. The major antioxidant enzymes are superoxide dismutase (SOD), glutathione peroxidase, and catalase.

Removal of Free Radicals.

Free radicals are inherently unstable and generally decay spontaneously. , for example, is unstable and decays (dismutates) spontaneously into O_2 and H_2O_2 in the presence of water. In addition, cells have developed multiple nonenzymatic and enzymatic mechanisms to remove free radicals and thereby minimize injury (see Fig. 1-20). These include the following:

- *Antioxidants* either block the initiation of free radical formation or inactivate (e.g., scavenge) free radicals. Examples are the lipid-soluble vitamins E and A as well as ascorbic acid and glutathione in the cytosol.
- As we have seen, *iron* and *copper* can catalyze the formation of ROS. The levels of these reactive metals are minimized by binding of the ions to storage and transport proteins (e.g., transferrin, ferritin, lactoferrin, and ceruloplasmin), thereby minimizing the formation of ROS.
- A series of *enzymes* acts as free radical–scavenging systems and breaks down H_2O_2 and  .[21,][23] These enzymes are lo-cated near the sites of generation of the oxidants and include the following:

  1. *Catalase*, present in peroxisomes, decomposes H_2O_2 ($2H_2O_2 \rightarrow O_2 + 2H_2O$).
  2. *Superoxide dismutases* (SODs) are found in many cell types and convert  to H_2O_2 (2 + $2H \rightarrow H_2O_2 + O_2$). This group includes both manganese–SOD, which is localized in mitochondria, and copper-zinc–SOD, which is found in the cytosol.
  3. *Glutathione peroxidase* also protects against injury by catalyzing free radical breakdown (H_2O_2 + $2GSH \rightarrow$ GSSG [glutathione homodimer] + $2H_2O$, or $2OH + 2GSH \rightarrow GSSG + 2H_2O$). The intracellular ratio of oxidized glutathione (GSSG) to reduced glutathione (GSH) is a reflection of the oxidative state of the cell and is an important indicator of the cell's ability to detoxify ROS.

Pathologic Effects of Free Radicals.

The effects of ROS and other free radicals are wide-ranging, but three reactions are particularly relevant to cell injury (see Fig. 1-20):

- *Lipid peroxidation in membranes*. In the presence of O_2, free radicals may cause peroxidation of lipids within plasma and organellar membranes. Oxidative damage is initiated when the double bonds in unsaturated fatty acids of membrane lipids are attacked by O_2-derived free radicals, particularly by

H. The lipid–free radical interactions yield peroxides, which are themselves unstable and reactive, and an autocatalytic chain reaction ensues (called *propagation*), which can result in extensive membrane damage.

- *Oxidative modification of proteins*. Free radicals promote oxidation of amino acid side chains, formation of protein-protein cross-linkages (e.g., disulfide bonds), and oxidation of the protein backbone. Oxidative modification of proteins may damage the active sites of enzymes, disrupt the conformation of structural proteins, and enhance proteasomal degradation of unfolded or misfolded proteins, raising havoc throughout the cell.
- *Lesions in DNA*. Free radicals are capable of causing single- and double-strand breaks in DNA, cross-linking of DNA strands, and formation of adducts. Oxidative DNA damage has been implicated in cell aging (discussed later in this chapter) and in malignant transformation of cells (Chapter 7).

The traditional thinking about free radicals was that they cause cell injury and death by necrosis, and, in fact, the production of ROS is a frequent prelude to necrosis. However, it is now clear that free radicals can trigger apoptosis as well.[24] Recent studies have also revealed a role of ROS in signaling by a variety of cellular receptors and biochemical intermediates.[25] In fact, according to one hypothesis, the major actions of stem from its ability to stimulate the production of degradative enzymes rather than direct damage of macromolecules. It is also possible that these potentially deadly molecules serve important physiologic functions.[26]

DEFECTS IN MEMBRANE PERMEABILITY

Early loss of selective membrane permeability leading ultimately to overt membrane damage is a consistent feature of most forms of cell injury (except apoptosis). Membrane damage may affect the functions and integrity of all cellular membranes. Below we discuss the mechanisms and pathologic consequences of membrane damage.

Mechanisms of Membrane Damage.

In ischemic cells membrane defects may be the result of ATP depletion and calcium-mediated activation of phospholipases (see below). The plasma membrane can also be damaged directly by various bacterial toxins, viral proteins, lytic complement components, and a variety of physical and chemical agents. Several biochemical mechanisms may contribute to membrane damage (Fig. 1-21):

- *Reactive oxygen species*. Oxygen free radicals cause injury to cell membranes by lipid peroxidation, discussed earlier.
- *Decreased phospholipid synthesis*. The production of phospholipids in cells may be reduced as a consequence of defective mitochondrial function or hypoxia, both of which decrease the production of ATP and thus affect energy-dependent enzymatic activities. The decreased phospholipid synthesis may affect all cellular membranes, including the mitochondria themselves.
- *Increased phospholipid breakdown*. Severe cell injury is associated with increased degradation of membrane phospholipids, probably due to activation of endogenous phospholipases by increased levels of cytosolic and mitochondrial Ca^{2+}.[19] Phospholipid breakdown leads to the accumulation of *lipid breakdown*

products, including unesterified free fatty acids, acyl carnitine, and lysophospholipids, which have a detergent effect on membranes. They may also either insert into the lipid bilayer of the membrane or exchange with membrane phospholipids, potentially causing changes in permeability and electrophysiologic alterations.

- *Cytoskeletal abnormalities*. Cytoskeletal filaments serve as anchors connecting the plasma membrane to the cell interior. Activation of proteases by increased cytosolic calcium may cause damage to elements of the cytoskeleton. In the presence of cell swelling, this damage results, particularly in myocardial cells, in detachment of the cell membrane from the cytoskeleton, rendering it susceptible to stretching and rupture.

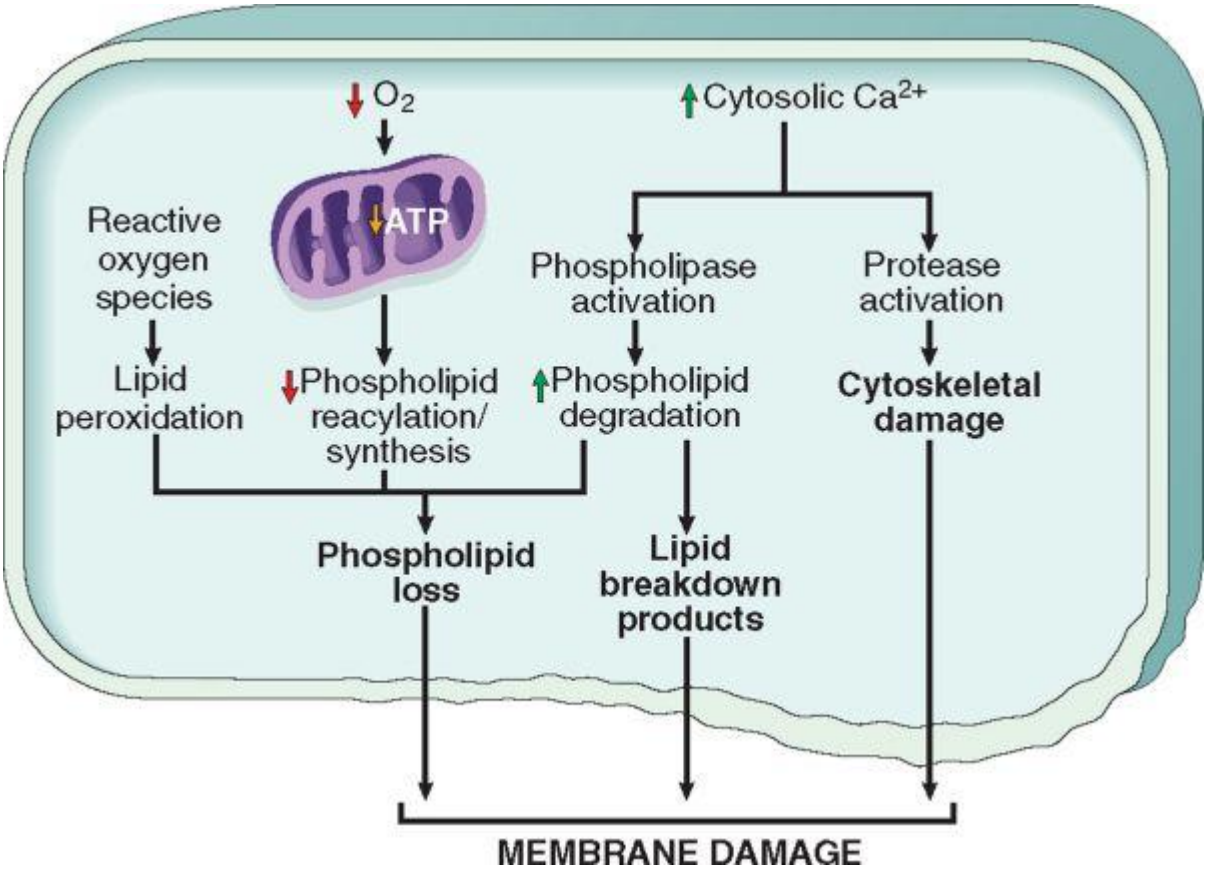

FIGURE 1-21 Mechanisms of membrane damage in cell injury. Decreased O_2 and increased cytosolic Ca^{2+} are typically seen in ischemia but may accompany other forms of cell injury. Reactive oxygen species, which are often produced on reperfusion of ischemic tissues, also cause membrane damage (not shown).

Consequences of Membrane Damage.

The most important sites of membrane damage during cell injury are the mitochondrial membrane, the plasma membrane, and membranes of lysosomes.

- *Mitochondrial membrane damage*. As discussed above, damage to mitochondrial membranes results in opening of the mitochondrial permeability transition pore leading to decreased ATP, and release of proteins that trigger apoptotic death.
- *Plasma membrane damage*. Plasma membrane damage results in loss of osmotic balance and influx of fluids and ions, as well as loss of cellular contents. The cells may also leak metabolites that are vital for the reconstitution of ATP, thus further depleting energy stores.
- *Injury to lysosomal membranes* results in leakage of their enzymes into the cytoplasm and activation of the acid hydrolases in the acidic intracellular pH of the injured (e.g., ischemic) cell. Lysosomes contain RNases,

DNases, proteases, phosphatases, glucosidases, and cathepsins. Activation of these enzymes leads to enzymatic digestion of proteins, RNA, DNA, and glycogen, and the cells die by necrosis.

DAMAGE TO DNA AND PROTEINS

Cells have mechanisms that repair damage to DNA, but if this damage is too severe to be corrected (e.g., after exposure to DNA damaging drugs, radiation, or oxidative stress), the cell initiates a suicide program that results in death by apoptosis. A similar reaction is triggered by improperly folded proteins, which may be the result of inherited mutations or external triggers such as free radicals. Because these mechanisms of cell injury typically cause apoptosis, they are discussed later in the chapter.

Before concluding our discussion of the mechanisms of cell injury, it is useful to consider the possible events that determine when reversible injury becomes irreversible and progresses to cell death. The clinical relevance of this question is obvious—if we can answer it we may be able to devise strategies for preventing cell injury from having permanent deleterious consequences. However, the molecular mechanisms connecting most forms of cell injury to ultimate cell death have proved elusive, for several reasons. The "point of no return," at which the damage becomes irreversible, is still largely undefined, and there are no reliable morphologic or biochemical correlates of irreversibility. *Two phenomena consistently characterize irreversibility—the inability to reverse mitochondrial dysfunction* (lack of oxidative phosphorylation and ATP generation) even after resolution of the original injury, and *profound disturbances in membrane function*. As mentioned earlier, injury to lysosomal membranes results in the enzymatic dissolution of the injured cell that is characteristic of necrosis.

Leakage of intracellular proteins through the damaged cell membrane and ultimately into the circulation provides a means of detecting tissue-specific cellular injury and necrosis using blood serum samples. Cardiac muscle, for example, contains a specific isoform of the enzyme creatine kinase and of the contractile protein troponin; liver (and specifically bile duct epithelium) contains an isoform of the enzyme alkaline phosphatase; and hepatocytes contain transaminases. Irreversible injury and cell death in these tissues are reflected in increased levels of such proteins in the blood, and measurement of these biomarkers is used clinically to assess damage to these tissues.

2.1.8 Clinico-Pathologic Correlations: Selected Examples of Cell Injury & Necrosis

Having briefly reviewed the causes, morphology, and mechanisms of cell injury and necrotic cell death, we now describe some common and clinically significant forms of cell injury that typically culminate in necrosis. These examples illustrate many of the mechanisms and sequence of events in cell injury that were described above.

ISCHEMIC AND HYPOXIC INJURY

This is the most common type of cell injury in clinical medicine and has been studied extensively in humans, in experimental animals, and in culture systems. Hypoxia, referring to reduced oxygen availability, may occur in a variety of clinical settings, described earlier. In ischemia, on the other hand, the supply of oxygen and nutrients is decreased most often because of reduced blood flow as a consequence of a mechanical obstruction in the arterial system. It can also be caused by reduced venous drainage. In contrast to hypoxia, during which energy production by anaerobic glycolysis can continue, ischemia compromises the delivery of substrates for glycolysis. Thus, in ischemic tissues, not only is aerobic metabolism compromised but anaerobic energy generation also stops after glycolytic substrates are exhausted, or glycolysis is inhibited by the accumulation of metabolites that would have been removed otherwise by blood flow. For this reason, *ischemia tends to cause more rapid and severe cell and tissue injury than does hypoxia in the absence of ischemia*.

Mechanisms of Ischemic Cell Injury

The sequence of events following hypoxia or ischemia reflects many of the biochemical alterations in cell injury that have been described above. As the oxygen tension within the cell decreases, there is loss of oxidative phosphorylation and decreased generation of ATP. The depletion of ATP results in failure of the sodium pump, with loss of potassium, influx of sodium and water, and cell swelling. There is also influx of Ca^{2+}, with its many deleterious effects. There is progressive loss of glycogen and decreased protein synthesis. The functional consequences may be severe at this stage. For instance, heart muscle ceases to contract within 60 seconds of coronary occlusion. Note, however, that loss of contractility does not mean cell death. If hypoxia continues, worsening ATP depletion causes further deterioration. The cytoskeleton disperses, resulting in the loss of ultrastructural features such as microvilli and the formation of "blebs" at the cell surface (see Figs. 1-9 and 1-10). "Myelin figures," derived from degenerating cellular membranes, may be seen within the cytoplasm (in autophagic vacuoles) or extracellularly. They are thought to result from unmasking of phosphatide groups, promoting the uptake and intercalation of water between the lamellar stacks of membranes. At this time the mitochondria are usually swollen, as a result of loss of volume control in these organelles; the ER remains dilated; and the entire cell is markedly swollen, with increased concentrations of water, sodium, and chloride and a decreased concentration of potassium. *If oxygen is restored, all of these disturbances are reversible*.

If ischemia persists, irreversible injury and necrosis ensue. Irreversible injury is associated morphologically with severe swelling of mitochondria, extensive damage to plasma membranes (giving rise to myelin figures) and swelling of lysosomes (see Fig. 1-10C). Large, flocculent, amorphous densities develop in the mitochondrial matrix. In the myocardium, these are indications of irreversible injury and can be seen as early as 30 to 40 minutes after ischemia. Massive influx of calcium into the cell then occurs, particularly if the ischemic zone is reperfused. Death is mainly by necrosis, but apoptosis also contributes; the apoptotic pathway is probably activated by release of pro-apoptotic molecules from leaky mitochondria. The cell's components are progressively degraded, and there is widespread leakage of cellular enzymes into the extracellular space and, conversely, entry of extracellular macromolecules from the interstitial space into the dying cells. Finally, the dead cells may become replaced by large masses composed of phospholipids in the form of myelin figures. These are then either phagocytosed by leukocytes or degraded further into fatty acids. *Calcification* of such fatty acid residues may occur, with the formation of calcium soaps.

As mentioned before, leakage of intracellular enzymes and other proteins across the abnormally permeable plasma membrane and into the blood provides important clinical indicators of cell death. For example, elevated serum levels of cardiac muscle creatine kinase MB and troponin are early signs of myocardial infarction, and may be seen before the infarct is detectable morphologically (Chapter 12).

Mammalian cells have developed protective responses to hypoxic stress. The best-defined of these is induction of a transcription factor called *hypoxia-inducible factor-1*, which promotes new blood vessel formation, stimulates cell survival pathways, and enhances anaerobic glycolysis.[27] It remains to be seen if understanding of such oxygen-sensing mechanisms will lead to new strategies for preventing or treating ischemic and hypoxic cell injury.

Despite many investigations in experimental models there are still no reliable therapeutic approaches for reducing the injurious consequences of ischemia in clinical situations. The strategy that is perhaps the most useful in ischemic (and traumatic) brain and spinal cord injury is the transient induction of hypothermia (reducing the core body temperature to 92°F). This treatment reduces the metabolic demands of the stressed cells, decreases cell swelling, suppresses the formation of free radicals, and inhibits the host inflammatory response. All of these may contribute to decreased cell and tissue injury.[28]

ISCHEMIA-REPERFUSION INJURY

Restoration of blood flow to ischemic tissues can promote recovery of cells if they are reversibly injured. However, under certain circumstances, when blood flow is restored to cells that have been ischemic but have not died, injury is paradoxically exacerbated and proceeds at an accelerated pace. As a consequence, *reperfused tissues may sustain loss of cells in addition to the cells that are irreversibly damaged at the end of ischemia*. This process, called *ischemia-reperfusion injury*, is clinically important because it contributes to tissue damage during myocardial and cerebral infarction and following therapies to restore blood flow (Chapters 12 and 28 .

How does reperfusion injury occur? The likely answer is that *new damaging processes* are set in motion during reperfusion, causing the death of cells that might have recovered otherwise.[29] Several mechanisms have been proposed:

- New damage may be initiated during reoxygenation by increased generation of *reactive oxygen and nitrogen species* from parenchymal and endothelial cells and from infiltrating leukocytes.[30,][31] These free radicals may be produced in reperfused tissue as a result of mitochondrial damage, causing incomplete reduction of oxygen, or because of the action of oxidases in leukocytes, endothelial cells, or parenchymal cells. Cellular antioxidant defense mechanisms may be compromised by ischemia, favoring the accumulation of free radicals. Other mediators of cell injury, such as calcium, may also enter reperfused cells, damaging various organelles, including mitochondria, and increasing the production of free radicals.
- Ischemic injury is associated with *inflammation* as a result of the production of cytokines and increased expression of adhesion molecules by hypoxic parenchymal and endothelial cells, which recruit circulating neutrophils to reperfused tissue.[32] The inflammation causes additional tissue injury (Chapter 2). The importance of neutrophil influx in reperfusion injury has been demonstrated experimentally by the ability of anti-inflammatory interventions, such as treatment with antibodies that block cytokines or adhesion molecules, to reduce the extent of the injury.
- Activation of the *complement system* may contribute to ischemia-reperfusion injury.[33] The complement system is involved in host defense and is an important mechanism of immune injury (Chapter 6). Some IgM antibodies have a propensity to deposit in ischemic tissues, for unknown reasons, and when blood flow is resumed, complement proteins bind to the deposited antibodies, are activated, and cause more cell injury and inflammation.[34]

CHEMICAL (TOXIC) INJURY

Chemical injury remains a frequent problem in clinical medicine and is a major limitation to drug therapy. Because many drugs are metabolized in the liver, this organ is a frequent target of drug toxicity. In fact, toxic liver injury is perhaps the most frequent reason for terminating the therapeutic use or development of a drug.[35] The mechanisms by which chemicals, certain drugs, and toxins produce injury are described in greater detail in Chapter 9 in the discussion of environmental diseases. Here we will describe the major pathways of chemically induced injury with selected examples.

Chemicals induce cell injury by one of two general mechanisms[36]:

- Some chemicals can injure cells *directly* by combining with critical molecular components. For example, in mercuric chloride poisoning, mercury binds to the sulfhydryl groups of cell membrane proteins, causing increased membrane permeability and inhibition of ion transport. In such instances, the greatest damage is usually to the cells that use, absorb, excrete, or concentrate the chemicals—in the case of mercuric chloride, the cells of the gastrointestinal tract and kidney (Chapter 9). *Cyanide* poisons mitochondrial cytochrome oxidase and thus inhibits oxidative phosphorylation. Many antineoplastic chemotherapeutic agents and antibiotic drugs also induce cell damage by direct cytotoxic effects.
- Most toxic chemicals are not biologically active in their native form but must be converted to reactive toxic metabolites, which then act on target molecules. This modification is usually accomplished by the cytochrome P-450 mixed-function oxidases in the smooth ER of the liver and other organs. The toxic metabolites cause membrane damage and cell injury mainly by formation of *free radicals* and subsequent lipid peroxidation; direct covalent binding to membrane proteins and lipids may also contribute. For instance, CCl_4, which was once widely used in the dry cleaning industry, is converted by cytochrome P-450 to the

highly reactive free radical $^{\bullet}CCl_3$, which causes lipid peroxidation and damages many cellular structures. Acetaminophen, an analgesic drug, is also converted to a toxic product during detoxification in the liver, leading to cell injury. These and other examples of chemical injury are described in Chapter 9 .

2.1.9 Apoptosis

Apoptosis is a pathway of cell death that is induced by a tightly regulated suicide program in which cells destined to die activate enzymes that degrade the cells' own nuclear DNA and nuclear and cytoplasmic proteins. Apoptotic cells break up into fragments, called apoptotic bodies, which contain portions of the cytoplasm and nucleus. The plasma membrane of the apoptotic cell and bodies remains intact, but its structure is altered in such a way that these become "tasty" targets for phagocytes. The dead cell and its fragments are rapidly devoured, before the contents have leaked out, and therefore cell death by this pathway does not elicit an inflammatory reaction in the host. The process was recognized in 1972 by the distinctive morphologic appearance of membrane-bound fragments derived from cells, and named after the Greek designation for "falling off."[37] It was quickly appreciated that apoptosis was a unique mechanism of cell death, distinct from necrosis, which is characterized by loss of membrane integrity, enzymatic digestion of cells, leakage of cellular contents, and frequently a host reaction (see Fig. 1-8 and Table 1-2). However, apoptosis and necrosis sometimes coexist, and apoptosis induced by some pathologic stimuli may progress to necrosis.

CAUSES OF APOPTOSIS

Apoptosis occurs normally both during development and throughout adulthood, and serves to eliminate unwanted, aged or potentially harmful cells. It is also a pathologic event when diseased cells become damaged beyond repair and are eliminated.

Apoptosis in Physiologic Situations

Death by apoptosis is a normal phenomenon that serves to eliminate cells that are no longer needed, and to maintain a steady number of various cell populations in tissues. It is important in the following physiologic situations:

- *The programmed destruction of cells during embryogenesis*, including implantation, organogenesis, developmental involution, and metamorphosis. The term "programmed cell death" was originally coined to denote death of specific cell types at defined times during the development of an organism.[38] Apoptosis is a generic term for this pattern of cell death, regardless of the context, but it is often used interchangeably with "programmed cell death."
- *Involution of hormone-dependent tissues upon hormone withdrawal*, such as endometrial cell breakdown during the menstrual cycle, ovarian follicular atresia in menopause, the regression of the lactating breast after weaning, and prostatic atrophy after castration.
- *Cell loss in proliferating cell populations*, such as immature lymphocytes in the bone marrow and thymus that fail to express useful antigen receptors (Chapter 6), B lymphocytes in germinal centers, and epithelial cells in intestinal crypts, so as to maintain a constant number *(homeostasis)*.
- *Elimination of potentially harmful self-reactive lymphocytes*, either before or after they have completed their maturation, so as to prevent reactions against one's own tissues (Chapter 6).
- Death of host cells that have served their useful purpose, such as neutrophils in an *acute inflammatory response*, and lymphocytes at the end of an *immune response*. In these situations cells undergo apoptosis because they are deprived of necessary survival signals, such as growth factors.

Apoptosis in Pathologic Conditions

Apoptosis eliminates cells that are injured beyond repair without eliciting a host reaction, thus limiting collateral tissue damage. Death by apoptosis is responsible for loss of cells in a variety of pathologic states:

- *DNA damage*. Radiation, cytotoxic anticancer drugs, and hypoxia can damage DNA, either directly or via production of free radicals. If repair mechanisms cannot cope with the injury, the cell triggers intrinsic mechanisms that induce apoptosis. In these situations elimination of the cell may be a better alternative than risking mutations in the damaged DNA, which may result in malignant transformation. These injurious stimuli can cause apoptosis if the insult is mild, but larger doses of the same stimuli may result in necrotic cell death.
- *Accumulation of misfolded proteins*. Improperly folded proteins may arise because of mutations in the genes encoding these proteins or because of extrinsic factors, such as damage caused by free radicals. Excessive accumulation of these proteins in the ER leads to a condition called *ER stress*, which culminates in apoptotic cell death. Apoptosis caused by the accumulation of misfolded proteins has been invoked as the basis of several degenerative diseases of the central nervous system and other organs.
- *Cell death in certain infections*, particularly viral infections, in which loss of infected cells is largely due to apoptosis that may be induced by the virus (as in adenovirus and HIV infections) or by the host immune response (as in viral hepatitis). An important host response to viruses consists of cytotoxic T lymphocytes specific for viral proteins, which induce apoptosis of infected cells in an attempt to eliminate reservoirs of infection. During this process there can be significant tissue damage. The same T-cell-mediated mechanism is responsible for cell death in *tumors* and cellular rejection of *transplants*.
- *Pathologic atrophy in parenchymal organs after duct obstruction*, such as occurs in the pancreas, parotid gland, and kidney.

MORPHOLOGIC AND BIOCHEMICAL CHANGES IN APOPTOSIS

Before discussing the mechanisms of apoptosis, we describe the morphologic and biochemical characteristics of this process.

Morphology. The following morphologic features, some best seen with the electron microscope, characterize cells undergoing apoptosis (Fig. 1-22 , and see Fig. 1-8).

Cell shrinkage. The cell is smaller in size; the cytoplasm is dense (Fig. 1-22A); and the organelles, though relatively normal, are more tightly packed. (Recall that in other forms of cell injury, an early feature is cell swelling, not shrinkage.)

Chromatin condensation. This is the most characteristic feature of apoptosis. The chromatin aggregates peripherally, under the nuclear membrane, into dense masses of various shapes and sizes (Fig. 1-22B). The nucleus itself may break up, producing two or more fragments.

Formation of cytoplasmic blebs and apoptotic bodies. The apoptotic cell first shows extensive surface blebbing, then undergoes fragmentation into membrane-bound apoptotic bodies composed of cytoplasm and tightly packed organelles, with or without nuclear fragments (Fig. 1-22C).

Phagocytosis of apoptotic cells or cell bodies, usually by macrophages. The apoptotic bodies are rapidly ingested by phagocytes and degraded by the phagocyte's lysosomal enzymes.

Plasma membranes are thought to remain intact during apoptosis, until the last stages, when they become permeable to normally retained solutes. This classical description is accurate with respect to apoptosis during physiologic conditions such as embryogenesis and deletion of immune cells. However, forms of cell death with features of necrosis as well as of apoptosis are not uncommon after many injurious stimuli.[39] Under such conditions the severity rather than the nature of the stimulus determines the pathway of cell death, necrosis being the major pathway when there is advanced ATP

depletion and membrane damage.

On histologic examination, in tissues stained with hematoxylin and eosin, the apoptotic cell appears as a round or oval mass of intensely eosinophilic cytoplasm with fragments of dense nuclear chromatin (Fig. 1-22A). Because the cell shrinkage and formation of apoptotic bodies are rapid and the pieces are quickly phagocytosed, considerable apoptosis may occur in tissues before it becomes apparent in histologic sections. In addition, apoptosis—in contrast to necrosis—does not elicit inflammation, making it more difficult to detect histologically.

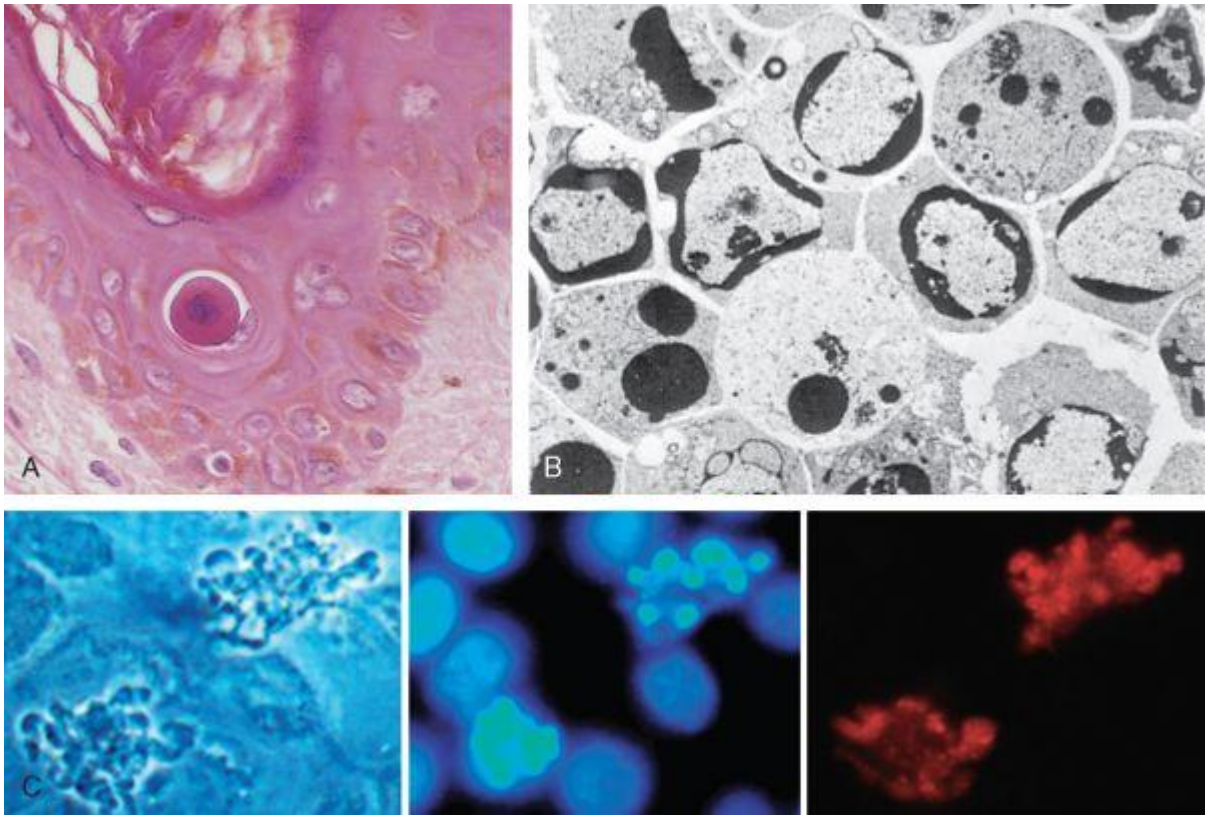

FIGURE 1-22 Morphologic features of apoptosis. **A**, Apoptosis of an epidermal cell in an immune reaction. The cell is reduced in size and contains brightly eosinophilic cytoplasm and a condensed nucleus. **B**, This electron micrograph of cultured cells undergoing apoptosis shows some nuclei with peripheral crescents of compacted chromatin, and others that are uniformly dense or fragmented. **C**, These images of cultured cells undergoing apoptosis show blebbing and formation of apoptotic bodies (*left panel*, phase contrast micrograph), a stain for DNA showing nuclear fragmentation (*middle panel*), and activation of caspase-3 (*right panel*, immunofluorescence stain with an antibody specific for the active form of caspase-3, revealed as red color). *(**B**, From Kerr JFR, Harmon BV: Definition and incidence of apoptosis: a historical perspective. Biochemical Features of Apoptosis

Apoptotic cells usually exhibit a distinctive constellation of biochemical alterations that underlie the structural changes described above.

Activation of Caspases.

A specific feature of apoptosis is the activation of several members of a family of cysteine proteases named *caspases*.[40] The term *caspase* is based on two properties of this family of enzymes: the "c" refers to a cysteine protease (i.e., an enzyme with cysteine in its active site), and "aspase" refers to the unique ability of these enzymes to cleave after aspartic acid residues. The caspase family, now including more than 10 members, can be divided functionally into two groups—initiator and executioner—depending on the order in which they are activated during apoptosis. Initiator caspases include caspase-8 and caspase-9. Several other caspases, including caspase-3 and caspase-6, serve as executioners. Like many proteases, caspases exist as inactive pro-enzymes, or zymogens, and must undergo an enzymatic cleavage to become active. The presence of cleaved, active caspases is a marker for cells undergoing apoptosis (Fig. 1-22C). We will discuss the roles of these enzymes in apoptosis later in this section.

DNA and Protein Breakdown.

Apoptotic cells exhibit a characteristic breakdown of DNA into large 50- to 300-kilobase pieces.[41] Subsequently, there is cleavage of DNA by Ca^{2+}- and Mg^{2+}-dependent endonucleases into fragments whose sizes are multiples of 180 to 200 base pairs, reflecting cleavage between nucleosomal subunits. The fragments may be visualized by electrophoresis as DNA "ladders" (Fig. 1-23). Endonuclease activity also forms the basis for detecting cell death by cytochemical techniques that recognize double-stranded breaks of DNA.[41] A "smeared" pattern of DNA fragmentation is thought to be indicative of necrosis, but this may be a late autolytic phenomenon, and typical DNA ladders are sometimes seen in necrotic cells as well.

Ethidium bromide stain; photographed under ultraviolet illumination. **Lane A**, Viable cells in culture. **Lane B**, Culture of cells exposed to heat showing extensive apoptosis; note ladder pattern of DNA fragments, which represent multiples of oligonucleosomes. **Lane C**, Culture showing cell necrosis; note diffuse smearing of DNA. *(From Kerr JFR, Harmon BV: Definition and incidence of apoptosis: a historical perspective. In Tomei LD, Cope FO: Apoptosis: The Molecular Basis of Cell Death. Cold Spring Harbor, NY, Cold Spring Harbor Laboratory Press, 1991, p 13.)*

Membrane Alterations and Recognition by Phagocytes.

The plasma membrane of apoptotic cells changes in ways that promote the recognition of the dead cells by phagocytes. One of these changes is the movement of some phospholipids (notably phosphatidylserine) from the inner leaflet to the outer leaflet of the membrane, where they are recognized by a number of receptors on phagocytes. These lipids are also detectable by binding of a protein called annexin V; thus, annexin V staining is commonly used to identify apoptotic cells. The clearance of apoptotic cells by phagocytes is described later.

MECHANISMS OF APOPTOSIS

All cells contain intrinsic mechanisms that signal death or survival, and apoptosis results from an imbalance in these signals. Because too much or too little apoptosis is thought to underlie many diseases, such as degenerative diseases and cancer, there is great interest in elucidating the mechanisms of this form of cell death. One of the remarkable facts to emerge is that the basic mechanisms of apoptosis—the genes and proteins that control the process and the sequence of events—are conserved in all multicellular organisms.[38] In fact, some of the major breakthroughs came from observations made in the nematode *Caenorhabditis elegans*, whose development proceeds by a highly reproducible, programmed pattern of cell growth followed by cell death. Studies of mutant worms have allowed the identification of specific genes (called *ced* genes, for *ce*ll *d*eath abnormal) that initiate or inhibit apoptosis and for which there are defined mammalian homologues.[38]

The process of apoptosis may be divided into an initiation phase, during which some caspases become catalytically active, and an execution phase, during which other caspases trigger the degradation of critical cellular components. *Initiation of apoptosis occurs principally by signals from two distinct pathways: the intrinsic, or mitochondrial, pathway, and the extrinsic, or death receptor–initiated, pathway* (Fig. 1-24).[42] These pathways are induced by distinct stimuli and involve different sets of proteins, although there is some cross-talk between them. Both pathways converge to activate caspases, which are the actual mediators of cell death.

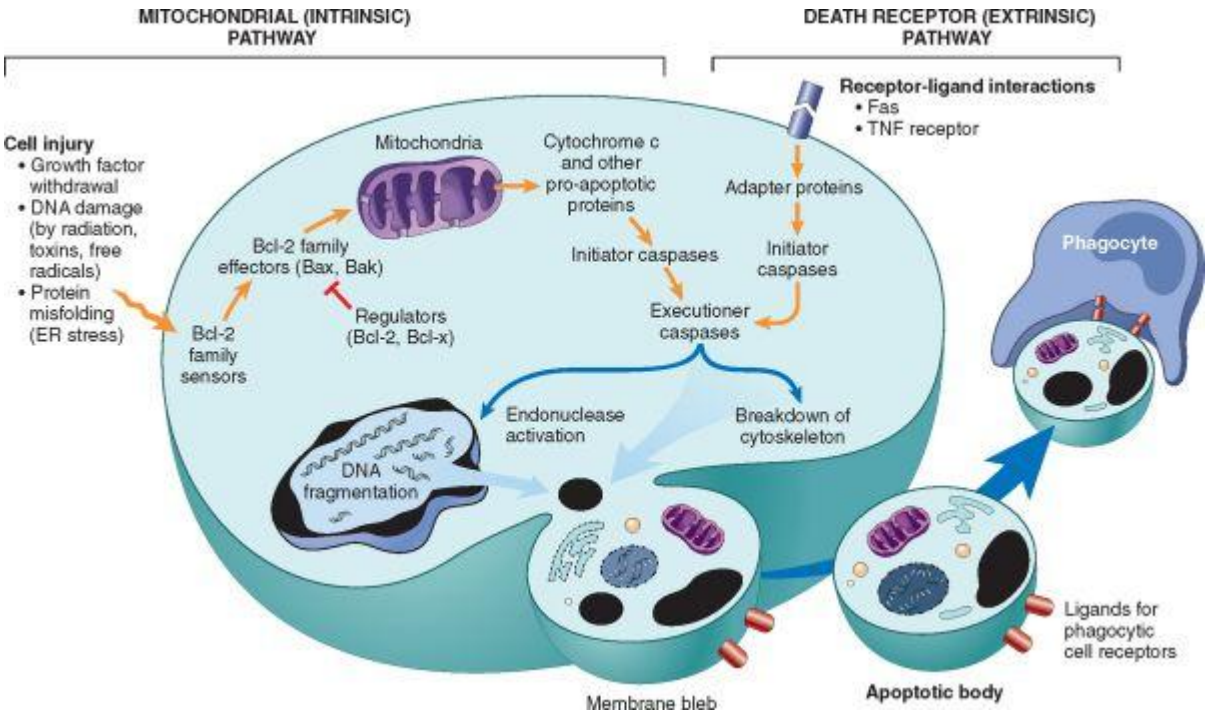

FIGURE 1-24 Mechanisms of apoptosis. The two pathways of apoptosis differ in their induction and regulation, and both culminate in the activation of "executioner" caspases. The induction of apoptosis by the mitochondrial pathway involves the action of sensors and effectors of the Bcl-2 family, which induce leakage of mitochondrial proteins. Also shown are some of the anti-apoptotic proteins ("regulators") that inhibit mitochondrial leakiness and cytochrome *c*–dependent caspase activation in the mitochondrial pathway. In the death receptor pathway engagement of death receptors leads directly to caspase activation. The regulators of death receptor–mediated caspase activation are not shown. ER, endoplasmic reticulum; TNF, tumor necrosis factor.

The Intrinsic (Mitochondrial) Pathway of Apoptosis

The mitochondrial pathway is the major mechanism of apoptosis in all mammalian cells, and its role in a variety of physiologic and pathologic processes is well established. This pathway of apoptosis is the result of increased mitochondrial permeability and release of pro-apoptotic molecules (death inducers) into the cytoplasm (Fig. 1-25).[42] Mitochondria are remarkable organelles in that they contain proteins such as cytochrome *c* that are essential for life, but some of the same proteins, when released into the cytoplasm (an indication that the cell is not healthy), initiate the suicide program of apoptosis. The release of these mitochondrial proteins is controlled by a finely orchestrated balance between pro- and anti-apoptotic members of the Bcl family of proteins.[43] This family is named after *Bcl-2*, which was identified as an oncogene in a B-cell lymphoma and is homologous to the *C. elegans* protein Ced-9. There are more than 20 members of the *Bcl* family, and most of them function to regulate apoptosis. Growth factors and other survival signals stimulate production of anti-apoptotic proteins, the main ones being Bcl-2, Bcl-x, and Mcl-1. These proteins normally reside in the cytoplasm and in mitochondrial membranes, where they control mitochondrial permeability and prevent leakage of mitochondrial proteins that have the ability to trigger cell death (Fig. 1-25A). When cells are deprived of survival signals or their DNA is damaged, or misfolded proteins induce ER stress, sensors of damage or stress are activated. These sensors are also members of the *Bcl* family, and they include proteins called Bim, Bid, and Bad that contain a single "Bcl-2 homology domain" (the third of the four such domains present in Bcl-2) and are called "BH3-only proteins." The sensors in turn activate two critical (proapoptotic) effectors, Bax and Bak, which form oligomers that insert into the mitochondrial membrane and create channels that allow proteins from the inner mitochondrial membrane to leak out into the cytoplasm. BH3-only proteins may also bind to and block the function of Bcl-2 and Bcl-x. At the same time, the synthesis of Bcl-2 and Bcl-x may decline. The net result of Bax-Bak activation coupled with loss of the protective functions of the anti-apoptotic Bcl family members is the release into the cytoplasm of several mitochondrial proteins that can activate the caspase cascade (Fig. 1-25B). One of these proteins is *cytochrome c*, well known for its role in mitochondrial respiration. Once released into the cytosol, cytochrome *c* binds to a protein called Apaf-1 (apoptosis-activating factor-1, homologous to Ced-4 in *C. elegans*), which forms a wheel-like hexamer that has been called the *apoptosome*.[44] This complex is able to bind caspase-9, the critical initiator caspase of the mitochondrial pathway, and the enzyme cleaves adjacent caspase-9 molecules, thus setting up an auto-amplification process. Other mitochondrial proteins, with arcane names like Smac/DIABLO, enter the cytoplasm, where they bind to and neutralize cytoplasmic proteins that function as physiologic inhibitors of apoptosis (called IAPs). The normal function of the IAPs is to block the activation of caspases, including executioners like caspase-3, and keep cells alive.[45,][46] Thus, the neutralization of these IAPs permits the initiation of a caspase cascade.

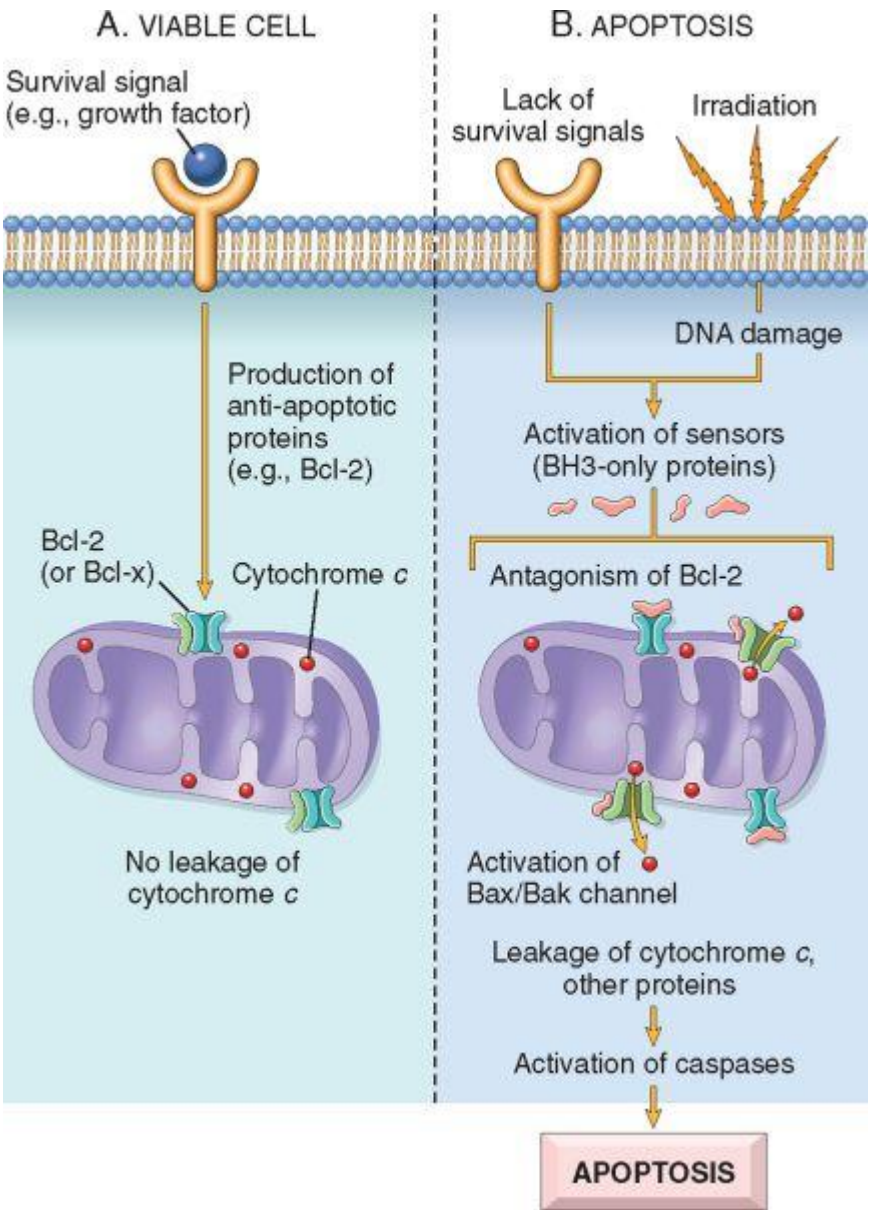

FIGURE 1-25 The intrinsic (mitochondrial) pathway of apoptosis. **A**, Cell viability is maintained by the induction of anti-apoptotic proteins such as Bcl-2 by survival signals. These proteins maintain the integrity of mitochondrial membranes and prevent leakage of mitochondrial proteins. **B**, Loss of survival signals, DNA damage, and other insults activate sensors that antagonize the anti-apoptotic proteins and activate the pro-apoptotic proteins Bax and Bak, which form channels in the mitochondrial membrane. The subsequent leakage of cytochrome *c* (and other proteins, not shown) leads to caspase activation and apoptosis.

There is some evidence that the intrinsic pathway of apoptosis can be triggered without a role for mitochondria.[47] Apoptosis may be initiated by caspase activation upstream of mitochondria, and the subsequent increase in mitochondrial permeability and release of pro-apoptotic molecules serve to amplify the death signal. However, mechanisms of apoptosis involving mitochondria-independent initiation are not well defined.

The Extrinsic (Death Receptor–Initiated) Pathway of Apoptosis

This pathway is initiated by engagement of plasma membrane death receptors on a variety of cells. [48] [49] [50] Death receptors are members of the TNF receptor family that contain a cytoplasmic domain involved in protein-protein interactions that is called the *death domain* because it is essential for delivering apoptotic signals. (Some TNF receptor family members do not contain cytoplasmic death domains; their function is to activate inflammatory cascades [Chapter 2], and their role in triggering apoptosis is much less established.) The best-known death receptors are the type 1 TNF receptor (TNFR1) and a related protein called Fas (CD95), but several others have been described. The mechanism of apoptosis induced by these death receptors is well illustrated by Fas, a death receptor expressed on many cell types (Fig. 1-26). The ligand for Fas is called Fas ligand (FasL). FasL is expressed on T cells that recognize self antigens (and functions to eliminate self-reactive lymphocytes), and on some cytotoxic T lymphocytes (which kill virus-infected and tumor cells). When FasL binds to Fas, three or more molecules of Fas are brought together, and their cytoplasmic death domains form a binding site for an adapter protein that also contains a death domain and is called FADD (*F*as-*a*ssociated *d*eath *d*omain). FADD that is attached to the death receptors in turn binds an inactive form of caspase-8 (and, in humans, caspase-10), again via a death domain. Multiple pro-caspase-8 molecules are thus brought into proximity, and they cleave one another to generate active caspase-8. The enzyme then triggers a cascade of caspase activation by cleaving and thereby activating other pro-caspases, and the active enzymes mediate the execution phase of apoptosis (discussed below). This pathway of apoptosis can be inhibited by a protein called FLIP, which binds to pro-caspase-8 but cannot cleave and activate the caspase because it lacks a protease domain.[51] Some viruses and normal cells produce FLIP and use this inhibitor to protect themselves from Fas-mediated apoptosis.

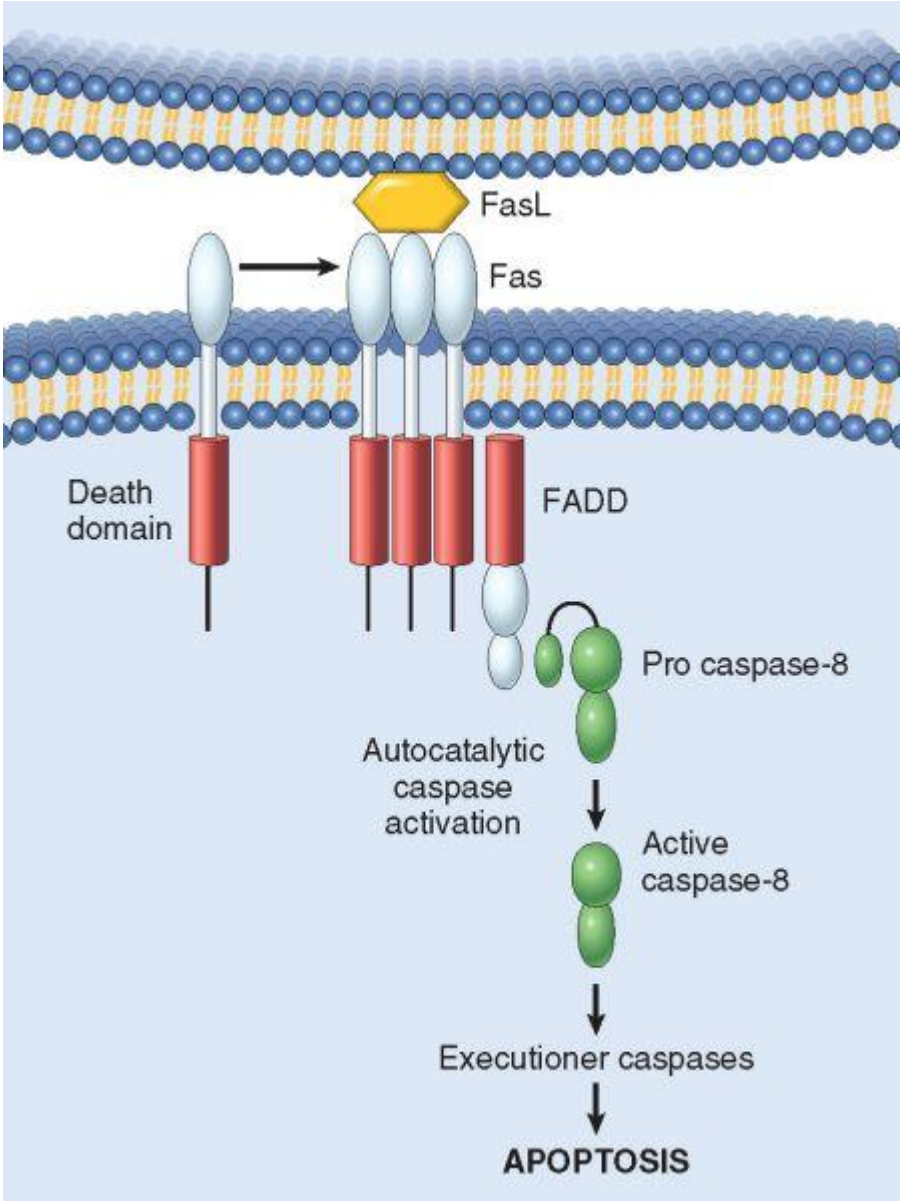

FIGURE 1-26 The extrinsic (death receptor–initiated) pathway of apoptosis, illustrated by the events following Fas engagement. FAAD, *F*as-*a*ssociated *d*eath *d*omain; FasL, Fas ligand.

We have described the extrinsic and intrinsic pathways for initiating apoptosis as distinct because they involve fundamentally different molecules for their initiation, but there may be interconnections between them. For instance, in hepatocytes and several other cell types, Fas signaling activates a BH3-only protein called Bid, which then activates the mitochondrial pathway.

The Execution Phase of Apoptosis

The two initiating pathways converge to a cascade of caspase activation, which mediates the final phase of apoptosis. As we have seen, the mitochondrial pathway leads to activation of the initiator caspase-9, and the death receptor pathway to the initiators caspase-8 and -10. After an initiator caspase is cleaved to generate its active form, the enzymatic death program is set in motion by rapid and sequential

activation of the executioner caspases. Executioner caspases, such as caspase-3 and -6, act on many cellular components. For instance, these caspases, once activated, cleave an inhibitor of a cytoplasmic DNase and thus make the DNase enzymatically active; this enzyme induces the characteristic cleavage of DNA into nucleosome-sized pieces, described earlier. Caspases also degrade structural components of the nuclear matrix, and thus promote fragmentation of nuclei. Some of the steps in apoptosis are not fully defined. For instance, we do not know how the structure of the plasma membrane is changed in apoptotic cells, or how membrane blebs and apoptotic bodies are formed.

Removal of Dead Cells

The formation of apoptotic bodies breaks cells up into "bite-sized" fragments that are edible for phagocytes. Apoptotic cells and their fragments also undergo several changes in their membranes that actively promote their phagocytosis so they are cleared before they undergo secondary necrosis and release their cellular contents (which can result in injurious inflammation). In healthy cells phosphatidylserine is present on the inner leaflet of the plasma membrane, but in apoptotic cells this phospholipid "flips" out and is expressed on the outer layer of the membrane, where it is recognized by several macrophage receptors. Cells that are dying by apoptosis secrete soluble factors that recruit phagocytes.[52] Some apoptotic bodies express thrombospondin, an adhesive glycoprotein that is recognized by phagocytes, and macrophages themselves may produce proteins that bind to apoptotic cells (but not to live cells) and thus target the dead cells for engulfment. Apoptotic bodies may also become coated with natural antibodies and proteins of the complement system, notably C1q, which are recognized by phagocytes.[53] Thus, numerous receptors on phagocytes and ligands induced on apoptotic cells are involved in the binding and engulfment of these cells. This process of phagocytosis of apoptotic cells is so efficient that dead cells disappear, often within minutes, without leaving a trace, and inflammation is absent even in the face of extensive apoptosis.

CLINICO-PATHOLOGIC CORRELATIONS: APOPTOSIS IN HEALTH AND DISEASE

Examples of Apoptosis

Cell death in many situations is known to be caused by apoptosis, and the selected examples listed below illustrate the role of this death pathway in normal physiology and in disease.[54]

Growth Factor Deprivation.

Hormone-sensitive cells deprived of the relevant hormone, lymphocytes that are not stimulated by antigens and cytokines, and neurons deprived of nerve growth factor die by apoptosis. In all these situations, apoptosis is triggered by the intrinsic (mitochondrial) pathway and is attributable to decreased synthesis of Bcl-2 and Bcl-x and activation of Bim and other pro-apoptotic members of the Bcl family.

DNA Damage.

Exposure of cells to radiation or chemotherapeutic agents induces apoptosis by a mechanism that is initiated by DNA damage (genotoxic stress) and that involves the tumor-suppressor gene *p53*.[55] p53 protein accumulates in cells when DNA is damaged, and it arrests the cell cycle (at the G_1 phase) to allow time for repair (Chapter 7). However, if the damage is too great to be repaired successfully, p53 triggers apoptosis. When p53 is mutated or absent (as it is in certain cancers), it is incapable of inducing apoptosis, so that cells with damaged DNA are allowed to survive. In such cells the DNA damage may result in mutations or translocations that lead to neoplastic transformation (Chapter 7). Thus, p53 serves as a critical "life or death" switch following genotoxic stress. The mechanism by which p53 triggers the distal death effector machinery—the caspases—is complex but seems to involve its function

in transcriptional activation. Among the proteins whose production is stimulated by p53 are several pro-apoptotic members of the Bcl family, notably Bax, Bak, and some BH3-only proteins, mentioned earlier.

Protein Misfolding.

Chaperones in the ER control the proper folding of newly synthesized proteins, and misfolded polypeptides are ubiquitinated and targeted for proteolysis in proteasomes. If, however, unfolded or misfolded proteins accumulate in the ER, because of inherited mutations or stresses, they trigger a number of cellular responses, collectively called the *unfolded protein response*.[56,][57] This unfolded protein response activates signaling pathways that increase the production of chaperones, enhance proteasomal degradation of abnormal proteins, and slow protein translation, thus reducing the load of misfolded proteins in the cell (Fig. 1-27). However, if this cytoprotective response is unable to cope with the accumulation of misfolded proteins, the cell activates caspases and induces apoptosis.[58] [59] [60] This process is called *ER stress*. Intracellular accumulation of abnormally folded proteins, caused by genetic mutations, aging, or unknown environmental factors, is now recognized as a feature of a number of neurodegenerative diseases, including Alzheimer, Huntington, and Parkinson diseases (Chapter 28), and possibly type 2 diabetes.[61] Deprivation of glucose and oxygen, and stress such as heat, also result in protein misfolding, culminating in cell injury and death.

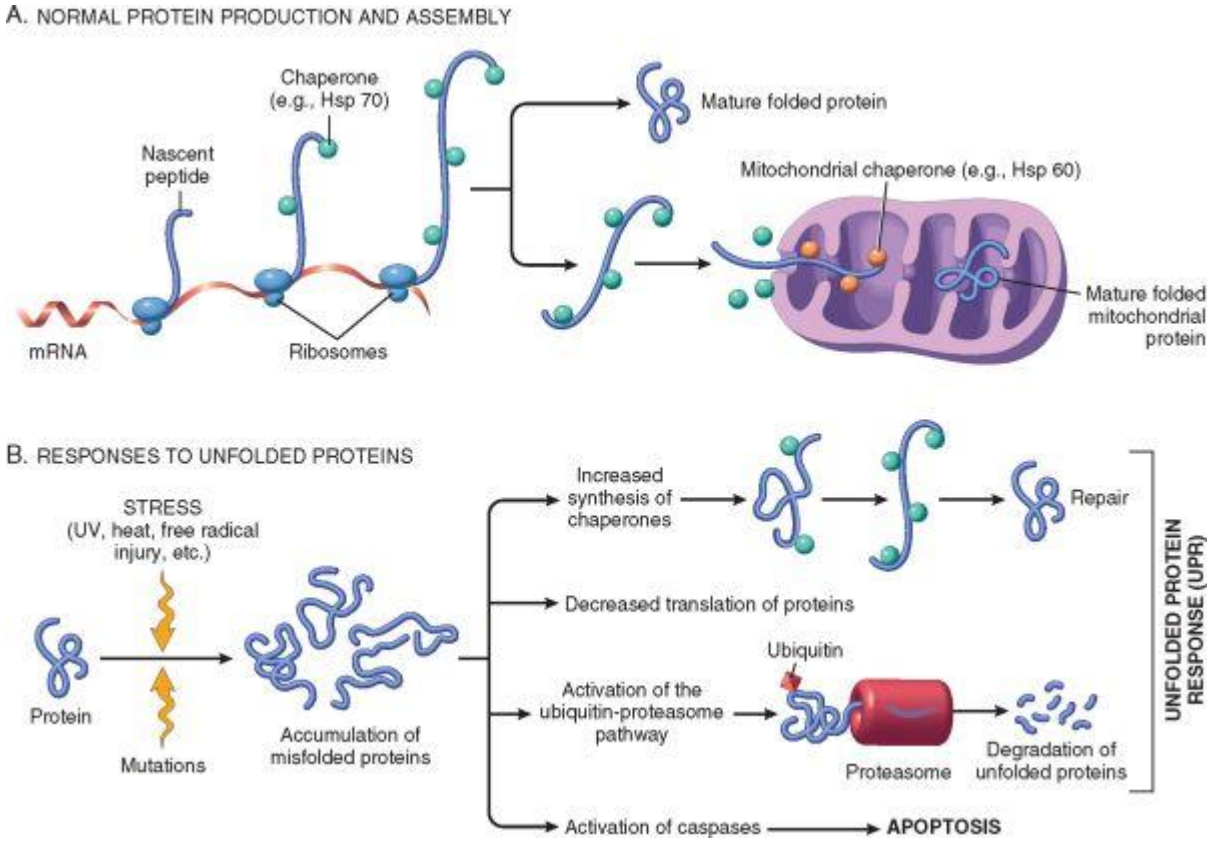

FIGURE 1-27 Mechanisms of protein folding and the unfolded protein response. **A**, Chaperones, such as heat shock proteins (Hsp), protect unfolded or partially folded proteins from degradation and guide proteins into organelles. **B**, Misfolded proteins trigger a protective unfolded protein response (UPR). If this response is inadequate to cope with the level of misfolded proteins, it induces apoptosis.

Apoptosis Induced By the TNF Receptor Family.

FasL on T cells binds to Fas on the same or neighboring lymphocytes. This interaction plays a role in the elimination of lymphocytes that recognize self-antigens, and mutations affecting Fas or FasL result in autoimmune diseases in humans and mice (Chapter 6).[62] The cytokine TNF is an important mediator of the inflammatory reaction (Chapter 2), but it is also capable of inducing apoptosis. (The name "tumor necrosis factor" arose not because the cytokine kills tumor cells directly but because it induces thrombosis of tumor blood vessels, resulting in ischemic death of the tumor.) TNF-mediated death is readily demonstrated in cell cultures, but its physiologic or pathologic significance in vivo is not known. In fact, the major physiologic functions of TNF are mediated not by inducing apoptosis but by activating the important transcription factor NF-κB (nuclear factor-κB), which promotes cell survival by stimulating synthesis of anti-apoptotic members of the Bcl-2 family and, as we shall see in Chapter 2 , activates a number of inflammatory responses. Since TNF can induce cell death and promote cell survival, what determines this *yin* and *yang* of its action? The answer is unclear, but it probably depends on which signaling proteins attach to the TNF receptor after binding of the cytokine.

Cytotoxic T Lymphocyte–Mediated Apoptosis.

Cytotoxic T lymphocytes (CTLs) recognize foreign antigens presented on the surface of infected host cells (Chapter 6). Upon activation, CTLs secrete *perforin*, a transmembrane pore-forming molecule, which promotes entry of the CTL granule serine proteases called *granzymes*. Granzymes have the ability to cleave proteins at aspartate residues and thus activate a variety of cellular caspases.[63] In this way the CTL kills target cells by directly inducing the effector phase of apoptosis. CTLs also express FasL on their surface and may kill target cells by ligation of Fas receptors.

Disorders Associated with Dysregulated Apoptosis

Dysregulated apoptosis ("too little or too much") has been postulated to explain aspects of a wide range of diseases.[56]

- *Disorders associated with defective apoptosis and increased cell survival*. An inappropriately low rate of apoptosis may permit the survival of abnormal cells, which may have a variety of consequences. For instance, if cells that carry mutations in *p53* are subjected to DNA damage, the cells not only fail to die but are susceptible to the accumulation of mutations because of defective DNA repair, and these abnormalities can give rise to *cancer*. The importance of apoptosis in preventing cancer development is emphasized by the fact that mutation of *p53* is the most common genetic abnormality found in human cancers (Chapter 7). In other situations defective apoptosis results in failure to eliminate potentially harmful cells, such as lymphocytes that can react against self-antigens, and failure to eliminate dead cells, a potential source of self-antigens. Thus, defective apoptosis may be the basis of *autoimmune disorders* (Chapter 6).
- *Disorders associated with increased apoptosis and excessive cell death*. These diseases are characterized by a loss of cells and include (1) *neurodegenerative diseases*, manifested by loss of specific sets of neurons, in which apoptosis is caused by mutations and misfolded proteins (Chapter 28); (2) *ischemic injury*, as in myocardial infarction (Chapter 12) and stroke (Chapter 28); and (3) *death of virus-infected cells*, in many viral infections (Chapter 8).

2.1.10 Autophagy

Autophagy is a process in which a cell eats its own contents. It is a survival mechanism in times of nutrient deprivation, when the starved cell lives by cannibalizing itself and recycling the digested contents. In this process intracellular organelles and portions of cytosol are first sequestered from the cytoplasm in an *autophagic vacuole*, which subsequently fuses with lysosomes to form an *autophagolysosome*, and the cellular components are digested by lysosomal enzymes (Fig. 1-28).[64,][65] Interest in autophagy has been spurred by the finding that it is regulated by a defined set of "autophagy genes" (called *Atg*s) in single-celled organisms and mammalian cells. The products of many of these genes function in the creation of the autophagic vacuole, but how they do so is unknown. It has also

been suggested that autophagy triggers cell death that is distinct from necrosis and apoptosis.[66] However, the mechanism of this type of cell death is not known, nor is it clear that the cell death is caused by autophagy rather than by the stress that triggers autophagy. Nevertheless, autophagy has been invoked as a mechanism of cell loss in various diseases, including degenerative diseases of the nervous system and muscle; in many of these disorders, the damaged cells contain abundant autophagic vacuoles.[67]

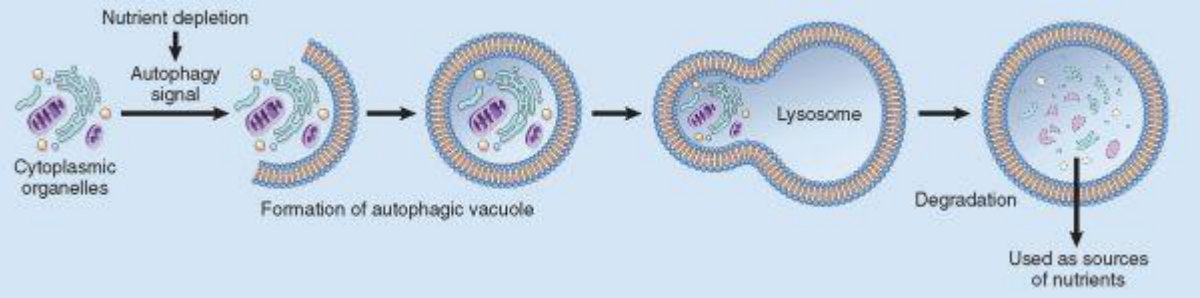

FIGURE 1-28 Autophagy. Cellular stresses, such as nutrient deprivation, activate autophagy genes that create vacuoles in which cellular organelles are sequestered and then degraded following fusion of the vesicles with lysosomes. The digested materials are recycled to provide nutrients for the cell.

2.1.11 Intracellular Accumulations

One of the manifestations of metabolic derangements in cells is the intracellular accumulation of abnormal amounts of various substances. The stockpiled substances fall into two categories: (1) a *normal cellular constituent*, such as water, lipids, proteins, and carbohydrates, that accumulates in excess; or (2) an *abnormal substance*, either exogenous, such as a mineral or products of infectious agents, or endogenous, such as a product of abnormal synthesis or metabolism. These substances may accumulate either transiently or permanently, and they may be harmless to the cells, but on occasion they are severely toxic. The substance may be located in either the cytoplasm (frequently within phagolysosomes) or the nucleus. In some instances the cell may be producing the abnormal substance, and in others it may be merely storing products of pathologic processes occurring elsewhere in the body.

Many processes result in abnormal intracellular accumulations, but most accumulations are attributable to four types of abnormalities (Fig. 1-29).

1. *A normal endogenous substance is produced at a normal or increased rate, but the rate of metabolism is inadequate to remove it*. Examples of this type of process are fatty change in the liver and reabsorption protein droplets in the tubules of the kidneys (see later).
2. An abnormal endogenous substance, typically the product of a mutated gene, accumulates because of defects in protein folding and transport and an inability to degrade the abnormal protein efficiently. Examples include the accumulation of mutated α1-antitrypsin in liver cells (Chapter 18) and various mutated proteins in degenerative disorders of the central nervous system (Chapter 28).
3. A normal endogenous substance accumulates because of defects, usually inherited, in enzymes that are required for the metabolism of the substance. Examples include diseases caused by genetic defects in enzymes involved in the metabolism of lipid and carbohydrates, resulting in intracellular deposition of these substances, largely in lysosomes. These storage diseases are discussed in Chapter 5 .
4. An abnormal exogenous substance is deposited and accumulates because the cell has neither the enzymatic machinery to degrade the substance nor the ability to transport it to other sites. Accumulations of carbon particles and nonmetabolizable chemicals such as silica are examples of this type of alteration.

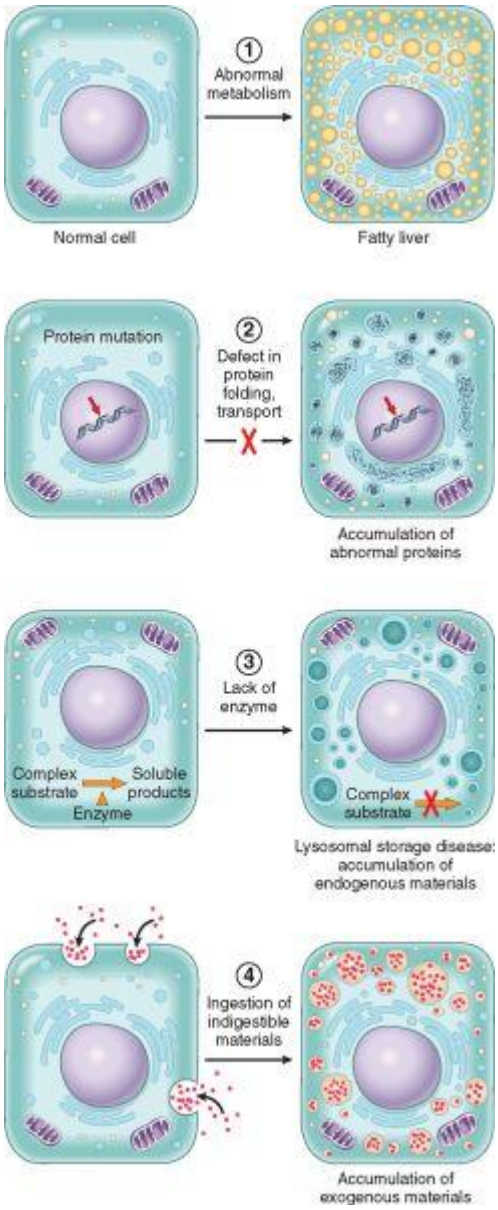

FIGURE 1-29 Mechanisms of intracellular accumulations discussed in the text.

In many cases, if the overload can be controlled or stopped, the accumulation is reversible. In inherited storage diseases accumulation is progressive, and the overload may cause cellular injury, leading in some instances to death of the tissue and the patient.

LIPIDS

All major classes of lipids can accumulate in cells: triglycerides, cholesterol/cholesterol esters, and phospholipids. Phospholipids are components of the myelin figures found in necrotic cells. In addition, abnormal complexes of lipids and carbohydrates accumulate in the lysosomal storage diseases (Chapter 5). Here we concentrate on triglyceride and cholesterol accumulations.

Steatosis (Fatty Change)

The terms *steatosis* and *fatty change* describe abnormal accumulations of triglycerides within parenchymal cells. Fatty change is often seen in the liver because it is the major organ involved in fat metabolism, but it also occurs in heart, muscle, and kidney. The causes of steatosis include toxins, protein malnutrition, diabetes mellitus, obesity, and anoxia. *In developed nations the most common causes of significant fatty change in the liver (fatty liver) are alcohol abuse and nonalcoholic fatty liver disease, which is often associated with diabetes and obesity* (Chapter 18).

Different mechanisms account for triglyceride accumulation in the liver. Free fatty acids from adipose tissue or ingested food are normally transported into hepatocytes. In the liver they are esterified to triglycerides, converted into cholesterol or phospholipids, or oxidized to ketone bodies. Some fatty acids are synthesized from acetate as well. Release of triglycerides from the hepatocytes requires association with apoproteins to form lipoproteins, which may then be transported from the blood into the tissues (Chapter 4). *Excess accumulation of triglycerides within the liver may result from excessive entry or defective metabolism and export of lipids* (Fig. 1-30A). Several such defects are induced by alcohol, a hepatotoxin that alters mitochondrial and microsomal functions, leading to increased synthesis and reduced breakdown of lipids (Chapter 18). CCl_4 and protein malnutrition cause fatty change by reducing synthesis of apoproteins, hypoxia inhibits fatty acid oxidation, and starvation increases fatty acid mobilization from peripheral stores.

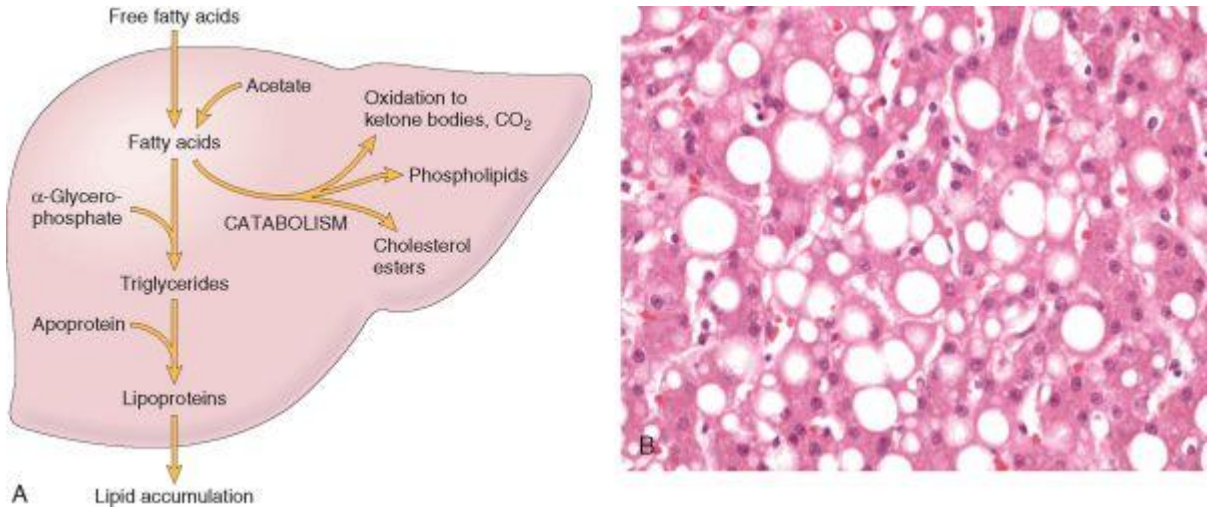

FIGURE 1-30 Fatty liver. **A**, Schematic diagram of the possible mechanisms leading to accumulation of triglycerides in fatty liver. Defects in any of the steps of uptake, catabolism, or secretion can result in lipid accumulation. **B**, High-power detail of fatty change of the liver. In most cells the well-preserved nucleus is squeezed into the displaced rim of cytoplasm about the fat vacuole. *(**B**, Courtesy of Dr. James Crawford, Department of Pathology, University of Florida School of Medicine, Gainesville, FL.)*

The significance of fatty change depends on the cause and severity of the accumulation. When mild it may have no effect on cellular function. More severe fatty change may impair cellular function and may be a harbinger of cell death.

Morphology. Fatty change is most often seen in the liver and heart. In all organs fatty change appears as clear vacuoles within parenchymal cells. Intracellular accumulations of water or polysaccharides (e.g., glycogen) may also produce clear vacuoles. The identification of lipids requires the avoidance of fat solvents commonly used in paraffin embedding for routine hematoxylin and eosin stains. To

identify the fat, it is necessary to prepare frozen tissue sections of either fresh or aqueous formalin-fixed tissues. The sections may then be stained with Sudan IV or Oil Red-O, both of which impart an orange-red color to the contained lipids. The periodic acid-Schiff (PAS) reaction, coupled with digestion by the enzyme diastase, is used to identify glycogen, although it is not specific. When neither fat nor polysaccharide can be demonstrated within a clear vacuole, it is presumed to contain water or fluid with a low protein content.

Liver. In the liver, mild fatty change may not affect the gross appearance. With progressive accumulation, the organ enlarges and becomes increasingly yellow until, in extreme instances, the liver may weigh two to four times normal and be transformed into a bright yellow, soft, greasy organ.

Fatty change begins with the development of minute, membrane-bound inclusions (liposomes) closely applied to the ER. Accumulation of fat is first seen by light microscopy as small vacuoles in the cytoplasm around the nucleus. As the process progresses the vacuoles coalesce, creating cleared spaces that displace the nucleus to the periphery of the cell (Fig. 1-30B). Occasionally contiguous cells rupture and the enclosed fat globules coalesce, producing so-called fatty cysts.

Heart. Lipid is found in cardiac muscle in the form of small droplets, occurring in two patterns. In one, prolonged moderate hypoxia, such as that produced by profound anemia, causes intracellular deposits of fat, which create grossly apparent bands of yellowed myocardium alternating with bands of darker, red-brown, uninvolved myocardium (**tigered effect**). The other pattern of fatty change is produced by more profound hypoxia or by some forms of myocarditis (e.g., diphtheria infection) and shows more uniformly affected myocytes.

Cholesterol and Cholesterol Esters

The cellular metabolism of cholesterol (discussed in detail in Chapter 5) is tightly regulated such that most cells use cholesterol for the synthesis of cell membranes without intracellular accumulation of cholesterol or cholesterol esters. Accumulations manifested histologically by intracellular vacuoles are seen in several pathologic processes.

- *Atherosclerosis*. In atherosclerotic plaques, smooth muscle cells and macrophages within the intimal layer of the aorta and large arteries are filled with lipid vacuoles, most of which are made up of cholesterol and cholesterol esters. Such cells have a foamy appearance (foam cells), and aggregates of them in the intima produce the yellow cholesterol-laden atheromas characteristic of this serious disorder. Some of these fat-laden cells may rupture, releasing lipids into the extracellular space. The mechanisms of cholesterol accumulation in atherosclerosis are discussed in detail in Chapter 11 . The extracellular cholesterol esters may crystallize in the shape of long needles, producing quite distinctive clefts in tissue sections.
- *Xanthomas*. Intracellular accumulation of cholesterol within macrophages is also characteristic of acquired and hereditary hyperlipidemic states. Clusters of foamy cells are found in the subepithelial connective tissue of the skin and in tendons, producing tumorous masses known as xanthomas.
- *Cholesterolosis*. This refers to the focal accumulations of cholesterol-laden macrophages in the lamina propria of the gallbladder (Fig. 1-31). The mechanism of accumulation is unknown.
- *Niemann-Pick disease, type C*. This lysosomal storage disease is caused by mutations affecting an enzyme involved in cholesterol trafficking, resulting in cholesterol accumulation in multiple organs (Chapter 5).

PROTEINS

Intracellular accumulations of proteins usually appear as rounded, eosinophilic droplets, vacuoles, or aggregates in the cytoplasm. By electron microscopy they can be amorphous, fibrillar, or crystalline in appearance. In some disorders, such as certain forms of amyloidosis, abnormal proteins deposit primarily in extracellular spaces (Chapter 6).

Excesses of proteins within the cells sufficient to cause morphologically visible accumulation have diverse causes.

- *Reabsorption droplets in proximal renal tubules* are seen in renal diseases associated with protein loss in the urine (proteinuria). In the kidney small amounts of protein filtered through the glomerulus are normally reabsorbed by pinocytosis in the proximal tubule. In disorders with heavy protein leakage across the glomerular filter there is increased reabsorption of the protein into vesicles, and the protein appears as pink hyaline droplets within the cytoplasm of the tubular cell (Fig. 1-32). The process is reversible; if the proteinuria diminishes, the protein droplets are metabolized and disappear.
- The proteins that accumulate may be normal secreted proteins that are produced in excessive amounts, as occurs in certain plasma cells engaged in active synthesis of immunoglobulins. The ER becomes hugely distended, producing large, homogeneous eosinophilic inclusions called *Russell bodies*.
- *Defective intracellular transport and secretion of critical proteins*. In α_1-antitrypsin deficiency, mutations in the protein significantly slow folding, resulting in the buildup of partially folded intermediates, which aggregate in the ER of the liver and are not secreted. The resultant deficiency of the circulating enzyme causes emphysema (Chapter 15). In many of these diseases the pathology results not only from loss of protein

function but also ER stress caused by the misfolded proteins, culminating in apoptotic death of cells (discussed above).

- *Accumulation of cytoskeletal proteins*. There are several types of cytoskeletal proteins, including microtubules (20–25 nm in diameter), thin actin filaments (6–8 nm), thick myosin filaments (15 nm) and intermediate filaments (10 nm). Intermediate filaments, which provide a flexible intracellular scaffold that organizes the cytoplasm and resists forces applied to the cell,[68] are divided into five classes – keratin filaments (characteristic of epithelial cells), neurofilaments (neurons), desmin filaments (muscle cells), vimentin filaments (connective tissue cells), and glial filaments (astrocytes). Accumulations of keratin filaments and neurofilaments are associated with certain types of cell injury. Alcoholic hyaline is an eosinophilic cytoplasmic inclusion in liver cells that is characteristic of alcoholic liver disease, and is composed predominantly of *keratin* intermediate filaments (Chapter 18). The *neurofibrillary tangle* found in the brain in Alzheimer disease contains neurofilaments and other proteins (Chapter 28).
- *Aggregation of abnormal proteins*. Abnormal or misfolded proteins may deposit in tissues and interfere with normal functions. The deposits can be intracellular, extracellular, or both, and the aggregates may either directly or indirectly cause the pathologic changes. Certain forms of *amyloidosis* (Chapter 6) fall in this category of diseases. These disorders are sometimes called *proteinopathies* or *protein-aggregation diseases*.

HYALINE CHANGE

The term *hyaline* usually refers to an alteration within cells or in the extracellular space that gives a homogeneous, glassy, pink appearance in routine histologic sections stained with hematoxylin and eosin. It is widely used as a descriptive histologic term rather than a specific marker for cell injury. This morphologic change is produced by a variety of alterations and does not represent a specific pattern of

accumulation. Intracellular accumulations of protein, described earlier (reabsorption droplets, Russell bodies, alcoholic hyaline), are examples of intracellular hyaline deposits.

Extracellular hyaline has been more difficult to analyze. Collagenous fibrous tissue in old scars may appear hyalinized, but the biochemical basis of this change is not clear. In long-standing hypertension and diabetes mellitus, the walls of arterioles, especially in the kidney, become hyalinized, resulting from extravasated plasma protein and deposition of basement membrane material.

GLYCOGEN

Glycogen is a readily available energy source stored in the cytoplasm of healthy cells. Excessive intracellular deposits of glycogen are seen in patients with an abnormality in either glucose or glycogen metabolism. Whatever the clinical setting, the glycogen masses appear as clear vacuoles within the cytoplasm. Glycogen dissolves in aqueous fixatives; for its localization, tissues are best fixed in absolute alcohol. Staining with Best carmine or the PAS reaction imparts a rose-to-violet color to the glycogen, and diastase digestion of a parallel section before staining serves as a further control by hydrolyzing the glycogen.

Diabetes mellitus is the prime example of a disorder of glucose metabolism. In this disease glycogen is found in renal tubular epithelial cells, as well as within liver cells, β cells of the islets of Langerhans, and heart muscle cells.

Glycogen accumulates within the cells in a group of related genetic disorders that are collectively referred to as the *glycogen storage diseases*, or *glycogenoses* (Chapter 5). In these diseases enzymatic defects in the synthesis or breakdown of glycogen result in massive accumulation, causing cell injury and cell death.

PIGMENTS

Pigments are colored substances, some of which are normal constituents of cells (e.g., melanin), whereas others are abnormal and accumulate in cells only under special circumstances. Pigments can be exogenous, coming from outside the body, or endogenous, synthesized within the body itself.

Exogenous Pigments

The most common *exogenous pigment* is carbon (coal dust), a ubiquitous air pollutant of urban life. When inhaled it is picked up by macrophages within the alveoli and is then transported through lymphatic channels to the regional lymph nodes in the tracheobronchial region. Accumulations of this pigment blacken the tissues of the lungs *(anthracosis)* and the involved lymph nodes. In coal miners the aggregates of carbon dust may induce a fibroblastic reaction or even emphysema and thus cause a serious lung disease known as *coal worker's pneumoconiosis* (Chapter 15). *Tattooing* is a form of localized, exogenous pigmentation of the skin. The pigments inoculated are phagocytosed by dermal macrophages, in which they reside for the remainder of the life of the embellished (sometimes with embarrassing consequences for the bearer of the tattoo!). The pigments do not usually evoke any inflammatory response.

Endogenous Pigments

Lipofuscin is an insoluble pigment, also known as lipochrome or wear-and-tear pigment. Lipofuscin is composed of polymers of lipids and phospholipids in complex with protein, suggesting that it is derived through lipid peroxidation of polyunsaturated lipids of subcellular membranes. Lipofuscin is not injurious to the cell or its functions. Its importance lies in its being a telltale sign of free radical injury and lipid peroxidation. The term is derived from the Latin (*fuscus*, brown), referring to brown lipid. In

tissue sections it appears as a yellow-brown, finely granular cytoplasmic, often perinuclear, pigment (Fig. 1-33). It is seen in cells undergoing slow, regressive changes and is particularly prominent in the liver and heart of aging patients or patients with severe malnutrition and cancer cachexia.

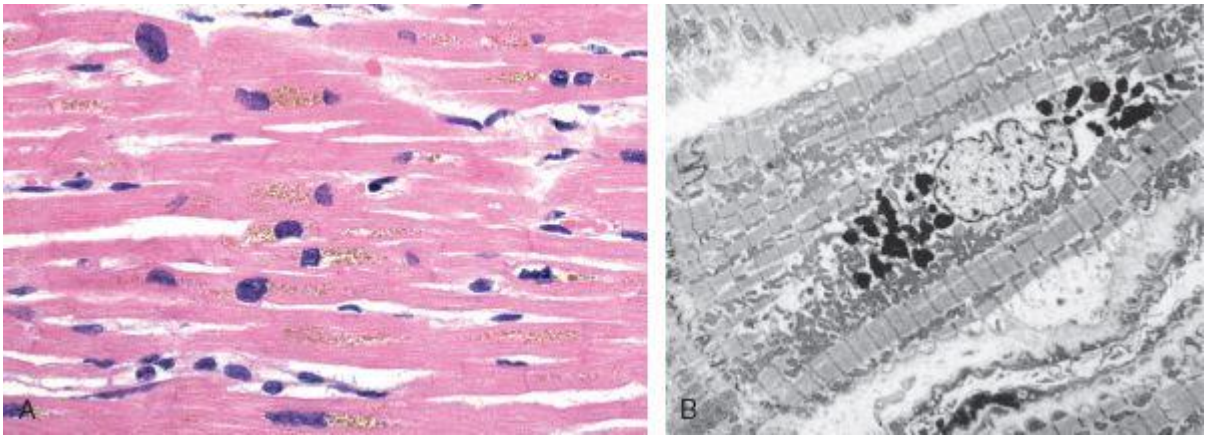

FIGURE 1-33 Lipofuscin granules in a cardiac myocyte shown by (**A**) light microscopy (deposits indicated by *arrows*), and (**B**) electron microscopy (note the perinuclear, intralysosomal location).

Melanin, derived from the Greek (*melas*, black), is an en-dogenous, non-hemoglobin-derived, brown-black pigment formed when the enzyme tyrosinase catalyzes the oxidation of tyrosine to dihydroxyphenylalanine in melanocytes. It is discussed further in Chapter 25 . For practical purposes melanin is the *only endogenous brown-black pigment*. The only other that could be considered in this category is homogentisic acid, a black pigment that occurs in patients with *alkaptonuria*, a rare metabolic disease. Here the pigment is deposited in the skin, connective tissue, and cartilage, and the pigmentation is known as *ochronosis* (Chapter 5).

Hemosiderin is a hemoglobin-derived, golden yellow-to-brown, granular or crystalline pigment that serves as one of the major storage forms of iron. Iron metabolism and hemosiderin are considered in detail in Chapters 14 and 18 . Iron is normally carried by specific transport proteins, transferrins. In cells, it is stored in association with a protein, apoferritin, to form ferritin micelles. Ferritin is a constituent of most cell types. *When there is a local or systemic excess of iron, ferritin forms hemosiderin granules*, which are easily seen with the light microscope (Fig. 1-34). Hemosiderin pigment represents aggregates of ferritin micelles. Under normal conditions small amounts of hemosiderin can be seen in the mononuclear phagocytes of the bone marrow, spleen, and liver, which are actively engaged in red cell breakdown.

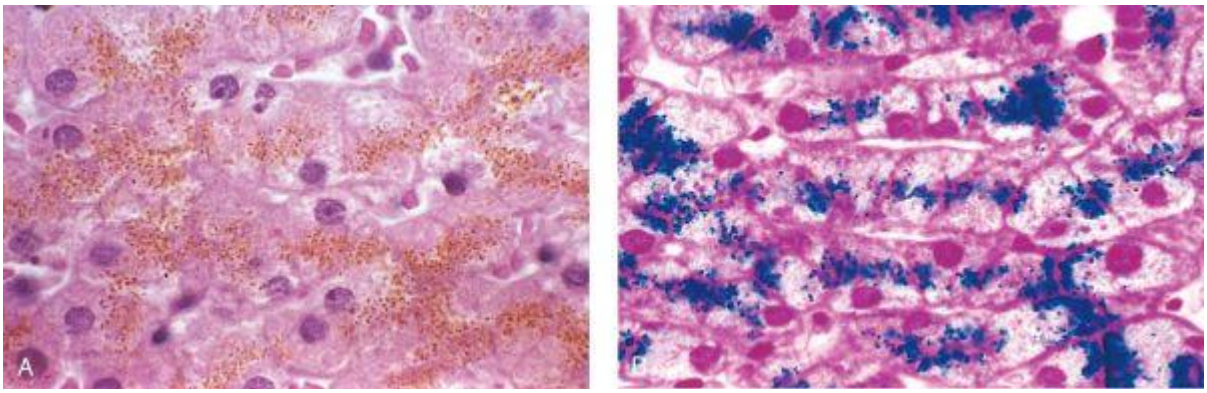

FIGURE 1-34 Hemosiderin granules in liver cells. **A**, H+E stain showing golden-brown, finely granular pigment. **B**, Prussian blue stain, specific for iron (seen as blue granules).

Local or systemic excesses of iron cause hemosiderin to accumulate within cells. *Local excesses* result from hemorrhages in tissues. The best example of localized hemosiderosis is the common bruise. Extravasated red blood cells at the site of injury are phagocytosed over several days by macrophages, which break down the hemoglobin and recover the iron. After removal of iron, the heme moiety is converted first to biliverdin ("green bile") and then to bilirubin ("red bile"). In parallel, the iron released from heme is incorporated into ferritin and eventually hemosiderin. These conversions account for the often dramatic play of colors seen in a healing bruise, which typically changes from red-blue to green-blue to golden-yellow before it is resolved.

When there is *systemic overload of iron* hemosiderin may be deposited in many organs and tissues, a condition called *hemosiderosis*. The main causes of hemosiderosis are (1) increased absorption of dietary iron, (2) hemolytic anemias, in which abnormal quantities of iron are released from erythrocytes, and (3) repeated blood transfusions because the transfused red cells constitute an exogenous load of iron. These conditions are discussed in Chapter 18 .

Morphology. Iron pigment appears as a coarse, golden, granular pigment lying within the cell's cytoplasm (Fig. 1-34A). It can be visualized in tissues by the Prussian blue histochemical reaction, in which colorless potassium ferrocyanide is converted by iron to blue-black ferric ferrocyanide (Fig. 1-34B). When the underlying cause is the localized breakdown of red cells, the hemosiderin is found initially in the phagocytes in the area. In systemic hemosiderosis it is found at first in the mononuclear phagocytes of the liver, bone marrow, spleen, and lymph nodes and in scattered macrophages throughout other organs such as the skin, pancreas, and kidneys. With progressive accumulation, parenchymal cells throughout the body (principally in the liver, pancreas, heart, and endocrine organs) become pigmented.

In most instances of systemic hemosiderosis the pigment does not damage the parenchymal cells or impair organ function. The more extreme accumulation of iron, however, in an inherited disease called **hemochromatosis**, is associated with liver, heart, and pancreatic damage, resulting in liver fibrosis, heart failure, and diabetes mellitus (Chapter 18).

Bilirubin is the normal major pigment found in bile. It is derived from hemoglobin but contains no iron. Its normal formation and excretion are vital to health, and jaundice is a common clinical disorder

caused by excesses of this pigment within cells and tissues. Bilirubin metabolism and jaundice are discussed in Chapter 18 .

2.1.12 Pathologic Calcification

Pathologic calcification is the abnormal tissue deposition of calcium salts, together with smaller amounts of iron, magnesium, and other mineral salts. There are two forms of pathologic calcification. When the deposition occurs locally in dying tissues it is known as *dystrophic calcification*; it occurs despite normal serum levels of calcium and in the absence of derangements in calcium metabolism. In contrast, the deposition of calcium salts in otherwise normal tissues is known as *metastatic calcification*, and it almost always results from hypercalcemia secondary to some disturbance in calcium metabolism.

DYSTROPHIC CALCIFICATION

Dystrophic calcification is encountered in areas of necrosis, whether they are of coagulative, caseous, or liquefactive type, and in foci of enzymatic necrosis of fat. Calcification is almost always present in the atheromas of advanced atherosclerosis. It also commonly develops in aging or damaged heart valves, further hampering their function (Fig. 1-35). Whatever the site of deposition, the calcium salts appear macroscopically as fine, white granules or clumps, often felt as gritty deposits. Sometimes a tuberculous lymph node is virtually converted to stone.

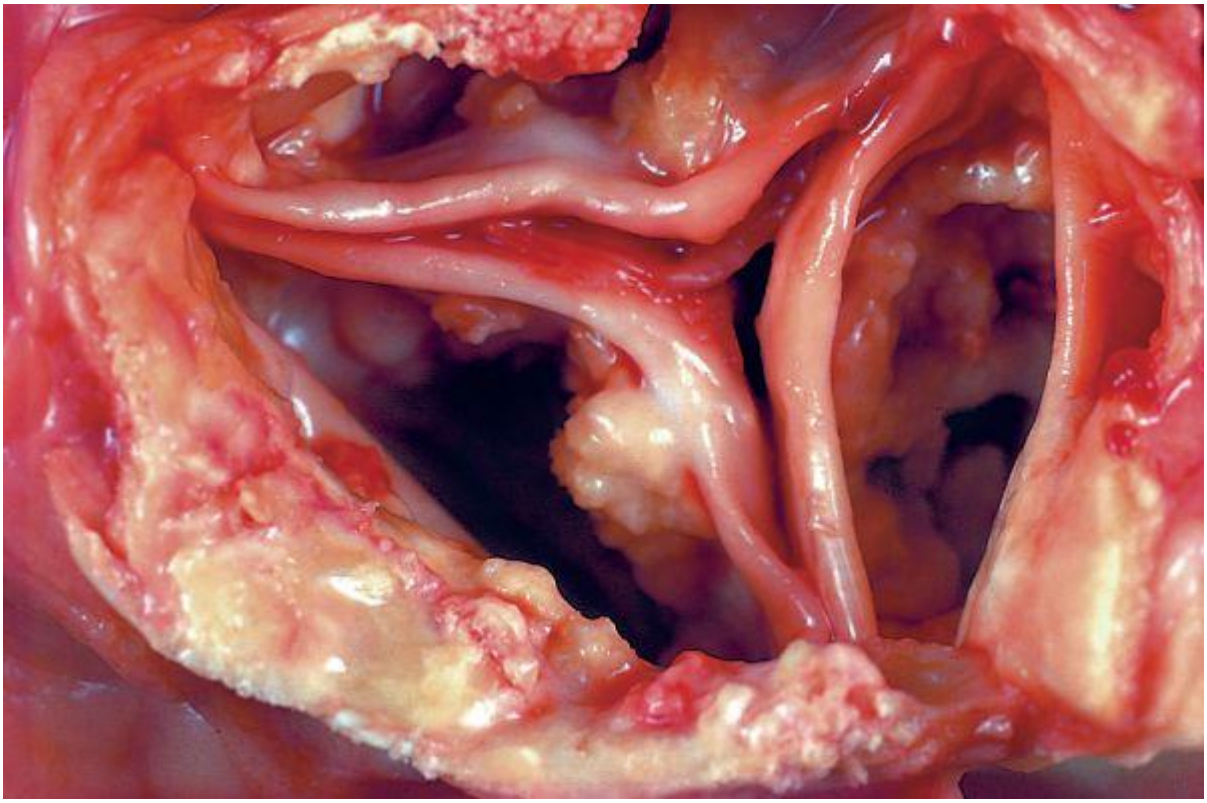

FIGURE 1-35 Dystrophic calcification of the aortic valve. View looking down onto the unopened aortic valve in a heart with calcific aortic stenosis. It is markedly narrowed (stenosis). The semilunar cusps are thickened and fibrotic, and behind each cusp are irregular masses of piled-up dystrophic calcification.

Morphology. Histologically, with the usual hematoxylin and eosin stain, calcium salts have a basophilic, amorphous granular, sometimes clumped appearance. They can be intracellular, extracellular, or in both locations. In the course of time, **heterotopic** bone may be formed in the focus of calcification. On occasion single necrotic cells may constitute seed crystals that become encrusted by the mineral deposits. The progressive acquisition of outer layers may create lamellated configurations, called **psammoma bodies** because of their resemblance to grains of sand. Some types of papillary cancers (e.g., thyroid) are apt to develop psammoma bodies. In asbestosis, calcium and iron salts gather about long slender spicules of asbestos in the lung, creating exotic, beaded dumbbell forms (Chapter 15).

Pathogenesis.

In the pathogenesis of dystrophic calcification, the final common pathway is the formation of crystalline calcium phosphate mineral in the form of an apatite similar to the hydroxyapatite of bone. It is thought that calcium is concentrated in membrane-bound vesicles in cells by a process that is initiated by membrane damage and has several steps: (1) calcium ion binds to the phospholipids present in the vesicle membrane; (2) phosphatases associated with the membrane generate phosphate groups, which bind to the calcium; (3) the cycle of calcium and phosphate binding is repeated, raising the local concentrations and producing a deposit near the membrane; and (4) a structural change occurs in the arrangement of calcium and phosphate groups, generating a microcrystal, which can then propagate and lead to more calcium deposition.

Although dystrophic calcification may simply be a telltale sign of previous cell injury, it is often a cause of organ dysfunction. Such is the case in calcific valvular disease and atherosclerosis, as will become clear in further discussion of these diseases.

METASTATIC CALCIFICATION

Metastatic calcification may occur in normal tissues whenever there is hypercalcemia. Hypercalcemia also accentuates dystrophic calcification. There are four principal causes of hypercalcemia: (1) increased secretion of parathyroid hormone (PTH) with subsequent bone resorption, as in *hyperparathyroidism* due to parathyroid tumors, and ectopic secretion of PTH-related protein by malignant tumors (Chapter 7); (2) *destruction of bone tissue*, secondary to primary tumors of bone marrow (e.g., multiple myeloma, leukemia) or diffuse skeletal metastasis (e.g., breast cancer), accelerated bone turnover (e.g., Paget disease), or immobilization; (3) *vitamin D–related disorders*, including vitamin D intoxication, sarcoidosis (in which macrophages activate a vitamin D precursor), and idiopathic hypercalcemia of infancy (Williams syndrome), characterized by abnormal sensitivity to vitamin D; and (4) *renal failure*, which causes retention of phosphate, leading to secondary hyperparathyroidism. Less common causes include aluminum intoxication, which occurs in patients on chronic renal dialysis, and milk-alkali syndrome, which is due to excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate.

Metastatic calcification may occur widely throughout the body but principally affects the interstitial tissues of the gastric mucosa, kidneys, lungs, systemic arteries, and pulmonary veins. Though quite different in location, all of these tissues excrete acid and therefore have an internal alkaline compartment that predisposes them to metastatic calcification. In all these sites the calcium salts morphologically resemble those described in dystrophic calcification. Thus, they may occur as noncrystalline amorphous deposits or, at other times, as hydroxyapatite crystals.

Usually the mineral salts cause no clinical dysfunction, but on occasion massive involvement of the lungs produces remarkable x-ray films and respiratory deficits. Massive deposits in the kidney (nephrocalcinosis) may in time cause renal damage (Chapter 20).

2.1.13 Cellular Aging

Shakespeare probably characterized aging best in his elegant description of the seven ages of man. It begins at the moment of conception, involves the differentiation and maturation of the organism and its cells, at some variable point in time leads to the progressive loss of functional capacity characteristic of senescence, and ends in death. With age there are physiologic and structural alterations in almost all organ systems. Aging in individuals is affected to a great extent by genetic factors, diet, social conditions, and occurrence of age-related diseases, such as atherosclerosis, diabetes, and osteoarthritis. In addition, there is good evidence that aging-induced alterations in cells are an important component of the aging of the organism. Here we discuss cellular aging because it could represent the progressive accumulation over the years of sublethal injury that may lead to cell death or to a diminished capacity of the cell to respond to injury.

Cellular aging is the result of a progressive decline in cellular function and viability caused by genetic abnormalities and the accumulation of cellular and molecular damage due to the effects of exposure to exogenous influences (Fig. 1-36). Studies in model systems have clearly established that aging is a regulated process that is influenced by a limited number of genes,[69] and genetic anomalies underlie syndromes resembling premature aging in humans as well.[70] Such findings suggest that aging is associated with definable mechanistic alterations. The known changes that contribute to cellular aging include the following.

- *Decreased cellular replication*. The concept that most normal cells have a limited capacity for replication was developed from a simple experimental model for aging. Normal human fibroblasts, when placed in tissue culture, have limited division potential.[71] After a fixed number of divisions all somatic cells become arrested in a terminally nondividing state, known as *senescence*. Cells from children undergo more rounds of replication than do cells from older people (Fig. 1-37). In contrast, cells from patients with *Werner syndrome*, a rare disease characterized by symptoms of premature aging, are defective in DNA replication and have a markedly reduced capacity to divide.
  It is still not known why aging is associated with progressive senescence of cells.[72] One probable mechanism in human cells is that with each cell division there is *incomplete replication of chromosome ends (telomere shortening), which ultimately results in cell cycle arrest*. *Telomeres* are short repeated sequences of DNA (TTAGGG) present at the linear ends of chromosomes that are important for ensuring the complete replication of chromosomal ends and for protecting chromosomal termini from fusion and degradation.[73] When somatic cells replicate, a small section of the telomere is not duplicated and telomeres become progressively shortened. As the telomeres become shorter the ends of chromosomes cannot be protected and are seen as broken DNA, which activates the DNA damage response and signals cell cycle arrest. Telomere length is normally maintained by nucleotide addition mediated by an enzyme called *telomerase*. Telomerase is a specialized RNA-protein complex that uses its own RNA as a template for adding nucleotides to the ends of chromosomes (Fig. 1-38A). The activity of telomerase is repressed by regulatory proteins, which provide a mechanism for sensing telomere length and restrict unnecessary elongation. Telomerase activity is highest in germ cells and present at lower levels in stem cells, but it is usually undetectable in most somatic tissues (Fig. 1-38B). Therefore, as somatic cells divide, their telomeres become shorter, and they exit the cell cycle, resulting in an inability to generate new cells to replace damaged ones. Thus, both accumulation of senescent cells and depletion of stem cell pools via senescence contribute to aging. Conversely, in immortal cancer cells telomerase is reactivated and telomeres are stable, suggesting that maintenance of telomere length might be an important—possibly essential—step in tumor formation (Chapter 7). Despite such alluring observations, however, the relationship of telomerase activity and telomeric length to aging and cancer still must be fully established.[74]
  Replicative senescence can also be induced by increased expression of the cell cycle inhibitor p16INK4a and by DNA damage (discussed further below). How these factors contribute to normal aging is not known.[75]
- *Accumulation of metabolic and genetic damage*. Cellular life span is determined by a balance between damage resulting from *metabolic events* occurring within the cell and counteracting molecular responses that

can repair the damage. One group of potentially toxic products of normal metabolism are *reactive oxygen species*. As we saw earlier, these by-products of oxidative phosphorylation cause covalent modifications of proteins, lipids, and nucleic acids. Increased oxidative damage could result from repeated environmental exposure to such influences as ionizing radiation, mitochondrial dysfunction, or reduction of antioxidant defense mechanisms with age (e.g., vitamin E, glutathione peroxidase). The amount of oxidative damage, which increases as an organism ages, may be an important cause of senescence.[76] Consistent with this proposal are the following observations: (1) variation in longevity among different species is inversely correlated with the rates of mitochondrial generation of $O_2^{\cdot -}$ anion radical, and (2) overexpression of the antioxidative enzymes SOD and catalase extends life span in transgenic forms of *Drosophila*. Free radicals may have deleterious effects on DNA, leading to breaks and genome instability, thus affecting all cellular functions.[77]

Several protective responses counterbalance progressive damage in cells, and an important one is the recognition and repair of damaged DNA. Although most DNA damage is repaired by endogenous DNA repair enzymes, some persists and accumulates as cells age. Several lines of evidence point to the importance of DNA repair in the aging process. Patients with *Werner syndrome* show premature aging, and the defective gene product is a DNA helicase—a protein involved in DNA replication and repair and other functions requiring DNA unwinding.[78] A defect in this enzyme causes rapid accumulation of chromosomal damage that may mimic the injury that normally accumulates during cellular aging. Genetic instability in somatic cells is also characteristic of other disorders in which patients display some of the manifestations of aging at an increased rate, such as *ataxia-telangiectasia*, in which the mutated gene encodes a protein involved in repairing double-strand breaks in DNA (Chapter 7). Thus, the balance between cumulative metabolic damage and the response to that damage could determine the rate at which we age. In this scenario aging can be delayed by decreasing the accumulation of damage or by increasing the response to that damage.

Not only damaged DNA but damaged cellular organelles also accumulate as cells age. In part this may be the result of declining function of the proteasome, the proteolytic machine that serves to eliminate abnormal and unwanted intracellular proteins.[79]

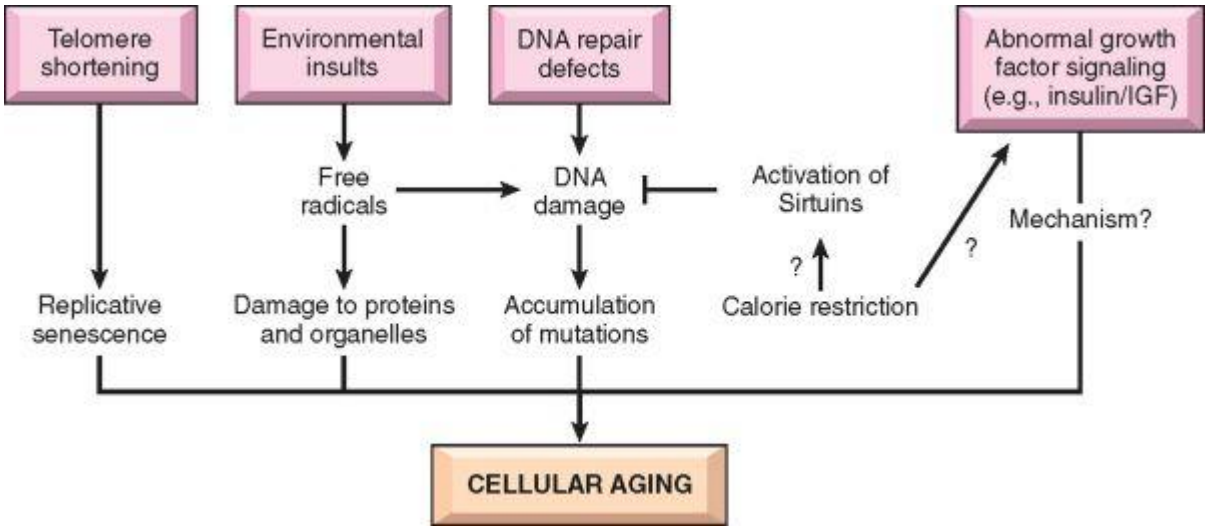

FIGURE 1-36 Mechanisms of cellular aging. Genetic factors and environmental insults combine to produce the cellular abnormalities characteristic of aging. How calorie restrictions prolong life span is net established. IGF, insulin-like growth factor.

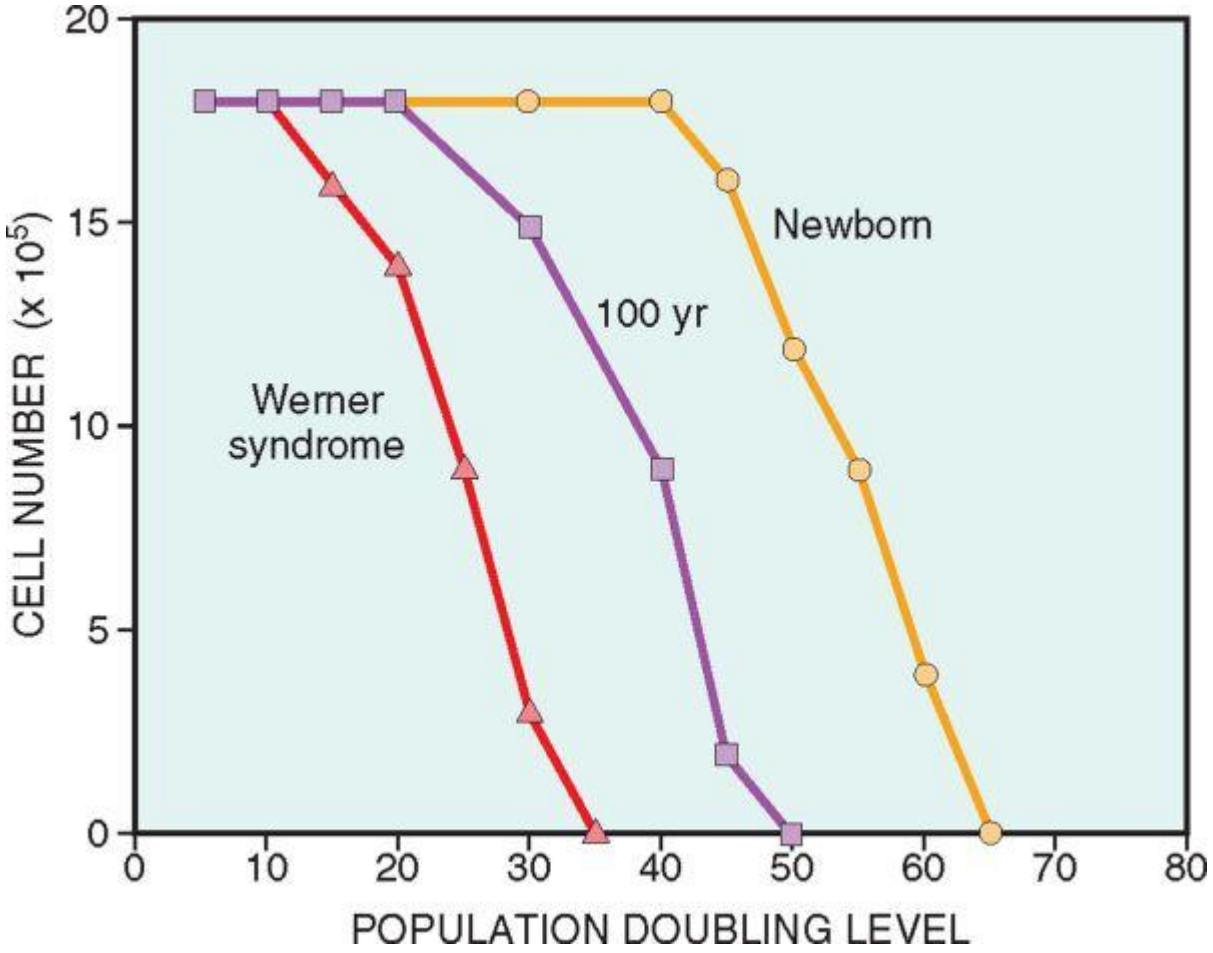

FIGURE 1-37 Finite population doublings of primary human fibroblasts derived from a newborn, a 100-year-old person, and a 20-year-old patient with Werner syndrome. The ability of cells to grow to a confluent monolayer decreases with increasing population-doubling levels. *(From Dice JF: Cellular and molecular mechanisms of aging. Physiol Rev 73:150, 1993.)*

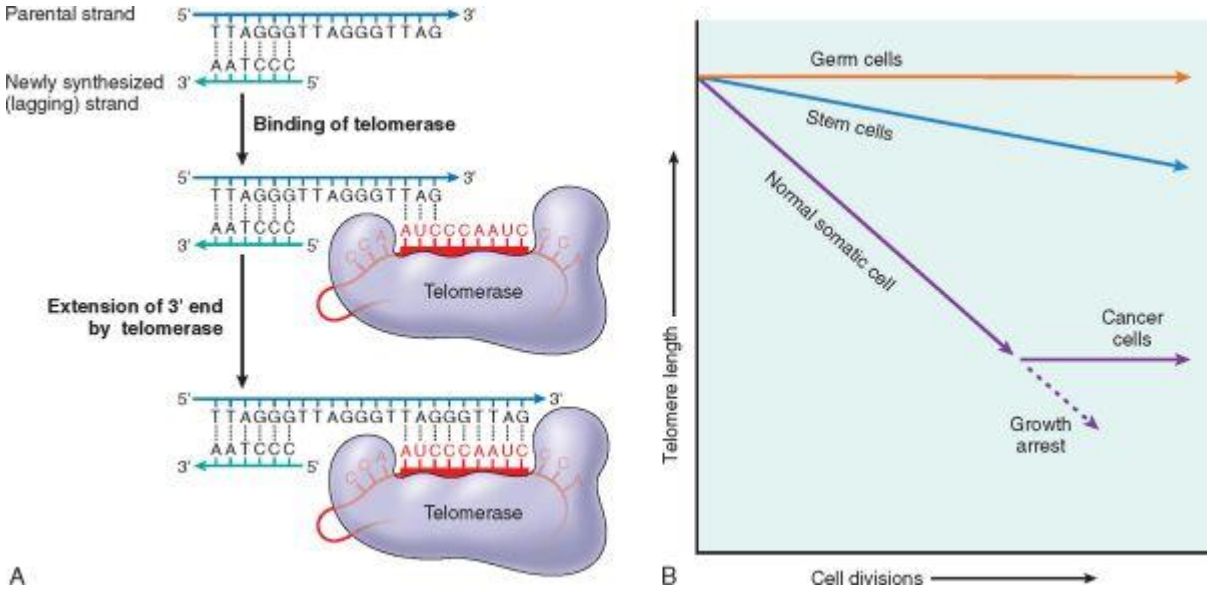

FIGURE 1-38 The role of telomeres and telomerase in replicative senescence of cells. **A**, Telomerase directs RNA template-dependent DNA synthesis, in which nucleotides are added to one strand at the end of a chromosome. The lagging strand is filled in by DNA polymerase. **B**,

Telomere-telomerase hypothesis and proliferative capacity of cells. Telomere length is plotted against the number of cell divisions. Germ cells and stem cells both contain active telomerase, but only the germ cells have sufficient levels of the enzyme to stabilize telomere length completely. In normal somatic cells there is no telomerase activity, and telomeres progressively shorten with successive cell divisions until growth arrest, or senescence, occurs. Telomerase activation in cancer cells counteracts the telomere shortening that limits the proliferative capacity of normal somatic cells. *(**A**, Data from Alberts BR, et al: Molecular Biology of the Cell. New York, Garland Science, 2002. **B**, Modified and redrawn with permission from Holt SE, et al: Refining the telomere-telomerase hypothesis of aging and cancer. Nat Biotechnol 14:836, 1996. Copyright 1996, Macmillan Magazines Limited.)*

Studies in model organisms, from yeast to mammals, have shown that the most effective way of prolonging life span is *calorie restriction*. How this works is still not established, but the effect of calorie restriction on longevity appears to be mediated by a family of proteins called *sirtuins*.[80] Sirtuins have histone deacetylase activity, and are thought to promote the expression of several genes whose products increase longevity. These products include proteins that increase metabolic activity, reduce apoptosis, stimulate protein folding, and inhibit the harmful effects of oxygen free radicals.[81] Sirtuins also increase insulin sensitivity and glucose metabolism, and may be targets for the treatment of diabetes. Not surprisingly, optimistic wine-lovers have been delighted to hear that a constituent of red wine may activate sirtuins and thus increase life span! Other studies have shown that growth factors, such as insulin-like growth factor, and intracellular signaling pathways triggered by these hormones also influence life span.[69] Transcription factors activated by insulin receptor signaling may induce genes that reduce longevity, and insulin receptor mutations are associated with increased life span. The relevance of these findings to aging in humans is an area of active investigation.

It should be apparent that the various forms of cellular derangements and adaptations described in this chapter cover a wide spectrum, ranging from adaptations in cell size, growth, and function; to the reversible and irreversible forms of acute cell injury; to the regulated type of cell death represented by apoptosis; to the pathologic alterations in cell organelles; and to the less ominous forms of intracellular accumulations, including pigmentations. Reference is made to all these alterations throughout this book, because all organ injury and ultimately all clinical disease arise from derangements in cell structure and function.

2.2 2. Acute & Chronic Inflammation

2.2.1 Overview of Inflammation

Overview of Inflammation

Essential to the survival of organisms is their ability to get rid of damaged or necrotic tissues and foreign invaders, such as microbes. The host response that accomplishes these goals is called *inflammation*. *This is fundamentally a protective response*, designed to rid the organism of both the initial cause of cell injury (e.g., microbes, toxins) and the consequences of such injury (e.g., necrotic cells and tissues). Without inflammation infections would go unchecked, wounds would never heal, and injured tissues might remain permanent festering sores. In the practice of medicine the importance of inflammation is that it can sometimes be inappropriately triggered or poorly controlled, and is thus the cause of tissue injury in many disorders.

Inflammation is a complex reaction in tissues that consists mainly of responses of blood vessels and leukocytes. The body's principal defenders against foreign invaders are plasma proteins and circulating leukocytes (white blood cells), as well as tissue phagocytes that are derived from circulating cells. The presence of proteins and leukocytes in the blood gives them the ability to home to any site where they may be needed. Because invaders such as microbes and necrotic cells are typically present in tissues, outside the circulation, it follows that the circulating cells and proteins have to be rapidly recruited to these extravascular sites. The inflammatory response coordinates the reactions of vessels, leukocytes, and plasma proteins to achieve this goal.

The vascular and cellular reactions of inflammation are triggered by soluble factors that are produced by various cells or derived from plasma proteins and are generated or activated in response to the inflammatory stimulus. Microbes, necrotic cells (whatever the cause of cell death) and even hypoxia can trigger the elaboration of inflammatory mediators, and thus elicit inflammation. Such mediators initiate and amplify the inflammatory response and determine its pattern, severity, and clinical and pathologic manifestations.

Inflammation may be acute or chronic, depending on the nature of the stimulus and the effectiveness of the initial reaction in eliminating the stimulus or the damaged tissues. *Acute inflammation* is rapid in onset (typically minutes) and is of short duration, lasting for hours or a few days; its main characteristics are the exudation of fluid and plasma proteins (edema) and the emigration of leukocytes, predominantly neutrophils (also called polymorphonuclear leukocytes). When acute inflammation is successful in eliminating the offenders the reaction subsides, but if the response fails to clear the invaders it can progress to a chronic phase. *Chronic inflammation* may follow acute inflammation or be insidious in onset. It is of longer duration and is associated with the presence of lymphocytes and macrophages, the proliferation of blood vessels, fibrosis, and tissue destruction.

Inflammation is terminated when the offending agent is eliminated. The reaction resolves rapidly, because the mediators are broken down and dissipated and the leukocytes have short life spans in tissues. In addition, anti-inflammatory mechanisms are activated that serve to control the response and prevent it from causing excessive damage to the host.

The inflammatory response is closely intertwined with the process of repair. At the same time as inflammation destroys, dilutes, and walls off the injurious agent, it sets into motion a series of events that try to heal the damaged tissue. Repair begins during inflammation but reaches completion usually after the injurious influence has been neutralized. In the process of repair the injured tissue is replaced through *regeneration* of native parenchymal cells, by filling of the defect with fibrous tissue *(scarring)* or, most commonly, by a combination of these two processes (Chapter 3).

Inflammation may be harmful in some situations. Mechanisms designed to destroy foreign invaders and necrotic tissues have an intrinsic ability to injure normal tissues. When inflammation is inappropriately directed against self tissues or is not adequately controlled, it becomes the cause of injury and disease. In fact, in clinical medicine, great attention is given to the damaging consequences of inflammation. Inflammatory reactions underlie common chronic diseases, such as rheumatoid arthritis, atherosclerosis, and lung fibrosis, as well as life-threatening hypersensitivity reactions to insect bites, drugs, and toxins. For this reason our pharmacies abound with anti-inflammatory drugs, which ideally would control the harmful sequelae of inflammation yet not interfere with its beneficial effects.

Inflammation may contribute to a variety of diseases that are not thought to be primarily due to abnormal host responses. For instance, chronic inflammation may play a role in atherosclerosis, type 2 diabetes, degenerative disorders like Alzheimer disease, and cancer. In recognition of the wide-ranging harmful consequences of inflammation, the lay press has rather melodramatically referred to it as “the silent killer.”

This chapter describes the sequence of events and mediators of acute inflammation, and then its morphologic patterns. This is followed by a discussion of the major features of chronic inflammation. Inflammation has a rich history, and we first touch on some of the historical highlights in our consideration of this fascinating process.

2.2.2 Historical Highlights

Although clinical features of inflammation were described in an Egyptian papyrus dated around 3000 BC, Celsus, a Roman writer of the first century AD, first listed the four cardinal signs of inflammation: *rubor* (redness), *tumor* (swelling), *calor* (heat), and *dolor* (pain).[1] These signs are typically more prominent in acute inflammation than in chronic inflammation. A fifth clinical sign, loss of function *(functio laesa)*, was added by Rudolf Virchow in the 19th century. In 1793 the Scottish surgeon John Hunter noted what is now considered an obvious fact: that inflammation is not a disease but a nonspecific response that has a *salutary* effect on its host.[2] In the 1880s the Russian biologist Elie Metchnikoff discovered the process of *phagocytosis* by observing the ingestion of rose thorns by

amebocytes of starfish larvae and of bacteria by mammalian leukocytes.[3] He concluded that the purpose of inflammation was to bring phagocytic cells to the injured area to engulf invading bacteria. This concept was elegantly satirized by George Bernard Shaw in his play "The Doctor's Dilemma," in which one physician's cure-all is to "stimulate the phagocytes"! Sir Thomas Lewis, studying the inflammatory response in skin, established the concept that *chemical substances, such as histamine (produced locally in response to injury), mediate the vascular changes of inflammation*. This fundamental concept underlies the important discoveries of chemical mediators of inflammation and the use of anti-inflammatory drugs in clinical medicine.

2.2.3 Acute Inflammation

Acute inflammation is a rapid host response that serves to deliver leukocytes and plasma proteins, such as antibodies, to sites of infection or tissue injury. Acute inflammation has three major components: (1) *alterations in vascular caliber that lead to an increase in blood flow*, (2) *structural changes in the microvasculature that permit plasma proteins and leukocytes to leave the circulation*, and (3) *emigration of the leukocytes* from the microcirculation, *their accumulation* in the focus of injury, and *their activation* to eliminate the offending agent (Fig. 2-1).

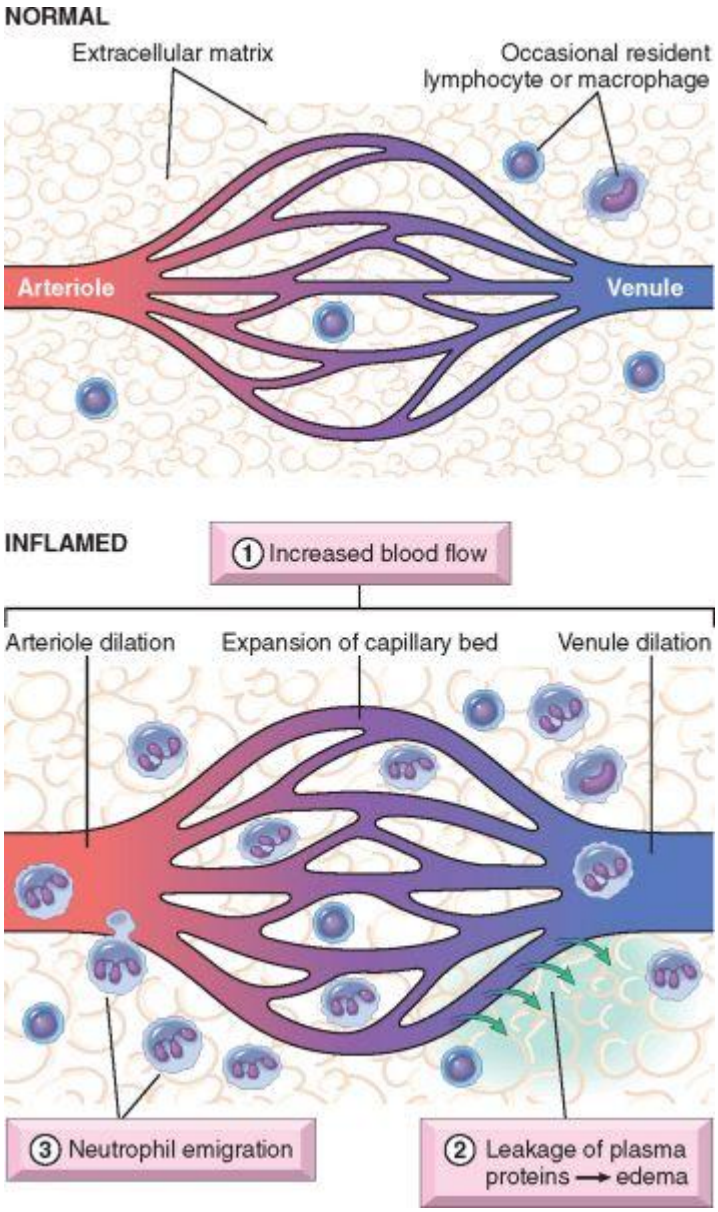

FIGURE 2-1 The major local manifestations of acute inflammation, compared to normal. (1) Vascular dilation and increased blood flow (causing erythema and warmth); (2) extravasation and extravascular deposition of plasma fluid and proteins (edema); (3) leukocyte emigration and accumulation in the site of injury.

STIMULI FOR ACUTE INFLAMMATION

Acute inflammatory reactions may be triggered by a variety of stimuli:

- *Infections* (bacterial, viral, fungal, parasitic) and microbial toxins are among the most common and medically important causes of inflammation. Mammals possess many mechanisms for sensing the presence of microbes. Among the most important receptors for microbial products are the family of Toll-like receptors (TLRs), named after the *Drosophila* protein Toll, and several cytoplasmic receptors, which can detect bacteria, viruses, and fungi (Chapter 6). Engagement of these receptors triggers signaling pathways that stimulate the production of various mediators.
- *Tissue necrosis* from any cause, including *ischemia* (as in a myocardial infarct), *trauma*, and *physical and chemical injury* (e.g., thermal injury, as in burns or frostbite; irradiation; exposure to some environmental chemicals). Several molecules released from necrotic cells are known to elicit inflammation; these include uric acid, a purine metabolite; adenosine triphosphate, the normal energy store; a DNA-binding protein of unknown function called HMGB-1; and even DNA when it is released into the cytoplasm and not sequestered in nuclei, as it should be normally.[4] *Hypoxia*, which often underlies cell injury, is also itself an inducer of the inflammatory response. This response is mediated largely by a protein called HIF-1α (hypoxia-induced factor-1α), which is produced by cells deprived of oxygen and activates the transcription of many genes involved in inflammation, including vascular endothelial growth factor (VEGF), which increases vascular permeability.[5]
- *Foreign bodies* (splinters, dirt, sutures) typically elicit inflammation because they cause traumatic tissue injury or carry microbes.
- *Immune reactions* (also called hypersensitivity reactions) are reactions in which the normally protective immune system damages the individual's own tissues. The injurious immune responses may be directed against self antigens, causing *autoimmune diseases*, or may be excessive reactions against environmental substances or microbes. Inflammation is a major cause of tissue injury in these diseases (Chapter 6). Because the stimuli for the inflammatory responses (i.e., self tissues) cannot be eliminated, autoimmune reactions tend to be persistent and difficult to cure, are associated with chronic inflammation, and are important causes of morbidity and mortality. The inflammation is induced by cytokines produced by T lymphocytes and other cells of the immune system (described later and in Chapter 6). The term *immune-mediated inflammatory disease* is often used to refer to this group of disorders.

All inflammatory reactions share the same basic features, although different stimuli may induce reactions with some distinctive characteristics. We first describe the typical sequence of events in acute inflammation, and then the chemical mediators responsible for inflammation and the morphologic appearance of these reactions.

REACTIONS OF BLOOD VESSELS IN ACUTE INFLAMMATION

In inflammation, blood vessels undergo a series of changes that are designed to maximize the movement of plasma proteins and circulating cells out of the circulation and into the site of infection or injury. The escape of fluid, proteins, and blood cells from the vascular system into the interstitial tissue or body cavities is known as *exudation*. An *exudate* is an extravascular fluid that has a high protein concentration, contains cellular debris, and has a high specific gravity. Its presence implies an increase in the normal permeability of small blood vessels in an area of injury and, therefore, an inflammatory reaction (Fig. 2-2). In contrast, a *transudate* is a fluid with low protein content (most of which is albumin), little or no cellular material, and low specific gravity. It is essentially an ultrafiltrate of blood

plasma that results from osmotic or hydrostatic imbalance across the vessel wall without an increase in vascular permeability (Chapter 4). *Edema* denotes an excess of fluid in the interstitial tissue or serous cavities; it can be either an exudate or a transudate. *Pus*, a *purulent* exudate, is an inflammatory exudate rich in leukocytes (mostly neutrophils), the debris of dead cells and, in many cases, microbes.

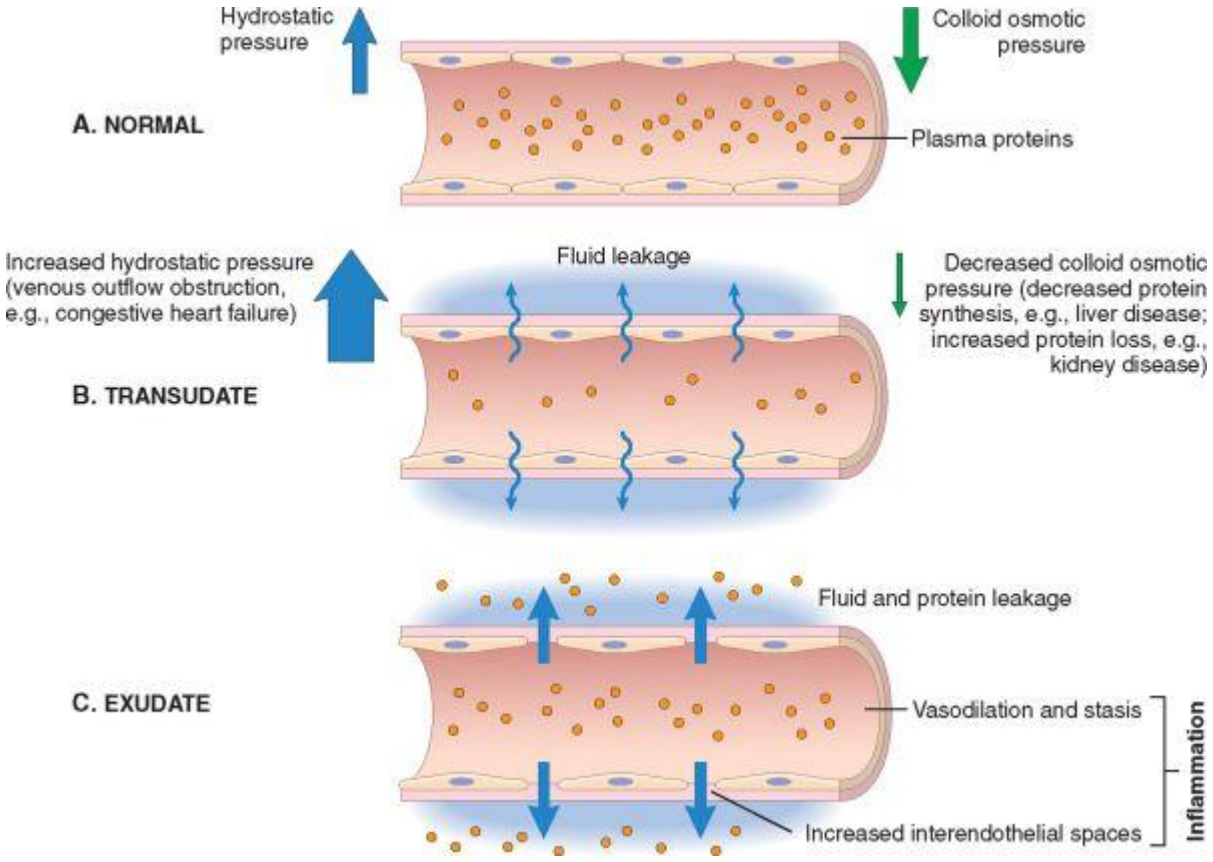

FIGURE 2-2 Formation of transudates and exudates. **A**, Normal hydrostatic pressure *(blue arrows)* is about 32 mm Hg at the arterial end of a capillary bed and 12 mm Hg at the venous end; the mean colloid osmotic pressure of tissues is approximately 25 mm Hg *(green arrows)*, which is equal to the mean capillary pressure. Therefore, the net flow of fluid across the vascular bed is almost nil. **B**, A transudate is formed when fluid leaks out because of increased hydrostatic pressure or decreased osmotic pressure. **C**, An exudate is formed in inflammation, because vascular permeability increases as a result of increased interendothelial spaces.

The vascular reactions of acute inflammation consist of changes in the flow of blood and the permeability of vessels. Proliferation of blood vessels (angiogenesis) is prominent during repair and in chronic inflammation; this process is discussed in Chapter 3 .

Changes in Vascular Flow and Caliber

Changes in vascular flow and caliber begin early after injury and consist of the following.

- *Vasodilation* is one of the earliest manifestations of acute inflammation; sometimes it follows a transient constriction of arterioles, lasting a few seconds. Vasodilation first involves the arterioles and then leads to opening of new capillary beds in the area. The result is *increased blood flow*, which is the cause of heat and redness *(erythema)* at the site of inflammation. *Vasodilation is induced by the action of several mediators, notably histamine and nitric oxide (NO), on vascular smooth muscle*.
- Vasodilation is quickly followed by *increased permeability of the microvasculature*, with the outpouring of

protein-rich fluid into the extravascular tissues; this process is described in detail below.

- The loss of fluid and increased vessel diameter lead to slower blood flow, concentration of red cells in small vessels, and increased viscosity of the blood. These changes result in dilation of small vessels that are packed with slowly moving red cells, a condition termed *stasis*, which is seen as *vascular congestion* (producing localized redness) upon examination of the involved tissue.
- As stasis develops, blood leukocytes, principally neutrophils, accumulate along the vascular endothelium. At the same time endothelial cells are activated by mediators produced at sites of infection and tissue damage, and express increased levels of adhesion molecules. Leukocytes then adhere to the endothelium, and soon afterward they migrate through the vascular wall into the interstitial tissue, in a sequence that is described later.

Increased Vascular Permeability (Vascular Leakage)

A hallmark of acute inflammation is increased vascular permeability leading to the escape of a protein-rich exudate into the extravascular tissue, causing *edema*. Several mechanisms are responsible for the increased vascular permeability (Fig. 2-3):

- *Contraction of endothelial cells resulting in increased interendothelial spaces* is the most common mechanism of vascular leakage and is elicited by histamine, bradykinin, leukotrienes, the neuropeptide substance P, and many other chemical mediators.[6,][7] It is called the *immediate transient response* because it occurs rapidly after exposure to the mediator and is usually short-lived (15–30 minutes). In some forms of mild injury (e.g. after burns, x-irradiation or ultraviolet radiation, and exposure to certain bacterial toxins), vascular leakage begins after a delay of 2 to 12 hours, and lasts for several hours or even days; this *delayed prolonged leakage* may be caused by contraction of endothelial cells or mild endothelial damage. Late-appearing sunburn is a good example of this type of leakage.
- *Endothelial injury, resulting in endothelial cell necrosis and detachment*.[8] Direct damage to the endothelium is encountered in severe injuries, for example, in burns, or by the actions of microbes that target endothelial cells.[9] Neutrophils that adhere to the endothelium during inflammation may also injure the endothelial cells and thus amplify the reaction. In most instances leakage starts immediately after injury and is sustained for several hours until the damaged vessels are thrombosed or repaired.
- Increased transport of fluids and proteins, called *transcytosis*, through the endothelial cell. This process may involve channels consisting of interconnected, uncoated vesicles and vacuoles called the *vesiculovacuolar organelle*, many of which are located close to intercellular junctions.[10] Certain factors, such as VEGF (Chapter 3), seem to promote vascular leakage in part by increasing the number and perhaps the size of these channels.

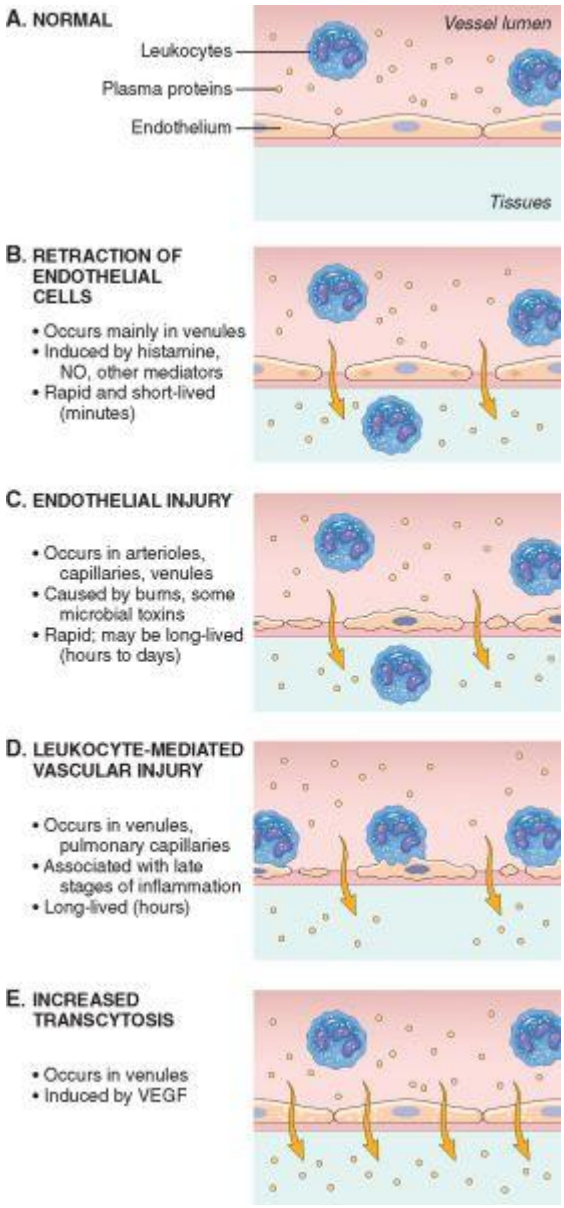

FIGURE 2-3 Principal mechanisms of increased vascular permeability in inflammation, and their features and underlying causes. NO, nitric oxide; VEGF, vascular endothelial growth factor.

Although these mechanisms of increased vascular permeability are described separately, all probably contribute in varying degrees in responses to most stimuli. For example, at different stages of a thermal burn, leakage results from chemically mediated endothelial contraction and direct and leukocyte-dependent endothelial injury. The vascular leakage induced by all these mechanisms can cause life-threatening loss of fluid in severely burned patients.

Responses of Lymphatic Vessels

Although much of the emphasis in our discussion of inflammation is on the reactions of blood vessels, lymphatic vessels also participate in the response. The system of lymphatics and lymph nodes filters and polices the extravascular fluids. Recall that lymphatics normally drain the small amount of extravascular

fluid that has seeped out of capillaries. In inflammation, lymph flow is increased and helps drain edema fluid that accumulates due to increased vascular permeability. In addition to fluid, leukocytes and cell debris, as well as microbes, may find their way into lymph. Lymphatic vessels, like blood vessels, proliferate during inflammatory reactions to handle the increased load.[11,][12] The lymphatics may become secondarily inflamed *(lymphangitis)*, as may the draining lymph nodes *(lymphadenitis)*. Inflamed lymph nodes are often enlarged because of hyperplasia of the lymphoid follicles and increased numbers of lymphocytes and macrophages. This constellation of pathologic changes is termed *reactive*, or *inflammatory*, *lymphadenitis* (Chapter 13). For clinicians the presence of red streaks near a skin wound is a telltale sign of an infection in the wound. This streaking follows the course of the lymphatic channels and is diagnostic of lymphangitis; it may be accompanied by painful enlargement of the draining lymph nodes, indicating lymphadenitis.

REACTIONS OF LEUKOCYTES IN INFLAMMATION

As mentioned earlier, a critical function of inflammation is to deliver leukocytes to the site of injury and to activate the leukocytes to eliminate the offending agents. The most important leukocytes in typical inflammatory reactions are the ones capable of phagocytosis, namely neutrophils and macrophages. These leukocytes ingest and kill bacteria and other microbes, and eliminate necrotic tissue and foreign substances. Leukocytes also produce growth factors that aid in repair. A price that is paid for the defensive potency of leukocytes is that, when strongly activated, they may induce tissue damage and prolong inflammation, because the leukocyte products that destroy microbes and necrotic tissues can also injure normal host tissues.

The processes involving leukocytes in inflammation consist of: their recruitment from the blood into extravascular tissues, recognition of microbes and necrotic tissues, and removal of the offending agent.

Recruitment of Leukocytes to Sites of Infection and Injury

The journey of leukocytes from the vessel lumen to the interstitial tissue, called extravasation, can be divided into the following steps[13] (Fig. 2-4):

1. In the lumen: *margination, rolling, and adhesion to endothelium*. Vascular endothelium in its normal, unactivated state does not bind circulating cells or impede their passage. In inflammation the endothelium is activated and can bind leukocytes, as a prelude to their exit from the blood vessels.
2. Migration across the endothelium and vessel wall
3. Migration in the tissues toward a chemotactic stimulus

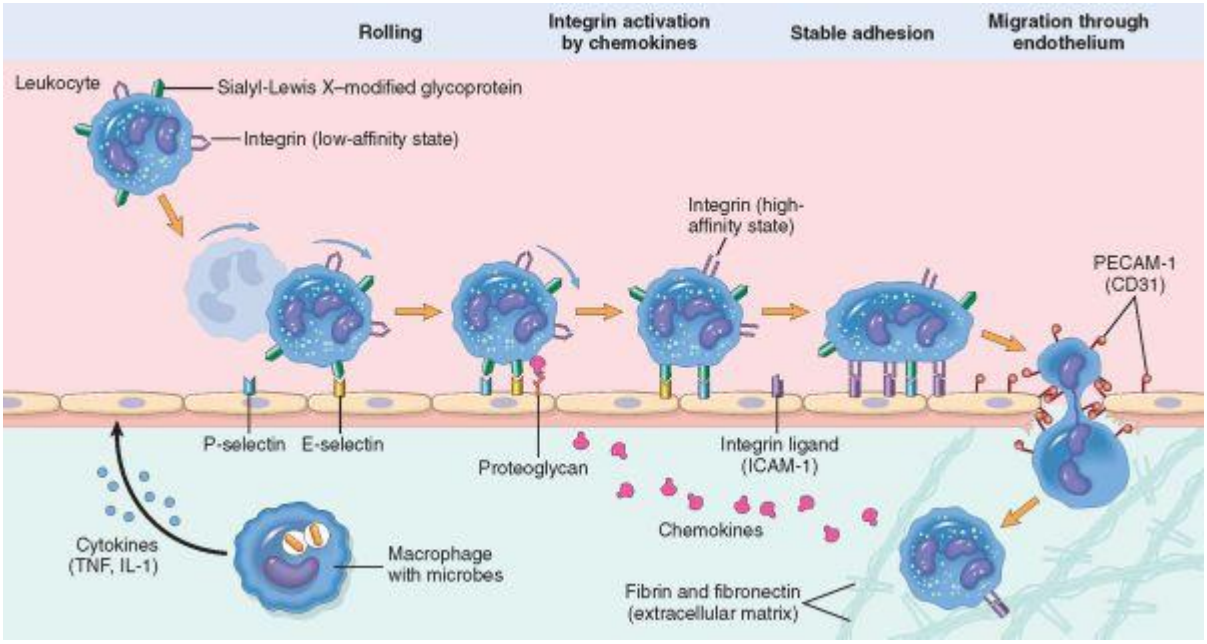

FIGURE 2-4 The multistep process of leukocyte migration through blood vessels, shown here for neutrophils. The leukocytes first roll, then become activated and adhere to endothelium, then transmigrate across the endothelium, pierce the basement membrane, and migrate toward chemoattractants emanating from the source of injury. Different molecules play predominant roles in different steps of this process—selectins in rolling; chemokines (usually displayed bound to proteoglycans) in activating the neutrophils to increase avidity of integrins; integrins in firm adhesion; and CD31 (PECAM-1) in transmigration. Neutrophils express low levels of L-selectin; they bind to endothelial cells predom in antly via P- and E-selectins. ICAM-1, intercellular adhesion molecule 1; TNF, tumor necrosis factor.

Leukocyte Adhesion to Endothelium.

In normally flowing blood in venules, red cells are confined to a central axial column, displacing the leukocytes toward the wall of the vessel. Because blood flow slows early in inflammation (stasis), hemodynamic conditions change (wall shear stress decreases), and more white cells assume a peripheral position along the endothelial surface. This process of leukocyte redistribution is called *margination*. Subsequently, individual and then rows of leukocytes adhere transiently to the endothelium, detach and bind again, thus *rolling* on the vessel wall. The cells finally come to rest at some point where they *adhere* firmly (resembling pebbles over which a stream runs without disturbing them).

The adhesion of leukocytes to endothelial cells is mediated by complementary adhesion molecules on the two cell types whose expression is enhanced by secreted proteins called cytokines.[13,][14] Cytokines are secreted by cells in tissues in response to microbes and other injurious agents, thus ensuring that leukocytes are recruited to the tissues where these stimuli are present. The initial rolling interactions are mediated by a family of proteins called *selectins*[15,][16] (Table 2-1). There are three types of selectins: one expressed on leukocytes (L-selectin), one on endothelium (E-selectin), and one in platelets and on endothelium (P-selectin). The ligands for selectins are sialylated oligosaccharides bound to mucin-like glycoprotein backbones. The expression of selectins and their ligands is regulated by cytokines produced in response to infection and injury. Tissue macrophages, mast cells, and endothelial cells that encounter microbes and dead tissues respond by secreting several cytokines, including tumor necrosis factor (TNF),[17] interleukin-1 (IL-1),[18] and chemokines (chemoattractant cytokines).[19,][20] (Cytokines are described in more detail below and in Chapter 6 .) TNF and IL-1 act on the endothelial cells of post-capillary venules adjacent to the infection and induce the coordinate expression of numerous adhesion molecules (Fig. 2-5). Within 1 to 2 hours the endothelial cells begin to express E-selectin and the ligands for L-selectin. Other mediators such as histamine, thrombin, and platelet-activating factor (PAF),

described later, stimulate the redistribution of P-selectin from its normal intracellular stores in endothelial cell granules (called Weibel-Palade bodies) to the cell surface. Leukocytes express L-selectin at the tips of their microvilli and also express ligands for E- and P-selectins, all of which bind to the complementary molecules on the endothelial cells. These are low-affinity interactions with a fast off-rate, and they are easily disrupted by the flowing blood. As a result, the bound leukocytes bind, detach, and bind again, and thus begin to roll along the endothelial surface.

TABLE 2-1 -- Endothelial-Leukocyte Adhesion Molecules

Endothelial Molecule	Leukocyte Molecule	Major Role
P-selectin	Sialyl-Lewis X–modified proteins	Rolling (neutrophils, monocytes, T lymphocytes)
E-selectin	Sialyl-Lewis X–modified proteins	Rolling and adhesion (neutrophils, monocytes, T lymphocytes)
GlyCam-1, CD34	L-selectin[*]	Rolling (neutrophils, monocytes)
ICAM-1 (immunoglobulin family)	CD11/CD18 (β_2) integrins (LFA-1, Mac-1)	Adhesion, arrest, transmigration (neutrophils, monocytes, lymphocytes)
VCAM-1 (immunoglobulin family)	VLA-4 (β_1) integrin	Adhesion (eosinophils, monocytes, lymphocytes)

[*] L-selectin is expressed weakly on neutrophils. It is involved in the binding of circulating T-lymphocytes to the high endothelial venules in lymph nodes and mucosal lymphoid tissues, and subsequent “homing” of lymphocytes to these tissues.

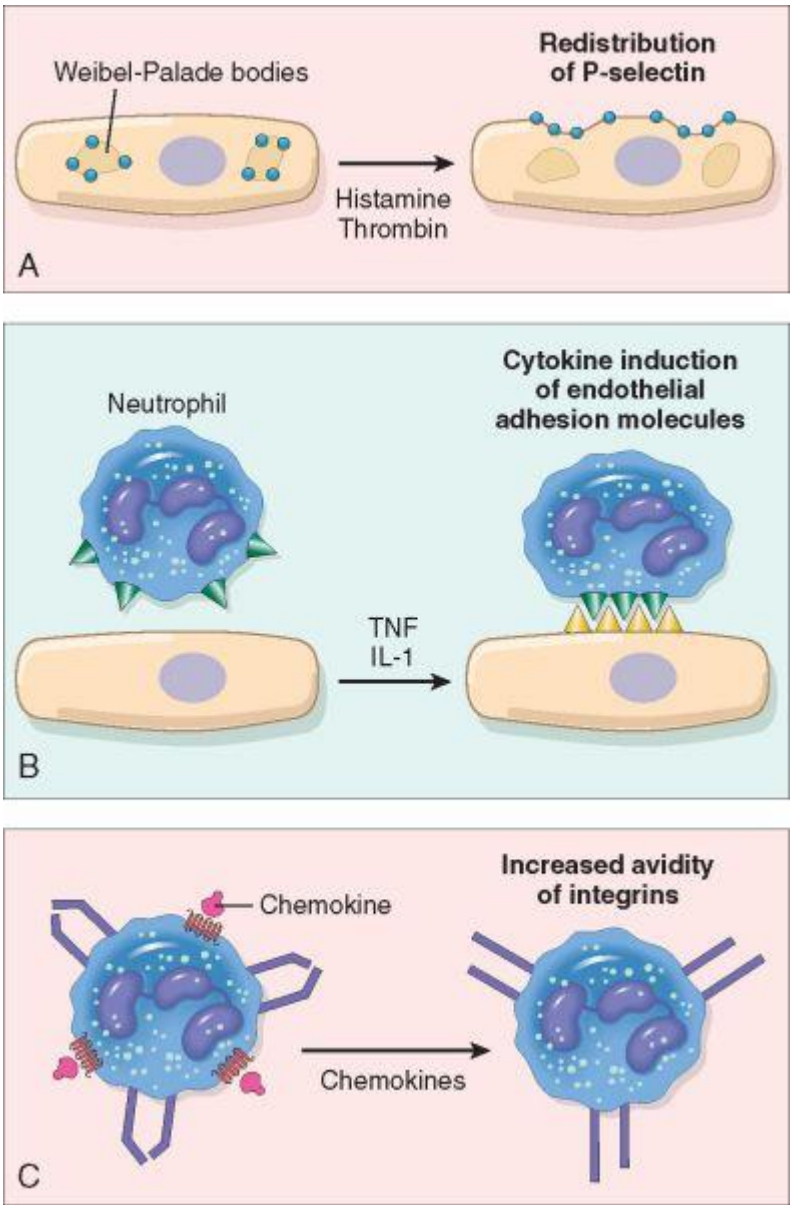

FIGURE 2-5 Regulation of expression of endothelial and leukocyte adhesion molecules. **A**, Redistribution of P-selectin from intracellular stores to the cell surface. **B**, Increased surface expression of selectins and ligands for integrins upon cytokine activation of endothelium. **C**, Increased binding avidity of integrins induced by chemokines. Clustering of integrins contributes to their increased binding avidity (not shown). IL-1, interleukin-1; TNF, tumor necrosis factor.

These weak rolling interactions slow down the leukocytes and give them the opportunity to bind more firmly to the endothelium. Firm adhesion is mediated by a family of heterodimeric leukocyte surface proteins called *integrins*[21] (see Table 2-1). TNF and IL-1 induce endothelial expression of ligands for integrins, mainly vascular cell adhesion molecule 1 (VCAM-1, the ligand for the VLA-4 integrin) and intercellular adhesion molecule-1 (ICAM-1, the ligand for the LFA-1 and Mac-1 integrins). Leukocytes normally express integrins in a low-affinity state. Meanwhile, chemokines that were produced at the site of injury enter the blood vessel, bind to endothelial cell proteoglycans, and are displayed at high concentrations on the endothelial surface. These chemokines bind to and activate the rolling leukocytes. One of the consequences of activation is the conversion of VLA-4 and LFA-1 integrins on the

leukocytes to a high-affinity state.[22] The combination of cytokine-induced expression of integrin ligands on the endothelium and activation of integrins on the leukocytes results in firm integrin-mediated binding of the leukocytes to the endothelium at the site of inflammation. The leukocytes stop rolling, their cytoskeleton is reorganized, and they spread out on the endothelial surface.

Leukocyte Migration through Endothelium.

The next step in the process of leukocyte recruitment is *migration of the leukocytes through the endothelium*, called transmigration or *diapedesis*. Transmigration of leukocytes occurs mainly in post-capillary venules. Chemokines act on the adherent leukocytes and stimulate the cells to migrate through interendothelial spaces toward the chemical concentration gradient, that is, toward the site of injury or infection where the chemokines are being produced.[23] Several adhesion molecules present in the intercellular junctions between endothelial cells are involved in the migration of leukocytes. These molecules include a member of the immunoglobulin superfamily called PECAM-1 (platelet endothelial cell adhesion molecule) or CD31[24] and several junctional adhesion molecules.[25] After traversing the endothelium, leukocytes pierce the basement membrane, probably by secreting collagenases, and enter the extravascular tissue. The cells then migrate toward the chemotactic gradient created by chemokines and accumulate in the extravascular site. In the connective tissue, the leukocytes are able to adhere to the extracellular matrix by virtue of integrins and CD44 binding to matrix proteins. Thus, *leukocytes are retained at the site where they are needed*.

The most telling proof of the importance of leukocyte adhesion molecules is the existence of genetic deficiencies in these molecules, which result in recurrent bacterial infections as a consequence of impaired leukocyte adhesion and defective inflammation.[26] Individuals with *leukocyte adhesion deficiency type 1* have a defect in the biosynthesis of the β_2 chain shared by the LFA-1 and Mac-1 integrins. *Leukocyte adhesion deficiency type 2* is caused by the absence of sialyl-Lewis X, the fucose-containing ligand for E- and P-selectins, as a result of a defect in a fucosyl transferase, the enzyme that attaches fucose moieties to protein backbones.

Chemotaxis of Leukocytes.

After exiting the circulation, leukocytes emigrate in tissues toward the site of injury by a process called *chemotaxis*, which is defined as locomotion oriented along a chemical gradient. Both exogenous and endogenous substances can act as chemoattractants. The most common exogenous agents are *bacterial products*, including peptides that possess an *N*-formylmethionine terminal amino acid, and some lipids. Endogenous chemoattractants include several chemical mediators (described later): (1) *cytokines*, particularly those of the chemokine family (e.g., IL-8); (2) *components of the complement system, particularly C5a*; and (3) *arachidonic acid (AA) metabolites, mainly leukotriene B_4 (LTB_4)*. All these chemotactic agents bind to specific seven-transmembrane G protein–coupled receptors on the surface of leukocytes.[27] Signals initiated from these receptors result in activation of second messengers that increase cytosolic calcium and activate small guanosine triphosphatases of the Rac/Rho/cdc42 family as well as numerous kinases. These signals induce polymerization of actin, resulting in increased amounts of polymerized actin at the leading edge of the cell and localization of myosin filaments at the back. The leukocyte moves by extending filopodia that pull the back of the cell in the direction of extension, much as an automobile with front-wheel drive is pulled by the wheels in front (Fig. 2-6). The net result is that leukocytes migrate toward the inflammatory stimulus in the direction of the gradient of locally produced chemoattractants.

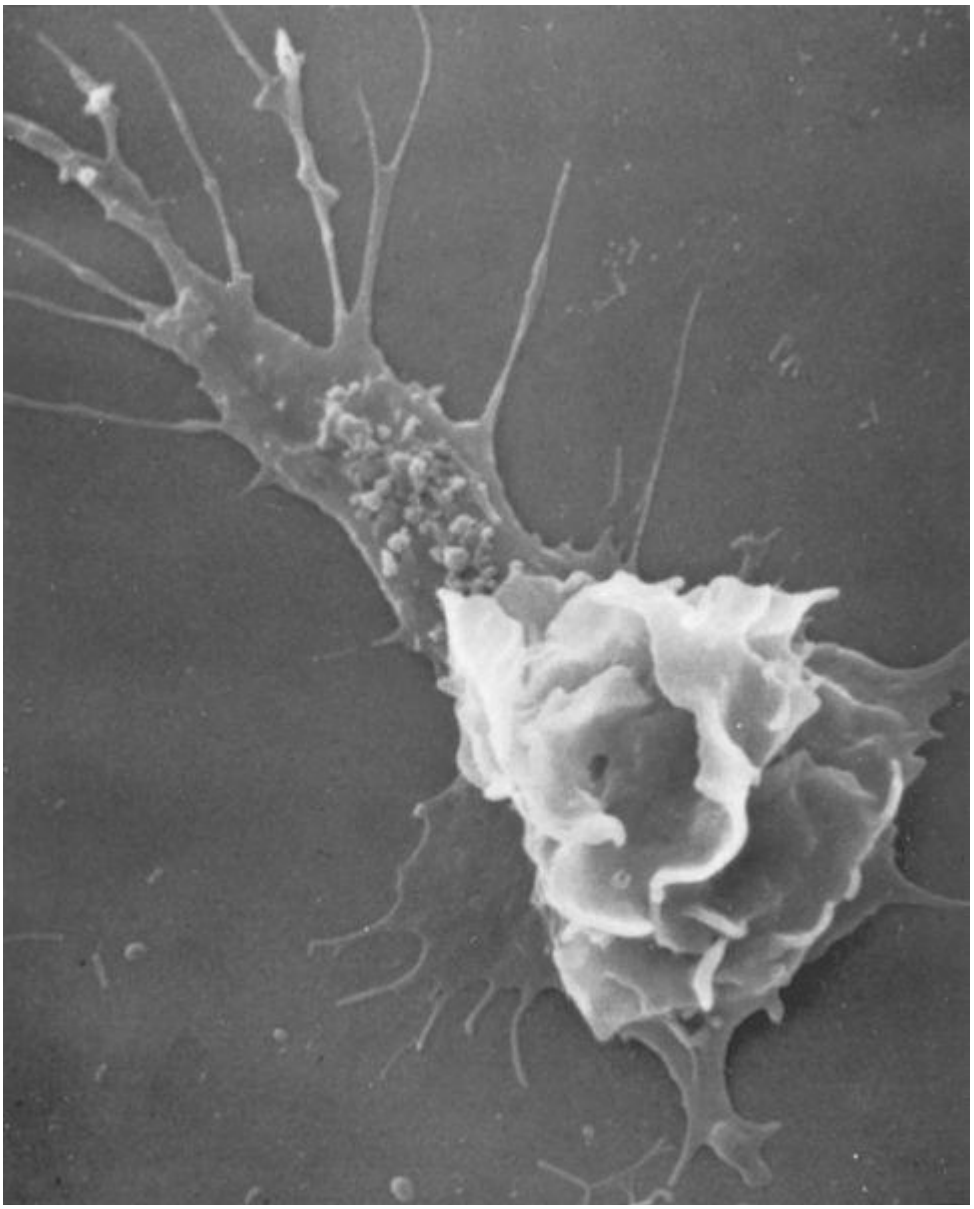

FIGURE 2-6 Scanning electron micrograph of a moving leukocyte in culture showing a filopodium *(upper left)* and a trailing tail. *(Courtesy of Dr. Morris J. Karnovsky, Harvard Medical School, Boston, MA.)*

The nature of the leukocyte infiltrate varies with the age of the inflammatory response and the type of stimulus. In most forms of acute inflammation *neutrophils predominate in the inflammatory infiltrate during the first 6 to 24 hours and are replaced by monocytes in 24 to 48 hours* (Fig. 2-7). Several reasons account for the early appearance of neutrophils: they are more numerous in the blood, they respond more rapidly to chemokines, and they may attach more firmly to the adhesion molecules that are rapidly induced on endothelial cells, such as P- and E-selectins. After entering tissues, neutrophils are short-lived; they undergo apoptosis and disappear after 24 to 48 hours. Monocytes not only survive longer but may proliferate in the tissues, and thus become the dominant population in chronic inflammatory reactions. There are, however, exceptions to this pattern of cellular infiltration. In certain infections—for example, those produced by *Pseudomonas* bacteria—the cellular infiltrate is dominated

by continuously recruited neutrophils for several days; in viral infections, lymphocytes may be the first cells to arrive; in some hypersensitivity reactions, eosinophils may be the main cell type.

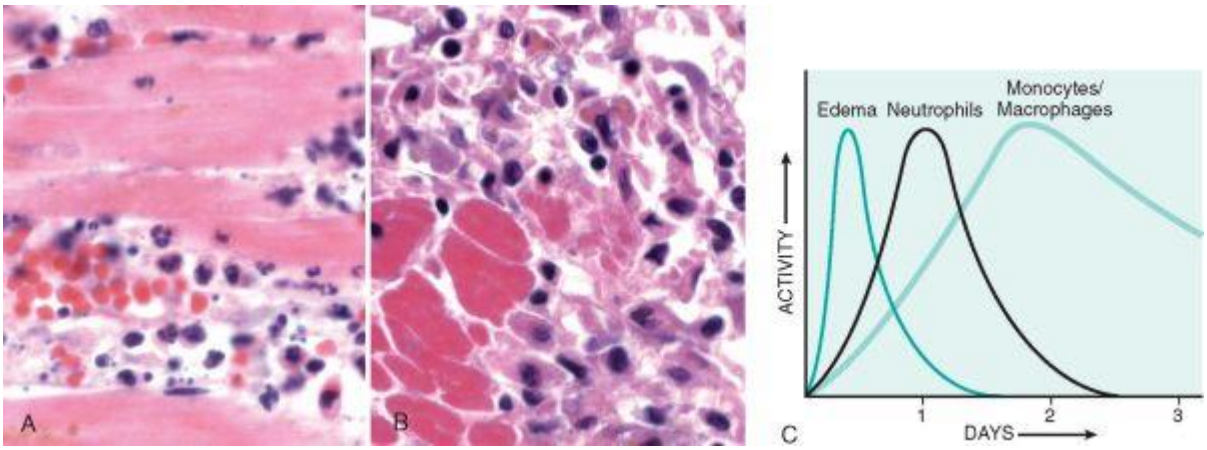

FIGURE 2-7 Nature of leukocyte infiltrates in inflammatory reactions. The photomicrographs are representative of the early (neutrophilic) (**A**) and later (mononuclear) cellular infiltrates (**B**) seen in an inflammatory reaction in the myocardium following ischemic necrosis (infarction). The kinetics of edema and cellular infiltration (**C**) are approximations.

The molecular understanding of leukocyte recruitment and migration has provided a large number of potential therapeutic targets for controlling harmful inflammation.[14] Agents that block TNF, one of the major cytokines in leukocyte recruitment, are among the most successful therapeutics ever developed for chronic inflammatory diseases, and antagonists of leukocyte integrins (e.g. VLA-4), selectins, and chemokines are approved for inflammatory diseases or in clinical trials. Predictably, these antagonists not only have the desired effect of controlling the inflammation but can compromise the ability of treated patients to defend themselves against microbes, which, of course, is the physiologic function of the inflammatory response.

Recognition of Microbes and Dead Tissues

Once leukocytes (neutrophils and monocytes) have been recruited to a site of infection or cell death, they must be activated to perform their functions. The responses of leukocytes consist of two sequential sets of events: (1) recognition of the offending agents, which deliver signals that (2) activate the leukocytes to ingest and destroy the offending agents and amplify the inflammatory reaction.

Leukocytes express several receptors that recognize external stimuli and deliver activating signals (Fig. 2-8).

- *Receptors for microbial products: Toll-like receptors (TLRs)* recognize components of different types of microbes. Thus far 10 mammalian TLRs have been identified, and each seems to be required for responses to different classes of infectious pathogens.[28] Different TLRs play essential roles in cellular responses to bacterial lipopolysaccharide (LPS, or endotoxin), other bacterial proteoglycans and lipids, and unmethylated CpG nucleotides, all of which are abundant in bacteria, as well as double-stranded RNA, which is produced by some viruses. TLRs are present on the cell surface and in the endosomal vesicles of leukocytes (and many other cell types), so they are able to sense products of extracellular and ingested microbes. These receptors function through receptor-associated kinases to stimulate the production of microbicidal substances and cytokines by the leukocytes. Various other cytoplasmic proteins in leukocytes recognize bacterial peptides and viral RNA.[29]

- *G protein–coupled receptors* found on neutrophils, macrophages, and most other types of leukocytes recognize short bacterial peptides containing *N*-formylmethionyl residues. Because all bacterial proteins and few mammalian proteins (only those synthesized within mitochondria) are initiated by *N*-formylmethionine, this receptor enables neutrophils to detect and respond to bacterial proteins. Other G protein–coupled receptors recognize chemokines, breakdown products of complement such as C5a, and lipid mediators, including platelet activating factor, prostaglandins, and leukotrienes, all of which are produced in response to microbes and cell injury. Binding of ligands, such as microbial products and mediators, to the G protein–coupled receptors induces migration of the cells from the blood through the endothelium and production of microbicidal substances by activation of the respiratory burst.
- *Receptors for opsonins*: Leukocytes express receptors for proteins that coat microbes. The process of coating a particle, such as a microbe, to target it for ingestion (phagocytosis) is called *opsonization*, and substances that do this are *opsonins*. These substances include antibodies, complement proteins, and lectins. One of the most efficient ways of enhancing the phagocytosis of particles is coating the particles with IgG antibodies specific for the particles, which are then recognized by the high-affinity Fcγ receptor of phagocytes, called FcγRI (Chapter 6). Components of the complement system, especially fragments of the complement protein C3, are also potent opsonins, because these fragments bind to microbes and phagocytes express a receptor, called the type 1 complement receptor (CR1), that recognizes breakdown products of C3 (discussed later). Plasma lectins, mainly mannan-binding lectin, also bind to bacteria and deliver them to leukocytes. The binding of opsonized particles to leukocyte Fc or C3 receptors promotes phagocytosis of the particles and activates the cells.
- *Receptors for cytokines*: Leukocytes express receptors for cytokines that are produced in response to microbes. One of the most important of these cytokines is interferon-γ (IFN-γ), which is secreted by natural killer cells reacting to microbes and by antigen-activated T lymphocytes during adaptive immune responses (Chapter 6). IFN-γ is the major macrophage-activating cytokine.

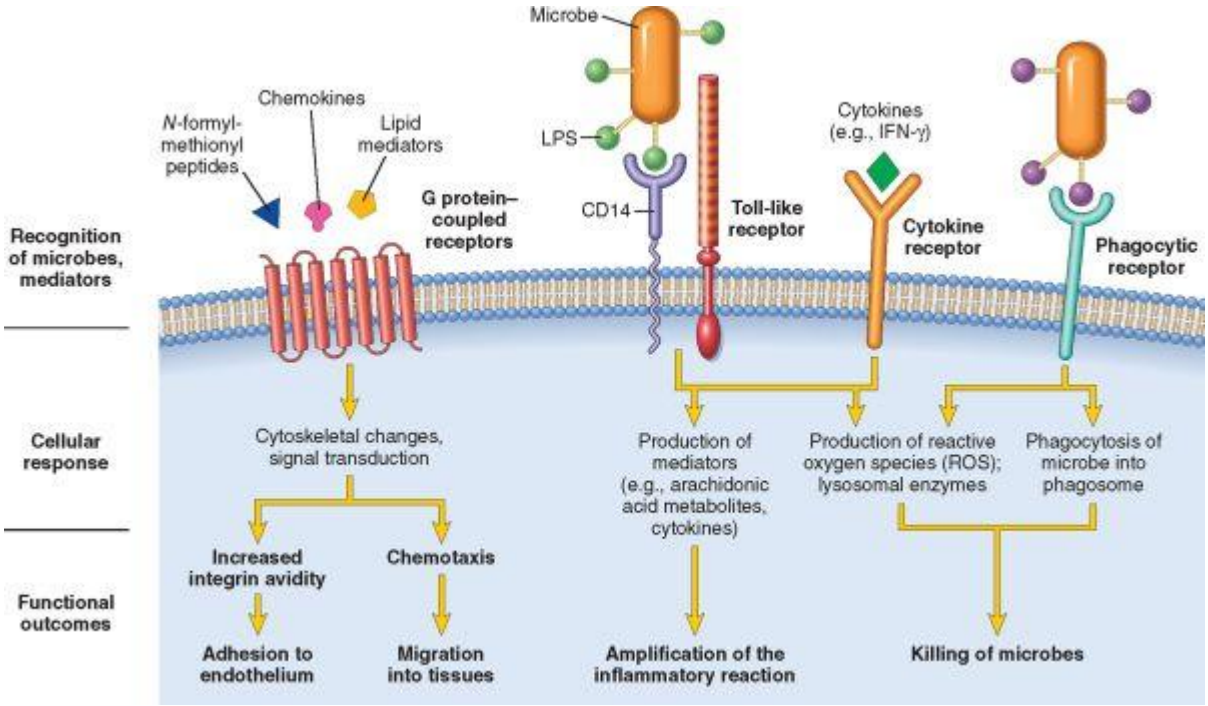

FIGURE 2-8 Leukocyte receptors and responses. Different classes of cell surface receptors of leukocytes recognize different stimuli. The receptors initiate responses that mediate the functions of the leukocytes. Only some receptors are depicted (see text for details). IFN-γ, interferon-γ; LPS, lipopolysaccharide(s).

Removal of the Offending Agents

Recognition of microbes or dead cells by the receptors described above induces several responses in leukocytes that are referred to under the rubric of *leukocyte activation* (see Fig. 2-8). Activation results from signaling pathways that are triggered in leukocytes, resulting in increases in cytosolic Ca^{2+} and activation of enzymes such as protein kinase C and phospholipase A_2. The functional responses that are most important for destruction of microbes and other offenders are phagocytosis and intracellular killing. Several other responses aid in the defensive functions of inflammation and may contribute to its injurious consequences.

Phagocytosis.

Phagocytosis involves three sequential steps (Fig. 2-9): (1) *recognition* and *attachment* of the particle to be ingested by the leukocyte; (2) its *engulfment*, with subsequent formation of a phagocytic vacuole; and (3) *killing* or *degradation* of the ingested material.[30]

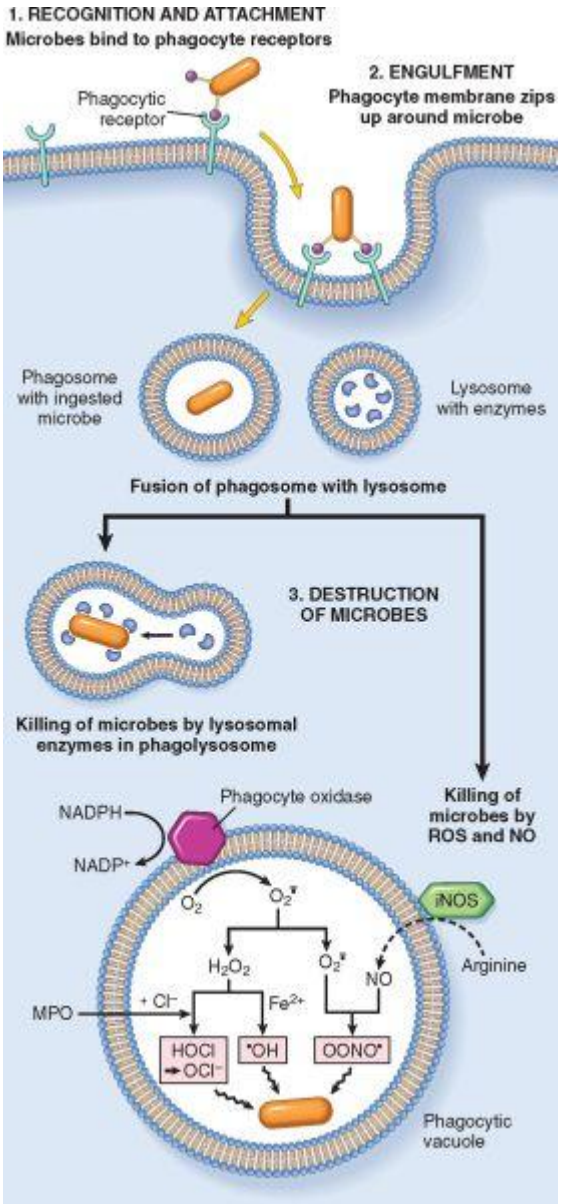

FIGURE 2-9 Phagocytosis and intracellular destruction of microbes. Phagocytosis of a particle (e.g., bacterium) involves binding to receptors on the leukocyte membrane, engulfment, and fusion of lysosomes with phagocytic vacuoles. This is followed by destruction of ingested particles within the phagolysosomes by lysosomal enzymes and by reactive oxygen and nitrogen species. The microbicidal products generated

from superoxide ( ) are hypochlorite (HOCl$^{\bullet}$) and hydroxyl radical ($^{\bullet}$OH), and from nitric oxide (NO) it is peroxynitrite (OONO$^{\bullet}$). During phagocytosis, granule contents may be released into extracellular tissues (not shown). MPO, myeloperoxidase; iNOS, inducible NO synthase.

Mannose receptors, scavenger receptors, and receptors for various opsonins all function to bind and ingest microbes. The macrophage mannose receptor is a lectin that binds terminal mannose and fucose residues of glycoproteins and glycolipids. These sugars are typically part of molecules found on microbial cell walls, whereas mammalian glycoproteins and glycolipids contain terminal sialic acid or *N*-acetylgalactosamine. Therefore, the mannose receptor recognizes microbes and not host cells. *Scavenger receptors* were originally defined as molecules that bind and mediate endocytosis of oxidized or acetylated low-density lipoprotein (LDL) particles that can no longer interact with the conventional LDL receptor. Macrophage scavenger receptors bind a variety of microbes in addition to modified LDL particles. Macrophage integrins, notably Mac-1 (CD11b/CD18), may also bind microbes for phagocytosis.

The efficiency of phagocytosis is greatly enhanced when microbes are opsonized by specific proteins (opsonins) for which the phagocytes express high-affinity receptors. As described above, the major opsonins are IgG antibodies, the C3b breakdown product of complement, and certain plasma lectins, notably mannan-binding lectin, all of which are recognized by specific receptors on leukocytes.

Engulfment.

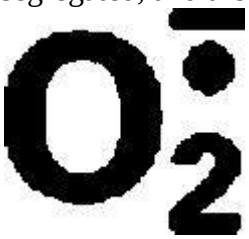
After a particle is bound to phagocyte receptors, extensions of the cytoplasm (pseudopods) flow around it, and the plasma membrane pinches off to form a vesicle (phagosome) that encloses the particle. The phagosome then fuses with a lysosomal granule, resulting in discharge of the granule's contents into the phagolysosome (see Fig. 2-9). During this process the phagocyte may also release granule contents into the extracellular space.

The process of phagocytosis is complex and involves the integration of many receptor-initiated signals to lead to membrane remodeling and cytoskeletal changes.[30] Phagocytosis is dependent on polymerization of actin filaments; it is, therefore, not surprising that the signals that trigger phagocytosis are many of the same that are involved in chemotaxis. (In contrast, fluid-phase pinocytosis and receptor-mediated endocytosis of small particles involve internalization into clathrin-coated pits and vesicles and are not dependent on the actin cytoskeleton.)

Killing and Degradation.

The final step in the elimination of infectious agents and necrotic cells is their killing and degradation within neutrophils and macrophages, which occur most efficiently after activation of the phagocytes. *Microbial killing is accomplished largely by reactive oxygen species* (*ROS*, also called reactive oxygen intermediates) and *reactive nitrogen species*, mainly derived from NO (see Fig. 2-9).[31,][32] The generation of ROS is due to the rapid assembly and activation of a multicomponent oxidase (NADPH oxidase, also called phagocyte oxidase), which oxidizes NADPH (reduced nicotinamide-adenine

dinucleotide phosphate) and, in the process, reduces oxygen to superoxide anion ( ). In neutrophils, this rapid oxidative reaction is triggered by activating signals and accompanies phagocytosis, and is called the *respiratory burst*. Phagocyte oxidase is an enzyme complex consisting of at least seven proteins.[33] In resting neutrophils, different components of the enzyme are located in the plasma membrane and the cytoplasm. In response to activating stimuli, the cytosolic protein components translocate to the phagosomal membrane, where they assemble and form the functional enzyme complex. Thus, the *ROS are produced within the lysosome* where the ingested substances are segregated, and the cell's own organelles are protected from the harmful effects of the ROS.



is then converted into hydrogen peroxide (H_2O_2), mostly by spontaneous dismutation. H_2O_2 is not able to efficiently kill microbes by itself. However, the azurophilic granules of neutrophils contain the enzyme *myeloperoxidase* (MPO), which, in the presence of a halide such as Cl^-, converts H_2O_2 to hypochlorite (OCl•, the active ingredient in household bleach). The latter is a potent antimicrobial agent that destroys microbes by *halogenation* (in which the halide is bound covalently to cellular constituents) or by oxidation of proteins and lipids (lipid peroxidation). *The H_2O_2-MPO-halide system is the most efficient bactericidal system of neutrophils*. H_2O_2 is also converted to hydroxyl radical ($^{\bullet}OH$), another powerful destructive agent.

NO, produced from arginine by the action of nitric oxide synthase (NOS), also participates in microbial

killing.[34] NO reacts with superoxide ( ) to generate the highly reactive free radical peroxynitrite ($ONOO^{\bullet}$). These oxygen- and nitrogen-derived free radicals attack and damage the lipids, proteins, and nucleic acids of microbes as they do with host macromolecules (Chapter 1). Reactive oxygen and nitrogen species have overlapping actions, as shown by the observation that knockout mice lacking either phagocyte oxidase or inducible nitric oxide synthase (iNOS) are only mildly susceptible to infections, but mice lacking both succumb rapidly to disseminated infections by normally harmless commensal bacteria. The roles of ROS and NO as mediators of inflammation are described later in the chapter.

Microbial killing can also occur through the action of other substances in leukocyte granules. Neutrophil granules contain many *enzymes*, such as elastase, that contribute to microbial killing.[35] Other microbicidal granule contents include *defensins*, cationic arginine-rich granule peptides that are toxic to microbes[36]; *cathelicidins*, antimicrobial proteins found in neutrophils and other cells[37]; *lysozyme*, which hydrolyzes the muramic acid–*N*-acetylglucosamine bond, found in the glycopeptide coat of all bacteria; *lactoferrin*, an iron-binding protein present in specific granules; *major basic protein*, a cationic protein of eosinophils, which has limited bactericidal activity but is cytotoxic to many

parasites; and *bactericidal/permeability increasing protein*, which binds bacterial endotoxin and is believed to be important in defense against some gram-negative bacteria.

Other Functional Responses of Activated Leukocytes

In addition to eliminating microbes and dead cells, activated leukocytes play several other roles in host defense. Importantly, these cells, especially macrophages, produce a number of growth factors that stimulate the proliferation of endothelial cells and fibroblasts and the synthesis of collagen, and enzymes that remodel connective tissues. These products drive the process of repair after tissue injury (Chapter 3). An emerging concept is that macrophages can be activated to perform different functions—"classically activated" macrophages respond to microbial products and T-cell cytokines such as IFN-γ and have strong microbicidal activity, whereas "alternatively activated" macrophages respond to cytokines such as IL-4 and IL-13 (typically, the products of the T_H2 subset of T-cells, see Chapter 6) and are mainly involved in tissue repair and fibrosis (Fig. 2-10).[38] Different stimuli activate leukocytes to secrete mediators of inflammation as well as inhibitors of the inflammatory response, and thus serve to both amplify and control the reaction. This may be another distinction between classically and alternatively activated macrophages—the former trigger inflammation and the latter function to limit inflammatory reactions.

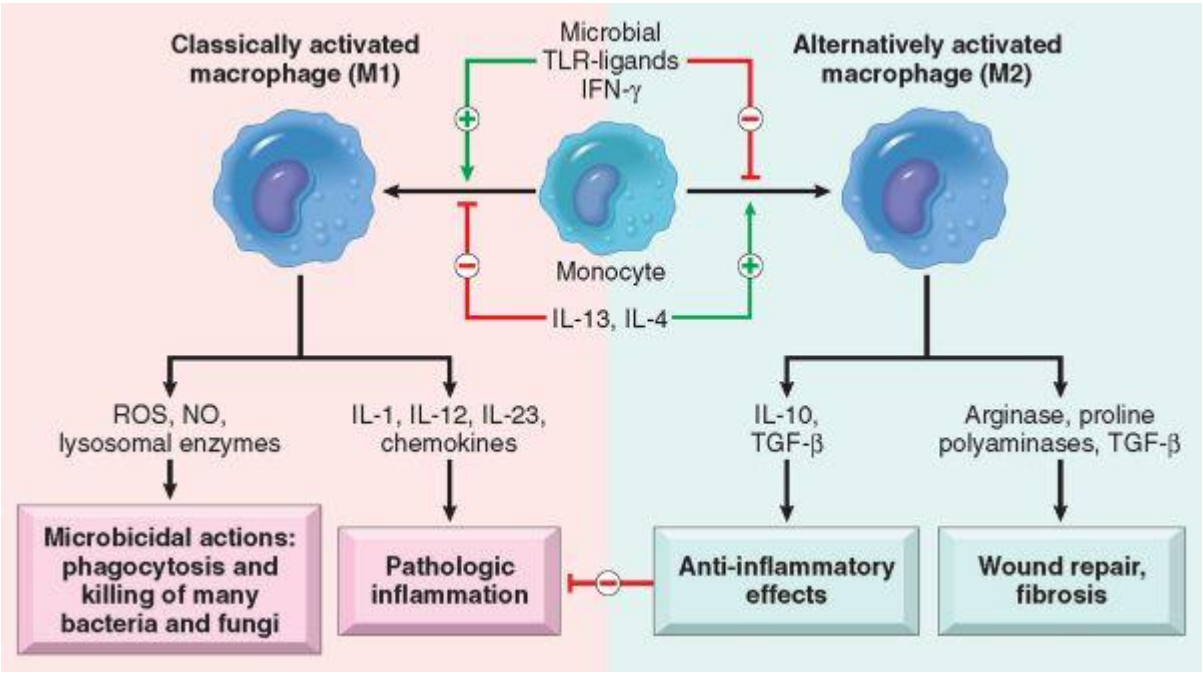


FIGURE 2-10 Subsets of activated macrophages. Different stimuli activate monocytes/macrophages to develop into functionally distinct populations. Classically activated macrophages are induced by microbial products and cytokines, particularly IFN-γ, and are microbicidal and involved in potentially harmful inflammation. Alternatively activated macrophages are induced by other cytokines and in response to helminths (not shown), and are important in tissue repair and the resolution of inflammation (and may play a role in defense against helminthic parasites, also not shown).

Release of Leukocyte Products and Leukocyte-Mediated Tissue Injury

Leukocytes are important causes of injury to normal cells and tissues under several circumstances:

- As part of a normal defense reaction against infectious microbes, when adjacent tissues suffer "collateral damage." In some infections that are difficult to eradicate, such as tuberculosis and certain viral diseases,

the prolonged host response contributes more to the pathology than does the microbe itself.

- When the inflammatory response is inappropriately directed against host tissues, as in certain autoimmune diseases.
- When the host reacts excessively against usually harmless environmental substances, as in allergic diseases, including asthma.

In all these situations, the mechanisms by which leukocytes damage normal tissues are the same as the mechanisms involved in antimicrobial defense, because once the leukocytes are activated, their effector mechanisms do not distinguish between offender and host. During activation and phagocytosis, neutrophils and macrophages release microbicidal and other products not only within the phagolysosome but also into the extracellular space. The most important of these substances are *lysosomal enzymes*, present in the granules, and *reactive oxygen and nitrogen species*. These released substances are capable of damaging normal cells and vascular endothelium, and may thus amplify the effects of the initial injurious agent. In fact, if unchecked or inappropriately directed against host tissues, the leukocyte infiltrate itself becomes the offender,[39] and indeed leukocyte-dependent tissue injury underlies many acute and chronic human diseases (Table 2-2). This fact becomes evident in the discussion of specific disorders throughout the book.

TABLE 2-2 -- Clinical Examples of Leukocyte-Induced Injury[*]

Disorders	Cells and Molecules Involved in Injury
ACUTE	
Acute respiratory distress syndrome	Neutrophils
Acute transplant rejection	Lymphocytes; antibodies and complement
Asthma	Eosinophils; IgE antibodies
Glomerulonephritis	Neutrophils, monocytes; antibodies and complement
Septic shock	Cytokines
Lung abscess	Neutrophils (and bacteria)
CHRONIC	
Arthritis	Lymphocytes, macrophages; antibodies?
Asthma	Eosinophils; IgE antibodies
Atherosclerosis	Macrophages; lymphocytes?
Chronic transplant rejection	Lymphocytes; cytokines
Pulmonary fibrosis	Macrophages; fibroblasts

[*] Listed are selected examples of diseases in which the host response plays a significant role in tissue injury, and the principal cells and molecules that cause the injury. These diseases and their pathogenesis will be discussed in detail in relevant chapters.

The contents of lysosomal granules are secreted by leukocytes into the extracellular milieu by several mechanisms.[40] Controlled secretion of granule contents is a normal response of activated leukocytes. If phagocytes encounter materials that cannot be easily ingested, such as immune complexes deposited on immovable flat surfaces (e.g., glomerular basement membrane), the inability of the leukocytes to surround and ingest these substances *(frustrated phagocytosis)* triggers strong activation, and the release of large amounts of lysosomal enzymes into the extracellular environment. Phagocytosis of membrane-damaging substances, such as urate crystals, may injure the membrane of the phagolysosome and also lead to the release of lysosomal granule contents.

Defects in Leukocyte Function

Because leukocytes play a central role in host defense, defects in leukocyte function, both inherited and acquired, lead to increased vulnerability to infections (Table 2-3). Impairments of virtually every phase of leukocyte function have been identified—from adherence to vascular endothelium to microbicidal activity. These include the following:

- *Inherited defects in leukocyte adhesion*. We previously mentioned the genetic defects of integrins and selectin-ligands that cause leukocyte adhesion deficiencies types 1 and 2. The major clinical problem in both is recurrent bacterial infections.
- *Inherited defects in phagolysosome function*. One such disorder is *Chédiak-Higashi syndrome*, an autosomal recessive condition characterized by defective fusion of phagosomes and lysosomes in phagocytes (causing susceptibility to infections), and abnormalities in melanocytes (leading to albinism), cells of the nervous system (associated with nerve defects), and platelets (causing bleeding disorders).[41] The main leukocyte abnormalities are neutropenia (decreased numbers of neutrophils), defective degranulation, and delayed microbial killing. Leukocytes contain *giant granules*, which can be readily seen in peripheral blood smears and are thought to result from aberrant phagolysosome fusion. The gene associated with this disorder encodes a large cytosolic protein called LYST, which is believed to regulate lysosomal trafficking.
- *Inherited defects in microbicidal activity*. The importance of oxygen-dependent bactericidal mechanisms is shown by the existence of a group of congenital disorders called *chronic granulomatous disease*, which are characterized by defects in bacterial killing and render patients susceptible to recurrent bacterial infection. Chronic granulomatous disease results from *inherited defects in the genes encoding components of phagocyte oxidase*, which generates . The most common variants are an X-linked defect in one of the membrane-bound components (gp91phox) and autosomal recessive defects in the genes encoding two of the cytoplasmic components (p47phox and p67phox).[42] The name of this disease comes from the macrophage-rich chronic inflammatory reaction that tries to control the infection when the initial neutrophil defense is inadequate. This often leads to collections of activated macrophages that wall off the microbes, forming aggregates called *granulomas* (described in more detail later in the chapter).
- *Acquired deficiencies*. Clinically, the most frequent cause of leukocyte defects is *bone marrow suppression*, leading to decreased production of leukocytes. This is seen following therapies for cancer (radiation and chemotherapy) and when the marrow space is compromised by tumors, which may arise in the marrow (e.g., leukemias) or be metastatic from other sites.

TABLE 2-3 -- Defects in Leukocyte Functions

Disease	Defect
GENETIC	
Leukocyte adhesion deficiency 1	Defective leukocyte adhesion because of mutations in β chain of CD11/CD18 integrins
Leukocyte adhesion deficiency 2	Defective leukocyte adhesion because of mutations in fucosyl transferase required for synthesis of sialylated oligosaccharide (ligand for selectins)
Chronic granulomatous disease X-linked Autosomal recessive	Decreased oxidative burst Phagocyte oxidase (membrane component) Phagocyte oxidase (cytoplasmic components)
MPO deficiency	Decreased microbial killing because of defective MPO—H_2O_2 system

Disease	Defect
Chédiak-Higashi syndrome	Decreased leukocyte functions because of mutations affecting protein involved in lysosomal membrane traffic
ACQUIRED	
Bone marrow suppression: tumors, radiation, and chemotherapy	Production of leukocytes
Diabetes, malignancy, sepsis, chronic dialysis	Adhesion and chemotaxis
Leukemia, anemia, sepsis, diabetes, malnutrition	Phagocytosis and microbicidal activity

Modified from Gallin JI: Disorders of phagocytic cells. In Gallin JI, et al (eds): Inflammation: Basic Principles and Clinical Correlates, 2nd ed. New York, Raven Press, 1992, pp 860, 861.

MPO, myeloperoxidase.

Although we have emphasized the role of leukocytes recruited from the circulation in the acute inflammatory response, *cells resident in tissues also serve important functions in initiating acute inflammation*. The two most important of these cell types are *mast cells* and tissue *macrophages*. These "sentinel" cells are stationed in tissues to rapidly recognize potentially injurious stimuli and initiate the host defense reaction. Mast cells react to physical trauma, breakdown products of complement, microbial products, and neuropeptides. These cells release histamine, leukotrienes, enzymes, and many cytokines (including TNF, IL-1, and chemokines), all of which contribute to inflammation. The functions of mast cells are discussed in more detail in Chapter 6 . Macrophages recognize microbial products and secrete most of the cytokines important in acute inflammation. We will return to a discussion of the role of macrophages in inflammation later in the chapter.

TERMINATION OF THE ACUTE INFLAMMATORY RESPONSE

It is predictable that such a powerful system of host defense, with its inherent capacity to cause tissue damage, needs tight controls to minimize the damage. In part, inflammation declines simply because the mediators of inflammation are produced in rapid bursts, only as long as the stimulus persists, have short half-lives, and are degraded after their release. Neutrophils also have short half-lives in tissues and die by apoptosis within a few hours after leaving the blood. In addition, as inflammation develops the process also triggers a variety of stop signals that serve to actively terminate the reaction.[43,][44] These active termination mechanisms include a switch in the type of arachidonic acid metabolite produced, from pro-inflammatory leukotrienes to anti-inflammatory lipoxins (described below); the liberation of anti-inflammatory cytokines, including transforming growth factor-β (TGF-β) and IL-10, from macrophages and other cells; the production of anti-inflammatory lipid mediators, called resolvins and protectins, derived from polyunsaturated fatty acids[45]; and neural impulses (cholinergic discharge) that inhibit the production of TNF in macrophages.[46]

2.2.4 Mediators of Inflammation

Having described the sequence of events in acute inflammation, we can now turn to a discussion of the chemical mediators that are responsible for these reactions. Many mediators have been identified, and how they function in a coordinated manner is still not fully understood. The sources of the principal mediators and their roles in the inflammatory reaction are summarized in Table 2-4 . We start our

discussion of the mediators of inflammation by reviewing some of their shared properties and the general principles of their production and actions.

- *Mediators are generated either from cells or from plasma proteins*. Cell-derived mediators are normally sequestered in intracellular granules and can be rapidly secreted by granule exocytosis (e.g., histamine in mast cell granules) or are synthesized de novo (e.g., prostaglandins, cytokines) in response to a stimulus. The major cell types that produce mediators of acute inflammation are platelets, neutrophils, monocytes/macrophages, and mast cells, but mesenchymal cells (endothelium, smooth muscle, fibroblasts) and most epithelia can also be induced to elaborate some of the mediators. Plasma-derived mediators (e.g., complement proteins, kinins) are produced mainly in the liver and present in the circulation as inactive precursors that must be activated, usually by a series of proteolytic cleavages, to acquire their biologic properties.
- *Active mediators are produced in response to various stimuli*. These stimuli include microbial products, substances released from necrotic cells, and the proteins of the complement, kinin, and coagulation systems, which are themselves activated by microbes and damaged tissues. This requirement for microbes or dead tissues as the initiating stimulus ensures that inflammation is normally triggered only when and where it is needed.
- *One mediator can stimulate the release of other mediators*. For instance, the cytokine TNF acts on endothelial cells to stimulate the production of another cytokine, IL-1, and many chemokines. The secondary mediators may have the same actions as the initial mediators but may also have different and even opposing activities. Such cascades provide mechanisms for amplifying—or, in certain instances, counteracting—the initial action of a mediator.
- *Mediators vary in their range of cellular targets*. They can act on one or a few target cell types, can have diverse targets, or may even have differing effects on different types of cells.
- *Once activated and released from the cell, most of these mediators are short-lived*. They quickly decay (e.g., arachidonic acid metabolites) or are inactivated by enzymes (e.g., kininase inactivates bradykinin), or they are otherwise scavenged (e.g., antioxidants scavenge toxic oxygen metabolites) or inhibited (e.g., complement regulatory proteins break up and degrade activated complement components). There is thus a system of checks and balances that regulates mediator actions.

TABLE 2-4 -- The Actions of the Principal Mediators of Inflammation

Mediator	Principal Sources	Actions
CELL-DERIVED		
Histamine	Mast cells, basophils, platelets	Vasodilation, increased vascular permeability, endothelial activation
Serotonin	Platelets	Vasodilation, increased vascular permeability
Prostaglandins	Mast cells, leukocytes	Vasodilation, pain, fever
Leukotrienes	Mast cells, leukocytes	Increased vascular permeability, chemotaxis, leukocyte adhesion and activation
Platelet-activating factor	Leukocytes, mast cells	Vasodilation, increased vascular permeability, leukocyte adhesion, chemotaxis, degranulation, oxidative burst
Reactive oxygen species	Leukocytes	Killing of microbes, tissue damage
Nitric oxide	Endothelium, macrophages	Vascular smooth muscle relaxation, killing of microbes
Cytokines (TNF, IL-1)	Macrophages, endothelial cells, mast cells	Local endothelial activation (expression of adhesion molecules), fever/pain/anorexia/hypotension, decreased vascular resistance (shock)
Chemokines	Leukocytes, activated macrophages	Chemotaxis, leukocyte activation
PLASMA PROTEIN–DERIVED		

Mediator	Principal Sources	Actions
Complement products (C5a, C3a, C4a)	Plasma (produced in liver)	Leukocyte chemotaxis and activation, vasodilation (mast cell stimulation)
Kinins	Plasma (produced in liver)	Increased vascular permeability, smooth muscle contraction, vasodilation, pain
Proteases activated during coagulation	Plasma (produced in liver)	Endothelial activation, leukocyte recruitment

IL-1, interleukin-1; MAC, membrane attack complex; TNF, tumor necrosis factor.

We now discuss some of the more important mediators of acute inflammation, starting with the cell-derived mediators and moving on to those derived from plasma proteins.

CELL-DERIVED MEDIATORS

Vasoactive Amines: Histamine and Serotonin

The two major vasoactive amines, so named because they have important actions on blood vessels, are histamine and serotonin. They are stored as preformed molecules in cells and are therefore among the first mediators to be released during inflammation. The richest sources of *histamine* are the mast cells that are normally present in the connective tissue adjacent to blood vessels. It is also found in blood basophils and platelets. Histamine is present in mast cell granules and is released by mast cell degranulation in response to a variety of stimuli, including (1) physical injury such as trauma, cold, or heat; (2) binding of antibodies to mast cells, which underlies allergic reactions (Chapter 6); (3) fragments of complement called *anaphylatoxins* (C3a and C5a); (4) histamine-releasing proteins derived from leukocytes; (5) neuropeptides (e.g., substance P); and (6) cytokines (IL-1, IL-8).

Histamine causes dilation of arterioles and increases the permeability of venules. It is considered to be the principal mediator of the immediate transient phase of increased vascular permeability, producing interendothelial gaps in venules, as we have seen. Its vasoactive effects are mediated mainly via binding to H_1 receptors on microvascular endothelial cells.[47]

Serotonin (5-hydroxytryptamine) is a preformed vasoactive mediator with actions similar to those of histamine. It is present in platelets and certain neuroendocrine cells, e.g. in the gastrointestinal tract, and in mast cells in rodents but not humans. Release of serotonin (and histamine) from platelets is stimulated when platelets aggregate after contact with collagen, thrombin, adenosine diphosphate, and antigenantibody complexes. Thus, the platelet release reaction, which is a key component of coagulation, also results in increased vascular permeability. This is one of several links between clotting and inflammation.

Arachidonic Acid (AA) Metabolites: Prostaglandins, Leukotrienes, and Lipoxins

When cells are activated by diverse stimuli, such as microbial products and various mediators of inflammation, membrane *AA* is rapidly converted by the actions of enzymes to produce *prostaglandins* and *leukotrienes*. These biologically active lipid mediators serve as intracellular or extracellular signals to affect a variety of biologic processes, including inflammation and hemostasis. [48] [49] [50]

AA is a 20-carbon polyunsaturated fatty acid (5,8,11,14-eicosatetraenoic acid) that is derived from dietary sources or by conversion from the essential fatty acid *linoleic acid*. It does not occur free in the

cell but is normally esterified in membrane phospholipids. Mechanical, chemical, and physical stimuli or other mediators (e.g., C5a) release AA from membrane phospholipids through the action of cellular phospholipases, mainly phospholipase A_2. The biochemical signals involved in the activation of phospholipase A_2 include an increase in cytoplasmic Ca^{2+} and activation of various kinases in response to external stimuli.[51] AA-derived mediators, also called *eicosanoids*, are synthesized by two major classes of enzymes: cyclooxygenases (which generate prostaglandins) and lipoxygenases (which produce leukotrienes and lipoxins) (Fig. 2-11). Eicosanoids bind to G protein–coupled receptors on many cell types and can mediate virtually every step of inflammation (Table 2-5).

- *Prostaglandins* (PGs) are produced by mast cells, macrophages, endothelial cells, and many other cell types, and are involved in the vascular and systemic reactions of inflammation. They are produced by the actions of two *cyclooxgenases*, the constitutively expressed COX-1 and the inducible enzyme COX-2. Prostaglandins are divided into series based on structural features as coded by a letter (PGD, PGE, PGF, PGG, and PGH) and a subscript numeral (e.g., 1, 2), which indicates the number of double bonds in the compound. The most important ones in inflammation are PGE_2, PGD_2, $PGF_{2\alpha}$, PGI_2 (prostacyclin), and TxA_2 (thromboxane), each of which is derived by the action of a specific enzyme on an intermediate in the pathway. Some of these enzymes have restricted tissue distribution. For example, platelets contain the enzyme thromboxane synthetase, and hence TxA_2 is the major product in these cells. TxA_2, a potent platelet-aggregating agent and vasoconstrictor, is itself unstable and rapidly converted to its inactive form TxB_2. Vascular endothelium lacks thromboxane synthetase but possesses prostacyclin synthetase, which leads to the formation of prostacyclin (PGI_2) and its stable end product $PGF_{1\alpha}$. Prostacyclin is a vasodilator, a potent inhibitor of platelet aggregation, and also markedly potentiates the permeability-increasing and chemotactic effects of other mediators. A thromboxane-prostacyclin imbalance has been implicated as an early event in thrombus formation in coronary and cerebral blood vessels (Chapter 4). PGD_2 is the major prostaglandin made by mast cells; along with PGE_2 (which is more widely distributed), it causes vasodilation and increases the permeability of post-capillary venules, thus potentiating edema formation. $PGF_{2\alpha}$ stimulates the contraction of uterine and bronchial smooth muscle and small arterioles, and PGD_2 is a chemoattractant for neutrophils.
  In addition to their local effects, the prostaglandins are involved in the pathogenesis of *pain* and *fever* in inflammation. PGE_2 is hyperalgesic and makes the skin hypersensitive to painful stimuli, such as intradermal injection of suboptimal concentrations of histamine and bradykinin. It is involved in cytokine-induced fever during infections (described later).
- The *lipoxygenase* enzymes are responsible for the production of *leukotrienes*, which are secreted mainly by leukocytes, are chemoattractants for leukocytes, and also have vascular effects. There are three different lipoxygenases, 5-lipoxygenase being the predominant one in neutrophils. This enzyme converts AA to 5-hydroxyeicosatetraenoic acid, which is chemotactic for neutrophils, and is the precursor of the leukotrienes. *LTB_4* is a potent chemotactic agent and activator of neutrophils, causing aggregation and adhesion of the cells to venular endothelium, generation of ROS, and release of lysosomal enzymes. The cysteinylcontaining leukotrienes C_4, D_4, and E_4 *(LTC_4, LTD_4, LTE_4)* cause intense vasoconstriction, bronchospasm (important in asthma), and increased vascular permeability. The vascular leakage, as with histamine, is restricted to venules. Leukotrienes are much more potent than is histamine in increasing vascular permeability and causing bronchospasm.
- *Lipoxins* are also generated from AA by the lipoxygenase pathway, but unlike prostaglandins and leukotrienes, the *lipoxins are inhibitors of inflammation*.[45] They are also unusual in that two cell populations are required for the transcellular biosynthesis of these mediators. Leukocytes, particularly neutrophils, produce intermediates in lipoxin synthesis, and these are converted to lipoxins by platelets interacting with the leukocytes. *The principal actions of lipoxins are to inhibit leukocyte recruitment and the cellular components of inflammation*. They inhibit neutrophil chemotaxis and adhesion to endothelium. There is an inverse relationship between the production of lipoxin and leukotrienes, suggesting that the lipoxins may be endogenous negative regulators of leukotrienes and may thus play a role in the resolution of inflammation.

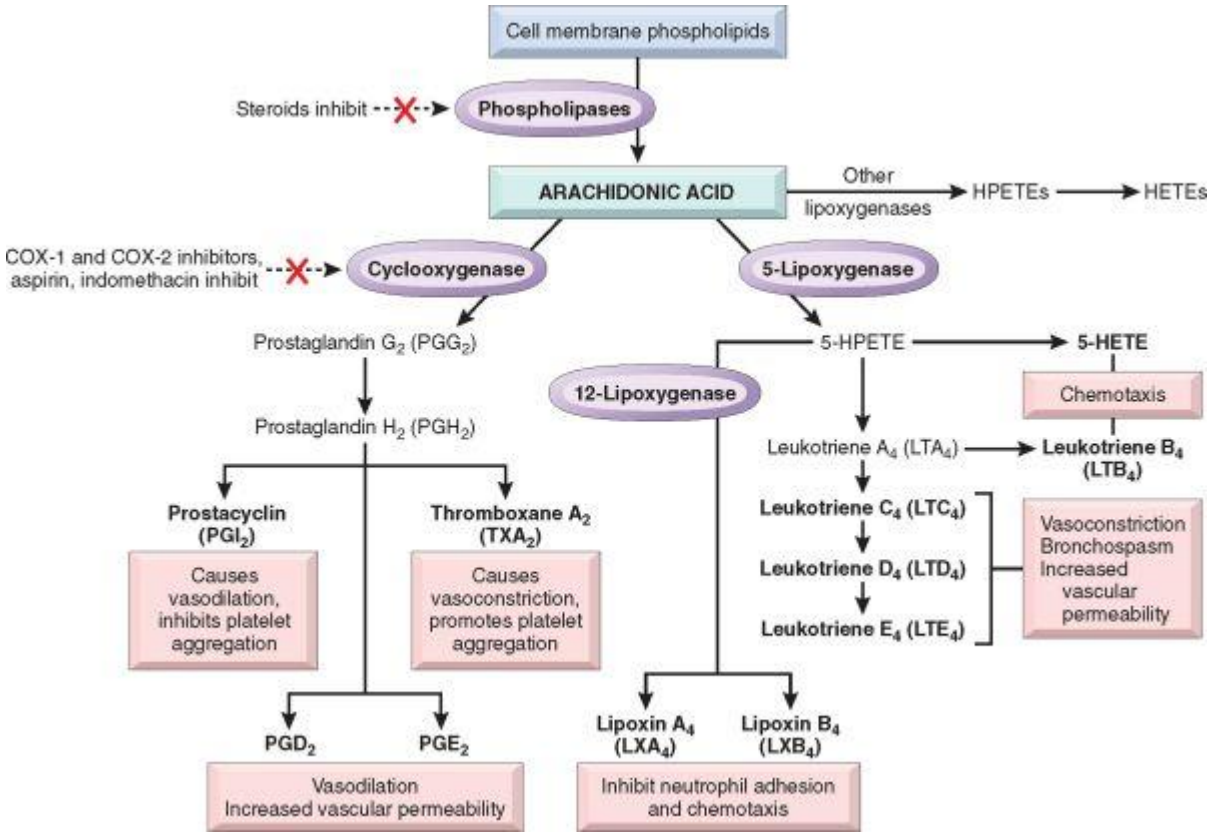

FIGURE 2-11 Generation of arachidonic acid metabolites and their roles in inflammation. The molecular targets of action of some anti-inflammatory drugs are indicated by a red X. Not shown are agents that inhibit leukotriene production by inhibition of 5-lipoxygenase (e.g., Zileuton) or block leukotriene receptors (e.g., Monteleukast). COX, cyclooxygenase; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid.

TABLE 2-5 -- Principal Inflammatory Actions of Arachidonic Acid Metabolites (Eicosanoids)

Action	Eicosanoid
Vasodilation	PGI_2 (prostacyclin), PGE_1, PGE_2, PGD_2
Vasoconstriction	Thromboxane A_2, leukotrienes C_4, D_4, E_4
Increased vascular permeability	Leukotrienes C_4, D_4, E_4
Chemotaxis, leukocyte adhesion	Leukotriene B_4, HETE

HETE, hydroxyeicosatetraenoic acid; PGI_2, etc., prostaglandin I_2, etc.

Many anti-inflammatory drugs work by inhibiting the synthesis of eicosanoids:

- *Cyclooxygenase inhibitors* include aspirin and other nonsteroidal anti-inflammatory drugs (*NSAIDs*), such as indomethacin. They inhibit both COX-1 and COX-2 and thus inhibit prostaglandin synthesis; aspirin does this by irreversibly acetylating and inactivating cyclooxygenases. Selective *COX-2 inhibitors* are a newer class of these drugs. There has been great interest in COX-2 as a therapeutic target because it is induced by a variety of inflammatory stimuli and is absent from most tissues under normal “resting” conditions.[52] COX-1,

by contrast, is produced in response to inflammatory stimuli and is also constitutively expressed in most tissues. This difference has led to the notion that COX-1 is responsible for the production of prostaglandins that are involved in both inflammation and homeostatic functions (e.g., fluid and electrolyte balance in the kidneys, cytoprotection in the gastrointestinal tract), whereas COX-2 generates prostaglandins that are involved only in inflammatory reactions. If this idea is correct, the selective COX-2 inhibitors should be anti-inflammatory without having the toxicities of the nonselective inhibitors, such as gastric ulceration. However, these distinctions are not absolute, as COX-2 also seems to play a role in normal homeostasis. Recently, results from large clinical trials have raised concerns that selective COX-2 inhibitors may increase the risk of cardiovascular and cerebrovascular events, leading to the removal of several of these drugs from the market in the United States and elsewhere. A possible explanation for the increased risk of arterial thrombosis is that COX-2 inhibitors impair endothelial cell production of prostacyclin, a vasodilator and inhibitor of platelet aggregation, while leaving intact the COX-1–mediated production by platelets of TxA_2, an important inducer of platelet aggregation and vasoconstriction. Thus, according to this hypothesis, selective COX-2 inhibition tilts the balance toward thromboxane and promotes vascular thrombosis, especially in individuals with other factors that increase the risk of thrombosis.[50,][53]

- *Lipoxygenase inhibitors*. 5-lipoxygenase is not affected by NSAIDs, and many new inhibitors of this enzyme pathway have been developed. Pharmacologic agents that inhibit leukotriene production (e.g. Zileuton) or block leukotriene receptors (e.g. Montelukast) are useful in the treatment of asthma.
- *Broad-spectrum inhibitors* include *corticosteroids*. These powerful anti-inflammatory agents may act by reducing the transcription of genes encoding COX-2, phospholipase A_2, pro-inflammatory cytokines (such as IL-1 and TNF), and iNOS.
- Another approach to manipulating inflammatory responses has been to modify the intake and content of dietary lipids by increasing the consumption of *fish oil*. The proposed explanation for the effectiveness of this approach is that the polyunsaturated fatty acids in fish oil serve as poor substrates for conversion to active metabolites by both the cyclooxygenase and lipoxygenase pathways but are excellent substrates for the production of anti-inflammatory lipid products called resolvins and protectins.[45]

Platelet-Activating Factor (PAF)

PAF is another phospholipid-derived mediator.[54] Its name comes from its discovery as a factor that causes platelet aggregation, but it is now known to have multiple inflammatory effects. A variety of cell types, including platelets themselves, basophils, mast cells, neutrophils, macrophages, and endothelial cells, can elaborate PAF, in both secreted and cell-bound forms. In addition to platelet aggregation, PAF causes vasoconstriction and bronchoconstriction, and at extremely low concentrations it induces vasodilation and increased venular permeability with a potency 100 to 10,000 times greater than that of histamine. PAF also causes increased leukocyte adhesion to endothelium (by enhancing integrin-mediated leukocyte binding), chemotaxis, degranulation, and the oxidative burst. Thus, PAF can elicit most of the vascular and cellular reactions of inflammation. PAF also boosts the synthesis of other mediators, particularly eicosanoids, by leukocytes and other cells. A role for PAF in vivo is supported by the ability of synthetic PAF receptor antagonists to inhibit inflammation in some experimental models.

Reactive Oxygen Species

Oxygen-derived free radicals may be released extracellularly from leukocytes after exposure to microbes, chemokines, and immune complexes, or following a phagocytic challenge.[55] Their production is dependent, as we have seen, on the activation of the NADPH oxidase system. Superoxide anion (), hydrogen peroxide (H_2O_2), and hydroxyl radical ($^{\bullet}OH$) are the major

species produced within cells, and $O_2^{\cdot-}$ can combine with NO to form reactive nitrogen species. Extracellular release of low levels of these potent mediators can increase the expression of chemokines (e.g., IL-8), cytokines, and endothelial leukocyte adhesion molecules, amplifying the inflammatory response. As mentioned earlier, the physiologic function of these ROS in leukocytes is to destroy phagocytosed microbes, but release of these potent mediators can be damaging to the host (Chapter 1). They are implicated in the following responses in inflammation:

- *Endothelial cell damage, with resultant increased vascular permeability*. Adherent neutrophils, when activated, not only produce their own toxic species but also stimulate production of ROS in the endothelial cells.
- *Injury to other cell types* (parenchymal cells, red blood cells).
- *Inactivation of antiproteases*, such as α_1-antitrypsin. This leads to unopposed protease activity, with increased destruction of extracellular matrix. In the lung, such inhibition of anti-proteases contributes to destruction of elastic tissues, as in emphysema (Chapter 15).

Serum, tissue fluids, and host cells possess *antioxidant mechanisms* that protect against these potentially harmful oxygen-derived radicals. These antioxidants were discussed in Chapter 1 ; they include (1) the enzyme *superoxide dismutase*, which is found in or can be activated in a variety of cell types; (2) the enzyme *catalase*, which detoxifies H_2O_2; (3) *glutathione peroxidase*, another powerful H_2O_2 detoxifier; (4) the copper-containing serum protein *ceruloplasmin*; and (5) the iron-free fraction of serum *transferrin*. Thus, the influence of oxygen-derived free radicals in any given inflammatory reaction depends on the balance between production and inactivation of these metabolites by cells and tissues.

Nitric Oxide (NO)

NO was discovered as a factor released from endothelial cells that caused vasodilation and was therefore called endothelium-derived relaxing factor. NO is a soluble gas that is produced not only by endothelial cells but also by macrophages and some neurons in the brain. It acts in a paracrine manner on target cells through induction of cyclic guanosine monophosphate, which, in turn, initiates a series of intracellular events leading to a response, such as the relaxation of vascular smooth muscle cells. Because the in vivo half-life of NO is only seconds, the gas acts only on cells in close proximity to where it is produced.

NO is synthesized from L-arginine by the enzyme nitric oxide synthase (NOS). There are three different types of NOS: endothelial (eNOS), neuronal (nNOS), and inducible (iNOS) (Fig. 2-12). eNOS and nNOS are constitutively expressed at low levels and can be activated rapidly by an increase in cytoplasmic Ca^{2+}. iNOS, in contrast, is induced when macrophages and other cells are activated by cytokines (e.g., TNF, IFN-γ) or microbial products.

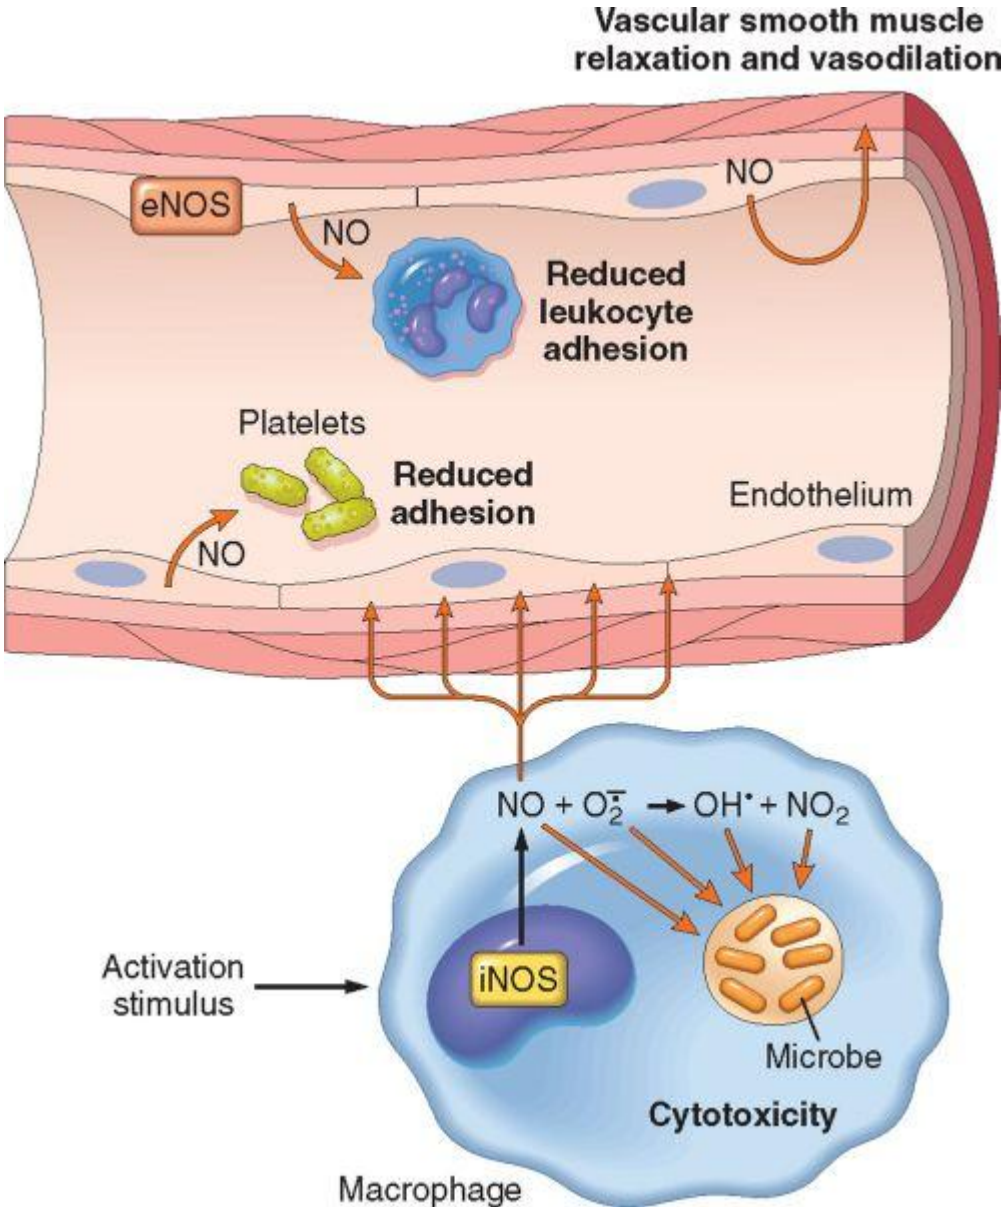

FIGURE 2-12 Functions of nitric oxide (NO) in blood vessels and macrophages. NO is produced by two NO synthase (NOS) enzymes. It causes vasodilation, and NO-derived free radicals are toxic to microbial and mammalian cells.

NO has dual actions in inflammation: it relaxes vascular smooth muscle and promotes vasodilation, thus contributing to the vascular reaction, but it is also an inhibitor of the cellular component of inflammatory responses.[56,][57] NO reduces platelet aggregation and adhesion (Chapter 4), inhibits several features of mast cell–induced inflammation, and inhibits leukocyte recruitment. *Because of these inhibitory actions, production of NO is thought to be an endogenous mechanism for controlling inflammatory responses*.

NO and its derivatives are microbicidal, and thus NO is a mediator of host defense against infection (discussed earlier). High levels of iNOS-induced NO are produced by leukocytes, mainly neutrophils and macrophages, in response to microbes.

Cytokines and Chemokines

Cytokines are proteins produced by many cell types (principally activated lymphocytes and macrophages, but also endothelial, epithelial, and connective tissue cells) that modulate the functions of other cell types. Long known to be involved in cellular immune responses, these products have additional effects that play important roles in both acute and chronic inflammation. Their general properties and functions are discussed in Chapter 6 . Here we review the pro-perties of cytokines that are involved in acute inflammation (Table 2-6).

TABLE 2-6 -- Cytokines in Inflammation

Cytokine	Principal Sources	Principal Actions in Inflammation
IN ACUTE INFLAMMATION		
TNF	Macrophages, mast cells, T lymphocytes	Stimulates expression of endothelial adhesion molecules and secretion of other cytokines; systemic effects
IL-1	Macrophages, endothelial cells, some epithelial cells	Similar to TNF; greater role in fever
IL-6	Macrophages, other cells	Systemic effects (acute-phase response)
Chemokines	Macrophages, endothelial cells, T lymphocytes, mast cells, other cell types	Recruitment of leukocytes to sites of inflammation; migration of cells to normal tissues
IN CHRONIC INFLAMMATION		
IL-12	Dendritic cells, macrophages	Increased production of IFN-γ
IFN-γ	T lymphocytes, NK cells	Activation of macrophages (increased ability to kill microbes and tumor cells)
IL-17	T lymphocytes	Recruitment of neutrophils and monocytes

IFN-γ, interferon-γ; IL-1, interleukin-1; NK cells, natural killer cells; TNF, tumor necrosis factor.

The most important cytokines involved in inflammatory reactions are listed. Many other cytokines may play lesser roles in inflammation. There is also considerable overlap between the cytokines involved in acute and chronic inflammation. Specifically, all the cytokines listed under acute inflammation may also contribute to chronic inflammatory reactions.

Tumor Necrosis Factor and Interleukin-1.

TNF and IL-1 are two of the major cytokines that mediate inflammation. They are produced mainly by activated macrophages. The secretion of TNF and IL-1 can be stimulated by endotoxin and other microbial products, immune complexes, physical injury, and a variety of inflammatory stimuli. Their most important actions in inflammation are their effects on endothelium, leukocytes, and fibroblasts, and induction of systemic acute-phase reactions (Fig. 2-13). In endothelium they induce a spectrum of changes referred to as *endothelial activation*.[58] In particular, they induce the expression of endothelial adhesion molecules; synthesis of chemical mediators, including other cytokines, chemokines, growth factors, eicosanoids, and NO; production of enzymes associated with matrix remodeling; and increases in the surface thrombogenicity of the endothelium.[59] TNF also augments responses of neutrophils to other stimuli such as bacterial endotoxin.

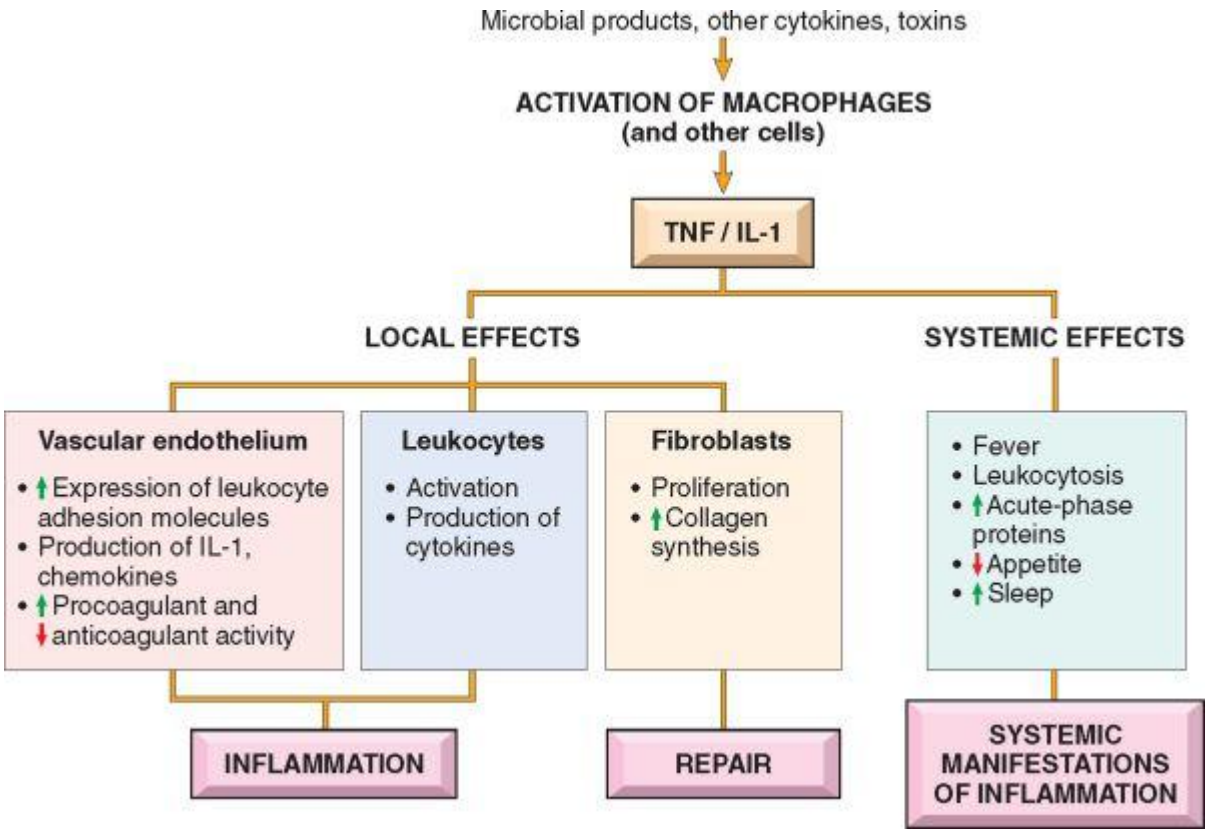

FIGURE 2-13 Principal local and systemic actions of tumor necrosis factor (TNF) and interleukin-1 (IL-1).

The production of IL-1 is controlled by a multi-protein cellular complex, sometimes called the "inflammasome," that responds to stimuli from microbes and dead cells. This complex activates proteases that are members of the caspase family, which function to cleave the newly synthesized inactive precursor of IL-1 into the biologically active cytokine. Mutations in genes encoding members of this protein complex are the cause of *inherited autoinflammatory syndromes*, the best known of which is familial Mediterranean fever.[60] The mutant proteins either constitutively activate the inflammatory caspases or interfere with the negative regulation of this enzymatic process. The net result is unregulated IL-1 production.[61,][62] Affected patients present with fever and other systemic manifestations of inflammation without overt provocation. Over time, some of these patients also develop amyloidosis, a disease of extracellular protein deposition that is often the result of persistent inflammation (Chapter 6). IL-1 antagonists are effective for treating these disorders, an excellent example of molecularly targeted rational therapy. The same inflammasome complex may be activated by urate crystals in the disease called gout, and the inflammation in this disease also seems to be, at least partly, mediated by IL-1 (Chapter 26).

IL-1 and TNF (as well as IL-6) induce the systemic *acute-phase responses* associated with infection or injury (described later in the chapter). TNF also regulates energy balance by promoting lipid and protein mobilization and by suppressing appetite. Therefore, sustained production of TNF contributes to *cachexia*, a pathologic state characterized by weight loss and anorexia that accompanies some chronic infections and neoplastic diseases (Chapter 9).

Chemokines.

Chemokines are a family of small (8 to 10 kD) proteins that act primarily as chemoattractants for specific types of leukocytes.[63] About 40 different chemokines and 20 different receptors for chemokines have been identified. They are classified into four major groups, according to the arrangement of the conserved cysteine (C) residues in the mature proteins[64,][65]:

- *C-X-C chemokines* (also called α chemokines) have one amino acid residue separating the first two conserved cysteine residues. The C-X-C chemokines act primarily on neutrophils. *IL-8* is typical of this group. It is secreted by activated macrophages, endothelial cells, and other cell types, and causes activation and chemotaxis of neutrophils, with limited activity on monocytes and eosinophils. Its most important inducers are microbial products and other cytokines, mainly IL-1 and TNF.
- *C-C chemokines* (also called β chemokines) have the first two conserved cysteine residues adjacent. The C-C chemokines, which include *monocyte chemoattractant protein* (MCP-1), *eotaxin, macrophage inflammatory protein-1α* (MIP-1α), and *RANTES* (regulated and normal T-cell expressed and secreted), generally attract monocytes, eosinophils, basophils, and lymphocytes but not neutrophils. Although most of the chemokines in this class have overlapping actions, eotaxin selectively recruits eosinophils.
- *C chemokines* (also called γ chemokines) lack two (the first and third) of the four conserved cysteines. The C chemokines (e.g., lymphotactin) are relatively specific for lymphocytes.
- *CX3C chemokines* contain three amino acids between the two cysteines. The only known member of this class is called *fractalkine*. This chemokine exists in two forms: the cell surface-bound protein can be induced on endothelial cells by inflammatory cytokines and promotes strong adhesion of monocytes and T cells, and a soluble form, derived by proteolysis of the membrane-bound protein, has potent chemoattractant activity for the same cells.

Chemokines mediate their activities by binding to seven-transmembrane G protein–coupled receptors. These receptors (called CXCR or CCR, for C-X-C or C-C chemokine receptors) usually exhibit overlapping ligand specificities, and leukocytes generally express more than one receptor type. As discussed in Chapter 6 , certain chemokine receptors (CXCR-4, CCR-5) act as coreceptors for a viral envelope glycoprotein of human immunodeficiency virus 1 and are thus involved in binding and entry of the virus into cells.

Chemokines have two main functions: they stimulate leukocyte recruitment in inflammation and control the normal migration of cells through various tissues.[20,][65] Some chemokines are produced transiently in response to inflammatory stimuli and promote the recruitment of leukocytes to the sites of inflammation. Other chemokines are produced constitutively in tissues and function to organize different cell types in different anatomic regions of the tissues. In both situations, chemokines may be displayed at high concentrations attached to proteoglycans on the surface of endothelial cells and in the extracellular matrix.

Other Cytokines in Acute Inflammation.

The list of cytokines implicated in inflammation is huge and constantly growing.[66] Two that have received considerable recent interest are: IL-6, made by macrophages and other cells, which is involved in local and systemic reactions[67]; and IL-17, produced mainly by T lymphocytes, which promotes neutrophil recruitment.[68] Antagonists against both are in clinical trials for inflammatory diseases. Cytokines also play central roles in chronic inflammation; these are described later in the chapter.

Lysosomal Constituents of Leukocytes

Neutrophils and monocytes contain lysosomal granules, which, when released, may contribute to the inflammatory response. Neutrophils have two main types of granules. The smaller *specific* (or secondary) granules contain lysozyme, collagenase, gelatinase, lactoferrin, plasminogen activator, histaminase, and alkaline phosphatase. The larger *azurophil* (or primary) granules contain myeloperoxidase, bactericidal factors (lysozyme, defensins), acid hydrolases, and a variety of neutral

proteases (elastase, cathepsin G, nonspecific collagenases, proteinase 3).[40] Both types of granules can fuse with phagocytic vacuoles containing engulfed material, or the granule contents can be released into the extracellular space.

Different granule enzymes serve different functions. *Acid proteases* degrade bacteria and debris *within the phagolysosomes*, in which an acid pH is readily reached. *Neutral proteases* are capable of degrading various *extracellular components*, such as collagen, basement membrane, fibrin, elastin, and cartilage, resulting in the tissue destruction that accompanies inflammatory processes. Neutral proteases can also cleave C3 and C5 complement proteins directly, releasing anaphylatoxins, and release a kinin-like peptide from kininogen. Neutrophil elastase has been shown to degrade virulence factors of bacteria and thus combat bacterial infections. *Monocytes* and *macrophages* also contain acid hydrolases, collagenase, elastase, phospholipase, and plasminogen activator. These may be particularly active in chronic inflammatory reactions.

Because of the destructive effects of lysosomal enzymes, the initial leukocytic infiltration, if unchecked, can potentiate further inflammation and tissue damage. These harmful proteases, however, are held in check by a system of *antiproteases* in the serum and tissue fluids. Foremost among these is α_1-antitrypsin, which is the major inhibitor of neutrophil elastase. A deficiency of these inhibitors may lead to sustained action of leukocyte proteases, as is the case in patients with α_1-antitrypsin deficiency (Chapter 15). α_2-Macroglobulin is another antiprotease found in serum and various secretions.

Neuropeptides

Neuropeptides are secreted by sensory nerves and various leukocytes, and play a role in the initiation and propagation of an inflammatory response. The small peptides, such as *substance P* and neurokinin A, belong to a family of tachykinin neuropeptides produced in the central and peripheral nervous systems.[69] Nerve fibers containing substance P are prominent in the lung and gastrointestinal tract. Substance P has many biologic functions, including the transmission of pain signals, regulation of blood pressure, stimulation of secretion by endocrine cells, and increasing vascular permeability. Sensory neurons can also produce other pro-inflammatory molecules, such as calcitonin-related gene product, which are thought to link the sensing of painful stimuli to the development of protective host responses.[70]

PLASMA PROTEIN–DERIVED MEDIATORS

A variety of phenomena in the inflammatory response are mediated by plasma proteins that belong to three interrelated systems: the complement, kinin, and clotting systems.

Complement System

The complement system consists of more than 20 proteins, some of which are numbered C1 through C9. This system functions in both innate and adaptive immunity for defense against microbial pathogens. [71] [72] [73] In the process of complement activation several cleavage products of complement proteins are elaborated that cause increased vascular permeability, chemotaxis, and opsonization. The activation and functions of the complement system are outlined in Figure 2-14 .

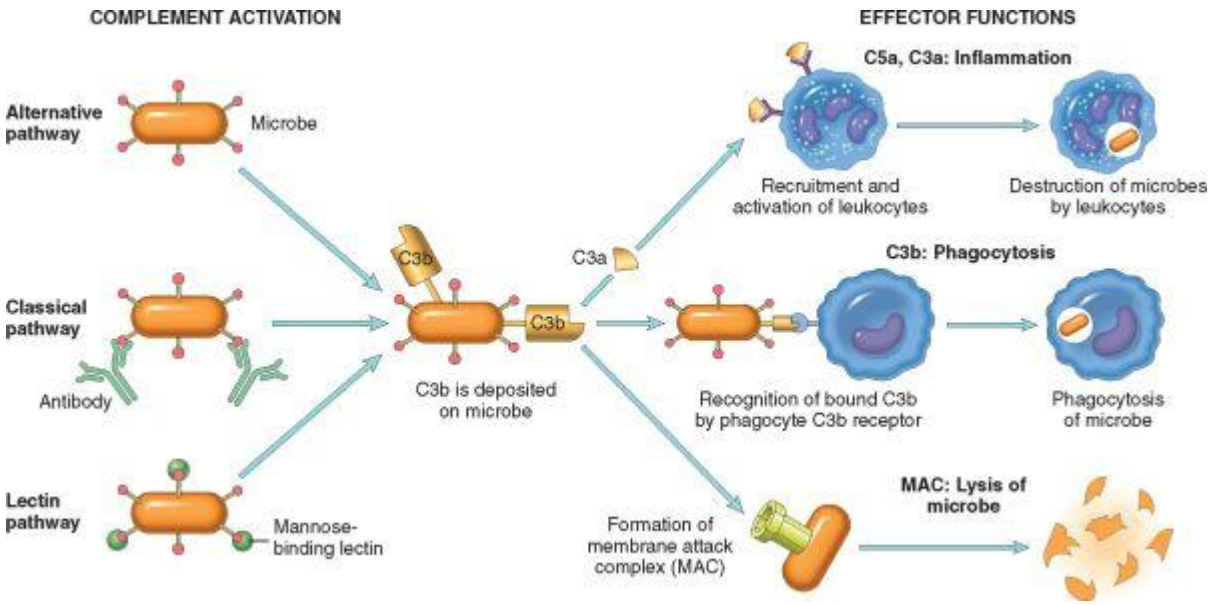

FIGURE 2-14 The activation and functions of the complement system. Activation of complement by different pathways leads to cleavage of C3. The functions of the complement system are mediated by breakdown products of C3 and other complement proteins, and by the membrane attack complex (MAC).

Complement proteins are present in inactive forms in the plasma, and many of them are activated to become proteolytic enzymes that degrade other complement proteins, thus forming an enzymatic cascade capable of tremendous amplification. The critical step in complement activation is the proteolysis of the third (and most abundant) component, C3. Cleavage of C3 can occur by one of three pathways: the *classical pathway*, which is triggered by fixation of C1 to antibody (IgM or IgG) that has combined with antigen; the *alternative pathway*, which can be triggered by microbial surface molecules (e.g., endotoxin, or LPS), complex polysaccharides, cobra venom, and other substances, in the absence of antibody; and the *lectin pathway*, in which plasma mannose-binding lectin binds to carbohydrates on microbes and directly activates C1. Whichever pathway is involved in the early steps of complement activation, they all lead to the formation of an active enzyme called the *C3 convertase*, which splits C3 into two functionally distinct fragments, C3a and C3b. C3a is released, and C3b becomes covalently attached to the cell or molecule where complement is being activated. More C3b then binds to the previously generated fragments to form *C5 convertase*, which cleaves C5 to release C5a and leave C5b attached to the cell surface. C5b binds the late components (C6–C9), culminating in the formation of the membrane attack complex (MAC, composed of multiple C9 molecules).

The biologic functions of the complement system fall into three general categories (see Fig. 2-14):

- *Inflammation*. *C3a*, *C5a*, and, to a lesser extent, *C4a* are cleavage products of the corresponding complement components that stimulate histamine release from mast cells and thereby increase vascular permeability and cause vasodilation. They are called *anaphylatoxins* because they have effects similar to those of mast cell mediators that are involved in the reaction called *anaphylaxis* (Chapter 6). C5a is also a powerful chemotactic agent for neutrophils, monocytes, eosinophils, and basophils. In addition, C5a activates the lipoxygenase pathway of AA metabolism in neutrophils and monocytes, causing further release of inflammatory mediators.
- *Phagocytosis*. *C3b* and its cleavage product *iC3b* (inactive C3b), when fixed to a microbial cell wall, act as opsonins and promote phagocytosis by neutrophils and macrophages, which bear cell surface receptors for the complement fragments.

- *Cell lysis*. The deposition of the MAC on cells makes these cells permeable to water and ions and results in death (lysis) of the cells.

Among the complement components, C3a and C5a are the most important inflammatory mediators. In addition to the mechanisms already discussed, *C3 and C5 can be cleaved by several proteolytic enzymes present within the inflammatory exudate*. These include plasmin and lysosomal enzymes released from neutrophils (discussed earlier). Thus, the chemotactic actions of complement and the complement-activating effects of neutrophils can initiate a self-perpetuating cycle of neutrophil recruitment.

The *activation of complement is tightly controlled by cell-associated and circulating regulatory proteins*. Different regulatory proteins inhibit the production of active complement fragments or remove fragments that deposit on cells. These regulators are expressed on normal host cells and are thus designed to prevent healthy tissues from being injured at sites of complement activation. Regulatory proteins can be overwhelmed when large amounts of complement are deposited on host cells and tissues, as happens in autoimmune diseases, in which individuals produce complement-fixing antibodies against their own tissue antigens (Chapter 6).

Coagulation and Kinin Systems

Inflammation and blood clotting are often intertwined, with each promoting the other.[74] The clotting system is divided into two pathways that converge, culminating in the activation of thrombin and the formation of fibrin (Fig. 2-15) (Chapter 4). The intrinsic clotting pathway is a series of plasma proteins that can be activated by Hageman factor (factor XII), a protein synthesized by the liver that circulates in an inactive form. Factor XII is activated upon contact with negatively charged surfaces, for instance when vascular permeability increases and plasma proteins leak into the extravascular space and come into contact with collagen, or when it comes into contact with basement membranes exposed as a result of endothelial damage. Factor XII then undergoes a conformational change (becoming factor XIIa), exposing an active serine center that can subsequently cleave protein substrates and activate a variety of mediator systems (see later). Inflammation increases the production of several coagulation factors, makes the endothelial surface pro-thrombogenic, and inhibits anticoagulation mechanisms, thus promoting clotting. Conversely, thrombin, a product of clotting, promotes inflammation by engaging receptors that are called *protease-activated receptors* (PARs) because they bind multiple trypsin-like serine proteases in addition to thrombin.[75] These receptors are seven-transmembrane G protein–coupled receptors that are expressed on platelets, endothelial and smooth muscle cells, and many other cell types. Engagement of the so-called type 1 receptor (PAR-1) by proteases, particularly thrombin, triggers several responses that induce inflammation. They include mobilization of P-selectin; production of chemokines and other cytokines; expression of endothelial adhesion molecules for leukocyte integrins; induction of cyclooxygenase-2 and production of prostaglandins; production of PAF and NO; and changes in endothelial shape.[75] As we have seen, these responses promote the recruitment of leukocytes and many other reactions of inflammation. Because coagulation and inflammation can initiate a vicious cycle of amplification, interfering with clotting is a potential therapeutic strategy for the systemic inflammatory disease seen with severe, disseminated bacterial infections. This is the rationale for treating this disorder with the anticoagulant, activated protein C, which may benefit a subset of the patients (Chapter 4).[76]

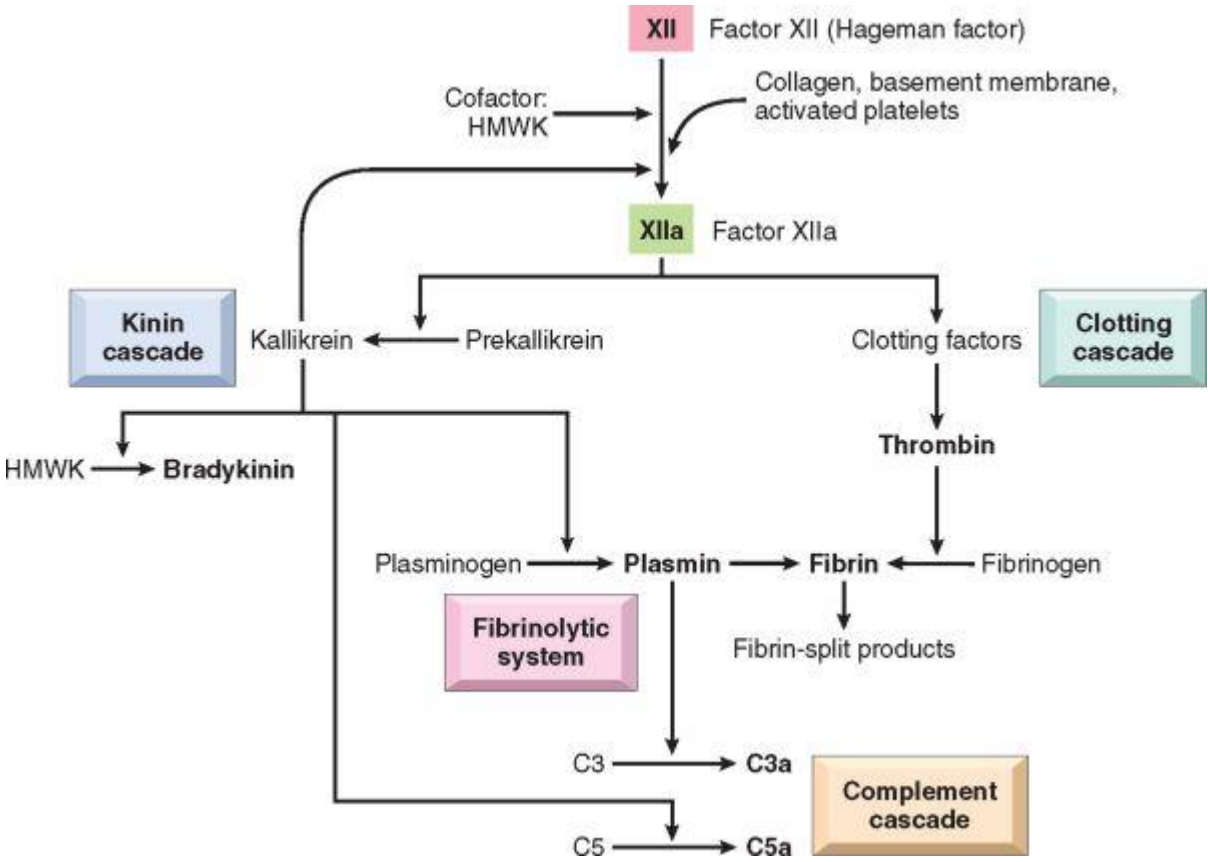

FIGURE 2-15 Interrelationships between the four plasma mediator systems triggered by activation of factor XII (Hageman factor). Note that thrombin induces inflammation by binding to protease-activated receptors (principally PAR-1) on platelets, endothelium, smooth muscle cells, and other cells. HMWK, high molecular weight kininogen.

Kinins are vasoactive peptides derived from plasma proteins, called kininogens, by the action of specific proteases called kallikreins. The kinin and coagulation systems are also intimately connected. The active form of factor XII, factor XIIa, converts plasma *prekallikrein* into an active proteolytic form, the enzyme *kallikrein*, which cleaves a plasma glycoprotein precursor, high-molecular-weight kininogen, to produce *bradykinin* (see Fig. 2-15).[77] *Bradykinin increases vascular permeability and causes contraction of smooth muscle, dilation of blood vessels, and pain when injected into the skin*. These effects are similar to those of histamine. The action of bradykinin is short-lived, because it is quickly inactivated by an enzyme called kininase. Any remaining kinin is inactivated during passage of plasma through the lung by angiotensin-converting enzyme. *Kallikrein itself is a potent activator of Hageman factor, allowing for autocatalytic amplification of the initial stimulus*. Kallikrein has chemotactic activity, and it also directly converts C5 to the chemoattractant product C5a.

At the same time that factor XIIa is inducing fibrin clot formation, it activates the *fibrinolytic system*. This cascade counterbalances clotting by cleaving fibrin, thereby solubilizing the clot. Kallikrein, as well as plasminogen activator (released from endothelium, leukocytes, and other tissues), cleaves plasminogen, a plasma protein that binds to the evolving fibrin clot to generate *plasmin*, a multifunctional protease. The fibrinolytic system contributes to the vascular phenomena of inflammation in several ways. Although the primary function of plasmin is to lyse fibrin clots, during inflammation it also cleaves the complement protein C3 to produce C3 fragments, and it degrades fibrin

to form *fibrin split products*, which may have permeability-inducing properties. Plasmin can also activate Hageman factor, which can trigger multiple cascades (see Fig. 2-15), amplifying the response.

From this discussion of the plasma proteases activated by the complement, kinin, and clotting systems, a few general conclusions can be drawn:

- *Bradykinin, C3a, and C5a (*as mediators of increased vascular permeability); *C5a (*as the mediator of chemotaxis); and *thrombin* (which has effects on endothelial cells and many other cell types) are likely to be the most important in vivo.
- *C3a* and *C5a* can be generated by several types of reactions: (1) immunologic reactions, involving antibodies and complement (the classical pathway); (2) activation of the alternative and lectin complement pathways by microbes, in the absence of antibodies; and (3) agents not directly related to immune responses, such as plasmin, kallikrein, and some serine proteases found in normal tissue.
- *Activated Hageman factor (factor XIIa)* initiates four systems involved in the inflammatory response: (1) the *kinin system*, which produces vasoactive kinins; (2) the *clotting system*, which induces formation of thrombin, which has inflammatory properties; (3) the *fibrinolytic system*, which produces plasmin and degrades fibrin to produce fibrinopeptides, which induce inflammation; and (4) the *complement system*, which produces anaphylatoxins and other mediators. Some of the products of this initiation—particularly kallikrein—can, by feedback, activate Hageman factor, resulting in amplification of the reaction.

When Lewis discovered the role of histamine in inflammation, one mediator was thought to be enough. Now, we are wallowing in them! Yet, from this large compendium, it is likely that a few mediators are most important for the reactions of acute inflammation in vivo, and these are summarized in Table 2-7 . The redundancy of the mediators and their actions ensures that this protective response remains robust and is not easy to perturb.

TABLE 2-7 -- Role of Mediators in Different Reactions of Inflammation

Role in Inflammation	Mediators
Vasodilation	Prostaglandins
	Nitric oxide
	Histamine
Increased vascular permeability	Histamine and serotonin
	C3a and C5a (by liberating vasoactive amines from mast cells, other cells)
	Bradykinin
	Leukotrienes C_4, D_4, E_4
	PAF
	Substance P
Chemotaxis, leukocyte recruitment and activation	TNF, IL-1
	Chemokines
	C3a, C5a
	Leukotriene B_4
	(Bacterial products, e.g., *N*-formyl methyl peptides)
Fever	IL-1, TNF
	Prostaglandins
Pain	Prostaglandins

Role in Inflammation	Mediators
	Bradykinin
Tissue damage	Lysosomal enzymes of leukocytes
	Reactive oxygen species
	Nitric oxide

IL-1, interleukin-1; PAF, platelet-activating factor; TNF, tumor necrosis factor.

2.2.5 Outcomes of Acute Inflammation

Although, as might be expected, many variables may modify the basic process of inflammation, including the nature and intensity of the injury, the site and tissue affected, and the responsiveness of the host, *all acute inflammatory reactions may have one of three outcomes* (Fig. 2-16):

- *Complete resolution*. In a perfect world, all inflammatory reactions, once they have succeeded in neutralizing and eliminating the injurious stimulus, should end with restoration of the site of acute inflammation to normal. This is called *resolution* and is the usual outcome when the injury is limited or short-lived or when there has been little tissue destruction and the damaged parenchymal cells can regenerate. Resolution involves removal of cellular debris and microbes by macrophages, and resorption of edema fluid by lymphatics.
- *Healing by connective tissue replacement (fibrosis)*. This occurs after substantial tissue destruction, when the inflammatory injury involves tissues that are incapable of regeneration, or when there is abundant fibrin exudation in tissue or serous cavities (pleura, peritoneum) that cannot be adequately cleared. In all these situations, connective tissue grows into the area of damage or exudate, converting it into a mass of fibrous tissue—a process also called *organization*.
- Progression of the response to *chronic inflammation* (discussed below). This may follow acute inflammation, or the response may be chronic from the onset. Acute to chronic transition occurs when the acute inflammatory response cannot be resolved, as a result of either the persistence of the injurious agent or some interference with the normal process of healing.[79] For example, bacterial infection of the lung may begin as a focus of acute inflammation (pneumonia), but its failure to resolve may lead to extensive tissue destruction and formation of a cavity in which the inflammation continues to smolder, leading eventually to a chronic lung abscess. Another example of chronic inflammation with a persisting stimulus is peptic ulcer of the duodenum or stomach. Peptic ulcers may persist for months or years and, as discussed below, are manifested by both acute and chronic inflammatory reactions.

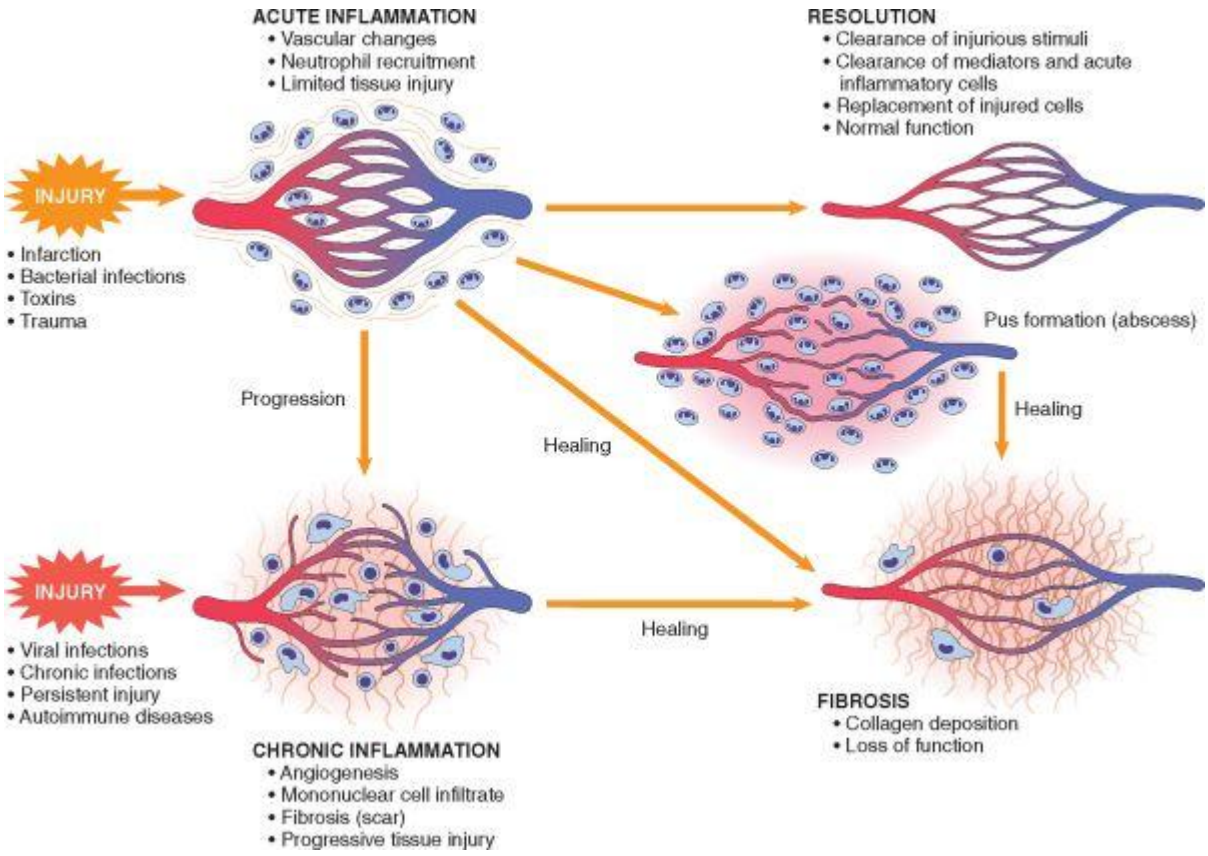

FIGURE 2-16 Outcomes of acute inflammation: resolution, healing by fibrosis, or chronic inflammation. The components of the various reactions and their functional outcomes are listed.

2.2.6 Morphologic Patterns of Acute Inflammation

The morphologic hallmarks of all acute inflammatory reactions are dilation of small blood vessels, slowing of blood flow, and accumulation of leukocytes and fluid in the extravascular tissue (Fig. 2-17). However, special morphologic patterns are often superimposed on these general features, depending on the severity of the reaction, its specific cause, and the particular tissue and site involved. The importance of recognizing the gross and microscopic patterns is that they often provide valuable clues about the underlying cause.

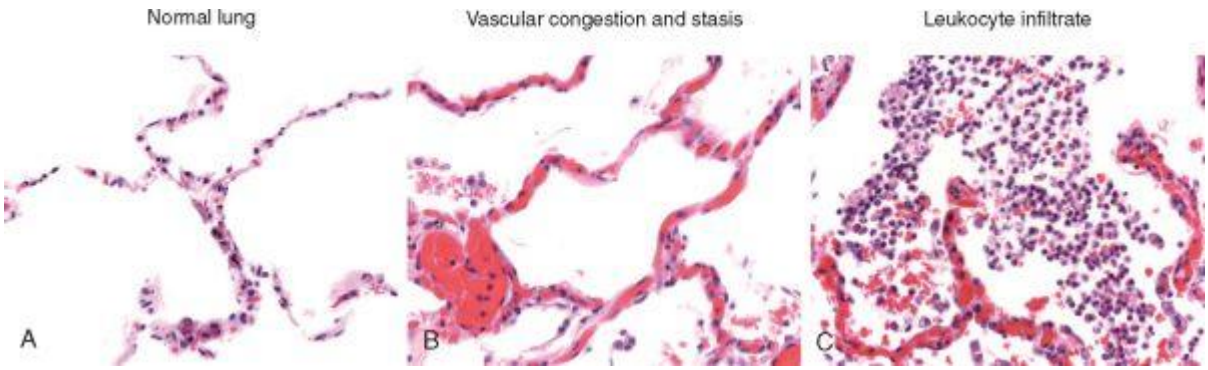

FIGURE 2-17 The characteristic histopathology of acute inflammation. **A**, Normal lung shows thin (virtually invisible) blood vessels in the alveolar walls and no cells in the alveoli. **B**, The vascular component of acute inflammation is manifested by congested blood vessels (packed with erythrocytes), resulting from stasis. **C**, The cellular component of the response is manifested by large numbers of leukocytes (neutrophils)

in the alveoli.

SEROUS INFLAMMATION

Serous inflammation is marked by the outpouring of a thin fluid that may be derived from the plasma or from the secretions of mesothelial cells lining the peritoneal, pleural, and pericardial cavities. Accumulation of fluid in these cavities is called an *effusion*. The skin blister resulting from a burn or viral infection represents a large accumulation of serous fluid, either within or immediately beneath the epidermis of the skin (Fig. 2-18).

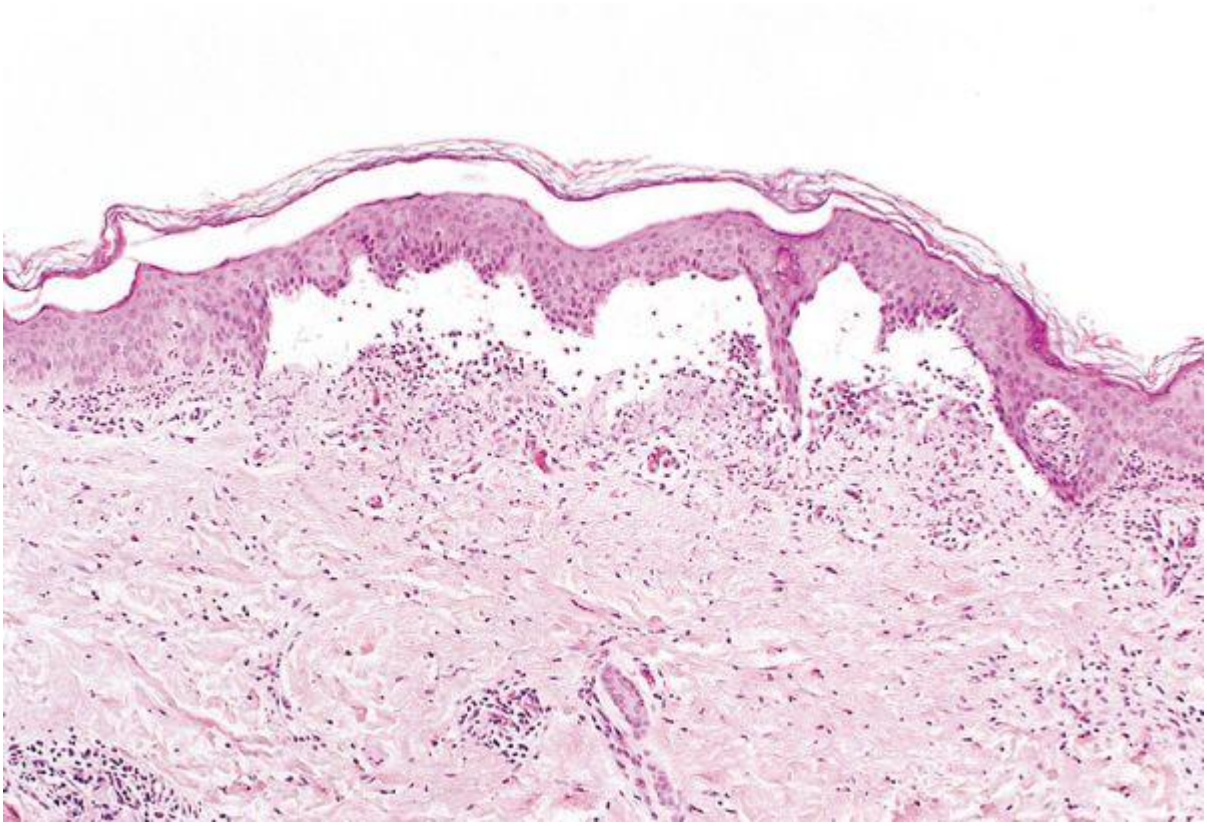

FIGURE 2-18 Serous inflammation. Low-power view of a cross-section of a skin blister showing the epidermis separated from the dermis by a focal collection of serous effusion.

FIBRINOUS INFLAMMATION

With greater increase in vascular permeability, large molecules such as fibrinogen pass the vascular barrier, and fibrin is formed and deposited in the extracellular space. A fibrinous exudate develops when the vascular leaks are large or there is a local procoagulant stimulus (e.g., cancer cells). A fibrinous exudate is characteristic of inflammation in the lining of body cavities, such as the meninges, pericardium (Fig. 2-19A) and pleura. Histologically, fibrin appears as an eosinophilic meshwork of threads or sometimes as an amorphous coagulum (Fig. 2-19B). Fibrinous exudates may be removed by fibrinolysis and clearing of other debris by macrophages. If the fibrin is not removed, over time it may stimulate the ingrowth of fibroblasts and blood vessels and thus lead to scarring. Conversion of the fibrinous exudate to scar tissue *(organization)* within the pericardial sac leads to opaque fibrous

thickening of the pericardium and epicardium in the area of exudation and, if the fibrosis is extensive, obliteration of the pericardial space.

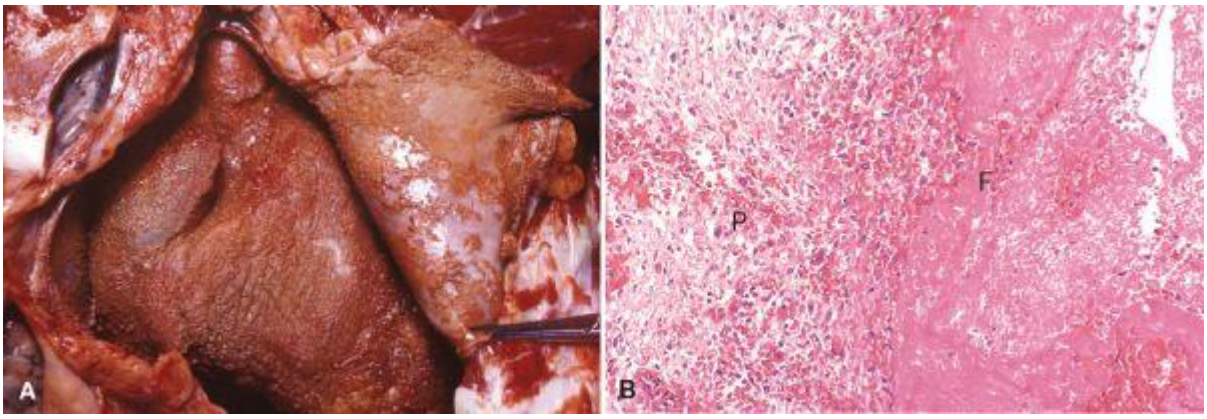

FIGURE 2-19 Fibrinous pericarditis. **A**, Deposits of fibrin on the pericardium. **B**, A pink meshwork of fibrin exudate (F) overlies the pericardial surface (P).

SUPPURATIVE OR PURULENT INFLAMMATION; ABSCESS

This type of inflammation is characterized by the production of large amounts of pus or purulent exudate consisting of neutrophils, liquefactive necrosis, and edema fluid. Certain bacteria (e.g., staphylococci) produce this localized suppuration and are therefore referred to as *pyogenic* (pus-producing) bacteria. A common example of an acute suppurative inflammation is acute appendicitis. *Abscesses are localized collections of purulent inflammatory tissue* caused by suppuration buried in a tissue, an organ, or a confined space. They are produced by deep seeding of pyogenic bacteria into a tissue (Fig. 2-20). Abscesses have a central region that appears as a mass of necrotic leukocytes and tissue cells. There is usually a zone of preserved neutrophils around this necrotic focus, and outside this region vascular dilation and parenchymal and fibroblastic proliferation occur, indicating chronic inflammation and repair. In time the abscess may become walled off and ultimately replaced by connective tissue.

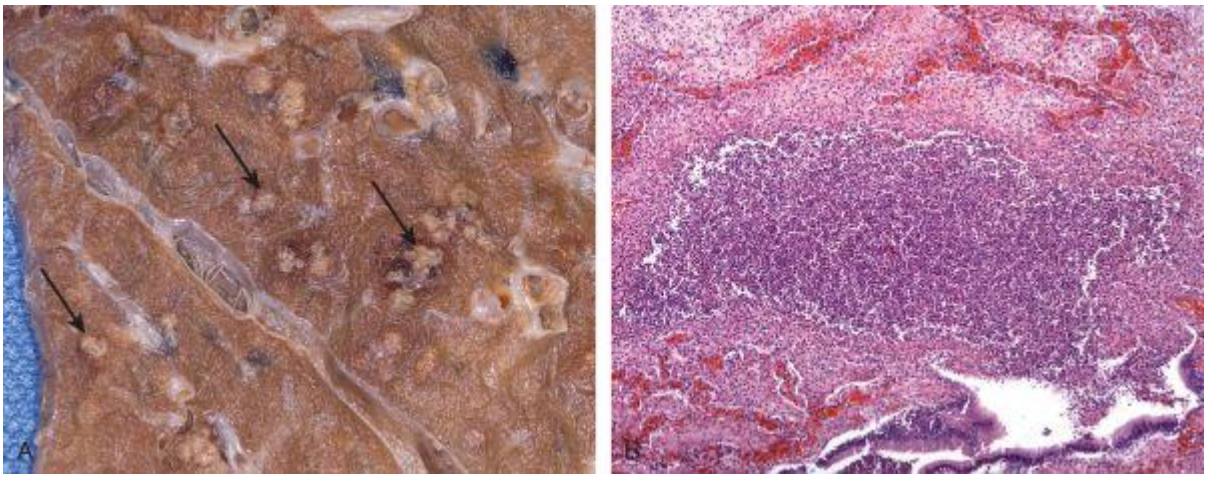

FIGURE 2-20 Purulent inflammation. **A**, Multiple bacterial abscesses in the lung, in a case of bronchopneumonia. **B**, The abscess contains

neutrophils and cellular debris, and is surrounded by congested blood vessels.

ULCERS

An ulcer is a local defect, or excavation, of the surface of an organ or tissue that is produced by the sloughing (shedding) of inflamed necrotic tissue (Fig. 2-21). Ulceration can occur only when tissue necrosis and resultant inflammation exist on or near a surface. It is most commonly encountered in (1) the mucosa of the mouth, stomach, intestines, or genitourinary tract; and (2) the skin and subcutaneous tissue of the lower extremities in older persons who have circulatory disturbances that predispose to extensive ischemic necrosis.

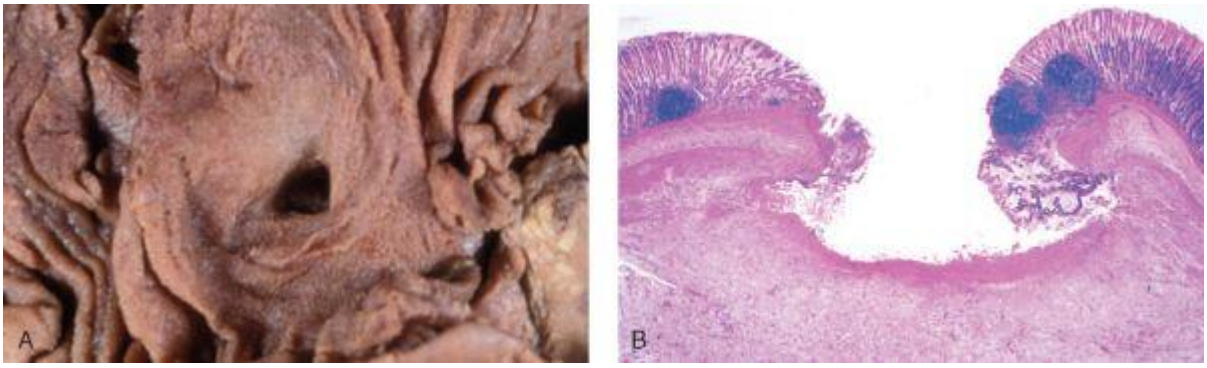

FIGURE 2-21 The morphology of an ulcer. **A**, A chronic duodenal ulcer. **B**, Low-power cross-section of a duodenal ulcer crater with an acute inflammatory exudate in the base.

Ulcerations are best exemplified by peptic ulcer of the stomach or duodenum, in which acute and chronic inflammation coexist. During the acute stage there is intense polymorphonuclear infiltration and vascular dilation in the margins of the defect. With chronicity, the margins and base of the ulcer develop fibroblastic proliferation, scarring, and the accumulation of lymphocytes, macrophages, and plasma cells.

2.2.7 Summary of Acute Inflammation

Now that we have described the components, mediators, and pathologic manifestations of acute inflammatory responses, it is useful to summarize the sequence of events in a typical response of this type.[78] When a host encounters an injurious agent, such as an infectious microbe or dead cells, phagocytes that reside in all tissues try to eliminate these agents. At the same time phagocytes and other host cells react to the presence of the foreign or abnormal substance by liberating cytokines, lipid messengers, and other mediators of inflammation. Some of these mediators act on small blood vessels in the vicinity and promote the efflux of plasma and the recruitment of circulating leukocytes to the site where the offending agent is located. The recruited leukocytes are activated by the injurious agent and by locally produced mediators, and the activated leukocytes try to remove the offending agent by phagocytosis. As the injurious agent is eliminated and anti-inflammatory mechanisms become active, the process subsides and the host returns to a normal state of health. If the injurious agent cannot be quickly eliminated, the result may be chronic inflammation.

The clinical and pathologic manifestations of the inflammatory response are caused by several reactions. The vascular phenomena of acute inflammation are characterized by increased blood flow to the injured area, resulting mainly from arteriolar dilation and opening of capillary beds induced by mediators such as histamine. Increased vascular permeability results in the accumulation of protein-rich extravascular fluid, which forms the exudate. Plasma proteins leave the vessels, most commonly through widened interendothelial cell junctions of the venules. The redness *(rubor),* warmth *(calor),* and swelling *(tumor)* of acute inflammation are caused by the increased blood flow and edema. Circulating leukocytes, initially predominantly neutrophils, adhere to the endothelium via adhesion molecules, traverse the endothelium, and migrate to the site of injury under the influence of chemotactic agents. Leukocytes that are activated by the offending agent and by endogenous mediators may release toxic metabolites and proteases extracellularly, causing tissue damage. During the damage, and in part as a result of the liberation of prostaglandins, neuropeptides, and cytokines, one of the local symptoms is pain *(dolor)*.

In clinical practice the underlying cause determines whether the therapeutic goal is to promote or reduce inflammation. In infections the treatment is intended to increase the host response and eliminate the infection—hence the practice of warm compresses and gargles in case of pharyngitis (sore throat). On the other hand, in traumatic injuries and chronic inflammatory diseases, inflammation serves no useful purpose and the goal is to reduce it with application of cold (in trauma) and anti-inflammatory drugs. At certain locations, such as the cornea, it may be desirable to suppress even acute inflammation so that corneal transparency can be maintained.

2.2.8 Chronic Inflammation

Chronic inflammation is inflammation of prolonged duration (weeks or months) in which inflammation, tissue injury, and attempts at repair coexist, in varying combinations. It may follow acute inflammation, as described earlier, or chronic inflammation may begin insidiously, as a low-grade, smoldering response without any manifestations of an acute reaction. This latter type of chronic inflammation is the cause of tissue damage in some of the most common and disabling human diseases, such as rheumatoid arthritis, atherosclerosis, tuberculosis, and pulmonary fibrosis. It has also been implicated in the progression of cancer and in diseases once thought to be purely degenerative, such as Alzheimer disease.

CAUSES OF CHRONIC INFLAMMATION

Chronic inflammation arises in the following settings:

- *Persistent infections* by microorganisms that are difficult to eradicate, such as mycobacteria, and certain viruses, fungi, and parasites. These organisms often evoke an immune reaction called *delayed-type hypersensitivity* (Chapter 6). The inflammatory response sometimes takes a specific pattern called a *granulomatous reaction* (discussed later).
- *Immune-mediated inflammatory diseases*. Chronic inflammation plays an important role in a group of diseases that are caused by excessive and inappropriate activation of the immune system. Under certain conditions immune reactions develop against the individual's own tissues, leading to *autoimmune diseases* (Chapter 6). In these diseases, auto-antigens evoke a self-perpetuating immune reaction that results in chronic tissue damage and inflammation; examples of such diseases are rheumatoid arthritis and multiple sclerosis. In other cases, chronic inflammation is the result of unregulated immune responses against microbes, as in inflammatory bowel disease. Immune responses against common environmental substances are the cause of *allergic diseases*, such as bronchial asthma (Chapter 6). Because these autoimmune and allergic reactions are inappropriately triggered against antigens that are normally harmless, the reactions serve no useful purpose and only cause disease. Such diseases may show morphologic patterns of mixed acute and chronic inflammation because they are characterized by repeated bouts of inflammation. Fibrosis may dominate the late stages.
- *Prolonged exposure to potentially toxic agents, either exogenous or endogenous*. An example of an exogenous agent is particulate silica, a nondegradable inanimate material that, when inhaled for prolonged

periods, results in an inflammatory lung disease called *silicosis* (Chapter 15). *Atherosclerosis* (Chapter 11) is thought to be a chronic inflammatory process of the arterial wall induced, at least in part, by endogenous toxic plasma lipid components.

MORPHOLOGIC FEATURES

In contrast to acute inflammation, which is manifested by vascular changes, edema, and predominantly neutrophilic infiltration, *chronic inflammation is characterized by:*

- *Infiltration with mononuclear cells*, which include macrophages, lymphocytes, and plasma cells (Fig. 2-22)
- *Tissue destruction*, induced by the persistent offending agent or by the inflammatory cells
- Attempts at *healing by connective tissue replacement of damaged tissue*, accomplished by proliferation of small blood vessels *(angiogenesis)* and, in particular, *fibrosis*[80]

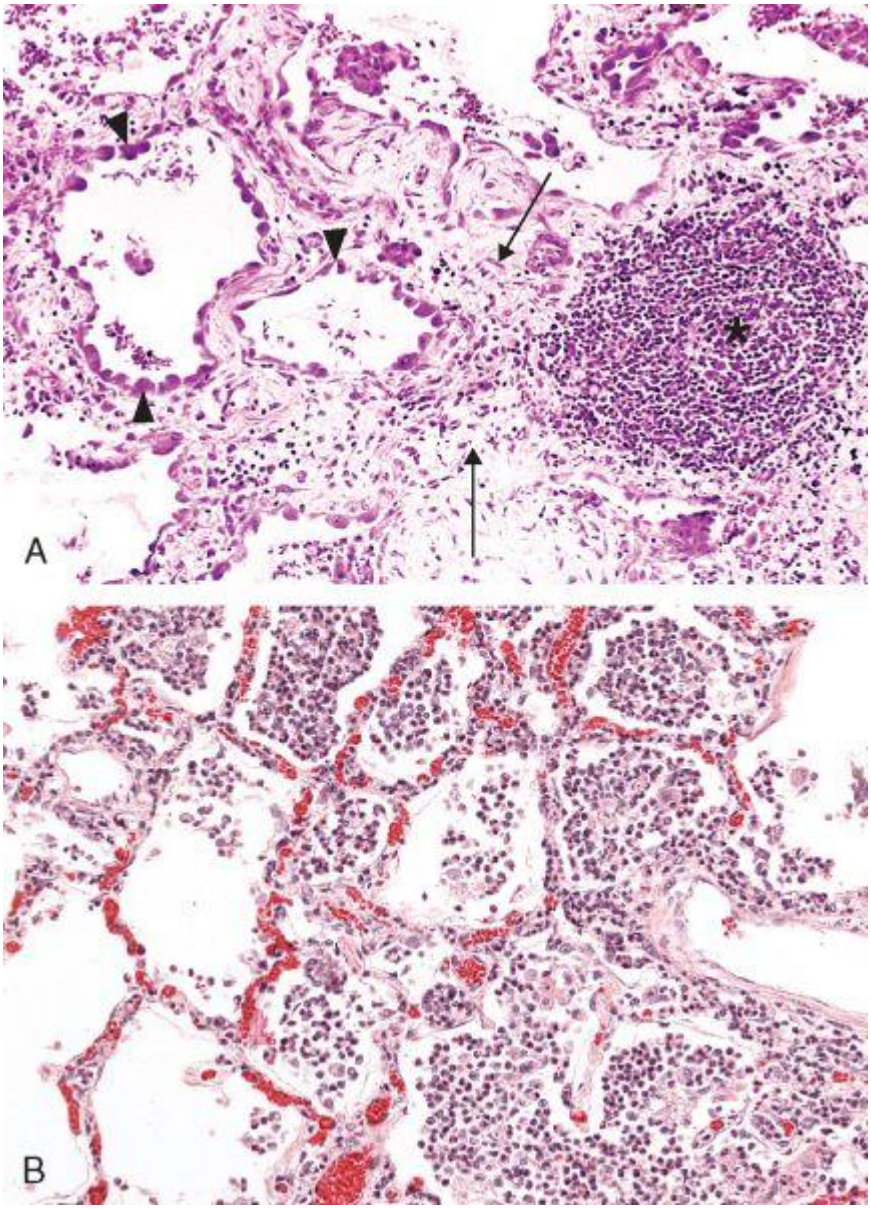

FIGURE 2-22 **A**, Chronic inflammation in the lung, showing all three characteristic histologic features: (1) collection of chronic inflammatory cells (*), (2) destruction of parenchyma (normal alveoli are replaced by spaces lined by cuboidal epithelium, *arrowheads*), and (3) replacement by connective tissue (fibrosis, *arrows*). **B**, By contrast, in acute inflammation of the lung (acute bronchopneumonia), neutrophils fill the

alveolar spaces and blood vessels are congested.

Because angiogenesis and fibrosis are also components of wound healing and repair, they are discussed more fully in Chapter 3 .

ROLE OF MACROPHAGES IN CHRONIC INFLAMMATION

The *macrophage* is the dominant cellular player in chronic inflammation, and we begin our discussion with a brief review of its biology. *Macrophages* are one component of the *mononuclear phagocyte system* (Fig. 2-23). The mononuclear phagocyte system (sometimes called reticuloendothelial system) consists of closely related cells of bone marrow origin, including blood monocytes and tissue macrophages. The latter are diffusely scattered in the connective tissue or located in organs such as the liver (Kupffer cells), spleen and lymph nodes (sinus histiocytes), lungs (alveolar macrophages), and central nervous system (microglia). Mononuclear phagocytes arise from a common precursor in the bone marrow, which gives rise to blood monocytes. From the blood, monocytes migrate into various tissues and differentiate into macrophages. The half-life of blood monocytes is about 1 day, whereas the life span of tissue macrophages is several months or years. The journey from bone marrow stem cell to tissue macrophage is regulated by a variety of growth and differentiation factors, cytokines, adhesion molecules, and cellular interactions.

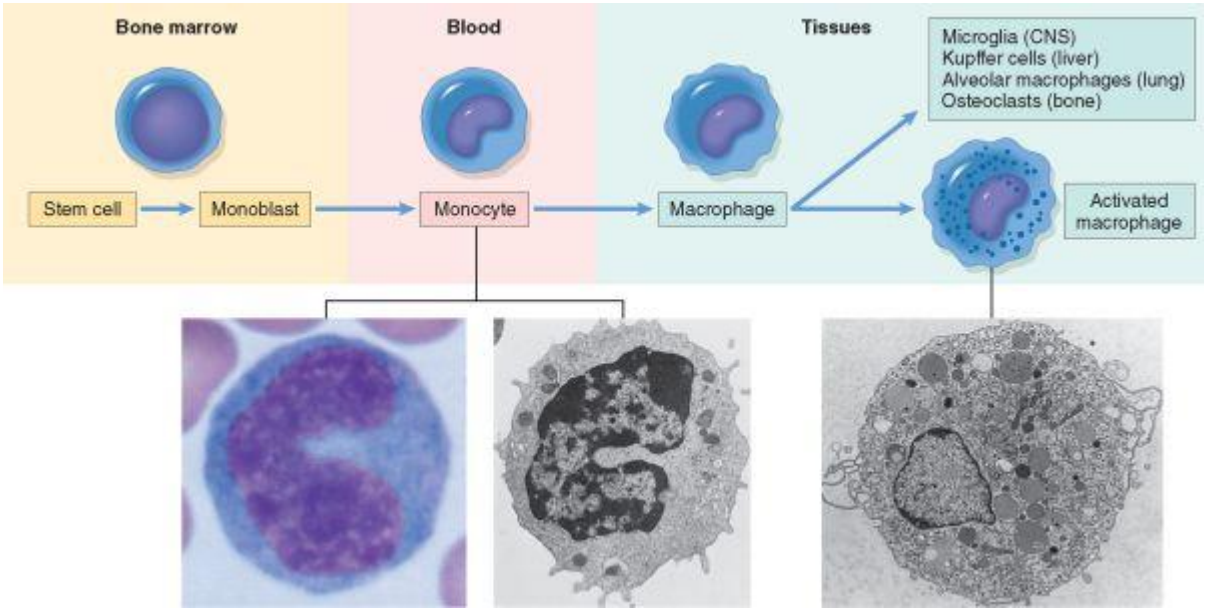

FIGURE 2-23 Maturation of mononuclear phagocytes. *(From Abbas AK et al: Cellular and Molecular Immunology, 5th ed. Philadelphia, WB Saunders, 2003.)*

As discussed earlier, monocytes begin to emigrate into extravascular tissues quite early in acute inflammation, and within 48 hours they may constitute the predominant cell type. Extravasation of monocytes is governed by the same factors that are involved in neutrophil emigration, that is, adhesion molecules and chemical mediators with chemotactic and activating properties.[81] When a monocyte

reaches the extravascular tissue, it undergoes transformation into a larger phagocytic cell, the *macrophage*. Macrophages may be *activated* by a variety of stimuli, including microbial products that engage TLRs and other cellular receptors, cytokines (e.g., IFN-γ) secreted by sensitized T lymphocytes and by natural killer cells, and other chemical mediators (Fig. 2-24).

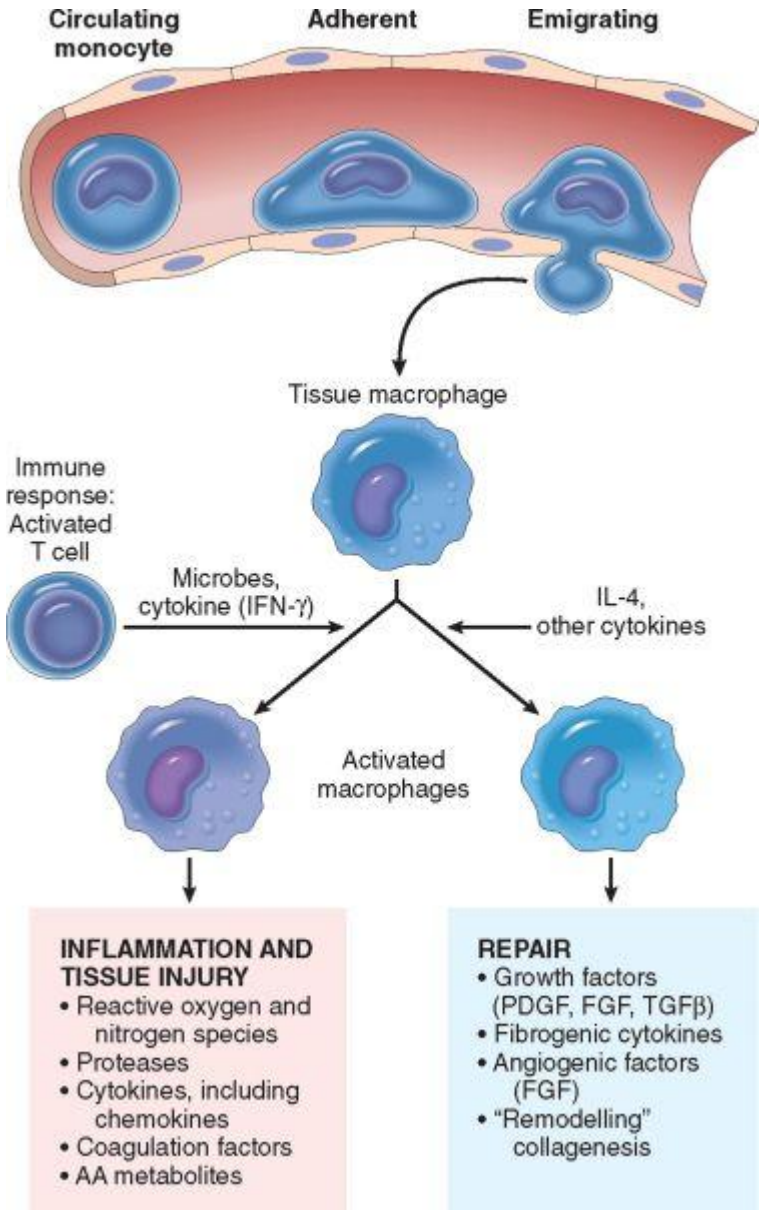

FIGURE 2-24 The roles of activated macrophages in chronic inflammation. Macrophages are activated by nonimmunologic stimuli such as endotoxin or by cytokines from immune-activated T cells (particularly IFN-γ). The products made by activated macrophages that cause tissue injury and fibrosis are indicated. AA, arachidonic acid; PDGF, platelet-derived growth factor; FGF, fibroblast growth factor; TGFβ, transforming growth factor β.

The products of activated macrophages serve to eliminate injurious agents such as microbes and to initiate the process of repair, and are responsible for much of the tissue injury in chronic inflammation. Activation of macrophages results in increased levels of lysosomal enzymes and reactive oxygen and nitrogen species, and production of cytokines, growth factors, and other mediators of inflammation.

Some of these products are toxic to microbes and host cells (e.g., reactive oxygen and nitrogen species) or to extracellular matrix (proteases); some cause influx of other cell types (e.g., cytokines, chemotactic factors); and still others cause fibroblast proliferation, collagen deposition, and angiogenesis (e.g., growth factors). As illustrated in Fig. 2-10 , different macrophage populations may serve distinct functions—some may be important for microbial killing and inflammation, and others for repair.[38] Their impressive arsenal of mediators makes macrophages powerful allies in the body's defense against unwanted invaders, but the same weaponry can also induce considerable tissue destruction when macrophages are inappropriately activated. It is because of the activities of these macrophages that *tissue destruction is one of the hallmarks of chronic inflammation*. The ongoing tissue destruction can itself activate the inflammatory cascade, so that features of both acute and chronic inflammation may coexist in certain circumstances.

In short-lived inflammation, if the irritant is eliminated, macrophages eventually disappear (either dying off or making their way into the lymphatics and lymph nodes). In chronic inflammation, macrophage accumulation persists, as a result of continuous recruitment from the circulation and local proliferation at the site of inflammation.

OTHER CELLS IN CHRONIC INFLAMMATION

Other cell types involved in chronic inflammation include lymphocytes, plasma cells, eosinophils, and mast cells:

- *Lymphocytes* are mobilized in both antibody-mediated and cell-mediated immune reactions. Antigen-stimulated (effector and memory) lymphocytes of different types (T and B cells) use various adhesion molecule pairs (selectins, integrins and their ligands) and chemokines to migrate into inflammatory sites. Cytokines from activated macrophages, mainly TNF, IL-1, and chemokines, promote leukocyte recruitment, setting the stage for persistence of the inflammatory response. Lymphocytes and macrophages interact in a bidirectional way, and these reactions play an important role in chronic inflammation (Fig. 2-25). Macrophages display antigens to T cells and produce membrane molecules (costimulators) and cytokines (notably IL-12) that stimulate T-cell responses (Chapter 6). Activated T lymphocytes produce cytokines, some of which recruit monocytes from the circulation and one, IFN-γ, is a powerful activator of macrophages. Because of these interactions between T cells and macrophages, once the immune system is involved in an inflammatory reaction the reaction tends to be chronic and severe. To highlight these special features, inflammation with a strong component of immune reactions (i.e., responses of T and B lymphocytes) is sometimes called *immune inflammation* (Chapter 6).
- *Plasma cells* develop from activated B lymphocytes and produce antibodies directed either against persistent foreign or self antigens in the inflammatory site or against altered tissue components. In some strong chronic inflammatory reactions, the accumulation of lymphocytes, antigen-presenting cells, and plasma cells may assume the morphologic features of lymphoid organs, particularly lymph nodes, even containing well-formed germinal centers. These are called *tertiary lymphoid organs*; this type of *lymphoid organogenesis* is often seen in the synovium of patients with long-standing rheumatoid arthritis.[82]
- *Eosinophils* are abundant in immune reactions mediated by IgE and in parasitic infections (Fig. 2-26). A chemokine that is especially important for eosinophil recruitment is eotaxin. Eosinophils have granules that contain *major basic protein*, a highly cationic protein that is toxic to parasites but also causes lysis of mammalian epithelial cells. This is why eosinophils are of benefit in controlling parasitic infections, but they contribute to tissue damage in immune reactions such as allergies (Chapter 6).[83]
- *Mast cells* are widely distributed in connective tissues and participate in both acute and chronic inflammatory reactions. Mast cells express on their surface the receptor (FcεRI) that binds the Fc portion of IgE antibody. In immediate hypersensitivity reactions, IgE antibodies bound to the cells' Fc receptors specifically recognize antigen, and the cells degranulate and release mediators, such as histamine and prostaglandins (Chapter 6). This type of response occurs during allergic reactions to foods, insect venom, or drugs, sometimes with catastrophic results (e.g. anaphylactic shock). Mast cells are also present in chronic inflammatory reactions, and because they secrete a plethora of cytokines, they have the ability to both promote and limit inflammatory reactions in different situations.

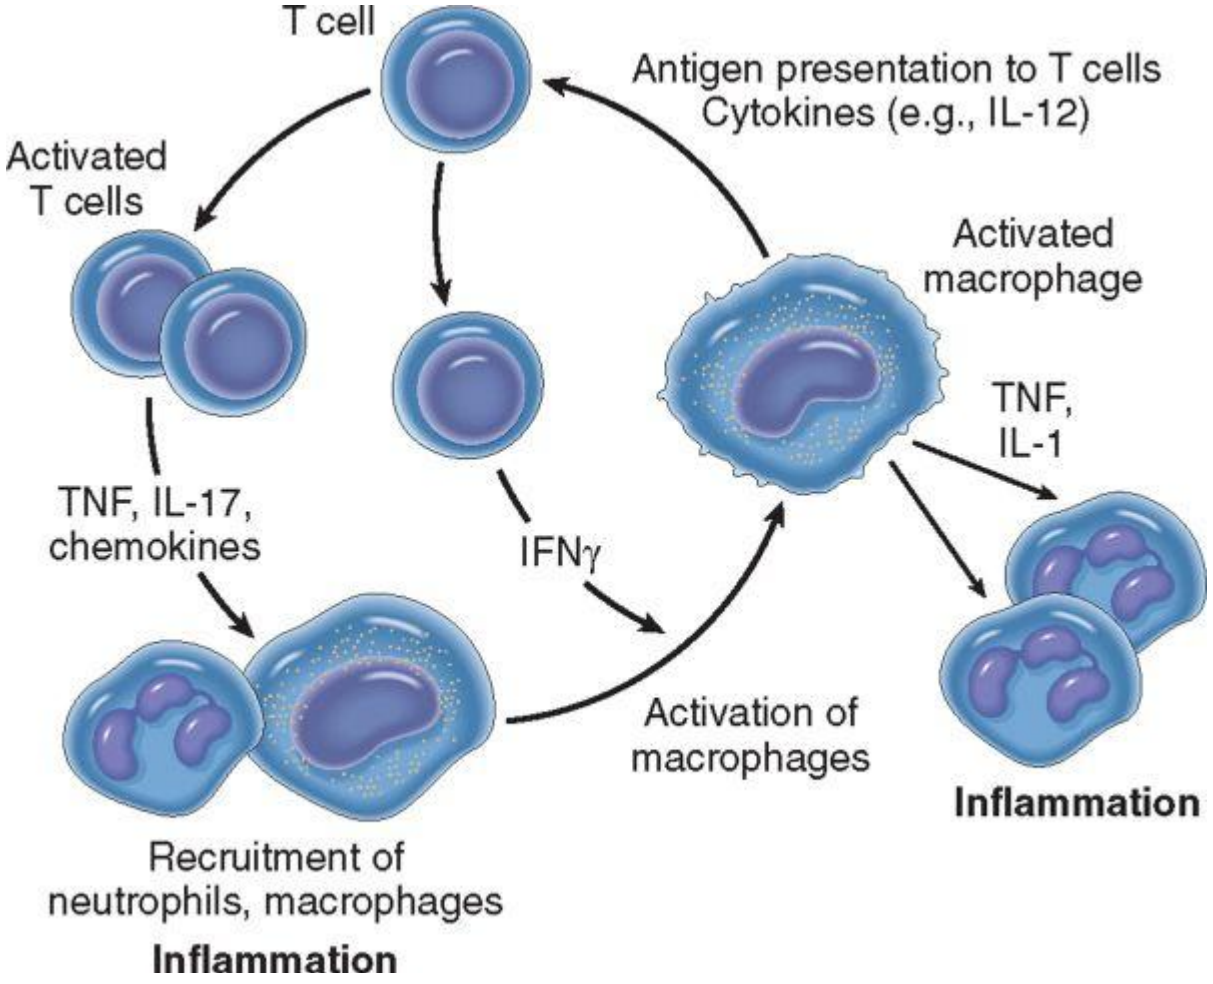

FIGURE 2-25 Macrophage-lymphocyte interactions in chronic inflammation. Activated T cells produce cytokines that recruit macrophages (TNF, IL-17, chemokines) and others that activate macrophages (IFNγ). Different subsets of T cells (called T_H1 and T_H17) may produce different sets of cytokines; these are described in Chapter 6 . Activated macrophages in turn stimulate T cells by presenting antigens and via cytokines (such as IL-12).

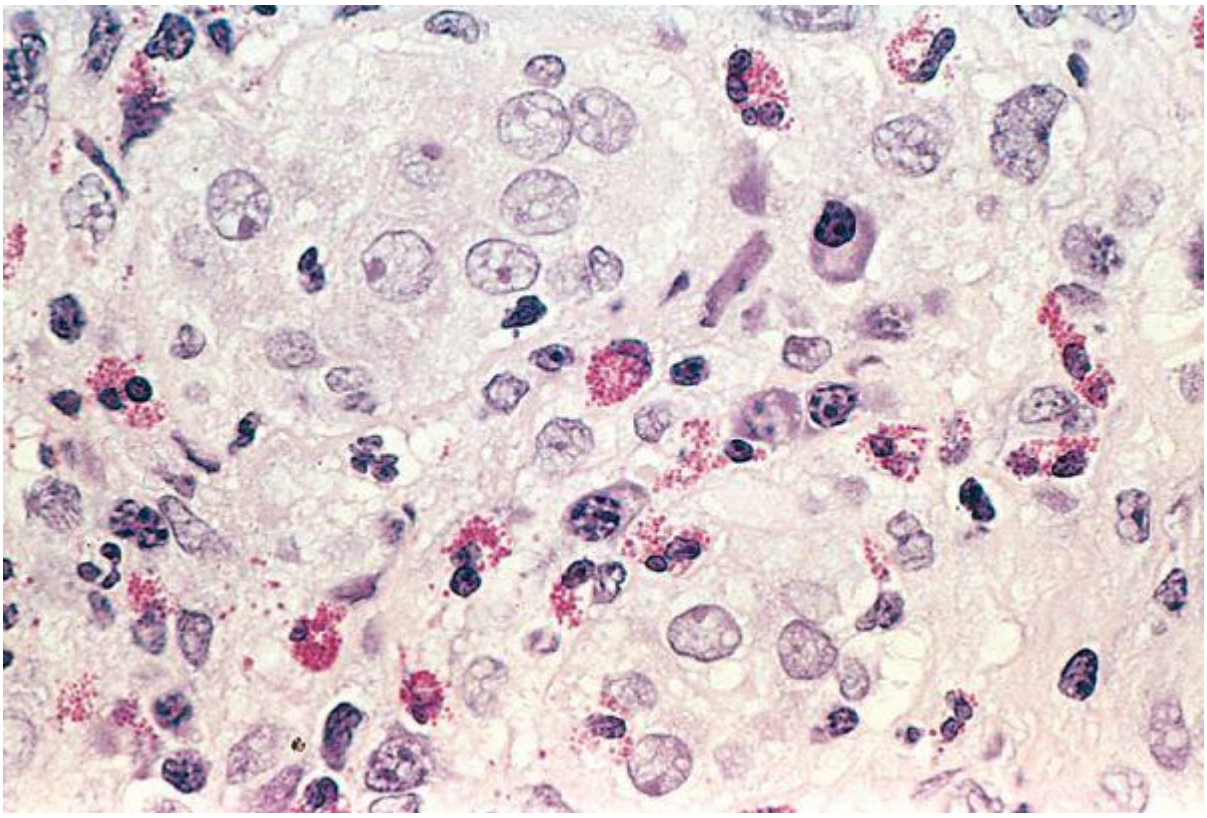

FIGURE 2-26 A focus of inflammation showing numerous eosinophils.

Although *neutrophils* are characteristic of acute inflammation, many forms of chronic inflammation, lasting for months, continue to show large numbers of neutrophils, induced either by persistent microbes or by mediators produced by activated macrophages and T lymphocytes. In chronic bacterial infection of bone (osteomyelitis), a neutrophilic exudate can persist for many months. Neutrophils are also important in the chronic damage induced in lungs by smoking and other irritant stimuli (Chapter 15).

In addition to cellular infiltrates, growth of *blood vessels and lymphatic vessels* is often prominent in chronic inflammatory reactions. This growth of vessels is stimulated by growth factors, such as VEGF, produced by macrophages and endothelial cells (Chapter 3).

GRANULOMATOUS INFLAMMATION

Granulomatous inflammation is a distinctive pattern of chronic inflammation that is encountered in a limited number of infectious and some noninfectious conditions. Immune reactions are usually involved in the development of granulomas, and therefore this process is described in more detail in Chapter 6 . Briefly, a granuloma is a cellular attempt to contain an offending agent that is difficult to eradicate. In this attempt there is often strong activation of T lymphocytes leading to macrophage activation, which can cause injury to normal tissues. Tuberculosis is the prototype of the granulomatous diseases, but sarcoidosis, cat-scratch disease, lymphogranuloma inguinale, leprosy, brucellosis, syphilis, some mycotic infections, berylliosis, reactions of irritant lipids, and some autoimmune diseases are also included (Table 2-8). Recognition of the granulomatous pattern in a biopsy specimen is important because of the limited number of possible conditions that cause it and the significance of the diagnoses associated with the lesions.

TABLE 2-8 -- Examples of Diseases with Granulomatous Inflammation

Disease	Cause	Tissue Reaction
Tuberculosis	*Mycobacterium tuberculosis*	Caseating granuloma (tubercle): focus of activated macrophages (epithelioid cells), rimmed by fibroblasts, lymphocytes, histiocytes, occasional Langhans giant cells; central necrosis with amorphous granular debris; acid-fast bacilli
Leprosy	*Mycobacterium leprae*	Acid-fast bacilli in macrophages; noncaseating granulomas
Syphilis	*Treponema pallidum*	Gumma: microscopic to grossly visible lesion, enclosing wall of histiocytes; plasma cell infiltrate; central cells necrotic without loss of cellular outline
Cat-scratch disease	Gram-negative bacillus	Rounded or stellate granuloma containing central granular debris and recognizable neutrophils; giant cells uncommon
Sarcoidosis	Unknown etiology	Noncaseating granulomas with abundant activated macrophages
Crohn disease (inflammatory bowel disease)	Immune reaction against intestinal bacteria, self-antigens	Occasional noncaseating granulomas in the wall of the intestine, with dense chronic inflammatory infiltrate

A granuloma is a focus of chronic inflammation consisting of a microscopic aggregation of macrophages that are transformed into epithelium-like cells, surrounded by a collar of mononuclear leukocytes, principally lymphocytes and occasionally plasma cells. In the usual hematoxylin and eosin–stained tissue sections, the epithelioid cells have a pale pink granular cytoplasm with indistinct cell boundaries, often appearing to merge into one another. The nucleus is less dense than that of a lymphocyte, is oval or elongate, and may show folding of the nuclear membrane. Older granulomas develop an enclosing rim of fibroblasts and connective tissue. Frequently, epithelioid cells fuse to form *giant cells* in the periphery or sometimes in the center of granulomas. These giant cells may attain diameters of 40 to 50 μm. They have a large mass of cytoplasm containing 20 or more small nuclei arranged either peripherally (Langhans-type giant cell) or haphazardly (foreign body–type giant cell) (Fig. 2-27). There is no known functional difference between these two types of giant cells, yet some pathologists persist in describing them—perhaps because they make nice exam questions!

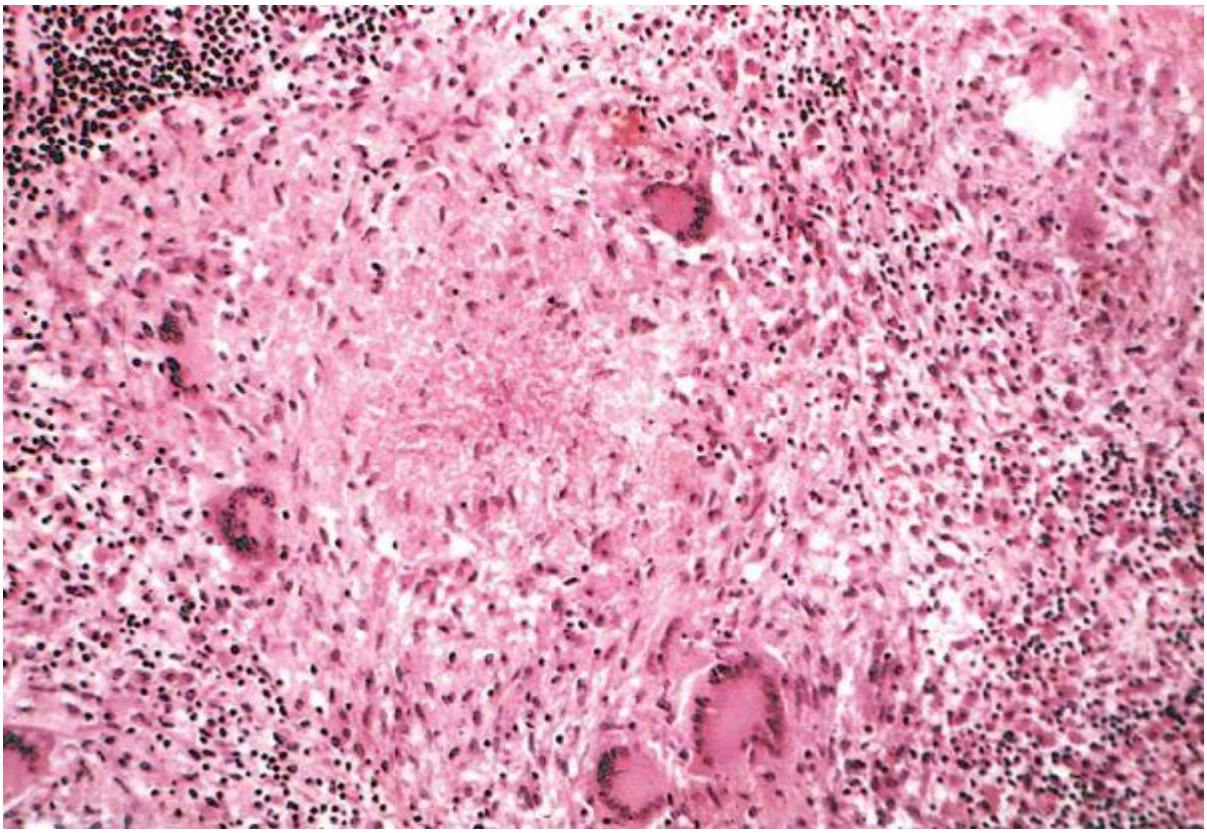

FIGURE 2-27 Typical tuberculous granuloma showing an area of central necrosis surrounded by multiple Langhans-type giant cells, epithelioid cells, and lymphocytes.

There are two types of granulomas, which differ in their pathogenesis. *Foreign body granulomas* are incited by relatively inert foreign bodies. Typically, foreign body granulomas form around material such as talc (associated with intravenous drug abuse) (Chapter 9), sutures, or other fibers that are large enough to preclude phagocytosis by a single macrophage and do not incite any specific inflammatory or immune response. Epithelioid cells and giant cells are apposed to the surface of the foreign body. The foreign material can usually be identified in the center of the granuloma, particularly if viewed with polarized light, in which it appears refractile.

Immune granulomas are caused by a variety of agents that are capable of inducing a cell-mediated immune response (Chapter 6). This type of immune response produces granulomas usually when the inciting agent is poorly degradable or particulate. In such responses macrophages engulf foreign protein antigen, process it, and present peptides to antigen-specific T lymphocytes, causing their activation (Chapter 6). The responding T cells produce cytokines, such as IL-2, which activates other T cells, perpetuating the response, and IFN-γ, which is important in activating macrophages and transforming them into epithelioid cells and multinucleate giant cells.

The prototype of the immune granuloma is that caused by infection with *Mycobacterium tuberculosis*. In this disease the granuloma is referred to as a *tubercle. It is often characterized by the presence of central caseous necrosis* (see Fig. 2-27). In contrast, caseous necrosis is rare in other granulomatous diseases. The morphologic patterns in the various granulomatous diseases may be sufficiently different to allow reasonably accurate diagnosis by an experienced pathologist (see Table 2-8); however, there

are so many atypical presentations that it is always necessary to identify the specific etiologic agent by special stains for organisms (e.g., acid-fast stains for tubercle bacilli), by culture methods (e.g., in tuberculosis and fungal diseases), by molecular techniques (e.g., the polymerase chain reaction in tuberculosis), and by serologic studies (e.g., in syphilis).

2.2.9 Systemic Effects of Inflammation

Anyone who has suffered a severe sore throat or a respiratory infection has experienced the systemic manifestations of acute inflammation. The systemic changes associated with acute inflammation are collectively called the *acute-phase response*, or the systemic inflammatory response syndrome. These changes are reactions to cytokines whose production is stimulated by bacterial products such as LPS and by other inflammatory stimuli. The acute-phase response consists of several clinical and pathologic changes:

- *Fever*, characterized by an elevation of body temperature, usually by 1° to 4°C, is one of the most prominent manifestations of the acute-phase response, especially when inflammation is associated with infection. Fever is produced in response to substances called *pyrogens* that act by stimulating prostaglandin synthesis in the vascular and perivascular cells of the hypothalamus. Bacterial products, such as LPS (called *exogenous pyrogens*), stimulate leukocytes to release cytokines such as IL-1 and TNF (called *endogenous pyrogens*) that increase the enzymes (cyclooxygenases) that convert AA into prostaglandins.[84] In the hypothalamus, the prostaglandins, especially PGE_2, stimulate the production of neurotransmitters such as cyclic adenosine monophosphate, which function to reset the temperature set point at a higher level. NSAIDs, including aspirin, reduce fever by inhibiting prostaglandin synthesis. An elevated body temperature has been shown to help amphibians ward off microbial infections, and it is assumed that fever does the same for mammals, although the mechanism is unknown. One hypothesis is that fever may induce heat shock proteins that enhance lymphocyte responses to microbial antigens.
- *Acute-phase proteins* are plasma proteins, mostly synthesized in the liver, whose plasma concentrations may increase several hundred-fold as part of the response to inflammatory stimuli.[85] Three of the best-known of these proteins are C-reactive protein (CRP), fibrinogen, and serum amyloid A (SAA) protein. Synthesis of these molecules by hepatocytes is up-regulated by cytokines, especially IL-6 (for CRP and fibrinogen) and IL-1 or TNF (for SAA). Many acute-phase proteins, such as CRP and SAA, bind to microbial cell walls, and they may act as opsonins and fix complement. They also bind chromatin, possibly aiding in the clearing of necrotic cell nuclei. During the acute-phase response SAA protein replaces apolipoprotein A, a component of high-density lipoprotein particles. This may alter the targeting of high-density lipoproteins from liver cells to macrophages, which can use these particles as a source of energy-producing lipids. Fibrinogen binds to red cells and causes them to form stacks (rouleaux) that sediment more rapidly at unit gravity than do individual red cells. This is the basis for measuring the *erythrocyte sedimentation rate* as a simple test for the systemic inflammatory response, caused by any stimulus. Acute-phase proteins have beneficial effects during acute inflammation, but as we shall see in Chapter 6 , prolonged production of these proteins (especially SAA) in states of chronic inflammation causes *secondary amyloidosis*. Elevated serum levels of CRP have been proposed as a marker for increased risk of myocardial infarction in patients with coronary artery disease.[86] It is postulated that inflammation involving atherosclerotic plaques in the coronary arteries may predispose to thrombosis and subsequent infarction, and CRP is produced during inflammation. Another peptide whose production is increased in the acute-phase response is the iron-regulating peptide *hepcidin*.[87] Chronically elevated plasma concentrations of hepcidin reduce the availability of iron and are responsible for the *anemia* associated with chronic inflammation (Chapter 14).
- *Leukocytosis* is a common feature of inflammatory reactions, especially those induced by bacterial infections. The leukocyte count usually climbs to 15,000 or 20,000 cells/μL, but sometimes it may reach extraordinarily high levels of 40,000 to 100,000 cells/μL. These extreme elevations are referred to as *leukemoid reactions*, because they are similar to the white cell counts observed in leukemia and have to be distinguished from leukemia. The leukocytosis occurs initially because of *accelerated release* of cells from the bone marrow postmitotic reserve pool (caused by cytokines, including TNF and IL-1) and is therefore associated with a rise in the number of more immature neutrophils in the blood *(shift to the left)*. Prolonged infection also induces proliferation of precursors in the bone marrow, caused by increased production of colony-stimulating factors. Thus, the bone marrow output of leukocytes is increased to compensate for the loss of these cells in the inflammatory reaction. (See also the discussion of leukocytosis in Chapter 13 .) Most bacterial infections induce an increase in the blood neutrophil count, called *neutrophilia*. Viral infections, such as infectious mononucleosis, mumps, and German measles, cause an absolute increase in the number of lymphocytes

(lymphocytosis). In bronchial asthma, allergy, and parasitic infestations, there is an increase in the absolute number of eosinophils, creating an *eosinophilia*. Certain infections (typhoid fever and infections caused by some viruses, rickettsiae, and certain protozoa) are associated with a decreased number of circulating white cells *(leukopenia)*. Leukopenia is also encountered in infections that overwhelm patients debilitated by disseminated cancer, rampant tuberculosis, or severe alcoholism.

- Other manifestations of the acute-phase response include increased pulse and blood pressure; decreased sweating, mainly because of redirection of blood flow from cutaneous to deep vascular beds, to minimize heat loss through the skin; rigors (shivering), chills (search for warmth), anorexia, somnolence, and malaise, probably because of the actions of cytokines on brain cells.
- In severe bacterial infections *(sepsis)* the large amounts of organisms and LPS in the blood stimulate the production of enormous quantities of several cytokines, notably TNF and IL-1.[88,][89] As a result, circulating levels of these cytokines increase and the nature of the host response changes. High levels of cytokines cause various clinical manifestations such as disseminated intravascular coagulation, cardiovascular failure, and metabolic disturbance, which are described as *septic shock*; it is discussed in more detail in Chapter 4 .

2.2.10 Consequences of Defective or Excessive Inflammation

Now that we have described the process of inflammation and its outcomes, it is helpful to summarize the clinical and pathologic consequences of too much or too little inflammation.

- *Defective inflammation* typically results in increased susceptibility to infections, because the inflammatory response is a central component of the early defense mechanisms that immunologists call *innate immunity* (Chapter 6). It is also associated with delayed wound healing, because inflammation is essential for clearing damaged tissues and debris, and provides the necessary stimulus to get the repair process started.
- *Excessive inflammation* is the basis of many types of human disease. Allergies, in which individuals mount unregulated immune responses against commonly encountered environmental antigens, and autoimmune diseases, in which immune responses develop against normally tolerated self-antigens, are disorders in which the fundamental cause of tissue injury is inflammation (Chapter 6). In addition, as we mentioned at the outset, recent studies are pointing to an important role of inflammation in a wide variety of human diseases that are not primarily disorders of the immune system. These include atherosclerosis and ischemic heart disease, and some neurodegenerative diseases such as Alzheimer disease. Prolonged inflammation and the fibrosis that accompanies it are also responsible for much of the pathology in many infectious, metabolic, and other diseases. The specific diseases are discussed in relevant chapters later in the book.

Now that our discussion of the molecular and cellular events in acute and chronic inflammation is concluded, in Chapter 3 we consider the body's attempts to heal the damage, the process of *repair*. Repair begins almost as soon as the inflammatory reaction has started and involves several processes, including cell proliferation, angiogenesis, and collagen synthesis and deposition. Many aspects of repair were mentioned in this chapter, but the process is sufficiently complex and important to deserve its own chapter!

2.3 3. Tissue Renewal, Regeneration & Repair

2.3.1 Control of Normal Cell Proliferation & Tissue Growth

Injury to cells and tissues sets in motion a series of events that contain the damage and initiate the healing process. This process can be broadly separated into *regeneration* and *repair* (Fig. 3-1). Regeneration results in the complete restitution of lost or damaged tissue; repair may restore some original structures but can cause structural derangements. In healthy tissues, healing, in the form of regeneration or repair, occurs after practically any insult that causes tissue destruction, and is essential for the survival of the organism.[1]

Regeneration refers to the proliferation of cells and tissues to replace lost structures, such as the growth of an amputated limb in amphibians. In mammals, whole organs and complex tissues rarely regenerate after injury, and the term is usually applied to processes such as liver growth after partial resection or necrosis, but these processes consist of compensatory growth rather than true regeneration.[2] Regardless, the term *regeneration* is well established and is used throughout this book. Tissues with high proliferative capacity, such as the hematopoietic system and the epithelia of the skin and gastrointestinal (GI) tract, renew themselves continuously and can regenerate after injury, as long as the *stem cells* of these tissues are not destroyed.[3]

Repair most often consists of a combination of regeneration and *scar formation* by the deposition of collagen. The relative contribution of regeneration and scarring in tissue repair depends on the ability of the tissue to regenerate and the extent of the injury. For instance, a superficial skin wound heals through the regeneration of the surface epithelium. However, as discussed later, scar formation is the predominant healing process that occurs when the extracellular matrix (ECM) framework is damaged by severe injury (Fig. 3-2). Chronic inflammation that accompanies persistent injury also stimulates scar formation because of local production of growth factors and cytokines that promote fibroblast proliferation and collagen synthesis. The term *fibrosis* is used to describe the extensive deposition of collagen that occurs under these situations. ECM components are essential for wound healing, because they provide the framework for cell migration, maintain the correct cell polarity for the re-assembly of multilayer structures,[4] and participate in the formation of new blood vessels (angiogenesis). Furthermore, cells in the ECM (fibroblasts, macrophages, and other cell types) produce growth factors, cytokines, and chemokines that are critical for regeneration and repair. Although repair is a healing process, it may itself cause tissue dysfunction, as, for instance, in the development of atherosclerosis (Chapter 11).

Understanding the mechanisms of regeneration and repair requires some knowledge of the control of cell proliferation and signal transduction pathways, and the many functions of ECM components.

In this chapter we first discuss the principles of cell proliferation, the proliferative capacity of tissues, and the role of stem cells in tissue homeostasis. This is followed by an overview of growth factors and cell signaling mechanisms relevant to healing processes. We then discuss regenerative processes with emphasis on liver regeneration, and examine the properties of the ECM and its components. These sections lay the foundation for the consideration of the main features of wound healing and fibrosis.

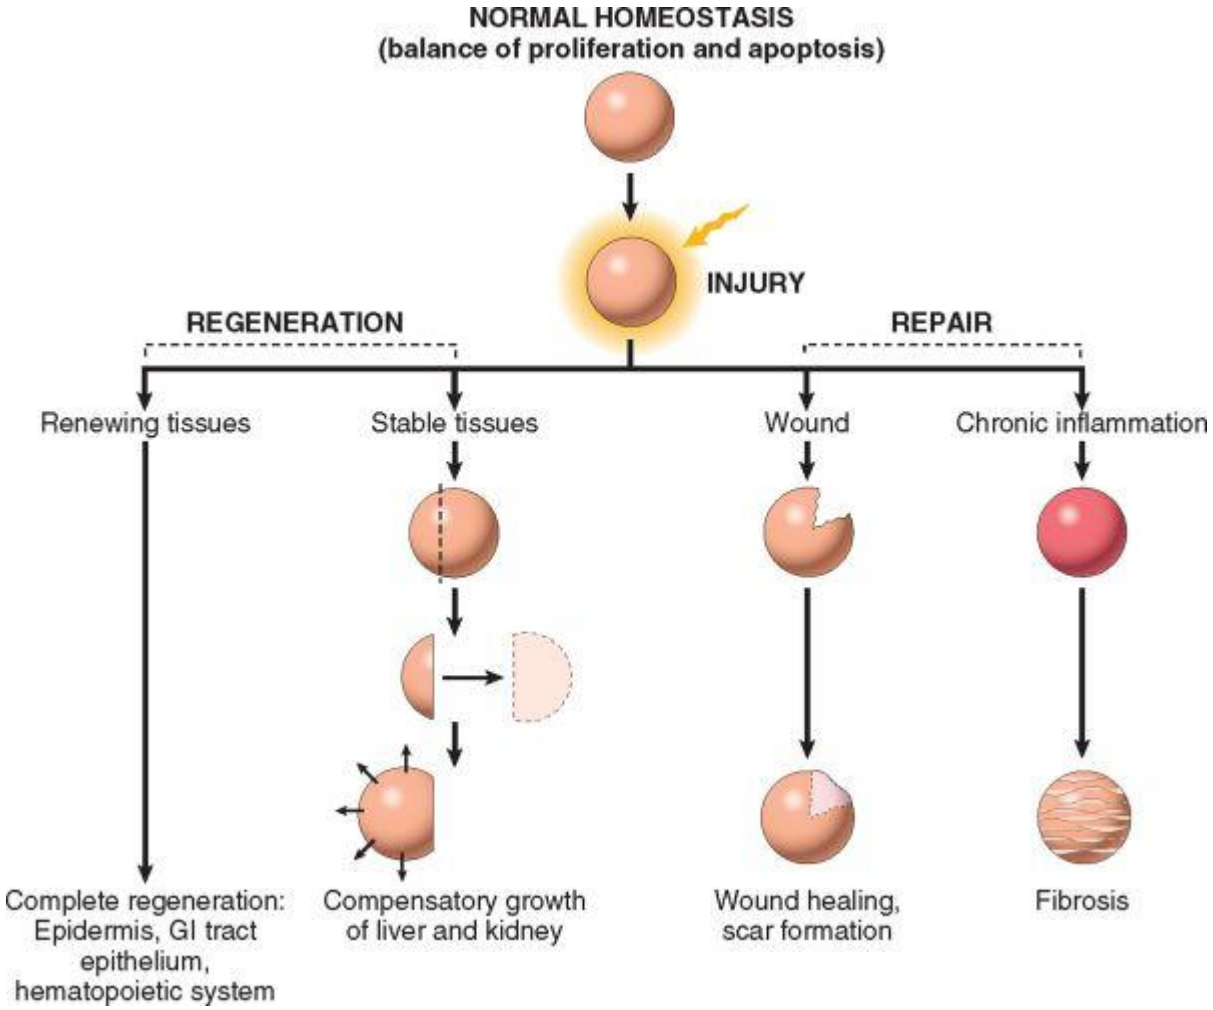

FIGURE 3-1 Overview of healing responses after injury. Healing after acute injury can occur by regeneration that restores normal tissue structure or by repair with scar formation. Healing in chronic injury involves scar formation and fibrosis (see text). GI, gastrointestinal.

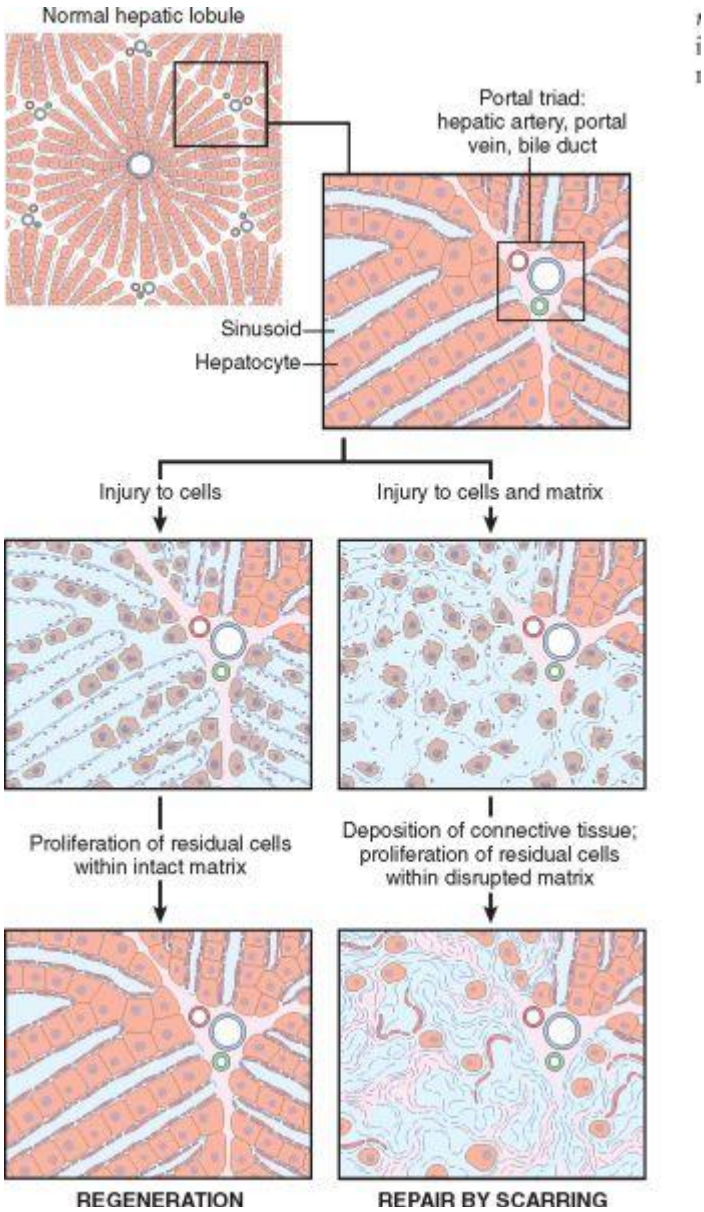

FIGURE 3-2 Role of the extracellular matrix in regeneration and repair. Liver regeneration with restoration of normal tissue after injury requires an intact cellular matrix. If the matrix is damaged the injury is repaired by fibrous tissue deposition and scar formation.

Control of Normal Cell Proliferation and Tissue Growth

In adult tissues the size of cell populations is determined by the rates of cell proliferation, differentiation, and death by apoptosis (Fig. 3-3), and increased cell numbers may result from either increased proliferation or decreased cell death.[5] *Apoptosis* is a physiologic process required for tissue homeostasis, but it can also be induced by a variety of pathologic stimuli (see Chapter 1). Differentiated cells incapable of replication are referred to as *terminally differentiated* cells. The impact of *differentiation* depends on the tissue under which it occurs: in some tissues differentiated cells are not replaced, while in others they die but are continuously replaced by new cells generated from stem cells (discussed in the next section).

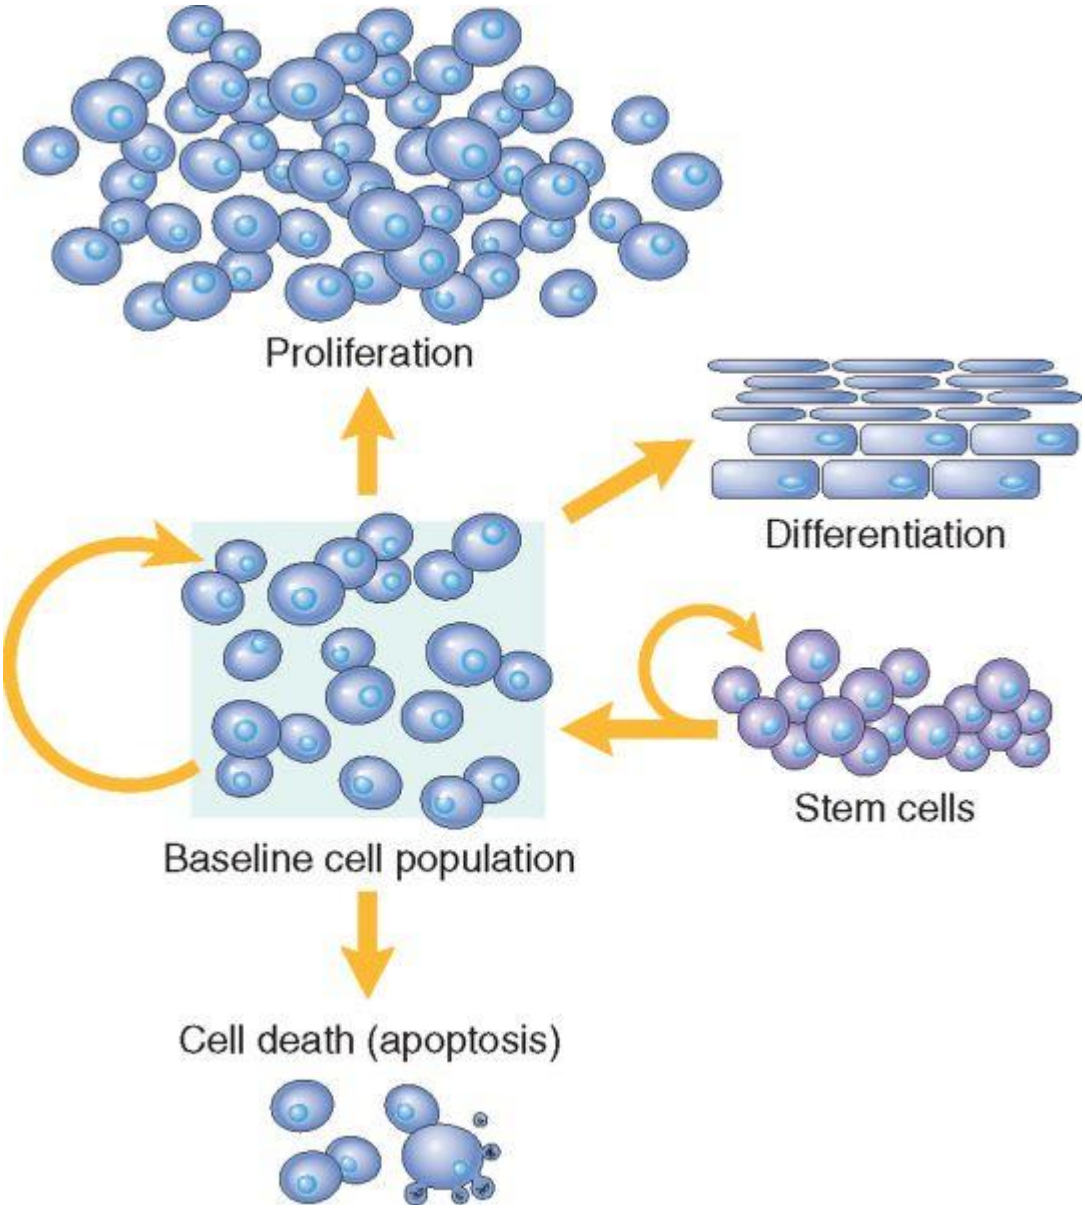

FIGURE 3-3 Mechanisms regulating cell populations. Cell numbers can be altered by increased or decreased rates of stem cell input, cell death due to apoptosis, or changes in the rates of proliferation or differentiation. *(Modified from McCarthy NJ et al: Apoptosis in the development of the immune system: growth factors, clonal selection and bcl-2. Cancer Metastasis Rev 11:157, 1992.)*

Cell proliferation can be stimulated by physiologic and pathologic conditions. The proliferation of endometrial cells under estrogen stimulation during the menstrual cycle and the thyroid-stimulating hormone–mediated replication of cells of the thyroid that enlarges the gland during pregnancy are examples of physiologic proliferation. Physiologic stimuli may become excessive, creating pathologic conditions such as nodular prostatic hyperplasia resulting from dihydrotestosterone stimulation (Chapter 21) and the development of nodular goiters in the thyroid as a consequence of increased serum levels of thyroid-stimulating hormone (Chapter 24). Cell proliferation is largely controlled by signals (soluble or contact-dependent) from the microenvironment that either stimulate or inhibit

proliferation. An excess of stimulators or a deficiency of inhibitors leads to net growth and, in the case of cancer, uncontrolled growth.

TISSUE PROLIFERATIVE ACTIVITY

The tissues of the body are divided into three groups on the basis of the proliferative activity of their cells: continuously dividing (labile tissues), quiescent (stable tissues), and nondividing (permanent tissues). This time-honored classification should be interpreted in the light of recent findings on stem cells and the reprogramming of cell differentiation.

- In *continuously dividing tissues* cells proliferate throughout life, replacing those that are destroyed. These tissues include surface epithelia, such as stratified squamous epithelia of the skin, oral cavity, vagina, and cervix; the lining mucosa of all the excretory ducts of the glands of the body (e.g., salivary glands, pancreas, biliary tract); the columnar epithelium of the GI tract and uterus; the transitional epithelium of the urinary tract, and cells of the bone marrow and hematopoietic tissues. In most of these tissues mature cells are derived from adult *stem cells*, which have a tremendous capacity to proliferate and whose progeny may differentiate into several kinds of cells (discussed in more detail later).
- *Quiescent tissues* normally have a low level of replication; however, cells from these tissues can undergo rapid division in response to stimuli and are thus capable of reconstituting the tissue of origin. In this category are the parenchymal cells of liver, kidneys, and pancreas; mesenchymal cells such as fibroblasts and smooth muscle; vascular endothelial cells; and lymphocytes and other leukocytes. The regenerative capacity of stable cells is best exemplified by the ability of the liver to regenerate after partial hepatectomy and after acute chemical injury. Fibroblasts, endothelial cells, smooth muscle cells, chondrocytes, and osteocytes are quiescent in adult mammals but proliferate in response to injury. Fibroblasts in particular can proliferate extensively, as in healing processes and fibrosis, discussed later in this chapter.
- *Nondividing tissues* contain cells that have left the cell cycle and cannot undergo mitotic division in postnatal life. To this group belong neurons and skeletal and cardiac muscle cells. If *neurons* in the central nervous system are destroyed, the tissue is generally replaced by the proliferation of the central nervous system–supportive elements, the glial cells. However, recent results demonstrate that limited neurogenesis from stem cells may occur in adult brains (discussed later). Although mature skeletal muscle cells do not divide, *skeletal muscle* does have regenerative capacity, through the differentiation of the *satellite cells* that are attached to the endomysial sheaths. *Cardiac muscle* has very limited, if any, regenerative capacity, and a large injury to the heart muscle, as may occur in myocardial infarction, is followed by scar formation.

STEM CELLS

Research on stem cells is at the forefront of modern-day biomedical investigation and stands at the core of a new field called *regenerative medicine*. The enthusiasm created by stem cell research derives from findings that challenge established views about cell differentiation, and from the hope that stem cells may one day be used to repair damaged human tissues, such as heart, brain, liver, and skeletal muscle.[3,][6,][7]

Stem cells are characterized by their self-renewal properties and by their capacity to generate differentiated cell lineages (Fig. 3-4). To give rise to these lineages, stem cells need to be maintained during the life of the organism. Such maintenance is achieved by two mechanisms[8]: (a) *obligatory asymmetric replication*, in which with each stem cell division, one of the daughter cells retains its self-renewing capacity while the other enters a differentiation pathway, and (b) *stochastic differentiation*, in which a stem cell population is maintained by the balance between stem cell divisions that generate either two self-renewing stem cells or two cells that will differentiate. In early stages of embryonic development, stem cells, known as *embryonic stem cells* or *ES cells*, are *pluripotent*, that is, they can generate all tissues of the body (Fig. 3-4). Pluripotent stem cells give rise to multipotent stem cells, which have more restricted developmental potential, and eventually produce differentiated cells from the three embryonic layers. The term *transdifferentiation* (discussed later) indicates a change in the lineage commitment of a stem cell.

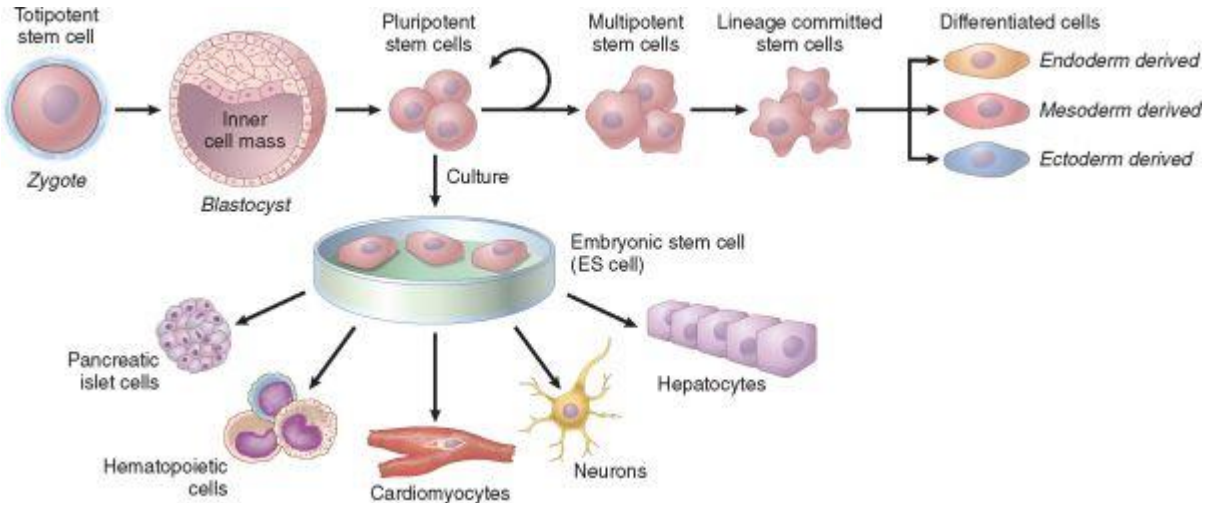

FIGURE 3-4 Stem cell generation and differentiation. The zygote, formed by the union of sperm and egg, divides to form blastocysts, and the inner cell mass of the blastocyst generates the embryo. The cells of the inner cell mass, known as embryonic stem (ES) cells, maintained in culture, can be induced to differentiate into cells of multiple lineages. In the embryo, pluripotent stem cells divide, but the pool of these cells is maintained (see text). As pluripotent cells differentiate, they give rise to cells with more restricted developmental capacity, and finally generate stem cells that are committed to specific lineages.

In adults, stem cells (often referred to as *adult stem cells* or *somatic stem cells)* with a more restricted capacity to generate different cell types have been identified in many tissues. They have been studied in detail in the skin, the lining of the gut, the cornea, and particularly in the hematopoietic tissue. An unexpected finding has been the discovery of stem cells and neurogenesis in areas of the central nervous system of adult animals and humans.[9] Somatic stem cells for the most part reside in special microenvironments called *niches* (Fig. 3-5), composed of mesenchymal, endothelial, and other cell types.[10,][11] It is believed *that niche cells generate or transmit stimuli that regulate stem cell self-renewal and the generation of progeny cells*. Recent groundbreaking research has now demonstrated that *differentiated cells of rodents and humans can be reprogrammed into pluripotent cells, similar to ES cells, by the transduction of genes encoding ES cell transcription factors*.[12,][13] These reprogrammed cells have been named *induced pluripotent stem cells (iPS cells)*. Their discovery has opened open an exciting new era in stem cell research and its applications.

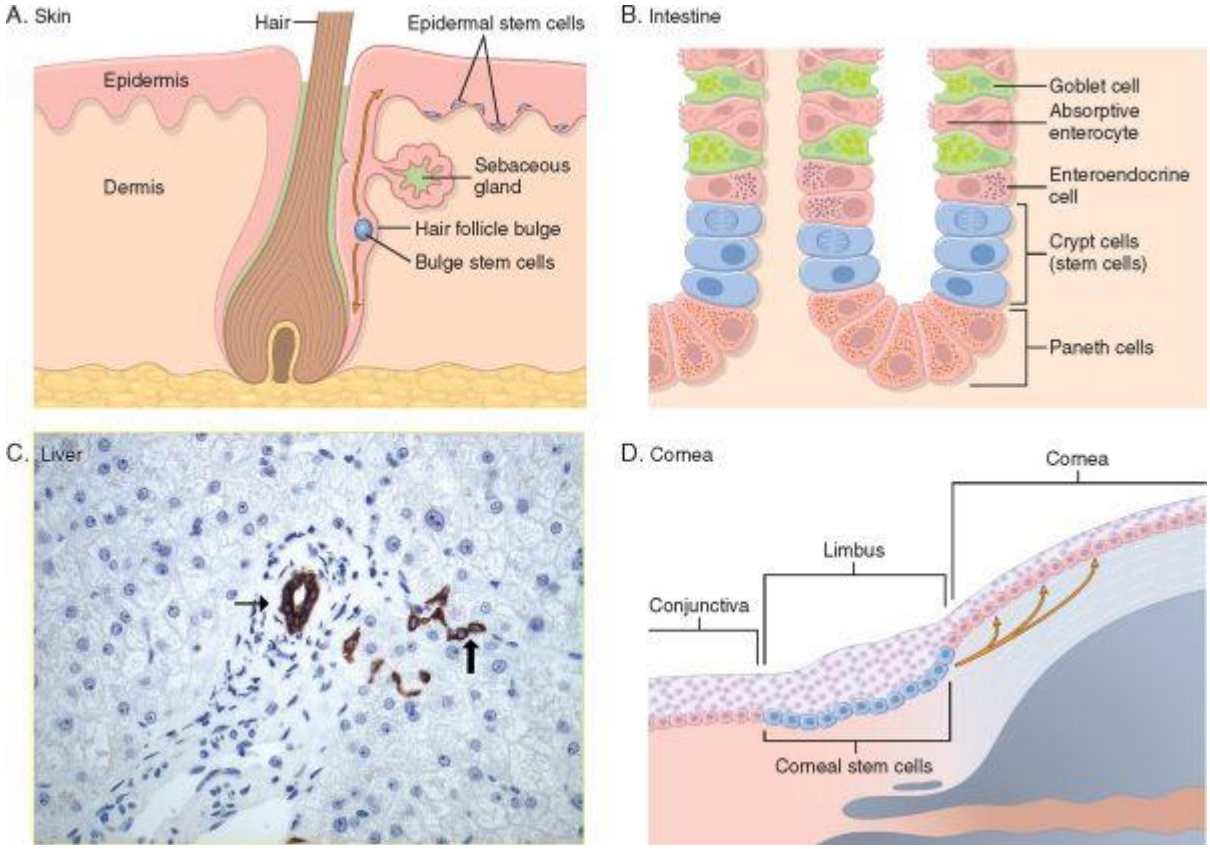

FIGURE 3-5 Stem cell niches in various tissues. **A**, Skin stem cells are located in the bulge area of the hair follicle, in sebaceous glands, and in the lower layer of the epidermis. **B**, Small intestine stem cells located near the base of a crypt, above Paneth cells (stem cells in the small intestine may also be located at the bottom of the crypt[25]). **C**, Liver stem (progenitor) cells, known as oval cells, are located in the canals of Hering *(thick arrow)*, structures that connect bile ductules *(thin arrow)* with parenchymal hepatocytes (bile duct and Hering canals are stained for cytokeratin 7). **D**, Corneal stem cells are located in the limbus region, between the conjunctiva and the cornea. ***(C**, courtesy of Tania Roskams, MD, University of Leuven, Leuven, Belgium; **D**, Courtesy of T-T Sun, MD, New York University, New York, NY.)*

We start our discussion of stem cells with a brief consideration of ES cells and the newly identified iPS cells. This is followed by a presentation on adult stem cells from a few selected tissues and the role they play in regeneration and repair.

Embryonic Stem Cells

The inner cell mass of blastocysts in early embryonic development contains pluripotent stem cells known as ES cells.[14] Cells isolated from blastocysts can be maintained in culture as undifferentiated cell lines or be induced to differentiate into specific lineages (see Fig. 3-4) such as heart and liver cells.[15]

The study of ES cells has had an enormous impact on biology and medicine:

- ES cells have been used to study the specific signals and differentiation steps required for the development of many tissues.
- *ES cells made possible the production of knockout mice, an essential tool to study the biology of particular genes and to develop models of human disease*. The first step in the production of knockout mice is the inactivation or deletion of a gene from cultured ES cells. The cells are then injected into blastocysts, which are implanted into the uterus of a surrogate mother. The genetically modified implanted blastocysts develop

into full embryos, as long as the gene defect does not cause embryonic lethality. Using similar techniques, "*knock-in*" mice have been developed, in which a mutated DNA sequence replaces the endogenous sequence.[16] Mice can also be produced with gene deficiencies that are specific for a single tissue or cell type, or to have "conditional gene deficiencies," that is, gene deficiencies that can be turned on and off in adult animals. Knockout mice have provided essential information about gene function in vivo. Thus far, more than 500 models of human diseases have been created using these animals.

- *ES cells may in the future be used to repopulate damaged organs*. ES cells capable of differentiating into insulin-producing pancreatic cells, nerve cells, myocardial cells, or hepatocytes have been implanted in animals with experimentally produced diabetes, neurologic defects, myocardial infarction, and liver damage, respectively. The effectiveness of these procedures in animals is under intense study, and there is much debate about the ethical issues associated with the derivation of ES cells from human blastocytes.

Reprogramming of Differentiated Cells: Induced Pluripotent Stem Cells

Differentiated cells of adult tissues can be reprogrammed to become pluripotent by transferring their nucleus to an enucleated oocyte. The oocytes implanted into a surrogate mother can generate cloned embryos that develop into complete animals. This procedure, known as *reproductive cloning*, was successfully demonstrated in 1997 by the cloning of Dolly the sheep.[17] There has been great hope that the technique of nuclear transfer to oocytes may be used for *therapeutic cloning* in the treatment of human diseases (illustrated in Fig. 3-6). In this technique the nucleus of a skin fibroblast from a patient is introduced into an enucleated human oocyte to generate ES cells, which are kept in culture, and then induced to differentiate into various cell types. In principle, these cells can then be transplanted into the patient to repopulate damaged organs.[18] In addition to the ethical issues associated with this technique, therapeutic as well as reproductive cloning are inefficient and often inaccurate. One of the main reasons for the inaccuracy is the deficiency in histone methylation in reprogrammed ES cells, which results in improper gene expression.

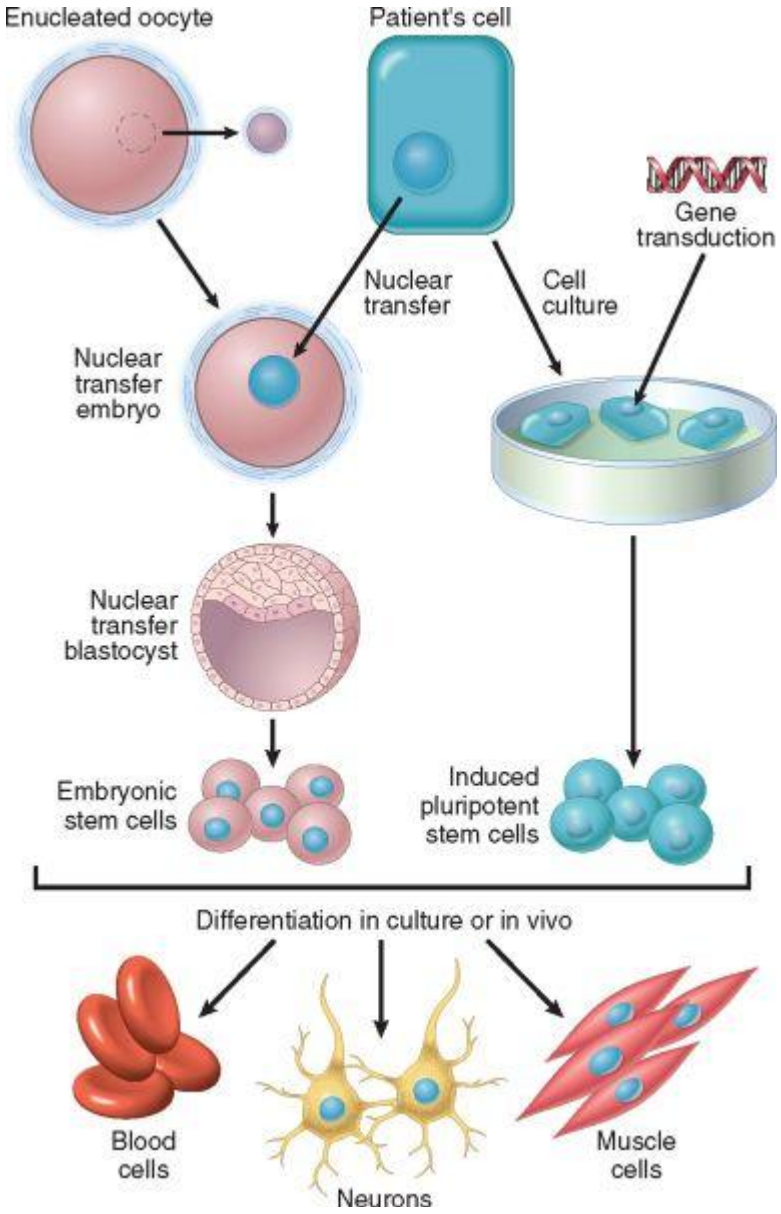

FIGURE 3-6 Steps involved in stem cell therapy, using embryonic stem (ES) cells or induced pluripotent stem (iPS) cells. *Left side*, Therapeutic cloning using ES cells. The diploid nucleus of an adult cell from a patient is introduced into an enucleated oocyte. The oocyte is activated, and the zygote divides to become a blastocyst that contains the donor DNA. The blastocyst is dissociated to obtain ES cells. *Right side*, Stem cell therapy using iPS cells. The cells of a patient are placed in culture and transduced with genes encoding transcription factors, to generate iPS cells. Both ES and iPS cells are capable of differentiating into various cell types. The goal of stem cell therapy is to repopulate damaged organs of a patient or to correct a genetic defect, using the cells of the same patient to avoid immunological rejection. *(Modified from Hochedlinger K, Jaenisch R: Nuclear transplantation, embryonic stem cells, and the potential for cell therapy. N Engl J Med 349:275–286, 2003.)*

Until recently there were no clues about the mechanisms that maintain pluripotency of ES cells. A series of landmark experiments have now demonstrated that the *pluripotency of mouse ES cells depends on the expression of four transcription factors, Oct3/4, Sox2, c-myc, and Klf4*, while the homeobox protein *Nanog* (named after Tir na n'Og, the Celtic land of the ever-young) acts to prevent differentiation. [19] [20] [21] [22] *Human fibroblasts from adults and newborns have been reprogrammed into pluripotent cells by the transduction of four genes encoding transcription factors* (*Oct3/4, Sox2, c-myc* and *Kfl4* in one

laboratory; *Oct3/4*, *Sox2*, *Nanog*, and *Lin28* in experiments from another laboratory).[12,][13] The reprogrammed cells, known as *iPS cells*, are able to generate cells from endodermal, mesodermal, and ectodermal origin. They have also been used to rescue mice with a model of sickle cell anemia, proving that they function in vivo even after genetic manipulation and transplantation.[23] More recently, pluripotent iPS cells were generated by transfecting mouse hepatocytes, gastric cells, and terminally differentiated mature B lymphocytes with genes for the same four transcription factors.[24,][25] Thus, *iPS cells may become a source of cells for patient-specific stem cell therapy, without the involvement of nuclear transfer into oocytes* (see Fig. 3-6). To make the dream of using iPS cells in human regenerative medicine a reality (iPS cells have been called ES cells without embryos), much additional work is required, including the development of new methods for gene delivery and the replacement of c-myc and Kfl4, which are oncogenes.[26] In any event, exciting new achievements can be expected in the near future from work on ES cells, iPS cells, and cell reprogramming.

Adult (Somatic) Stem Cells

In the adult organism, stem cells are present in tissues that continuously divide such as the bone marrow, the skin, and the lining of the GI tract. Stem cells may also be present in organs such as liver, pancreas, and adipose tissue, in which, under normal conditions, they do not actively produce differentiated cell lineages. Stem cells divide very slowly in most tissues, but there is evidence that they may be continuously cycling in the small intestine epithelium.[27] Regardless of their proliferative activity, somatic stem cells generate rapidly dividing cells known as *transit amplifying cells*. These cells lose the capacity of self-perpetuation, and give rise to cells with restricted developmental potential known as *progenitor cells*. Regrettably, the terms *stem cell* and *progenitor cell* continue to be used interchangeably, despite the fact that cell lineage hierarchies have been well defined only for hemopoietic stem cells (HSC).

A change in the differentiation of a cell from one type to another is known as *transdifferentiation*, and the capacity of a cell to transdifferentiate into diverse lineages is referred to as *developmental plasticity*. HSCs maintained in culture have been shown to transdifferentiate into other cell types, such as hepatocytes and neurons. In addition, some studies indicated that when injected in appropriate sites, HSC could transdifferentiate in vivo into cells such as neurons, skeletal and cardiac myocytes, and hepatocytes. However, *many of the findings attributed to HSC transdifferentiation in vivo have been difficult to reproduce*, because cells assumed to be the product of transdifferentiation could not be detected or were present at a very low frequency.[28] Moreover, the reported generation of neurons, skeletal myocytes, and hepatocytes from injected HSCs seems to be caused primarily by *fusion of the hematopoietic cells or their progeny with differentiated or progenitor cells* of the appropriate tissues.[29,][30] *Hence, so far, there is little conclusive evidence that transdifferentiation of HSCs contributes to tissue renewal in normal homeostasis or tissue regeneration and repair after injury*.[31] On the other hand, it is possible that HSCs may migrate to sites of inflammation and injury, where they generate innate immune cells, or release growth factors and cytokines that promote repair and cell replication through a paracrine effect.[32] The issue of transdifferentiation and developmental plasticity in tissue repopulation continues to be explored.

Stem Cells in Tissue Homeostasis

To illustrate the importance of stem cells in tissue maintenance and regeneration, we briefly discuss stem cells in the bone marrow, skin, gut, liver, brain, muscle, and cornea.

- *Bone marrow*. The bone marrow contains HSCs and stromal cells (also known as multipotent stromal cells, mesenchymal stem cells or MSCs).
    - *Hematopoietic Stem Cells*. HSCs generate all of the blood cell lineages (Chapter 13), can

reconstitute the bone marrow after depletion caused by disease or irradiation, and are widely used for the treatment of hematologic diseases.[33] They can be collected directly from the bone marrow, from umbilical cord blood, and from the peripheral blood of individuals receiving cytokines such as granulocyte-macrophage colony-stimulating factor, which mobilize HSCs.[34] It is estimated that the human bone marrow produces approximately 1.5×10^6 blood cells per second, an astonishing rate of cell-generating activity!

- *Marrow Stromal Cells*. MSCs are multipotent. *They have potentially important therapeutic applications, because they can generate chondrocytes, osteoblasts, adipocytes, myoblasts, and endothelial cell precursors depending on the tissue to which they migrate*. MSCs migrate to injured tissues and generate stromal cells or other cell lineages, but do not seem to participate in normal tissue homeostasis.[35,][36]

- *Liver. The liver contains stem cells/progenitor cells in the canals of Hering* (see Fig. 3-5), the junction between the biliary ductular system and parenchymal hepatocytes (Chapter 18). Cells located in this niche can give rise to a population of precursor cells known as *oval cells*, which are bipotential progenitors, capable of differentiating into hepatocytes and biliary cells.[2,][37] In contrast to stem cells in proliferating tissues, liver stem cells function as a secondary or reserve compartment activated only when hepatocyte proliferation is blocked. Oval cell proliferation and differentiation are prominent in the livers of patients recovering from fulminant hepatic failure, in liver tumorigenesis, and in some cases of chronic hepatitis and advanced liver cirrhosis.

- *Brain. Neurogenesis from neural stem cells (NSCs) occurs in the brain of adult rodents and humans*. Thus, the long-established dogma that no new neurons are generated in the brain of normal adult mammals is now known to be incorrect. NSCs (also known as *neural precursor cells*), capable of generating neurons, astrocytes, and oligodendrocytes, have been identified in two areas of adult brains, the subventricular zone (SVZ) and the dentate gyrus of the hippocampus.[38] It is not clear if newly generated neurons in the adult human brain are integrated into neural circuits under physiologic and pathologic conditions, and, more broadly, what might be the purpose of adult neurogenesis.[39] There is much hope that stem cell transplantation, or the induction of differentiation of endogenous NSCs, may be used in treatment of stroke, neurodegenerative disorders such as Parkinson and Alzheimer diseases, and spinal cord injury.[40]

- *Skin. Stem cells are located in three different areas of the epidermis: the hair follicle bulge, interfollicular areas of the surface epidermis, and sebaceous glands* (see Fig. 3-5).[41] The *bulge area of the hair follicle* constitutes a niche for stem cells that produce all of the cell lineages of the hair follicle.[42] *Interfollicular stem cells are scattered individually in the epidermis* and are not contained in niches. They divide infrequently but generate transit amplifying cells that generate the differentiated epidermis.[43] The human epidermis has a high turnover rate of about 4 weeks. Bulge stem cells have been characterized in mice and humans.[44] They contribute to the replenishment of surface epidermal cells after skin wounding but not during normal homeostasis. Their activation is regulated by stimulatory signals from the *Wnt pathway and inhibition of signaling from the bone morphogenetic protein (BMP) system*.

- *Intestinal epithelium. In the small intestine, crypts are monoclonal structures derived from single stem cells: the villus is a differentiated compartment that contains cells from multiple crypts* (see Fig. 3-5). Stem cells in small intestine crypts regenerate the crypt in 3 to 5 days.[45] As with skin stem cells, *the Wnt and BMP pathways are important in the regulation of proliferation and differentiation of intestinal stem cells*. Stem cells may be located immediately above Paneth cells in the small intestine, or at the base of the crypt, as is the case in the colon.[27,][46]

- *Skeletal and cardiac muscle. Skeletal muscle myocytes do not divide, even after injury; growth and regeneration of injured skeletal muscle occur by replication of satellite cells*. These cells, located beneath the myocyte basal lamina, constitute a reserve pool of stem cells that can generate differentiated myocytes after injury.[47] Active Notch signaling, triggered by up-regulation of delta-like (Dll) ligands, stimulates the proliferation of satellite cells (Notch signaling is discussed later in “Mechanisms of Angiogenesis”). The presence of stem cells in the heart continues to be debated. It has been proposed that the heart may contain progenitor-like cells with the capacity to generate progeny after injury, but not during physiologic aging.[48,][49]

- *Cornea*. The transparency of the cornea depends on the integrity of the outermost corneal epithelium, which is maintained by *limbal stem cells (LSCs)*. These cells are located at the junction between the epithelium of the cornea and the conjunctiva[50] (see Fig. 3-5). Hereditary or acquired conditions that result in LSC deficiency and corneal opacification can be treated by limbal transplantation or LSC grafting. Animal experiments indicate that it might also be possible to correct the loss of photoreceptors that occurs in *degenerative diseases of the retina* by transplanting retinal stem cells.[51]

2.3.2 Cell Cycle & the Regulation of Cell Replication

Cell proliferation is a tightly regulated process that involves a large number of molecules and interrelated pathways. To understand how cells proliferate during regeneration and repair, it is useful to summarize the key features of the normal cell cycle and its regulation. We discuss the details of the cell cycle and its abnormalities in Chapter 7 , in the context of cancer. Here we summarize some salient features of the process of cellular proliferation.

The replication of cells is stimulated by growth factors or by signaling from ECM components through integrins. To achieve DNA replication and division, the cell goes through a tightly controlled sequence of events known as the *cell cycle*. *The cell cycle consists of G_1 (presynthetic), S (DNA synthesis), G_2 (premitotic), and M (mitotic) phases. Quiescent cells that have not entered the cell cycle are in the G_0 state* (Fig. 3-7). Each cell cycle phase is dependent on the proper activation and completion of the previous one, and the cycle stops at a place at which an essential gene function is deficient. Because of its central role in maintaining tissue homeostasis and regulating physiologic growth processes such as regeneration and repair, *the cell cycle has multiple controls and redundancies, particularly during the transition between the G_1 and S phases*. These controls include activators and inhibitors, as well as sensors that are responsible for checkpoints, described below.[52]

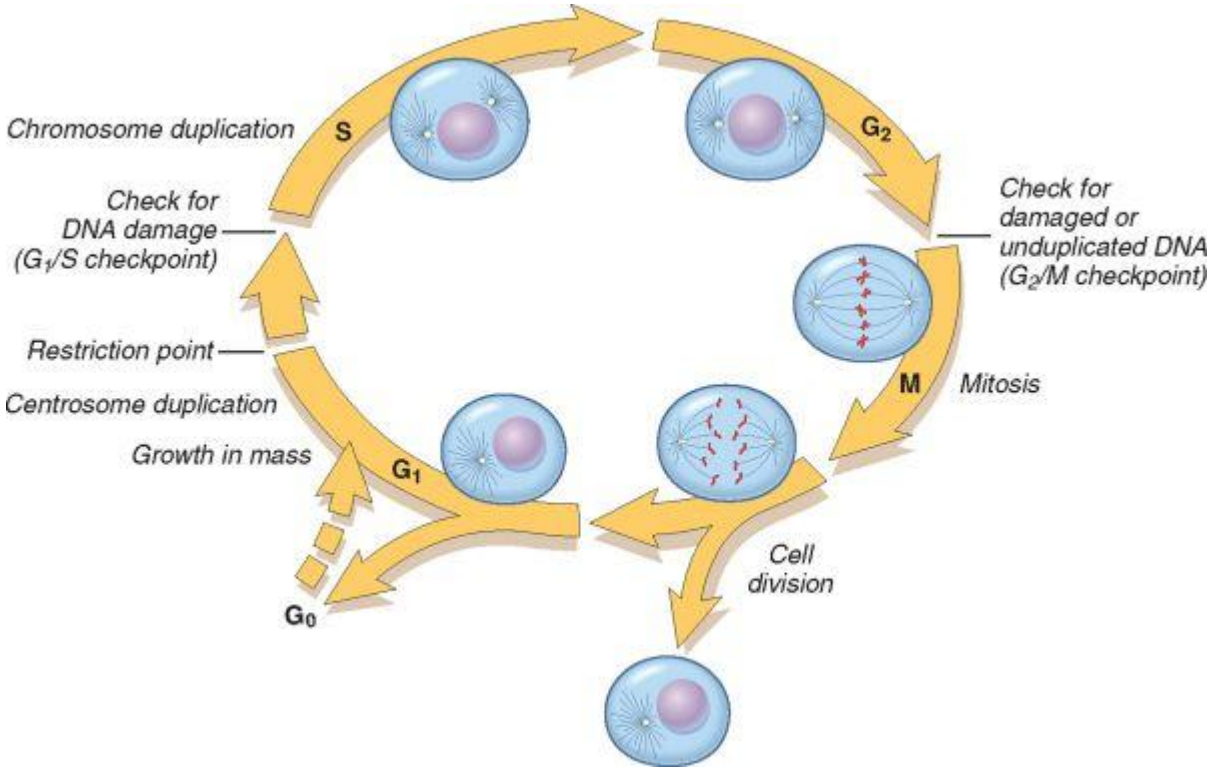

FIGURE 3-7 Cell cycle landmarks. The figure shows the cell cycle phases (G_0, G_1, G_2, S, and M), the location of the G_1 restriction point, and the G_1/S and G_2/M cell cycle checkpoints. Cells from labile tissues such as the epidermis and the GI tract may cycle continuously; stable cells such as hepatocytes are quiescent but can enter the cell cycle; permanent cells such as neurons and cardiac myocytes have lost the capacity to proliferate. *(Modified from Pollard TD, Earnshaw WC: Cell Biology. Philadelphia, Saunders, 2002.)*

Cells can enter G_1 either from G_0 (quiescent cells) or after completing mitosis (continuously replicating cells). Quiescent cells first must go through the transition from G_0 to G_1, the first decision step, which functions as a gateway to the cell cycle. This transition involves the transcriptional activation of a large set of genes, including various proto-oncogenes and genes required for ribosome synthesis and protein translation. Cells in G_1 progress through the cycle and reach a critical stage at the G_1/S transition, known as a *restriction point*, a ratelimiting step for replication (see Fig. 3-7). Upon passing this restriction point, normal cells become irreversibly committed to DNA replication. *Progression through the cell cycle, particularly at the G_1/S transition, is tightly regulated by proteins called cyclins and associated enzymes called cyclin-dependent kinases (CDKs*). CDKs acquire catalytic activity by binding to and forming complexes with the cyclins. Activated CDKs in these complexes drive the cell cycle by phosphorylating proteins that are critical for cell cycle transitions. One such protein is the retinoblastoma susceptibility (RB) protein, which normally prevents cells from replicating by forming a tight, inactive complex with the transcription factor E2F. Phosphorylation of RB causes its release, which activates E2F and allows it to stimulate transcription of genes whose products drive cells through the cycle. More details are provided in Chapter 7 .

The activity of cyclin-CDK complexes is tightly regulated by *CDK inhibitors*. Some growth factors shut off production of these inhibitors. Embedded in the cell cycle are surveillance mechanisms that are geared primarily at sensing damage to DNA and chromosomes. These quality control checks are called *checkpoints*; they ensure that cells with damaged DNA or chromosomes do not complete replication.[53] The G_1/S checkpoint monitors the integrity of DNA before replication, whereas the G_2/M checkpoint checks DNA after replication and monitors whether the cell can safely enter mitosis. When cells sense DNA damage, checkpoint activation delays the cell cycle and triggers DNA repair mechanisms. If DNA damage is too severe to be repaired, the cells are eliminated by apoptosis, or enter a nonreplicative state called *senescence*, primarily through p53-dependent mechanisms. Checkpoint defects that allow cells with DNA strand breaks and chromosome abnormalities to divide produce mutations in daughter cells that may lead to neoplasia (Chapter 7).[54]

GROWTH FACTORS

The proliferation of many cell types is driven by polypeptides known as growth factors. These factors, which can have restricted or multiple cell targets, may also promote cell survival, locomotion, contractility, differentiation, and angiogenesis, activities that may be as important as their growth-promoting effects. All growth factors function as *ligands* that bind to specific *receptors*, which deliver signals to the target cells. These signals stimulate the transcription of genes that may be silent in resting cells, including genes that control *cell cycle entry and progression*. Table 3-1 lists some of the most important growth factors involved in tissue regeneration and repair. Here we review only those that have major roles in these processes. Other growth factors are alluded to in various sections of the book.

TABLE 3-1 -- Growth Factors and Cytokines Involved in Regeneration and Wound Healing

Growth Factor	Symbol	Source	Functions
Epidermal growth α	EGF	Platelets, macrophages, saliva, urine, milk, plasma	Mitogenic for keratinocytes and fibroblasts; stimulates keratinocyte migration and granulation tissue formation
Transforming growth factor α	TGF-α	Macrophages, T lymphocytes, keratinocytes, and many tissues	Similar to EGF; stimulates replication of hepatocytes and most epithelial cells
Heparin-binding EGF	HB-EGF	Macrophages, mesenchymal cells	Keratinocyte replication

Growth Factor	Symbol	Source	Functions
Hepatocyte growth factor/scatter factor	HGF	Mesenchymal cells	Enhances proliferation of hepatocytes, epithelial cells, and endothelial cells; increases cell motility, keratinocyte replication
Vascular endothelial cell growth factor (isoforms A, B, C, D)	VEGF	Many types of cells	Increases vascular permeability; mitogenic for endothelial cells (see Table 3-3); angiogenesis
Platelet-derived growth factor (isoforms A, B, C, D)	PDGF	Platelets, macrophages, endothelial cells, keratinocytes, smooth muscle cells	Chemotactic for PMNs, macrophages, fibroblasts, and smooth muscle cells; activates PMNs, macrophages, and fibroblasts; mitogenic for fibroblasts, endothelial cells, and smooth muscle cells; stimulates production of MMPs, fibronectin, and HA; stimulates angiogenesis and wound contraction
Fibroblast growth factor 1 (acidic), 2 (basic), and family	FGF	Macrophages, mast cells, T lymphocytes, endothelial cells, fibroblasts	Chemotactic for fibroblasts; mitogenic for fibroblasts and keratinocytes; stimulates keratinocyte migration, angiogenesis, wound contraction, and matrix deposition
Transforming growth factor β (isoforms 1, 2, 3); other members of the family are BMPs and activin	TGF-β	Platelets, T lymphocytes, macrophages, endothelial cells, keratinocytes, smooth muscle cells, fibroblasts	Chemotactic for PMNs, macrophages, lymphocytes, fibroblasts, and smooth muscle cells; stimulates TIMP synthesis, angiogenesis, and fibroplasia; inhibits production of MMPs and keratinocyte proliferation
Keratinocyte growth factor (also called FGF-7)	KGF	Fibroblasts	Stimulates keratinocyte migration, proliferation, and differentiation
Tumor necrosis factor	TNF	Macrophages, mast cells, T lymphocytes	Activates macrophages; regulates other cytokines; multiple functions

Modified from Schwartz SI: Principles of Surgery. New York, McGraw-Hill, 1999.

BMP, bone morphogenetic proteins; HA, hyaluronate; MMPs, matrix metalloproteinases; PMNs, polymorphonuclear leukocytes; TIMP, tissue inhibitor of MMP.

Epidermal Growth Factor (EGF) and Transforming Growth Factor α (TGF-α).

These two factors belong to the EGF family and share a common receptor (EGFR).[55] EGF is mitogenic for a variety of epithelial cells, hepatocytes, and fibroblasts, and is widely distributed in tissue secretions and fluids. In healing wounds of the skin, EGF is produced by keratinocytes, macrophages, and other inflammatory cells that migrate into the area. TGF-α was originally extracted from sarcoma virus–transformed cells and is involved in epithelial cell proliferation in embryos and adults, and in malignant transformation of normal cells to cancer. TGF-α has homology with EGF, binds to EGFR, and shares most of the biologic activities of EGF. The "EGF receptor" is actually a family of four membrane receptors with intrinsic tyrosine kinase activity. The best-characterized EGFR is referred to as EGFR1, ERB B1, or simply EGFR. It responds to EGF, TGF-α, and other ligands of the EGF family, such as *HB-EGF* (*heparin-binding EGF*) *and amphiregulin*. *EGFR1 mutations and amplification have been detected in cancers of the lung, head and neck, and breast, glioblastomas, and other cancers, leading to the development of new types of treatments for these conditions*. The *ERB B2 receptor* (also known as *HER-2* or HER2/Neu), whose main ligand has not been identified, has received great attention because it is overexpressed in a subset of breast cancers and is an important therapeutic target.

Hepatocyte Growth Factor (HGF).

HGF was originally isolated from platelets and serum. Subsequent studies demonstrated that it is identical to a previously identified growth factor isolated from fibroblasts known as *scatter factor*.[56] The factor is often referred to as HGF/SF, but in this chapter we will use the simpler notation, HGF.

HGF has mitogenic effects on hepatocytes and most epithelial cells, including cells of the biliary epithelium, and epithelial cells of the lungs, kidney, mammary gland, and skin. HGF acts as a morphogen in embryonic development, promotes cell scattering and migration, and enhances survival of hepatocytes. It is produced by fibroblasts and most mesenchymal cells, endothelial cells, and liver nonparenchymal cells. It is produced as an inactive single-chain form (pro-HGF) that is activated by serine proteases released in damaged tissues. The receptor for HGF, c-MET, is often highly expressed or mutated in human tumors, especially in renal and thyroid papillary carcinomas. HGF signaling is required for survival during embryonic development, as demonstrated by defects in the development of muscles, kidney, liver, and brain, and the lethality of knockout mice that lack c-*met*. Several HGF and c-MET inhibitors are presently being evaluated in cancer therapy clinical trials.

Platelet-Derived Growth Factor (PDGF).

PDGF is a family of several closely related proteins, each consisting of two chains. Three isoforms of PDGF (AA, AB, and BB) are secreted as biologically active molecules. The more recently identified isoforms PDGF-CC and PDGF-DD require extracellular proteolytic cleavage to release the active growth factor.[57] All PDGF isoforms exert their effects by binding to two cell surface receptors, designated PDGFR α and β, which have different ligand specificities. PDGF is stored in platelet granules and is released on platelet activation. It is produced by a variety of cells, including activated macrophages, endothelial cells, smooth muscle cells, and many tumor cells. PDGF causes migration and proliferation of fibroblasts, smooth muscle cells, and monocytes to areas of inflammation and healing skin wounds, as demonstrated by defects in these functions in mice deficient in either the A or the B chain of PDGF. PDGF-B and C participate in the activation of hepatic stellate cells in the initial steps of liver fibrosis (Chapter 18) and stimulate wound contraction.

Vascular Endothelial Growth Factor (VEGF).

VEGFs are a family of homodimeric proteins that include *VEGF-A (referred throughout as VEGF*), *VEGF-B, VEGF*-C, *VEGF-D*, and *PIGF* (*placental growth factor*).[58] VEGF is a potent inducer of blood vessel formation in early development *(vasculogenesis)* and has a central role in the growth of new blood vessels *(angiogenesis)* in adults (see Table 3-3). *It promotes angiogenesis in chronic inflammation, healing of wounds, and in tumors* (discussed later in this chapter, in "Mechanisms of Angiogenesis"). Mice that lack a single VEGF allele (heterozygous VEGF knockout mice) die during embryonic development as a result of defective vasculogenesis and hematopoiesis. VEGF family members signal through three tyrosine kinase receptors: VEGFR-1, VEGFR-2, and VEGFR-3. VEGFR-2, located in endothelial cells and many other cell types, is the main receptor for the vasculogenic and angiogenic effects of VEGF. The role of VEGFR-1 is less well understood, but it may facilitate the mobilization of endothelial stem cells and has a role in inflammation. VEGF-C and VEGF-D bind to VEGFR-3 and act on lymphatic endothelial cells to induce the production of lymphatic vessels *(lymphangiogenesis)*.

TABLE 3-3 -- Vascular Endothelial Growth Factor (VEGF)

Proteins	Family members: VEGF (VEGF-A), VEGF-B, VEGF-C, VEGF-D
	Dimeric glycoprotein with multiple isoforms

	Targeted mutations in VEGF result in defective vasculogenesis and angiogenesis.
Production	Expressed at low levels in a variety of adult tissues and at higher levels in a few sites, such as podocytes in the glomerulus and cardiac myocytes
Inducing agents	Hypoxia
	TGF-β
	PDGF
	TGF-α
Receptors	VEGFR-1
	VEGFR-2
	VEGFR-3 (lymphatic endothelial cells)
	Targeted mutations in the receptors result in lack of vasculogenesis
Functions	Promotes angiogenesis
	Increases vascular permeability
	Stimulates endothelial cell migration
	Stimulates endothelial cell proliferation
	VEGF-C selectively induces hyperplasia of lymphatic vasculature
	Up-regulates endothelial expression of plasminogen activator, plasminogen activator inhibitor 1, and collagenase

PDGF, platelet-derived growth factor; TGF-β, -α, transforming growth factor beta, alpha.

Fibroblast Growth Factor (FGF).

This is a family of growth factors containing more than 20 members, of which acidic FGF (aFGF, or FGF-1) and basic FGF (bFGF, or FGF-2) are the best characterized.[59] FGFs transduce signals through four tyrosine kinase receptors (FGFRs 1–4). FGF-1 binds to all receptors; FGF-7 is referred to as *keratinocyte growth factor* or *KGF*. Released FGFs associate with heparan sulfate in the ECM, which can serve as a reservoir for the storage of inactive factors. FGFs contribute to wound healing responses, hematopoiesis, angiogenesis, development, and other processes through several functions:

- *Wound repair:* FGF-2 and KGF (FGF-7) contribute to re-epithelialization of skin wounds.
- *New blood vessel formation (angiogenesis):* FGF-2, in particular, has the ability to induce new blood vessel formation (discussed later).
- *Hematopoiesis:* FGFs have been implicated in the differentiation of specific lineages of blood cells and development of bone marrow stroma.
- *Development:* FGFs play a role in skeletal and cardiac muscle development, lung maturation, and the specification of the liver from endodermal cells.

Transforming Growth Factor β (TGF-β) and Related Growth Factors.

TGF-β belongs to a superfamily of about 30 members that includes three TGF-β isoforms (TGF-β1, TGF-β2, TGF-β3) and factors with wide-ranging functions, such as BMPs, activins, inhibins, and müllerian inhibiting substance.[60] TGF-β1 has the most widespread distribution in mammals and will be referred to as TGF-β. It is a homodimeric protein produced by a variety of different cell types, including platelets, endothelial cells, lymphocytes, and macrophages. Native TGF-β is synthesized as a precursor

protein, which is secreted and then proteolytically cleaved to yield the biologically active growth factor and a second *latent* component. Active TGF-β binds to two cell surface receptors (types I and II) with serine/threonine kinase activity and triggers the phosphorylation of cytoplasmic transcription factors called *Smads* (of which there are several forms, e.g., Smad 1, 2, 3, 5, and 8). These phosphorylated Smads in turn form heterodimers with Smad 4, which enter the nucleus and associate with other DNA-binding proteins to activate or inhibit gene transcription. TGF-β has multiple and often opposing effects depending on the tissue and the type of injury. Agents that have multiple effects are called pleiotropic; because of the large diversity of TGF-β effects, it has been said that TGF-β is pleiotropic with a vengeance.

- *TGF-β is a growth inhibitor for most epithelial cells*. It blocks the cell cycle by increasing the expression of cell cycle inhibitors of the Cip/Kip and INK4/ARF families (see Chapter 7). The effects of TGF-β on mesenchymal cells depend on the tissue environment, but it can promote invasion and metastasis during tumor growth. Loss of TGF-β receptors frequently occurs in human tumors, providing a proliferative advantage to tumor cells. At the same time TGF-β expression may increase in the tumor microenvironment, creating stromal-epithelial interactions that enhance tumor growth and invasion.
- *TGF-β is a potent fibrogenic agent* that stimulates fibroblast chemotaxis and enhances the production of collagen, fibronectin, and proteoglycans. It inhibits collagen degradation by decreasing matrix proteases and increasing protease inhibitor activities. TGF-β is involved in the development of fibrosis in a variety of chronic inflammatory conditions particularly in the lungs, kidney, and liver. High TGF-β expression also occurs in hypertrophic scars (discussed later), systemic sclerosis (Chapter 6), and the Marfan syndrome (Chapter 5).
- *TGF-β has a strong anti-inflammatory effect but may enhance some immune functions*. Knockout mice lacking the *TGF-β1* gene in T cells have defects in regulatory T cells leading to widespread inflammation with abundant T-cell proliferation and CD4+ differentiation into T_H1 and T_H2 helper cells. However, TGF-β also enhances the development of interleukin-17 (IL-17)–producing T cells (T_H17) that may be involved in autoimmune tissue injury, and stimulates the production of IgA in the gut mucosa.

Cytokines.

Cytokines have important functions as mediators of inflammation and immune responses (Chapter 6). Some of these proteins can also be considered as growth factors, because they have growth-promoting activities for a variety of cells. Cytokines are discussed in Chapters 2 and 6 . Tumor necrosis factor (TNF) and IL-1 participate in wound healing reactions (see Table 3-1), and TNF and IL-6 are involved in the initiation of liver regeneration (discussed later).

SIGNALING MECHANISMS IN CELL GROWTH

In this section we review the process of *receptor-mediated signal transduction*, which is activated by the binding of ligands such as growth factors, and cytokines to specific receptors. Different classes of receptor molecules and pathways initiate a cascade of events by which receptor activation leads to expression of specific genes. Here we focus on the biochemical pathways and transcriptional regulation that mediate growth factor activity.

According to the source of the ligand and the location of its receptors (i.e., in the same, adjacent, or distant cells), three general modes of signaling, named autocrine, paracrine, and endocrine, can be distinguished (Fig. 3-8).

- *Autocrine signaling:* Cells respond to the signaling molecules that they themselves secrete, thus establishing an *autocrine loop*. Autocrine growth regulation plays a role in liver regeneration and the proliferation of antigen-stimulated lymphocytes. Tumors frequently overproduce growth factors and their receptors, thus stimulating their own proliferation through an autocrine loop.
- *Paracrine signaling:* One cell type produces the ligand, which then acts on adjacent target cells that express the appropriate receptor. The responding cells are in close proximity to the ligand-producing cell and are

generally of a different type. Paracrine stimulation is common in connective tissue repair of healing wounds, in which a factor produced by one cell type (e.g., a macrophage) has a growth effect on adjacent cells (e.g., a fibroblast). It is also necessary for hepatocyte replication during liver regeneration (discussed later), and for Notch effects in embryonic development, wound healing, and renewing tissues.

- *Endocrine signaling:* Hormones synthesized by cells of endocrine organs act on target cells distant from their site of synthesis, being usually carried by the blood. Growth factors may also circulate and act at distant sites, as is the case for HGF. Several cytokines, such as those associated with the systemic aspects of inflammation discussed in Chapter 2 , also act as endocrine agents.

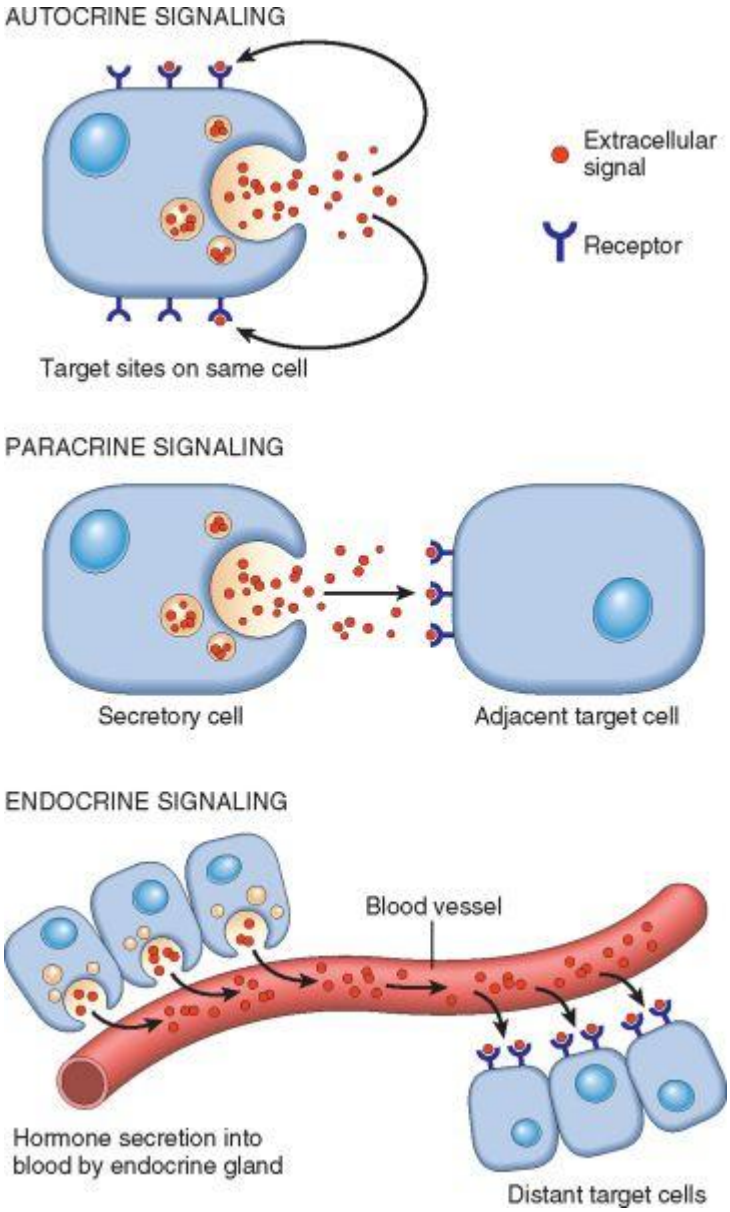

FIGURE 3-8 General patterns of intercellular signaling demonstrating autocrine, paracrine, and endocrine signaling (see text). *(Modified from Lodish H et al [eds]: Molecular Cell Biology, 3rd ed. New York, WH Freeman, 1995, p 855. © 1995 by Scientific American Books. Used with permission of WH Freeman and Company.)*

The binding of a ligand to its receptor triggers a series of events by which extracellular signals are transduced into the cell resulting in changes in gene expression. Although single receptor molecules can transduce some signals upon ligand binding, signaling typically involves clustering of two or more receptor molecules by the ligand. Receptors are generally located on the surface of the target cell but can also be found in the cytoplasm or nucleus.

It is useful at this point to summarize the properties of the major types of receptors and how they deliver signals to the cell interior (Fig. 3-9). This is pertinent to an understanding of normal and unregulated (neoplastic) cell growth (discussed in Chapter 7).

- *Receptors with intrinsic tyrosine kinase activity*. The ligands for receptors with tyrosine kinase activity include most growth factors such as EGF, TGF-α, HGF, PDGF, VEGF, FGF, c-KIT ligand, and insulin. Receptors belonging to this family have an extracellular ligand-binding domain, a transmembrane region, and a cytoplasmic tail that has intrinsic tyrosine kinase activity.[61] Binding of the ligand induces *dimerization of the receptor*, tyrosine phosphorylation, and activation of the receptor tyrosine kinase (Fig. 3-10). The active kinase then phosphorylates, and thereby activates, many downstream *effector molecules* (molecules that mediate the effects of receptor engagement with a ligand). Activation of effector molecules can be direct or through the involvement of *adapter proteins*. A prototypical adapter protein is GRB-2, which binds a guanosine triphosphate–guanosine diphosphate (GTP-GDP) exchange factor called SOS. SOS acts on the GTP-binding (G) protein RAS and catalyzes the formation of RAS-GTP, which triggers the mitogen-activated protein kinase (MAP kinase) cascade (see Fig. 3-10). Active MAP kinases stimulate the synthesis and phosphorylation of transcription factors, such as FOS and JUN. The transcription factors activated by these various signaling cascades in turn stimulate the production of growth factors, receptors for growth factors, and proteins that directly control the entry of cells into the cell cycle. Other effector molecules activated by receptors with intrinsic tyrosine kinase activity include *phospholipase Cγ* (PLCγ) and *phosphatidyl inositol-3 kinase (PI3K)* (see Fig. 3-9). PLCγ catalyzes the breakdown of membrane inositol phospholipids into inositol 1,4,5-triphosphate (IP_3), which functions to increase concentrations of calcium, an important effector molecule, and diacylglycerol, which activates the serine-threonine kinase protein kinase C that in turn activates various transcription factors. PI3K phosphorylates a membrane phospholipid, generating products that activate the kinase Akt (also referred to as protein kinase B), which is involved in cell proliferation and cell survival through inhibition of apoptosis. Alterations in tyrosine kinase activity and receptor mutations have been detected in many forms of cancer and are important targets for therapy (Chapter 7).
- *Receptors lacking intrinsic tyrosine kinase activity that recruit kinases*. Ligands for these receptors include many cytokines, such as IL-2, IL-3, and other interleukins; interferons α, β, and γ; erythropoietin; granulocyte colony-stimulating factor; growth hormone; and prolactin. These receptors transmit extracellular signals to the nucleus by activating members of the JAK (Janus kinase) family of proteins (see Fig. 3-9). The JAKs link the receptors with and activate cytoplasmic transcription factors called STATs (signal transducers and activation of transcription), which directly shuttle into the nucleus and activate gene transcription.[62] Cytokine receptors can also activate other signaling pathways, such as the MAP kinase pathways already mentioned.
- *G protein–coupled receptors*. These receptors transmit signals into the cell through trimeric GTP-binding proteins *(G proteins)*. They contain *seven transmembrane α-helices* (see Fig. 3-9) and constitute the largest family of plasma membrane receptors, with nonodorant G protein–coupled receptors accounting for about 1% of the human genome. A large number of ligands signal through this type of receptor, including chemokines, vasopressin, serotonin, histamine, epinephrine and norepinephrine, calcitonin, glucagon, parathyroid hormone, corticotropin, and rhodopsin. An enormous number of common pharmaceutical drugs targets such receptors.[63] Binding of the ligand induces changes in the conformation of the receptors, causing their activation and allowing their interaction with many different G proteins. Activation of G proteins occurs by the exchange of GDP, present in the inactive protein, with GTP, which activates the protein. Among the many branches of this signal transduction pathway are those involving *calcium and 3′,5′-cyclic adenosine monophosphate (cAMP) as second messengers*. Activation of G protein–coupled receptors (as well as of tyrosine kinase receptors, discussed above) can produce inositol triphosphate (IP_3), which releases calcium from the endoplasmic reticulum. Calcium signals, which are generally oscillatory, have multiple targets, including cytoskeletal proteins, chloride- and potassium-activated ion pumps, enzymes such as calpain, and calcium-binding proteins such as calmodulin. cAMP activates a more restricted set of targets that include protein kinase A and cAMP-gated ion channels, important in vision and olfactory sensing. Inherited defects involving G protein–coupled receptor signal transduction are associated with retinitis pigmentosa, corticotropin deficiencies, and hyperparathyroidism.

- *Steroid hormone receptors. These receptors are generally located in the nucleus and function as ligand-dependent transcription factors*. The ligands diffuse through the cell membrane and bind the inactive receptors, causing their activation. *The activated receptor then binds to specific DNA sequences known as hormone response elements within target genes, or they can bind to other transcription factors*. In addition to steroid hormones, other ligands that bind to members of this receptor family include thyroid hormone, vitamin D, and retinoids. A group of receptors belonging to this family are called *peroxisome proliferator-activated receptors*.[64] They are nuclear receptors that are involved in a broad range of responses that include adipogenesis (Chapter 24), inflammation, and atherosclerosis.

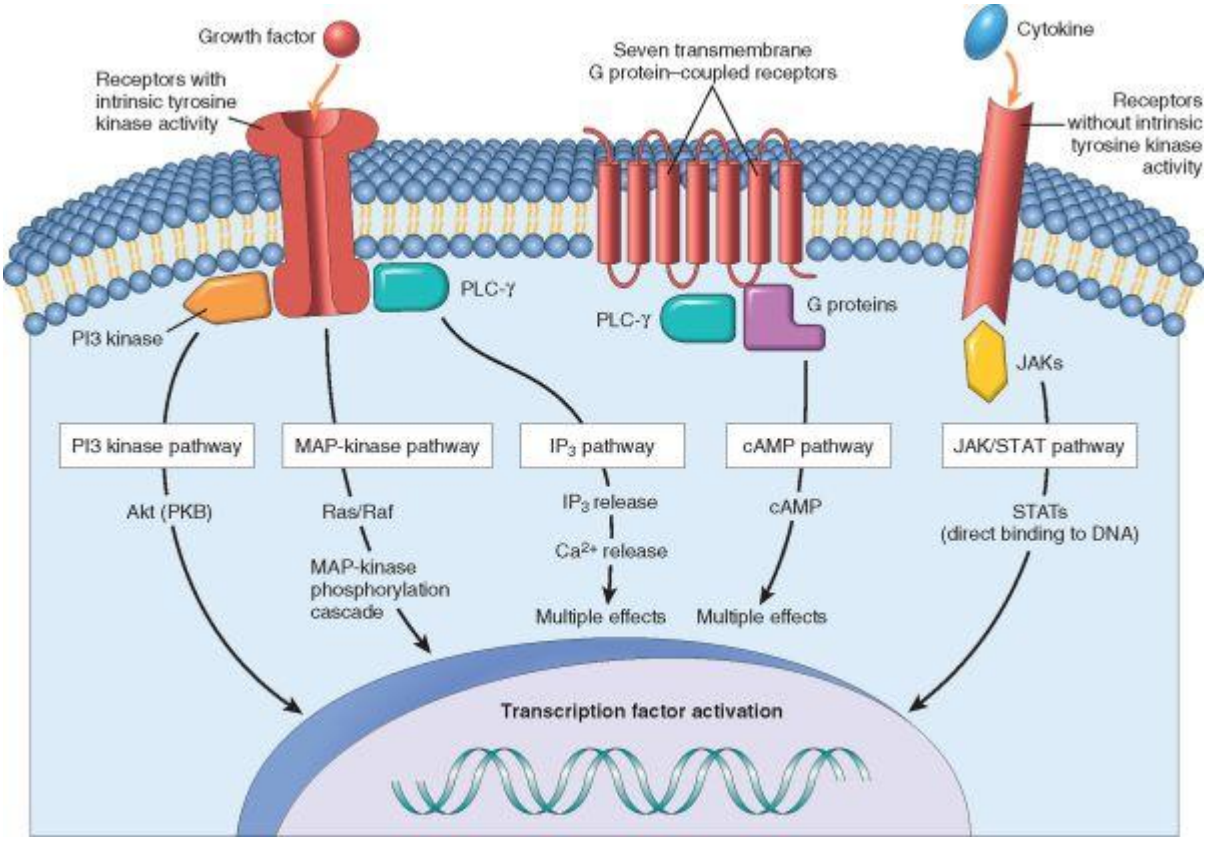

FIGURE 3-9 Overview of the main types of cell surface receptors and their principal signal transduction pathways (see text). Shown are receptors with intrinsic tyrosine kinase activity, seven transmembrane G protein–coupled receptors, and receptors without intrinsic tyrosine kinase activity. cAMP, cyclic adenosine monophosphate: IP_3, inositol triphosphate; JAK, Janus kinase; MAP kinase, mitogen-activated protein kinase; PI3 kinase, phosphatidylinositol 3-kinase; PKB, protein kinase B, also known as Akt; PLC-γ, phospholipase C gamma; STATs, signal transducers and activators of transcription.

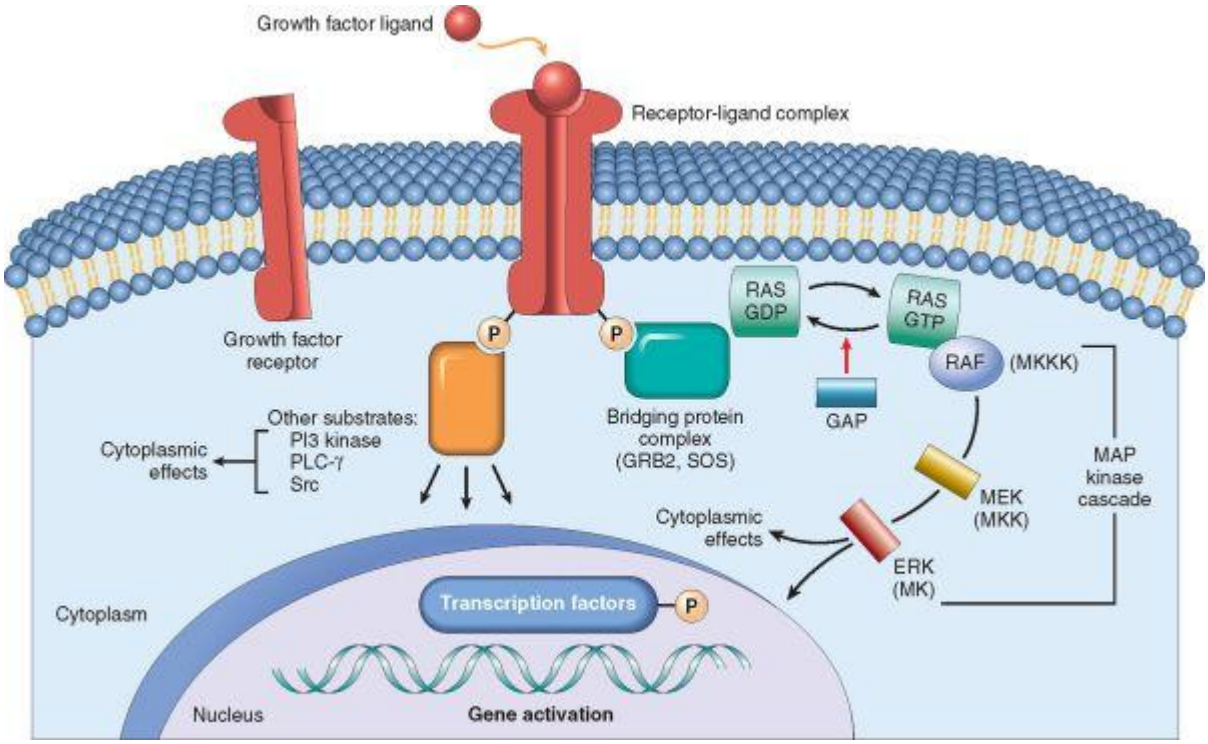

FIGURE 3-10 Signaling from tyrosine kinase receptors. Binding of the growth factor (ligand) causes receptor dimerization and autophosphorylation of tyrosine residues. Attachment of adapter (or bridging) proteins (e.g., GRB2 and SOS) couples the receptor to inactive RAS. Cycling of RAS between its inactive and active forms is regulated by GAP. Activated RAS interacts with and activates RAF (also known as MAP kinase kinase kinase). This kinase then phosphorylates a component of the MAP kinase signaling pathway, MEK (also known as MAP kinase kinase or MKK), which then phosphorylates ERK (MAP kinase or MK). Activated MAP kinase phosphorylates other cytoplasmic proteins and nuclear transcription factors, generating cellular responses. The phosphorylated tyrosine kinase receptor can also bind other components, such as phosphatidyl 3-kinase (PI3 kinase), which activates other signaling systems.

Transcription Factors

Many of the signal transduction systems used by growth factors transfer information to the nucleus and modulate gene transcription through the activity of *transcription factors*. Among the transcription factors that regulate cell proliferation are products of several growth-promoting genes, such as c-*MYC* and c-*JUN*, and of cell cycle–inhibiting genes, such as *p53*. Transcription factors have a modular design and contain domains for DNA binding and for transcriptional regulation. The DNA-binding domain permits binding to short sequence motifs of DNA, which may be unique to a particular target gene or may be present in many genes. The transactivating domain stimulates transcription of the adjacent gene.

Growth factors induce the synthesis or activity of transcription factors. Cellular events requiring rapid responses do not rely on new synthesis of transcription factors but depend on post-translational modifications that lead to their activation. These modifications include (a) *heterodimerization*, as for instance, the dimerization of the products of the protooncogenes c-*FOS* and c-*JUN* to form the transcription factor activator protein-1 (AP-1), which is activated by MAP kinase signaling pathways, (b) *phosphorylation*, as for STATs in the JAK/STAT pathway, (c) *release of inhibition* to permit migration into the nucleus, as for NF-κB, and (d) *release from membranes* by proteolytic cleavage, as for Notch receptors (see Fig. 3-16).

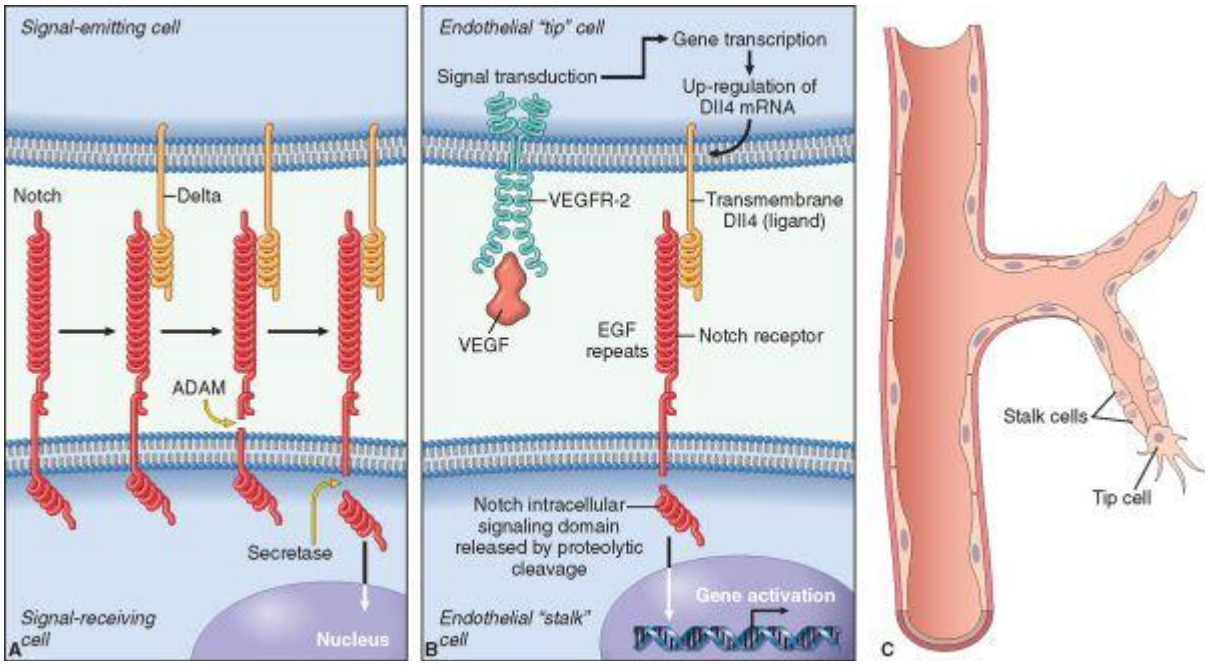

FIGURE 3-16 Notch signaling and angiogenesis. **A**, The Notch receptor binds a ligand (a delta-like ligand, Dll, is shown in the figure) located in an adjacent cell, and undergoes two proteolytic cleavages (the first cleavage by ADAM protease, the second by δ-secretase), releasing a C-terminal fragment known as Notch intracellular domain (Notch-ICD). **B**, Notch signaling in endothelial cells during angiogenesis, triggered by the binding of the Dll4 ligand in a tip cell to a Notch receptor in a stalk cell. Notch-ICD migrates into the nucleus and activates the transcription of target genes. **C**, Sprouting angiogenesis, showing a migrating tip cell and stalk cells connected to the endothelial cells of the main vessel. *(**A**, modified from Weinberg RA: The Biology of Cancer. New York, Garland Science, 2007, Fig. 5.22; **B**, modified from Kerbel RS: Tumor angiogenesis. N Engl J Med 358:2039, 2008.)*

2.3.3 Mechanisms of Tissue & Organ Regeneration

Urodele amphibians such as the newt can regenerate their tails, limbs, lens, retina, jaws, and even a large portion of the heart, but *the capacity for regeneration of whole tissues and organs has been lost in mammals*.[1] The inadequacy of true regeneration in mammals has been attributed to the absence of *blastema* formation (the source of cells for regeneration) and to the rapid fibroproliferative response after wounding. *The Wnt/β-catenin is a highly conserved pathway* that participates in the regeneration of planaria flatworms, fin and heart regeneration in zebra fish, and blastema and patterning formation in limb regeneration in newts. In mammals, Wnt/β-catenin modulates stem cell functions in the intestinal epithelium, bone marrow, and muscle, participates in liver regeneration after partial hepatectomy, and stimulates oval cell proliferation after liver injury.[27,][65,][66]

In this section we have chosen the liver to illustrate the mechanisms of regeneration, because it has been studied in detail and has important biologic and clinical aspects. Even this process is not one of true regeneration, because the resection of tissue does not cause new growth of liver but instead triggers a process of compensatory hyperplasia in the remaining parts of the organ (discussed below). Other organs, including kidney, pancreas, adrenal glands, thyroid, and the lungs of very young animals, are also capable of compensatory growth, although they display it in less dramatic form than the liver. Because new nephrons cannot be generated in the adult kidney, the growth of the contralateral kidney after unilateral nephrectomy involves nephron hypertrophy and some replication of proximal tubule cells. The pancreas has a limited capacity to regenerate its exocrine components and islets. Regeneration of pancreatic beta cells may involve beta-cell replication, transdifferentiation of ductal cells, or

differentiation of putative stem cells that express the transcription factors Oct4 and Sox2.[67] Recently, pancreatic exocrine cells have been reprogrammed into insulin-secreting β-cells.

LIVER REGENERATION

The human liver has a remarkable capacity to regenerate, as demonstrated by its growth after partial hepatectomy, which may be performed for tumor resection or for living-donor hepatic transplantation (Fig. 3-11). The popular image of liver regeneration is the daily regrowth of the liver of Prometheus, which was eaten every day by an eagle sent by Zeus (Zeus was angry at Prometheus for stealing the secret of fire, but did he know that Prometheus's liver would regenerate?). The reality, although less dramatic, is still quite impressive. In humans, resection of approximately 60% of the liver in living donors results in the doubling of the liver remnant in about one month. The portions of the liver that remain after partial hepatectomy constitute an intact "mini-liver" that rapidly expands and reaches the mass of the original liver (see Fig. 3-11). *Restoration of liver mass is achieved without the regrowth of the lobes that were resected at the operation*. Instead, growth occurs by enlargement of the lobes that remain after the operation, a process known as *compensatory growth or compensatory hyperplasia*. In both humans and rodents, the end point of liver regeneration after partial hepatectomy is the restitution of functional mass rather than the reconstitution of the original form.[69]

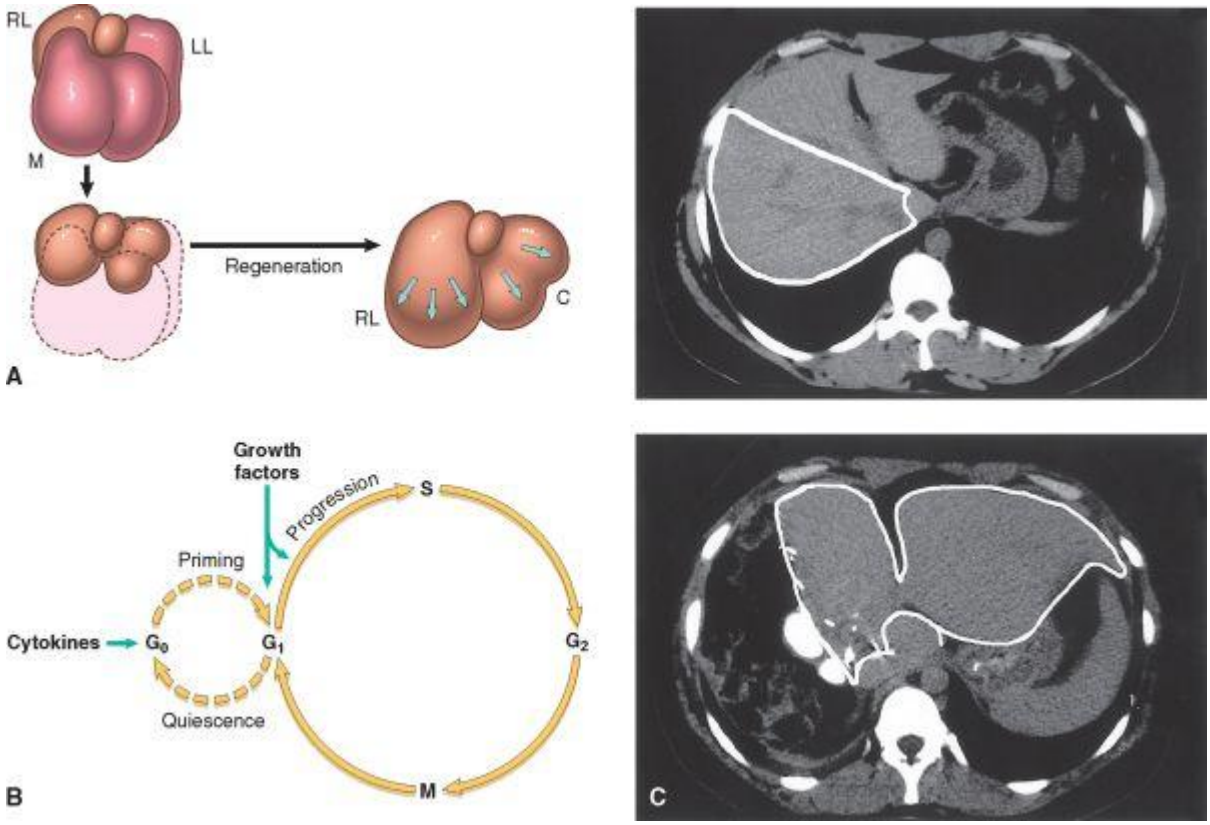

FIGURE 3-11 Liver regeneration after partial hepatectomy. **A**, The lobes of the liver of a rat (M, median; RL and LL, right and left lateral lobes; C, caudate lobe). Partial hepatectomy removes two thirds of the liver (median and left lateral lobes). After 3 weeks the right lateral and caudate lobes enlarge to reach a mass equivalent to that of the original liver without regrowth of the median and left lateral lobes. **B**, Entry and progression of hepatocytes in the cell cycle (see text for details). **C**, *Regeneration of the human liver in living-donor transplantation*. Computed tomography scans of the donor liver in living-donor hepatic transplantation. Upper panel is a scan of the liver of the donor before the operation. The right lobe, to be used as a transplant, is outlined. Lower panel is a scan of the liver 1 week after performance of partial hepatectomy. Note the great enlargement of the left lobe (outlined in the panel) without regrowth of the right lobe. *(**A**, From Goss RJ: Regeneration versus repair. In Cohen IK et al [eds]: Wound Healing. Biochemical and Clinical Aspects. Philadelphia, WB Saunders, 1992, pp 20–39; **C**, courtesy of R. Troisi, MD, Ghent University, Ghent, Belgium; reproduced in part from Fausto N: Liver regeneration. In Arias I, et al: The Liver: Biology and Pathobiology, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2001.)*

Almost all hepatocytes replicate during liver regeneration after partial hepatectomy. Because hepatocytes are quiescent cells, it takes them several hours to enter the cell cycle, progress through G_1, and reach the S phase of DNA replication. The wave of hepatocyte replication is synchronized and is followed by synchronous replication of nonparenchymal cells (Kupffer cells, endothelial cells, and stellate cells).

There is substantial evidence that *hepatocyte proliferation in the regenerating liver is triggered by the combined actions of cytokines and polypeptide growth factors*. With the exception of the autocrine activity of TGF-α, hepatocyte replication is strictly dependent on paracrine effects of growth factors and cytokines such as HGF and IL-6 produced by hepatic nonparenchymal cells. There are two major restriction points for hepatocyte replication: the G_0/G_1 transition that bring quiescent hepatocytes into the cell cycle, and the G_1/S transition needed for passage through the late G_1 restriction point. Gene expression in the regenerating liver proceeds in phases, starting with the immediate early gene response, which is a transient response that corresponds to the G_0/G_1 transition. More than 70 genes are activated during this response, including the proto-oncogenes c-*FOS* and c-*JUN*, whose products dimerize to form the transcription factor AP-1; c-*MYC*, which encodes a transcription factor that activates many different genes; and other transcription factors, such as NF-κB, STAT-3, and C/EBP.[70] The immediate early gene response sets the stage for the sequential activation of multiple genes, as hepatocytes progress into the G_1 phase. The G_1 to S transition occurs as previously described (see Fig. 3-7).

Quiescent hepatocytes become competent to enter the cell cycle through a priming phase that is mostly mediated by the cytokines TNF and IL-6, and components of the complement system. Priming signals activate several signal transduction pathways as a necessary prelude to cell proliferation. Under the stimulation of HGF, TGFα, and HB-EGF, primed hepatocytes enter the cell cycle and undergo DNA replication (Fig. 3-11). Norepinephrine, serotonin, insulin, thyroid and growth hormone, act as adjuvants for liver regeneration, facilitating the entry of hepatocytes into the cell cycle.

Individual hepatocytes replicate once or twice during regeneration and then return to quiescence in a strictly regulated sequence of events, but the mechanisms of growth cessation have not been established. Growth inhibitors, such as TGF-β and activins, may be involved in terminating hepatocyte replication, but there is no clear understanding of their mode of action. *Intrahepatic stem or progenitor cells do not play a role in the compensatory growth that occurs after partial hepatectomy*, and there is no evidence for hepatocyte generation from bone marrow–derived cells during this process.[28,][37] However, endothelial cells and other nonparenchymal cells in the regenerating liver may originate from bone marrow precursors.

2.3.4 Extracellular Matrix & Cell-Matrix Interactions

Tissue repair and regeneration depend not only on the activity of soluble factors, but also on interactions between cells and the components of the *extracellular matrix (ECM)*. The ECM regulates the growth, proliferation, movement, and differentiation of the cells living within it. It is constantly remodeling, and its synthesis and degradation accompanies morphogenesis, regeneration, wound healing, chronic fibrotic processes, tumor invasion, and metastasis. The ECM sequesters water, providing turgor to soft tissues, and minerals that give rigidity to bone, but it does much more than just fill the spaces around cells to maintain tissue structure. Its various functions include:

- *Mechanical support* for cell anchorage and cell migration, and maintenance of cell polarity
- *Control of cell growth*. ECM components can regulate cell proliferation by signaling through cellular

receptors of the integrin family.

- *Maintenance of cell differentiation*. The type of ECM proteins can affect the degree of differentiation of the cells in the tissue, also acting largely via cell surface integrins.
- *Scaffolding for tissue renewal*. The maintenance of normal tissue structure requires a basement membrane or stromal scaffold. The integrity of the basement membrane or the stroma of the parenchymal cells is critical for the organized regeneration of tissues. It is particularly noteworthy that although labile and stable cells are capable of regeneration, injury to these tissues results in restitution of the normal structure only if the ECM is not damaged. Disruption of these structures leads to collagen deposition and scar formation (see Fig. 3-2).
- *Establishment of tissue microenvironments*. Basement membrane acts as a boundary between epithelium and underlying connective tissue and also forms part of the filtration apparatus in the kidney.
- *Storage and presentation of regulatory molecules*. For example, growth factors like FGF and HGF are secreted and stored in the ECM in some tissues. This allows the rapid deployment of growth factors after local injury, or during regeneration.

The ECM is composed of three groups of macromolecules: *fibrous structural proteins*, such as collagens and elastins that provide tensile strength and recoil; *adhesive glycoproteins* that connect the matrix elements to one another and to cells; and *proteoglycans and hyaluronan* that provide resilience and lubrication. These molecules assemble to form two basic forms of ECM: *interstitial matrix and basement membranes*. The interstitial matrix is found in spaces between epithelial, endothelial, and smooth muscle cells, as well as in connective tissue. It consists mostly of fibrillar and nonfibrillar collagen, elastin, fibronectin, proteoglycans, and hyaluronan. Basement membranes are closely associated with cell surfaces, and consist of nonfibrillar collagen (mostly type IV), laminin, heparin sulfate, and proteoglycans.[71]

We will now consider the main components of the ECM.

COLLAGEN

Collagen is the most common protein in the animal world, providing the extracellular framework for all multicellular organisms. Without collagen, a human being would be reduced to a clump of cells, like the "Blob" (the "gelatinous horror from outer space" of 1950s movie fame), interconnected by a few neurons. Currently, 27 different types of collagens encoded by 41 genes dispersed on at least 14 chromosomes are known[72] (Table 3-2). Each *collagen* is composed of three chains that form a trimer in the shape of a triple helix. The polypeptide is characterized by a repeating sequence in which glycine is in every third position (Gly-X-Y, in which X and Y can be any amino acid other than cysteine or tryptophan), and it contains

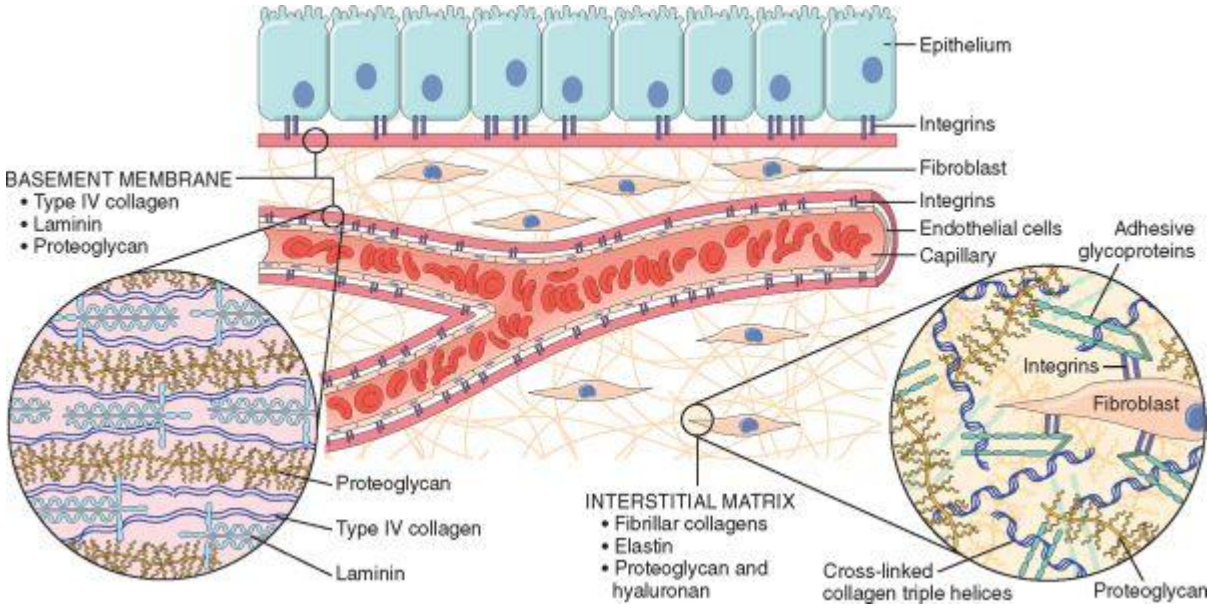

FIGURE 3-12 Main components of the extracellular matrix (ECM), including collagens, proteoglycans, and adhesive glycoproteins. Both epithelial and mesenchymal cells (e.g., fibroblasts) interact with ECM via integrins. Basement membranes and interstitial ECM have different architecture and general composition, although there is some overlap in their constituents. For the sake of simplification, many ECM components (e.g., elastin, fibrillin, hyaluronan, and syndecan) are not included.

the specialized amino acids 4-hydroxyproline and hydroxylysine. Prolyl residues in the Y-position are characteristically hydroxylated to produce hydroxyproline, which serves to stabilize the triple helix. Types I, II, III and V, and XI are the *fibrillar collagens*, in which the triple-helical domain is uninterrupted for more than 1000 residues; these proteins are found in extracellular fibrillar structures. *Type IV collagens have long but interrupted triple-helical domains and form sheets instead of fibrils; they are the main components of the basement membrane, together with laminin*. Another collagen with a long interrupted triple-helical domain (type VII) forms the anchoring fibrils between some epithelial and mesenchymal structures, such as epidermis and dermis. Still other collagens are transmembrane and may also help to anchor epidermal and dermal structures.

TABLE 3-2 -- Main Types of Collagens, Tissue Distribution, and Genetic Disorders

Collagen Type	Tissue Distribution	Genetic Disorders
FIBRILLAR COLLAGENS		
I	Ubiquitous in hard and soft tissues	Osteogenesis imperfecta; Ehlers-Danlos syndrome—arthrochalasias type I
II	Cartilage, intervertebral disk, vitreous	Achondrogenesis type II, spondyloepiphysea dysplasia syndrome
III	Hollow organs, soft tissues	Vascular Ehlers-Danlos syndrome
V	Soft tissues, blood vessels	Classical Ehlers-Danlos syndrome
IX	Cartilage, vitreous	Stickler syndrome
BASEMENT MEMBRANE COLLAGENS		
IV	Basement membranes	Alport syndrome
OTHER COLLAGENS		
VI	Ubiquitous in microfibrils	Bethlem myopathy
VII	Anchoring fibrils at dermal-epidermal	Dystrophic epidermolysis bullosa

Collagen Type	Tissue Distribution	Genetic Disorders
	junctions	
IX	Cartilage, intervertebral disks	Multiple epiphyseal dysplasias
XVII	Transmembrane collagen in epidermal cells	Benign atrophic generalized epidermolysis bullosa
XV and XVIII	Endostatin-forming collagens, endothelial cells	Knobloch syndrome (type XVIII collagen)

Courtesy of Dr. Peter H. Byers, Department of Pathology, University of Washington, Seattle, WA.

The messenger RNAs transcribed from fibrillar collagen genes are translated into pre-pro-α chains that assemble in a type-specific manner into trimers. Hydroxylation of proline and lysine residues and lysine glycosylation occur during translation. Three chains of a particular collagen type assemble to form the triple helix (Fig. 3-15). Procollagen is secreted from the cell and cleaved by proteases to form the basic unit of the fibrils. Collagen fibril formation is associated with the oxidation of lysine and hydroxylysine residues by the extracellular enzyme *lysyl oxidase*. This results in *cross-linking* between the chains of adjacent molecules, which stabilizes the array, and is a major contributor to the tensile strength of collagen. *Vitamin C is required for the hydroxylation of procollagen*, a requirement that explains the inadequate wound healing in scurvy (Chapter 9). Genetic defects in collagen production (see Table 3-2) cause many inherited syndromes, including various forms of the Ehlers-Danlos syndrome and osteogenesis imperfecta[73] (Chapters 5 and 26 .

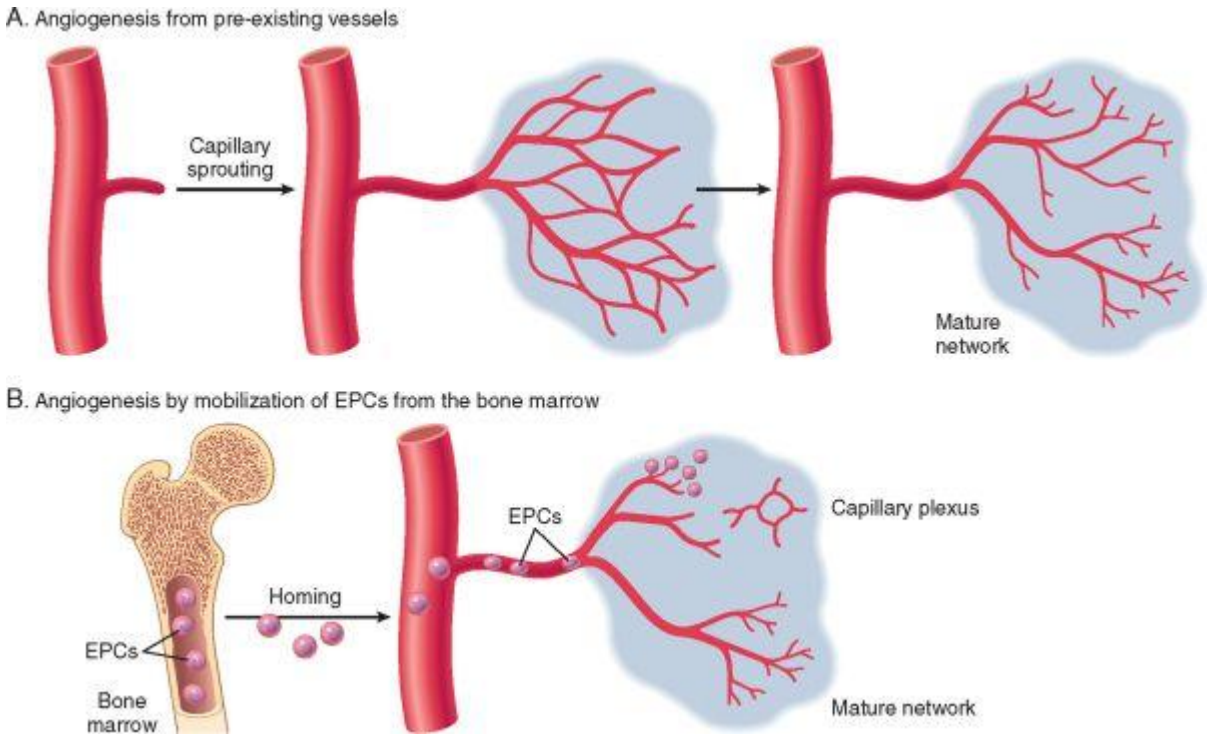

FIGURE 3-15 Angiogenesis by mobilization of endothelial precursor cells (EPCs) from the bone marrow and from preexisting vessels (capillary growth). **A**, In angiogenesis from preexisting vessels, endothelial cells from these vessels become motile and proliferate to form capillary sprouts. Regardless of the initiating mechanism, vessel maturation (stabilization) involves the recruitment of pericytes and smooth muscle cells to form the periendothelial layer. **B**, EPCs are mobilized from the bone marrow and may migrate to a site of injury or tumor growth. At these sites, EPCs differentiate and form a mature network by linking to existing vessels. *(Modified from Conway EM et al: Molecular mechanisms of blood vessel growth. Cardiovasc Res 49:507, 2001.)*

ELASTIN, FIBRILLIN, AND ELASTIC FIBERS

Tissues such as blood vessels, skin, uterus, and lung require elasticity for their function. Proteins of the collagen family provide tensile strength, but the ability of these tissues to expand and recoil (compliance) depends on the elastic fibers. These fibers can stretch and then return to their original size after release of the tension. Morphologically, elastic fibers consist of a central core made of *elastin*, surrounded by a peripheral network of microfibrils. Substantial amounts of elastin are found in the walls of large blood vessels, such as the aorta, and in the uterus, skin, and ligaments. The peripheral microfibrillar network that surrounds the core consists largely of *fibrillin*, a 350-kD secreted glycoprotein, which associates either with itself or with other components of the ECM. The microfibrils serve, in part, as scaffolding for deposition of elastin and the assembly of elastic fibers. They also influence the availability of active TGFβ in the ECM. As already mentioned, inherited defects in fibrillin result in formation of abnormal elastic fibers in *Marfan syndrome*, manifested by changes in the cardiovascular system (aortic dissection) and the skeleton[74] (Chapter 5).

CELL ADHESION PROTEINS

Most adhesion proteins, also called CAMs (cell adhesion molecules), can be classified into four main families: immunoglobulin family CAMs, cadherins, integrins, and selectins. These proteins function as transmembrane receptors but are sometimes stored in the cytoplasm.[75] As receptors, CAMs can bind to similar or different molecules in other cells, providing for interaction between the same cells (homotypic interaction) or different cell types (heterotypic interaction). Selectins have been discussed in Chapter 2 in the context of leukocyte/endothelial interactions. Selected aspects of other cell adhesion proteins are described here. *Integrins* bind to ECM proteins such as fibronectin, laminin, and osteopontin providing a connection between cells and ECM, and also to adhesive proteins in other cells, establishing cell-to-cell contact. *Fibronectin* is a large protein that binds to many molecules, such as collagen, fibrin, proteoglycans, and cell surface receptors. It consists of two glycoprotein chains, held together by disulfide bonds. Fibronectin messenger RNA has two splice forms, giving rise to tissue fibronectin and plasma fibronectin. The plasma form binds to fibrin, helping to stabilize the blood clot that fills the gaps created by wounds, and serves as a substratum for ECM deposition and formation of the provisional matrix during wound healing (discussed later). *Laminin* is the most abundant glycoprotein in the basement membrane and has binding domains for both ECM and cell surface receptors. In the basement membrane, polymers of laminin and collagen type IV form tightly bound networks. Laminin can also mediate the attachment of cells to connective tissue substrates.

Cadherins and integrins link the cell surface with the cytoskeleton through binding to actin and intermediate filaments. These linkages, particularly for the integrins, provide a mechanism for the transmission of mechanical force and the activation of intracellular signal transduction pathways that respond to these forces. Ligand binding to integrins causes clustering of the receptors in the cell membrane and formation of *focal adhesion* complexes. The cytoskeletal proteins that co-localize with integrins at the cell focal adhesion complex include talin, vinculin, and paxillin. The integrin-cytoskeleton complexes function as activated receptors and trigger a number of signal transduction pathways, including the MAP kinase, PKC, and PI3K pathways, which are also activated by growth factors. Not only is there a functional overlap between integrin and growth factor receptors, *but integrins and growth factor receptors interact ("cross-talk") to transmit environmental signals to the cell* that regulate proliferation, apoptosis, and differentiation (Fig. 3-13).

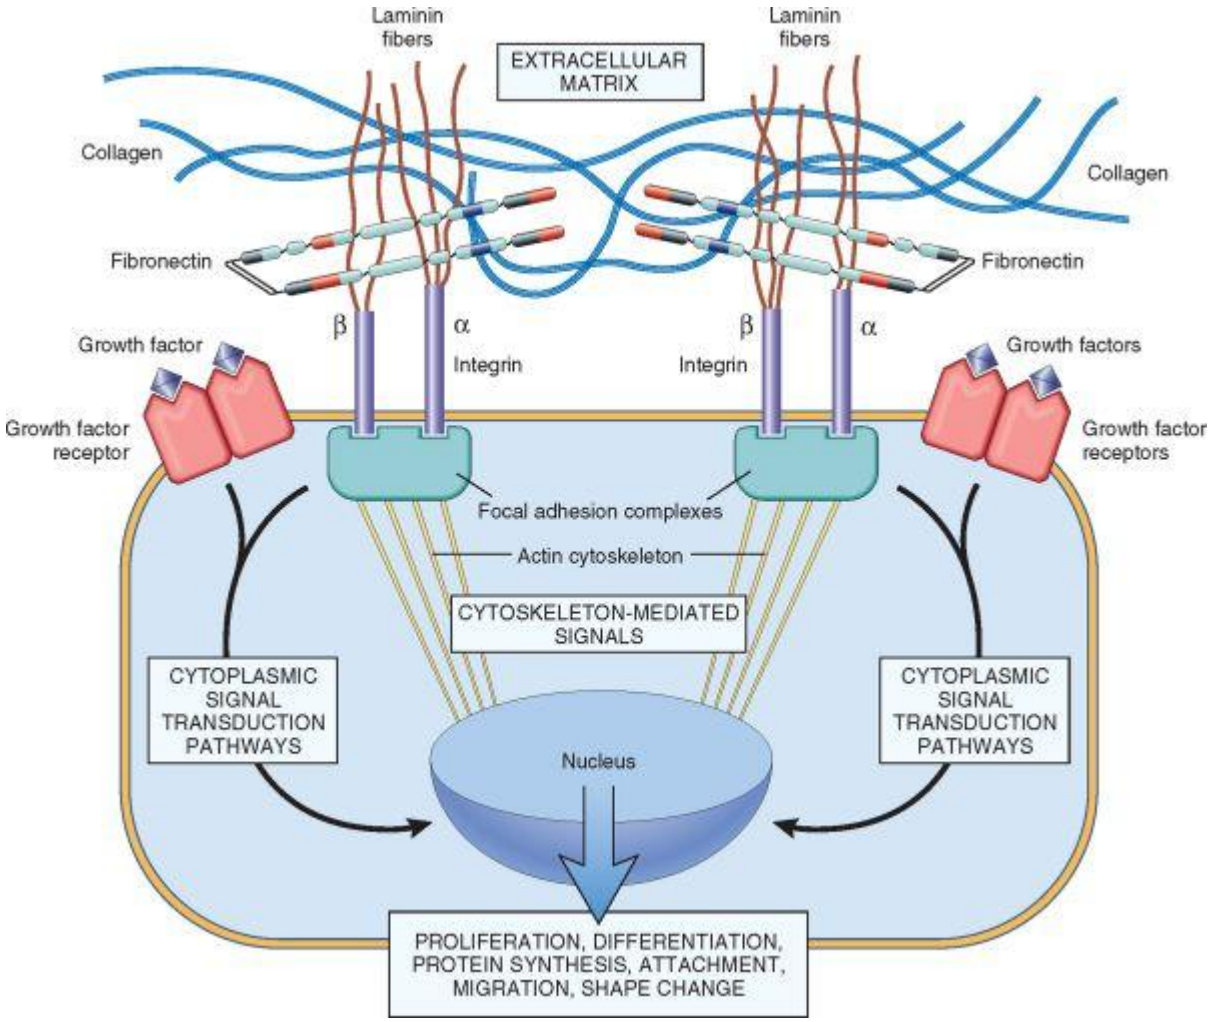

FIGURE 3-13 Mechanisms by which ECM components and growth factors interact and activate signaling pathways. Integrins bind ECM components and interact with the cytoskeleton at focal adhesion complexes (protein aggregates that include vinculin, α-actin, and talin). This can initiate the production of intracellular messengers or can directly mediate nuclear signals. Cell surface receptors for growth factors may activate signal transduction pathways that overlap with those activated by integrins. Signaling from ECM components and growth factors is integrated by the cell to produce various responses, including changes in cell proliferation, locomotion, and differentiation.

The name *cadherin* is derived from the term "calcium-dependent adherence protein." This family contains almost 90 members, which participate in interactions between cells of the same type. These interactions connect the plasma membrane of adjacent cells, forming two types of cell junctions called (1) *zonula adherens*, small, spotlike junctions located near the apical surface of epithelial cells, and (2) *desmosomes*, stronger and more extensive junctions, present in epithelial and muscle cells. Migration of keratinocytes in the re-epithelialization of skin wounds is dependent on the formation of dermosomal junctions. Linkage of cadherins with the cytoskeleton occurs through two classes of *catenins*. β-catenin links cadherins with α-catenin, which, in turn, connects to actin, thus completing the connection with the cytoskeleton. Cell-to-cell interactions mediated by cadherins and catenins play a major role in regulating cell motility, proliferation, and differentiation and account for the inhibition of cell proliferation that occurs when cultured normal cells contact each other ("contact inhibition"). Diminished function of E-cadherin contributes to certain forms of breast and gastric cancer. As already mentioned, free β-catenin acts independently of cadherins in the Wnt signaling pathway, which participates in stem cell homeostasis and regeneration. Mutation and altered expression of the Wnt/β-

catenin pathway is implicated in cancer development, particularly in gastrointestinal and liver cancers (Chapter 7).

In addition to the main families of adhesive proteins described earlier, some other secreted adhesion molecules are mentioned because of their potential role in disease processes: (1) *SPARC* (secreted protein acidic and rich in cysteine), also known as *osteonectin*, contributes to tissue remodeling in response to injury and functions as an angiogenesis inhibitor; (2) the *thrombospondins*, a family of large multifunctional proteins, some of which, similar to SPARC, also inhibit angiogenesis; (3) *osteopontin (OPN)* is a glycoprotein that regulates calcification, is a mediator of leukocyte migration involved in inflammation, vascular remodeling, and fibrosis in various organs[76,][77] (discussed later in this chapter); and (4) the *tenascin* family, which consist of large multimeric proteins involved in morphogenesis and cell adhesion.

GLYCOSAMINOGLYCANS (GAGS) AND PROTEOGLYCANS

GAGs make up the third type of component in the ECM, besides the fibrous structural proteins and cell adhesion proteins. *GAGs* consist of long repeating polymers of specific disaccharides. With the exception of *hyaluronan* (discussed later), GAGs are linked to a core protein, forming molecules called *proteoglycans*.[78] Proteoglycans are remarkable in their diversity. At most sites, ECM may contain several different core proteins, each containing different GAGs. Proteoglycans were originally described as ground substances or *mucopolysaccharides*, whose main function was to organize the ECM, but it is now recognized that these molecules have diverse roles in regulating connective tissue structure and permeability (Fig. 3-14). Proteoglycans can be integral membrane proteins and, through their binding to other proteins and the activation of growth factors and chemokines, act as modulators of inflammation, immune responses, and cell growth and differentiation.

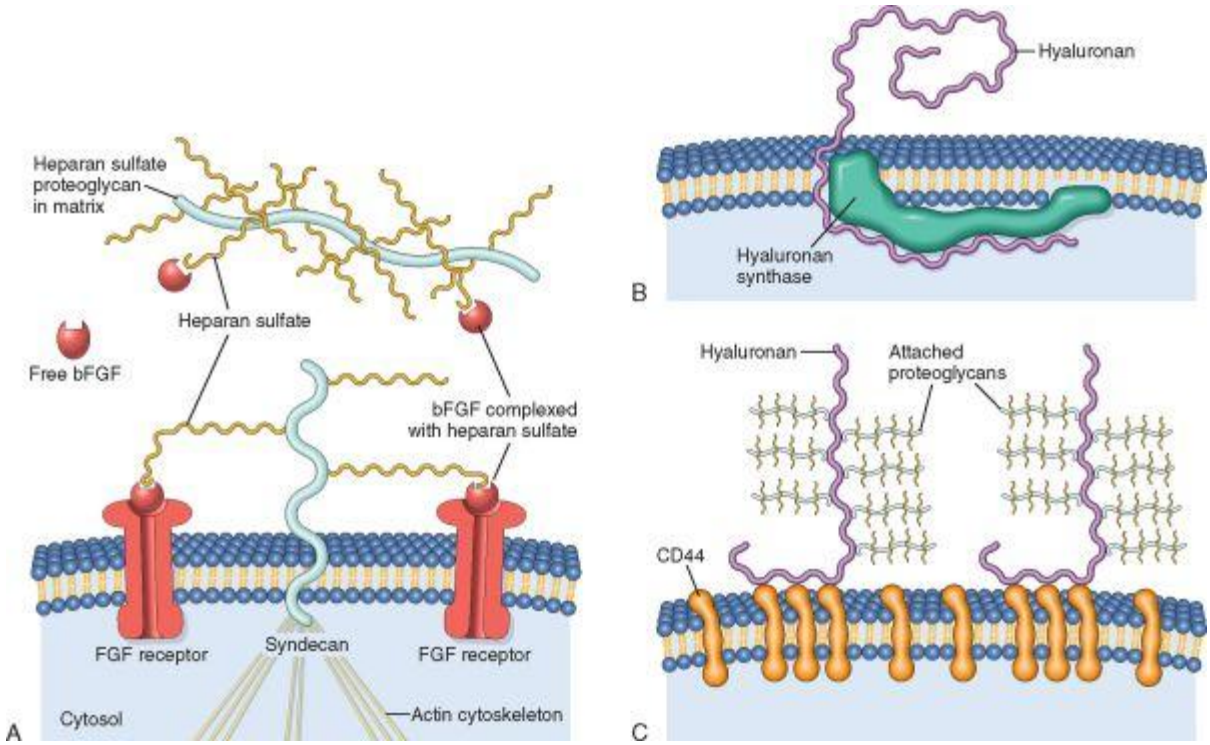

FIGURE 3-14 Proteoglycans, glycosaminoglycans (GAGs), and hyaluronan. **A**, Regulation of FGF-2 activity by ECM and cellular proteoglycans. Heparan sulfate binds FGF-2 (basic FGF) secreted into the ECM. Syndecan is a cell surface proteoglycan with a transmembrane core protein, extracellular GAG side chains that can bind FGF-2, and a cytoplasmic tail that binds to the actin cytoskeleton. Syndecan side chains bind FGF-2 released by damage to the ECM and facilitate the interaction with cell surface receptors. **B**, Synthesis of hyaluronan at the

inner surface of the plasma membrane. The molecule extends to the extracellular space, while still attached to hyaluronan synthase. **C**, Hyaluronan chains in the extracellular space are bound to the plasma membrane through the CD44 receptor. Multiple proteoglycans may attach to hyaluronan chains in the ECM. *(**B** and **C**, modified from Toole KR: Hyaluronan: from extracellular glue to pericellular cue. Nat Rev Cancer 4:528, 2004.)*

There are four structurally distinct families of GAGs: *heparan sulfate, chondroitin/dermatan sulfate, keratan sulfate, and hyaluronan (HA)*. The first three of these families are synthesized and assembled in the Golgi apparatus and rough endoplasmic reticulum as proteoglycans. By contrast, HA is produced at the plasma membrane by enzymes called hyaluronan synthases and is not linked to a protein backbone.

HA is a polysaccharide of the GAG family found in the ECM of many tissues and is abundant in heart valves, skin and skeletal tissues, synovial fluid, the vitreous of the eye, and the umbilical cord.[79] It is a huge molecule that consists of many repeats of a simple disaccharide stretched end-to-end. It binds a large amount of water (about 1000-fold its own weight), forming a viscous hydrated gel that gives connective tissue the ability to resist compression forces. HA helps provide resilience and lubrication to many types of connective tissue, notably for the cartilage in joints. Its concentration increases in inflammatory diseases such as rheumatoid arthritis, scleroderma, psoriasis, and osteoarthritis. Enzymes called hyaluronidases fragment HA into lower molecular weight molecules (LMW HA) that have different functions than the parent molecule. LMW HA produced by endothelial cells binds to the CD44 receptor on leukocytes, promoting the recruitment of leukocytes to the sites of inflammation. In addition, LMW HA molecules stimulate the production of inflammatory cytokines and chemokines by white cells recruited to the sites of injury. The leukocyte recruitment process and the production of pro-inflammatory molecules by LMW HA are strictly regulated processes; these activities are beneficial if short-lived, but their persistence may lead to prolonged inflammation.

2.3.5 Healing by Repair, Scar Formation & Fibrosis

If tissue injury is severe or chronic, and results in damage of both parenchymal cells and the stromal framework of the tissue, healing can not be accomplished by regeneration. Under these conditions, the main healing process is *repair by deposition of collagen and other ECM components, causing the formation of* a *scar*. In contrast to regeneration which involves the restitution of tissue components, repair is a fibroproliferative response that "patches" rather than restores the tissue. The term scar is most often used in connection to *wound healing* in the skin, but is also used to describe the replacement of parenchymal cells in any tissue by collagen, as in the heart after myocardial infarction. Repair by connective tissue deposition includes the following basic features:

- *inflammation*
- *angiogenesis*,
- *migration and proliferation of fibroblasts*,
- *scar formation*
- *connective tissue remodeling*.

We will examine all of these events under the context of cutaneous wound healing, as a prototype repair process. Suffice to say here that regardless of site, the inflammatory reaction elicited by the injury contains the damage, removes injured tissue, and promotes the deposition of ECM components in the area of injury, at the same time that angiogenesis is stimulated. However, if the damage persists, inflammation becomes chronic, leading to an excess deposition of connective tissue known as *fibrosis*.

In most healing processes, a combination of repair and regeneration occurs. The relative contributions of repair and regeneration are influenced by: (1) the proliferative capacity of the cells of the tissue; (2) the integrity of the extracellular matrix; and (3) the resolution or chronicity of the injury and inflammation.

Because of the great importance of angiogenesis in processes other than wound healing, we start with a discussion of the mechanisms of angiogenesis before considering the steps of cutaneous wound healing.

MECHANISMS OF ANGIOGENESIS

Angiogenesis is a fundamental process that affects physiologic reactions (e.g. wound healing, regeneration, the vascularization of ischemic tissues, and menstruation), and pathologic processes, such as tumor development and metastasis, diabetic retinopathy, and chronic inflammation. Therefore great efforts have been made to understand the mechanisms of angiogenesis, and to develop agents that have pro- or anti-angiogenic activity.

Around 4000 BC, Egyptian physicians believed that there were "vessels for every part of the body, which are hollow, having a mouth which opens to absorb medications and eliminate waste".[80] Fortunately, our understanding of blood vessels has clearly improved since then.[81,][82] We know now that blood vessels are assembled during embryonic development by *vasculogenesis*, in which a primitive vascular network is established from endothelial cell precursors (*angioblasts*), or from dual hemopoietic/endothelial cell precursors called *hemangioblasts*. Blood vessel formation in adults, known as *angiogenesis* or *neovascularization*, involves the branching and extension of adjacent pre-existing vessels, but it can also occur by recruitment of endothelial progenitor cells (EPCs) from the bone marrow (Fig. 3-15).[81]

Angiogenesis from Preexisting Vessels.

In this type of angiogenesis there is vasodilation and increased permeability of the existing vessels, degradation of ECM, and migration of endothelial cells. The major steps are listed below.

- *Vasodilation* in response to nitric oxide, and VEGF-induced increased permeability of the preexisting vessel
- Proteolytic *degradation of the basement membrane of* the parent vessel by matrix metalloproteinases (MMPs) and disruption of cell-to-cell contact between endothelial cells by plasminogen activator
- *Migration of endothelial cells* toward the angiogenic stimulus
- *Proliferation of endothelial cells*, just behind the leading front of migrating cells
- *Maturation of endothelial cells*, which includes inhibition of growth and remodeling into capillary tubes
- *Recruitment of periendothelial cells* (pericytes and vascular smooth muscle cells) to form the mature vessel

Angiogenesis from Endothelial Precursor Cells (EPCs).

EPCs can be recruited from the bone marrow into tissues to initiate angiogenesis (Fig. 3-15). The nature of the homing mechanism is uncertain. These cells express some markers of hematopoietic stem cells as well as VEGFR-2, and vascular endothelial–cadherin (VE-cadherin). EPCs may contribute to the re-endothelization of vascular implants and the neovascularization of ischemic organs, cutaneous wounds, and tumors. The number of circulating EPCs increases greatly in patients with ischemic conditions, suggesting that EPCs may influence vascular function and determine the risk of cardiovascular diseases.

Growth Factors and Receptors Involved in Angiogenesis

Despite the diversity of factors that participate in angiogenesis, VEGF is the most important growth factor in adult tissues undergoing physiologic angiogenesis (e.g., proliferating endometrium) as well as angiogenesis occurring in chronic inflammation, wound healing, tumors, and diabetic retinopathy.[81,][82]

As mentioned earlier,[58] VEGF is secreted by many mesenchymal and stromal cells. Of the various receptors for VEGF, VEGFR-2, a tyrosine kinase receptor, is the most important in angiogenesis. It is expressed by endothelial cells and their precursors, by other cell types, and by many tumor cells. VEGF, or more specifically, its circulating isoforms $VEGF_{121}$ and $VEGF_{165}$, signal through VEGFR-2 (also known as KDR in humans and flk-1 in mice). VEGF induces the migration of EPCs in the bone marrow, and enhances the proliferation and differentiation of these cells at sites of angiogenesis. In angiogenesis originating from preexisting local vessels, VEGF signaling stimulates the survival of endothelial cells, their proliferation and their motility, initiating the sprouting of new capillaries. The main components of the VEGF/VEGFR system and their main actions are listed in Table 3-3 . Endothelial cell proliferation, differentiation, and migration can also be stimulated by FGF-2.

Given the multiplicity of VEGF effects and the diverse mechanisms that regulate its expression, how do endothelial cells develop into a perfect pattern of vessels during angiogenesis? One recently identified mechanism for the modulation of vasculogenesis is the Notch pathway, which promotes the proper branching of new vessels and prevents excessive angiogenesis by decreasing the responsiveness to VEGF. [83] [84] [85] Notch ligands and receptors are membrane-bound molecules conserved between species. In mammals there are five Notch ligands (Jagged 1 and 2, and Delta-like ligand [Dll] 1, 3, and 4) and four transmembrane receptors (Notch 1–4). The receptors contain EGF-like repeats on their extracellular surface that serve as ligand-binding sites (Fig. 3-16). The Delta-like ligand 4 (Dll4) ligand is endothelial cell–specific and is expressed in arteries and capillaries but not in veins; the importance of this ligand is demonstrated by the embryonic lethality of mice that lack a single Delta-like ligand 4 allele. During angiogenesis the leading cell, known as a tip cell, undergoes proliferation and migration, but stalk cells maintain their connection with the existing vessel. VEGF induces Delta-like ligand 4 in tip cells, while Notch1 and Notch4 are expressed in stalk cells (see Fig. 3-16C). The interaction between Delta-like ligand 4 and Notch receptors in adjacent tip and stalk cells leads to a two-step proteolytic cleavage of the receptor, releasing the Notch intracellular domain, which translocates to the nucleus and activates genes that dampen responsiveness to VEGF. Blockade of Delta-like ligand 4 causes increased proliferation of endothelial cells and capillary sprouting; VEGF blockade has the opposite effects and also decreases the survival of endothelial cells (Fig. 3-17).

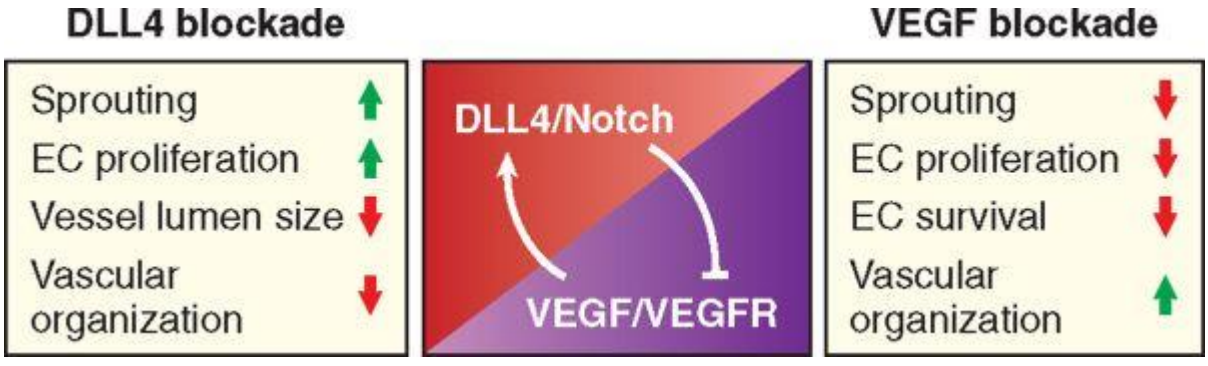

FIGURE 3-17 Interactions between Notch and VEGF during angiogenesis. VEGF stimulates delta-like ligand 4 (Dll4)/Notch, which inhibits VEGFR signaling. Compared with unperturbed angiogenesis, Dll4 blockade causes an increase in capillary sprouting and endothelial cell (EC) proliferation, creating vessels that are disorganized and have a small lumen size. VEGF blockade decreases capillary sprouting, and the proliferation and survival of ECs. *(Courtesy of Minhong Yan, Genentech, San Francisco, CA).*

Regardless of the process that leads to capillary formation, newly formed vessels are fragile and need to become "stabilized." Stabilization requires the recruitment of pericytes and smooth muscle cells (periendothelial cells) and the deposition of ECM proteins. *Angiopoietins 1 and 2 (Ang1 and Ang2*), PDGF, and TGF-β participate in the stabilization process. Ang1 interacts with a receptor on endothelial cells called *Tie2* to recruit periendothelial cells. PDGF participates in the recruitment of smooth muscle cells, while TGF-β stabilizes newly formed vessels by enhancing the production of ECM proteins.[58] The Ang1-Tie2 interaction mediates vessel maturation from simple endothelial tubes into more elaborate vascular structures and helps maintain endothelial quiescence. Ang2, in contrast, which also interacts with Tie2, has the opposite effect, making endothelial cells become either more responsive to stimulation by growth factors such as VEGF or, in the absence of VEGF, more responsive to inhibitors of angiogenesis. A telling proof of the importance of these molecules is the existence of a genetic disorder caused by mutations in *Tie2* that is characterized by venous malformations. Agents or conditions that stimulate VEGF expression, such as certain cytokines and growth factors (e.g., TGF-β, PDGF, TGF-α), and notably, *tissue hypoxia*, can influence physiologic and pathologic angiogenesis. *VEGF transcription is regulated by the transcription factor HIF, which is induced by hypoxia*.

ECM Proteins as Regulators of Angiogenesis

A key component of angiogenesis is the motility and directed migration of endothelial cells, required for the formation of new blood vessels. These processes are controlled by several classes of proteins, including (1) *integrins*, especially $\alpha_v\beta_3$, which is critical for the formation and maintenance of newly formed blood vessels, (2) *matricellular proteins*, including thrombospondin 1, SPARC, and tenascin C, which destabilize cell-matrix interactions and therefore promote angiogenesis, and (3) *proteinases*, such as the plasminogen activators and *MMPs*, which are important in tissue remodeling during endothelial invasion. Additionally, these proteinases cleave extracellular proteins, releasing matrix-bound growth factors such as VEGF and FGF-2 that stimulate angiogenesis. Proteinases can also release inhibitors such as *endostatin*, a small fragment of collagen that inhibits endothelial proliferation and angiogenesis. $\alpha_V\beta_3$ Integrin expression in endothelial cells is stimulated by hypoxia and has multiple effects on angiogenesis: it interacts with a metalloproteinase (MMP-2, discussed below), it binds to and regulates the activity of VEGFR-2, and it mediates adhesion to ECM components such as fibronectin, thrombospondin, and OPN.[72]

The review of ECM components, cell-matrix interactions, and the mechanisms of angiogenesis sets the stage for the discussion of tissue healing that involves repair and scar formation, with special emphasis on the steps and main mechanisms of cutaneous wound healing.

CUTANEOUS WOUND HEALING

Cutaneous wound healing is divided into three phases: inflammation, proliferation, and maturation[86] (Fig. 3-18). These phases overlap, and their separation is somewhat arbitrary, but they help to understand the sequence of events that take place in the healing of skin wounds. The initial injury causes platelet adhesion and aggregation and the formation of a clot in the surface of the wound, leading to *inflammation*. In the *proliferative phase* there is formation of granulation tissue, proliferation and migration of connective tissue cells, and re-epithelialization of the wound surface. *Maturation* involves ECM deposition, tissue remodeling, and wound contraction.

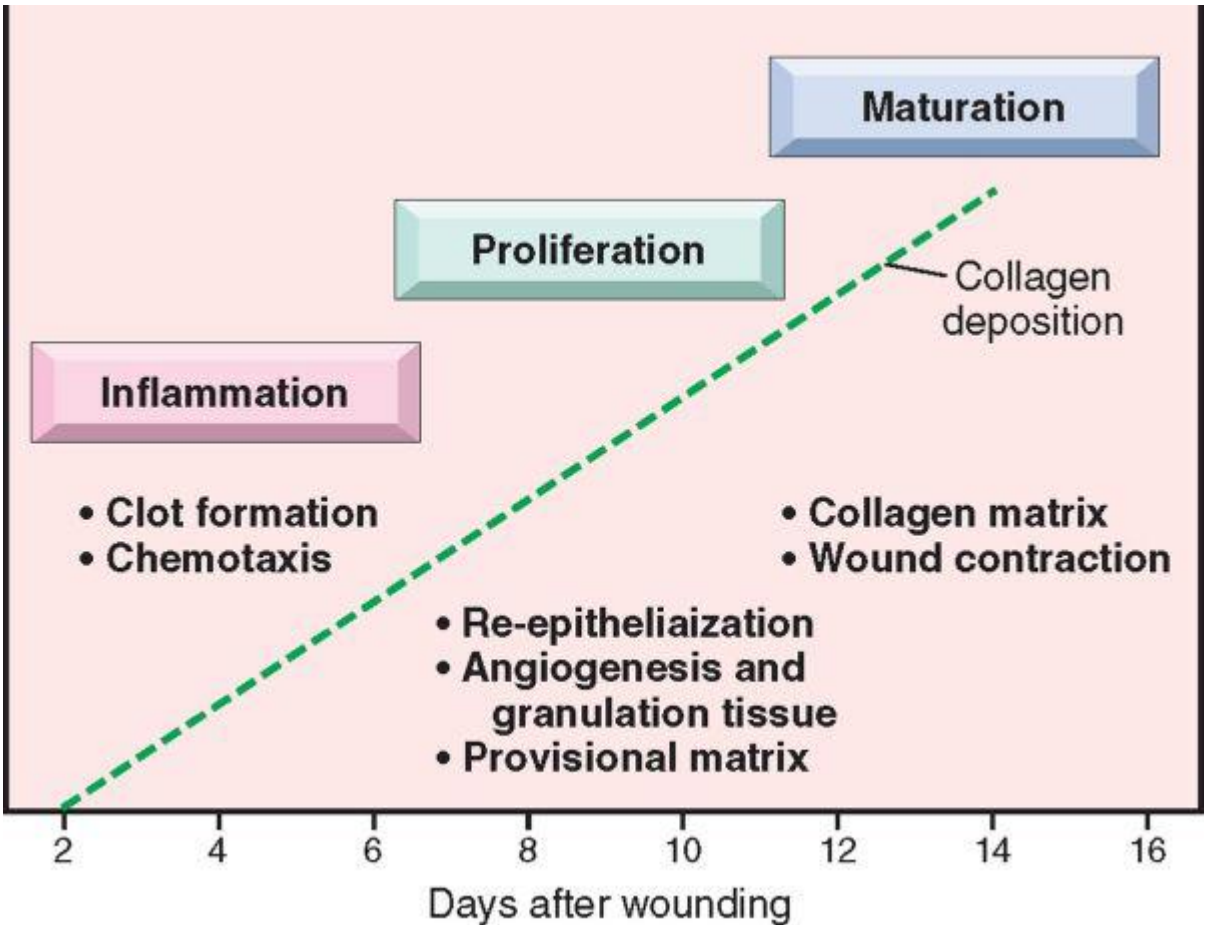

FIGURE 3-18 Phases of cutaneous wound healing: inflammation, proliferation, and maturation (see text for details). *(Modified from Broughton G et al: The basic science of wound healing. Plast Reconstr Surg 117:12S–34S, 2006.)*

The simplest type of cutaneous wound repair is the healing of a clean, uninfected surgical incision approximated by surgical sutures (Fig. 3-19). Such healing is referred to as *healing by primary union* or *by first intention*.[86] [87] [88] The incision causes death of a limited number of epithelial and connective tissue cells and disruption of epithelial basement membrane continuity. *Re-epithelialization to close the wound occurs with formation of a relatively thin scar*. The repair process is more complicated in excisional wounds that create large defects on the skin surface, causing extensive loss of cells and tissue. *The healing of these wounds involves a more intense inflammatory reaction, the formation of abundant granulation tissue (described below), and extensive collagen deposition, leading to the formation of a substantial scar, which generally contracts*. This form of healing is referred to as *healing by secondary union* or *by second intention* (see Figs. 3-19 and 3-20). Despite these differences, the basic mechanisms of healing by primary (first intention) and secondary (second intention) union are similar. They are described together and the differences will be indicated where appropriate.

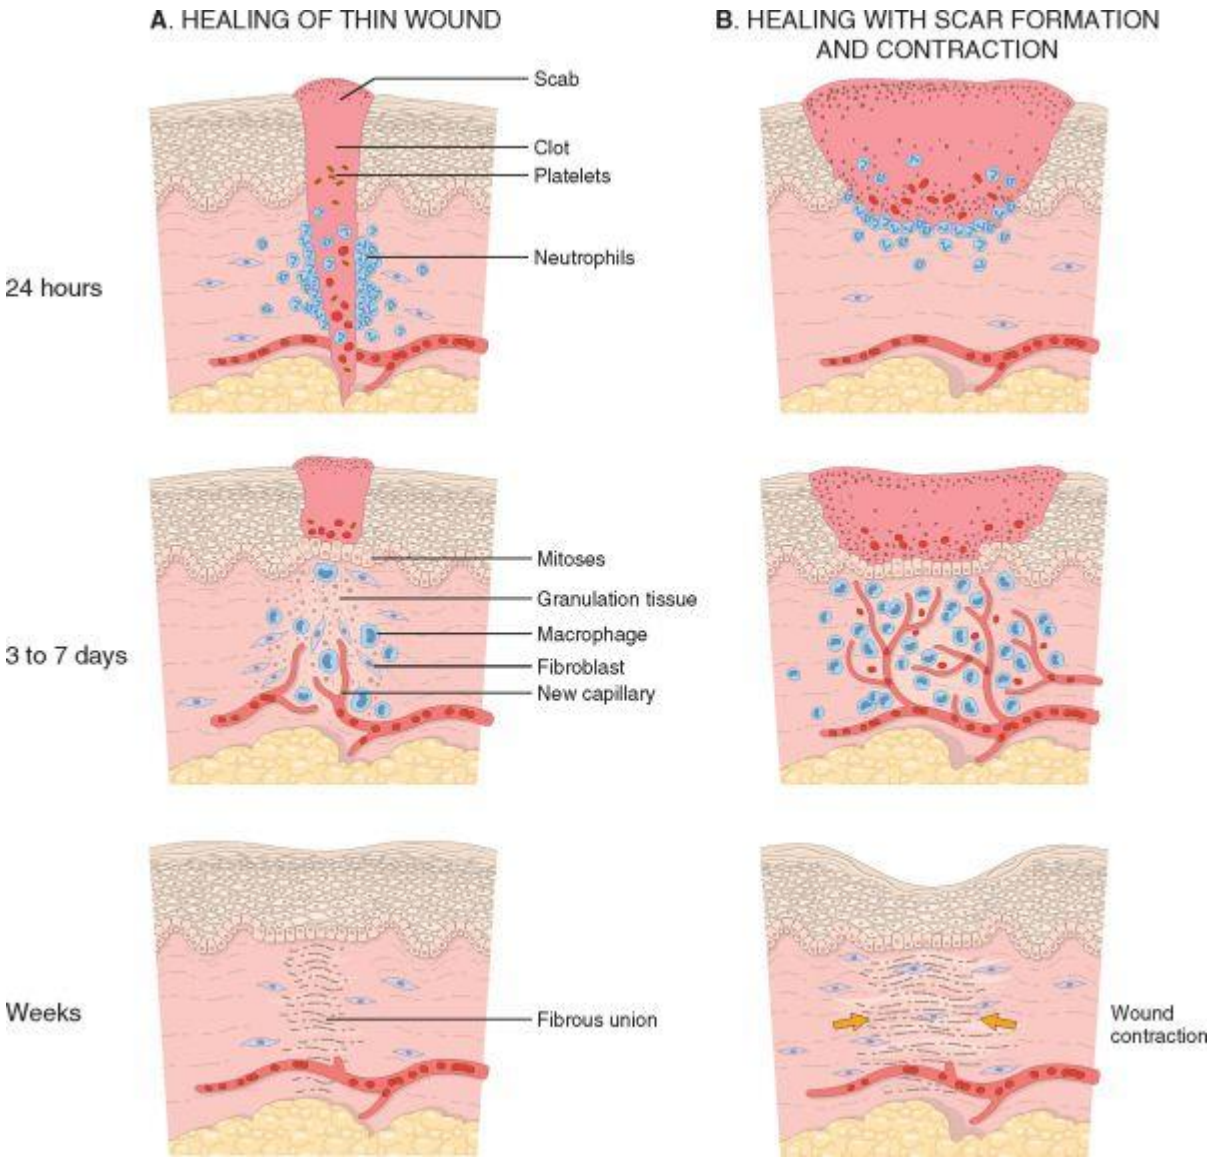

FIGURE 3-19 Wound healing and scar formation. **A**, Healing of wound that caused little loss of tissue: note the small amount of granulation tissue, and formation of a thin scar with minimal contraction. **B**, Healing of large wound: note large amounts of granulation tissue and scar tissue, and wound contraction.

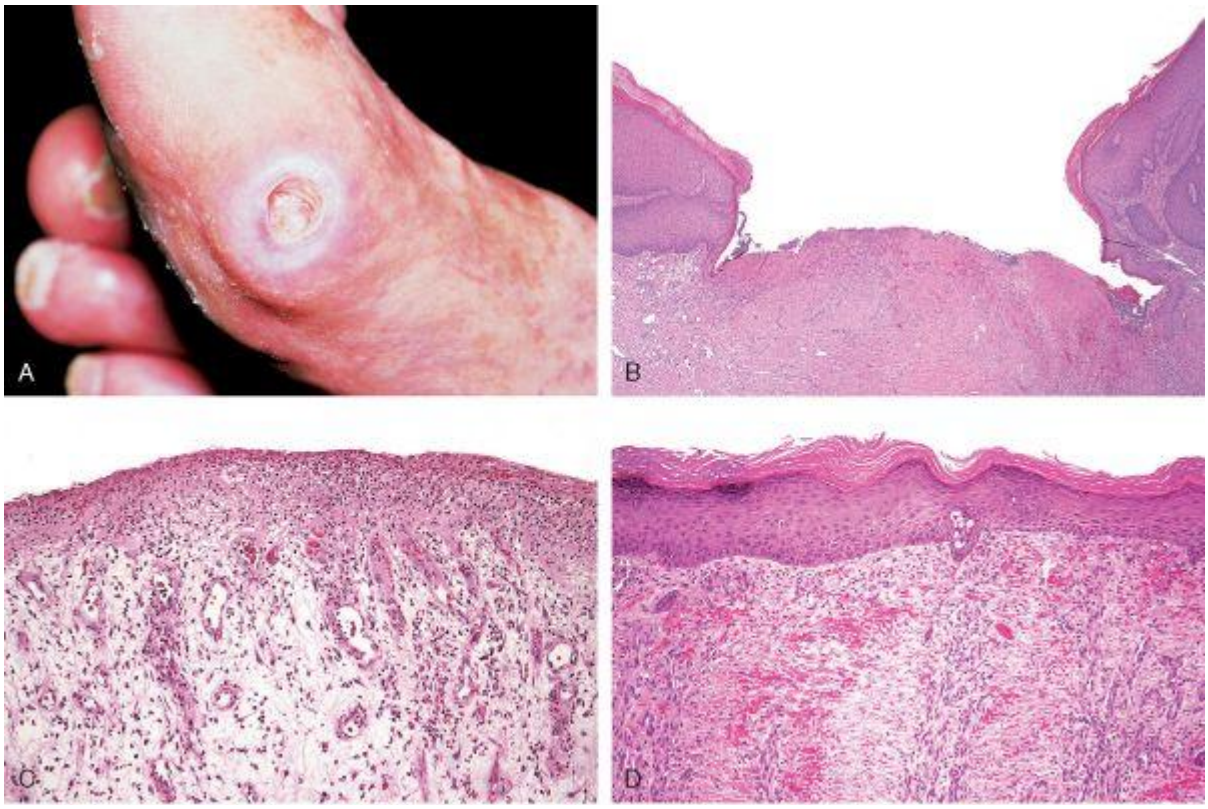

FIGURE 3-20 Healing of skin ulcers. **A**, Pressure ulcer of the skin, commonly found in diabetic patients. The histologic slides show: **B**, a skin ulcer with a large gap between the edges of the lesion; **C**, a thin layer of epidermal re-epithelialization and extensive granulation tissue formation in the dermis; and **D**, continuing re-epithelialization of the epidermis and wound contraction. *(Courtesy of Z. Argenyi, MD, University of Washington, Seattle, WA.)*

A large number of growth factors and cytokines are involved in cutaneous wound healing.[89] The main agents, and the steps at which they participate in the repair process, are listed in Table 3-4 . We next discuss the sequence of events in wound healing.

TABLE 3-4 -- Growth Factors and Cytokines Affecting Various Steps in Wound Healing

Monocyte chemotaxis	Chemokines, TNF, PDGF, FGF, TGF-β
Fibroblast migration/replication	PDGF, EGF, FGF, TGF-β, TNF, IL-1
Keratinocyte replication	HB-EGF, FGF-7, HGF
Angiogenesis	VEGF, angiopoietins, FGF
Collagen synthesis	TGF-β, PDGF
Collagenase secretion	PDGF, FGF, TNF; TGF-β inhibits

HB-EGF, heparin-binding EGF; IL-1, interleukin 1; TNF, tumor necrosis factor; other abbreviations as given in Table 3-1 .

Formation of Blood Clot.

Wounding causes the rapid activation of coagulation pathways, which results in *the formation of a blood clot on the wound surface* (Chapter 4). In addition to entrapped red cells, the clot contains fibrin, fibronectin, and complement components. *The clot serves to stop bleeding and also as a scaffold for migrating cells, which are attracted by growth factors, cytokines and chemokines released into the area*.[89] Release of VEGF leads to increased vessel permeability and edema. However, dehydration occurs at the external surface of the clot, forming a scab that covers the wound. In wounds causing large tissue deficits, the fibrin clot is larger, and there is more exudate and necrotic debris in the wounded area. Within 24 hours, *neutrophils* appear at the margins of the incision, and use the scaffold provided by the fibrin clot to march in. They release proteolytic enzymes that clean out debris and invading bacteria.

Formation of Granulation Tissue.

Fibroblasts and vascular endothelial cells proliferate in the first 24 to 72 hours of the repair process to form a specialized type of tissue called *granulation tissue*, which is a hallmark of tissue repair. The term derives from its pink, soft, granular appearance on the surface of wounds. Its characteristic histologic feature is *the presence of new small blood vessels (angiogenesis) and the proliferation of fibroblasts* (Fig. 3-21). These new vessels are leaky, allowing the passage of plasma proteins and fluid into the extravascular space. Thus, new granulation tissue is often edematous. Granulation tissue progressively invades the incision space; the amount of *granulation tissue that is formed depends on the size of the tissue deficit created by the wound and the intensity of inflammation*. Hence, it is much more prominent in healing by secondary union. By 5 to 7 days, granulation tissue fills the wound area and neovascularization is maximal. The mechanisms of angiogenesis in repair processes were discussed earlier in this chapter.

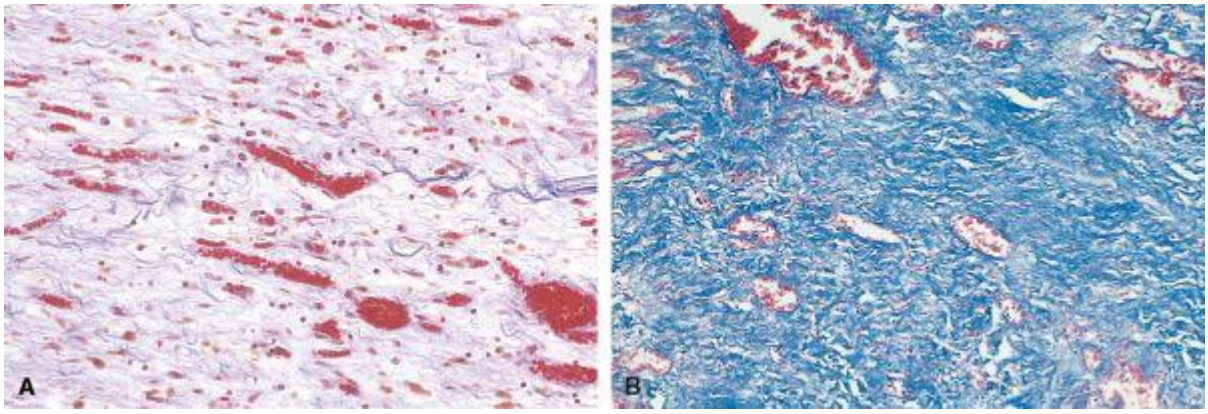

FIGURE 3-21 **A**, Granulation tissue showing numerous blood vessels, edema, and a loose ECM containing occasional inflammatory cells. Collagen is stained blue by the trichrome stain; minimal mature collagen can be seen at this point. **B**, Trichrome stain of mature scar, showing dense collagen, with only scattered vascular channels.

Cell Proliferation and Collagen Deposition.

Neutrophils are largely replaced by *macrophages* by 48 to 96 hours. *Macrophages are key cellular constituents of tissue repair*, clearing extracellular debris, fibrin, and other foreign material at the site of repair, and promoting angiogenesis and ECM deposition (Fig. 3-22).

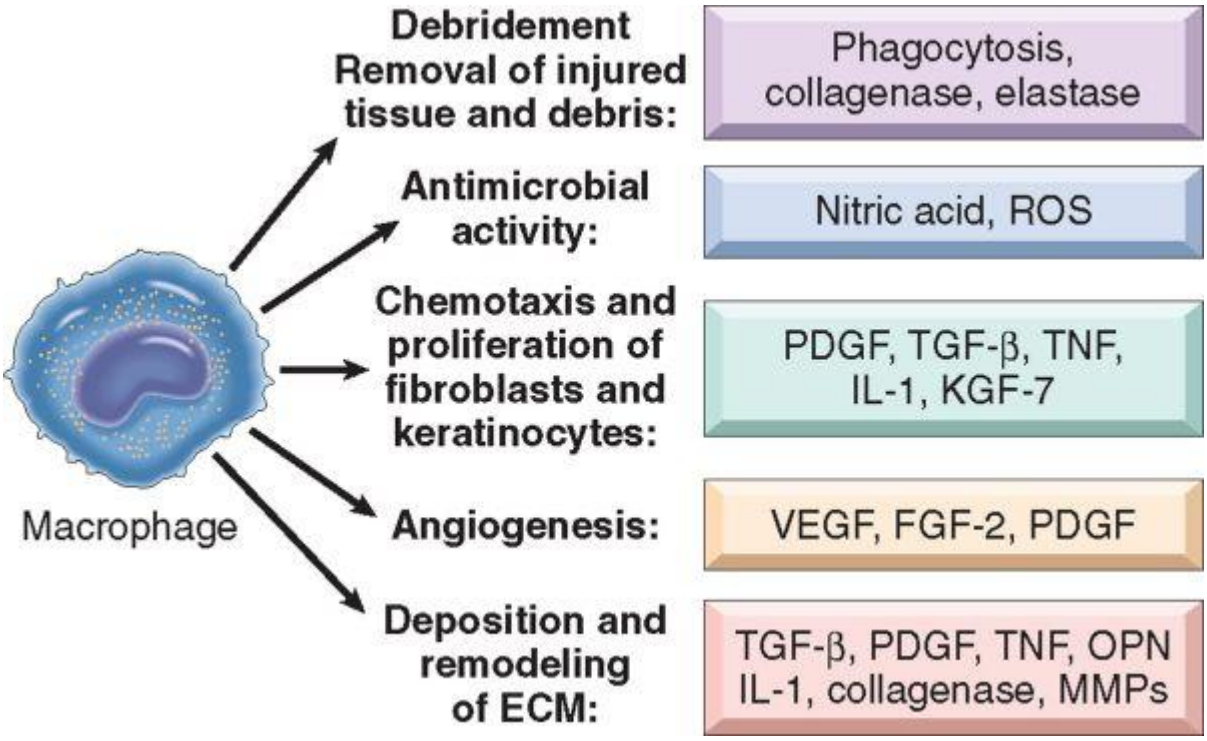

FIGURE 3-22 Multiple roles of macrophages in wound healing. Macrophages participate in wound debridement, have antimicrobial activity, stimulate chemotaxis and the activation of inflammatory cells and fibroblasts, promote angiogenesis, and stimulate matrix remodeling and synthesis. ROS, reactive oxygen species.

Migration of fibroblasts to the site of injury is driven by chemokines, TNF, PDGF, TGF-β, and FGF. Their subsequent proliferation is triggered by multiple growth factors, including PDGF, EGF, TGF-β, FGF, and the cytokines IL-1 and TNF (see Table 3-4). Macrophages are the main source for these factors, although other inflammatory cells and platelets may also produce them. Collagen fibers are now present at the margins of the incision, but at first these are vertically oriented and do not bridge the incision. In 24 to 48 hours, *spurs of epithelial cells move from the wound edge (initially with little cell proliferation) along the cut margins of the dermis, depositing basement membrane components* as they move. They fuse in the midline beneath the surface scab, producing a thin, continuous epithelial layer that closes the wound. Full epithelialization of the wound surface is much slower in healing by secondary union because the gap to be bridged is much greater. Subsequent epithelial cell proliferation thickens the epidermal layer. Macrophages stimulate fibroblasts to produce FGF-7 (keratinocyte growth factor) and IL-6, which enhance keratinocyte migration and proliferation. Other mediators of re-epithelialization are HGF and HB-EGF.[89] Signaling through the chemokine receptor CXCR 3 also promotes skin re-epithelialization.

Concurrently with epithelialization, collagen fibrils become more abundant and begin to bridge the incision. At first a provisional matrix containing fibrin, plasma fibronectin, and type III collagen is formed, but this is replaced by a matrix composed primarily of type I collagen. *TGF-β is the most important fibrogenic agent* (see Table 3-4). It is produced by most of the cells in granulation tissue and causes fibroblast migration and proliferation, increased synthesis of collagen and fibronectin, and decreased degradation of ECM by metalloproteinases. The epidermis recovers its normal thickness and architecture, and surface keratinization.

Scar Formation.

The leukocytic infiltrate, edema, and increased vascularity largely disappear during the second week. Blanching begins, accomplished by the increased accumulation of collagen within the wound area and regression of vascular channels. Ultimately, the original granulation tissue scaffolding is converted into a pale, avascular scar, composed of spindle-shaped fibroblasts, dense collagen, fragments of elastic tissue, and other ECM components. The dermal appendages that have been destroyed in the line of the incision are permanently lost, although in rats new hair follicles may develop in large healing wounds under Wnt stimulation.[90] This result suggests that, with appropriate treatment procedures, regrowth of skin appendages during wound healing might be achieved in humans. *By the end of the first month, the scar is made up of acellular connective tissue devoid of inflammatory infiltrate, covered by intact epidermis*.

Wound Contraction.

Wound contraction generally occurs in large surface wounds. The contraction helps to close the wound by decreasing the gap between its dermal edges and by reducing the wound surface area. Hence, it is an important feature in healing by secondary union. The initial steps of wound contraction involve the formation, at the edge of the wound, of a network of *myofibroblasts* that express smooth muscle α-actin and vimentin. These cells have ultrastructural characteristics of smooth muscle cells, contract in the wound tissue, and may produce large amounts of ECM components (see discussion of hypertrophic scars in this chapter), such as type I collagen, tenascin-C, SPARC, and extra-domain fibronectin.[91] Myofibroblasts are formed from tissue fibroblasts through the effects of PDGF, TGF-β, and FGF-2 released by macrophages at the wound site, but they can also originate from bone marrow precursors known as fibrocytes, or from epithelial cells, through the process of epithelial-to-mesenchymal transition.

Connective Tissue Remodeling.

The replacement of granulation tissue with a scar involves changes in the composition of the ECM. The balance between ECM synthesis and degradation results in remodeling of the connective tissue framework – an important feature of tissue repair. Some of the growth factors that stimulate synthesis of collagen and other connective tissue molecules also modulate the synthesis and activation of metalloproteinases, enzymes that degrade these ECM components.

Degradation of collagen and other ECM proteins is achieved by matrix metalloproteinases (MMPs), a family of enzymes that includes more than 20 members that have in common a 180-residue zinc-protease domain (MMPs should be distinguished from neutrophil elastase, cathepsin G, kinins, plasmin, and other important proteolytic enzymes, which also degrade EMC components and which are *serine proteinases, not metalloenzymes*). Matrix metalloproteinases include *interstitial collagenases (MMP-1, -2, and -3)*, which cleave the fibrillar collagen types I, II, and III; *gelatinases (MMP-2 and 9)*, which degrade amorphous collagen as well as fibronectin; *stromelysins (MMP-3, 10, and 11)*, which act on a variety of ECM components, including proteoglycans, laminin, fibronectin, and amorphous collagens; and the family of *membrane-bound MMPs* (ADAMs) described below. MMPs are produced by fibroblasts, macrophages, neutrophils, synovial cells, and some epithelial cells. Their secretion is induced by growth factors (PDGF, FGF), cytokines (IL-1, TNF), and phagocytosis in macrophages, and is inhibited by TGF-β and steroids. Collagenases cleave collagen under physiologic conditions. They are synthesized as a latent precursor (procollagenase) that is activated by chemicals, such as free radicals produced during the oxidative burst of leukocytes, and proteinases (plasmin). Once formed, activated collagenases are rapidly inhibited by a family of specific tissue *inhibitors of metalloproteinases*, which are produced by most mesenchymal cells, thus preventing uncontrolled

action of these proteases. Collagenases and their inhibitors are essential in the debridement of injured sites and in the remodeling of connective tissue necessary to repair the defect.

A large and important family of enzymes related to MMPs is called ADAM (disintegrin and metalloproteinase-domain family). Most ADAMs are anchored by a single transmembrane domain to cell surface. ADAM-17 (also known as TACE, for TNF-converting enzyme) cleaves the membrane-bound precursor forms of TNF and TGF-α, releasing the active molecules. ADAM-17 deficiency in mice causes embryonic or neonatal lethality associated with pulmonary hypoplasia. Members of the ADAM family are also involved in the pathogenesis of bronchial asthma (Chapter 15), and thrombotic microangiopathies (Chapter 13).

Recovery of Tensile Strength.

Fibrillar collagens (mostly type I collagen) form a major portion of the connective tissue in repair sites and are essential for the development of strength in healing wounds. *Net collagen accumulation, however, depends not only on increased collagen synthesis but also on decreased degradation*. How long does it take for a skin wound to achieve its maximal strength? When sutures are removed from an incisional surgical wound, usually at the end of the first week, wound strength is approximately 10% that of unwounded skin. *Wound strength* increases rapidly over the next 4 weeks, slows down at approximately the third month after the original incision, and reaches a plateau at about 70% to 80% of the tensile strength of unwounded skin. Lower tensile strength in the healed wound area may persist for life. The recovery of tensile strength results from the excess of collagen synthesis over collagen degradation during the first 2 months of healing, and, at later times, from structural modifications of collagen fibers (cross-linking, increased fiber size) after collagen synthesis ceases.

LOCAL AND SYSTEMIC FACTORS THAT INFLUENCE WOUND HEALING

The adequacy of wound repair may be impaired by systemic and local host factors.

Systemic factors include those listed below:

- *Nutrition* has profound effects on wound healing. Protein deficiency, for example, and particularly vitamin C deficiency, inhibit collagen synthesis and retard healing.
- *Metabolic status* can change wound healing. Diabetes mellitus, for example, is associated with delayed healing, as a consequence of the microangiopathy that is a frequent feature of this disease (Chapter 24).
- *Circulatory status* can modulate wound healing. *Inadequate blood supply*, usually caused by arteriosclerosis or venous abnormalities (e.g., varicose veins) that retard venous drainage, also impairs healing.
- *Hormones* such as *glucocorticoids* have well-documented anti-inflammatory effects that influence various components of inflammation. These agents also inhibit collagen synthesis.

Local factors that influence healing include those listed here:

- *Infection* is the single most important cause of delay in healing, because it results in persistent tissue injury and inflammation.
- *Mechanical factors*, such as early motion of wounds, can delay healing, by compressing blood vessels and separating the edges of the wound.
- *Foreign bodies*, such as unnecessary sutures or fragments of steel, glass, or even bone, constitute impediments to healing.
- *Size, location, and type of wound*. Wounds in richly vascularized areas, such as the face, heal faster than those in poorly vascularized ones, such as the foot. As we have discussed, small incisional injuries heal faster and with less scar formation than large excisional wounds or wounds caused by blunt trauma.

PATHOLOGIC ASPECTS OF REPAIR

Complications in wound healing can arise from abnormalities in any of the basic components of the repair process. These aberrations can be grouped into three general categories: (1) *deficient scar formation*, (2) *excessive formation of the repair components*, and (3) *formation of contractures*.

- *Inadequate formation of granulation tissue or assembly of a scar* can lead to two types of complications: *wound dehiscence* and *ulceration*. Dehiscence or rupture of a wound is most common after abdominal surgery and is due to increased abdominal pressure. Vomiting, coughing, or ileus can generate mechanical stress on the abdominal wound. Wounds can ulcerate because of inadequate vascularization during healing. For example, lower extremity wounds in individuals with atherosclerotic peripheral vascular disease typically ulcerate (Chapter 11). Nonhealing wounds also form in areas devoid of sensation. These neuropathic ulcers are occasionally seen in patients with diabetic peripheral neuropathy (Chapters 24 and 27 .
- *Excessive formation of the components of the repair process* can give rise to hypertrophic scars and keloids. The accumulation of excessive amounts of collagen may give rise to a raised scar known as a *hypertrophic scar*; if the scar tissue grows beyond the boundaries of the original wound and does not regress, it is called a *keloid* (Fig. 3-23). Keloid formation seems to be an individual predisposition, and for unknown reasons this aberration is somewhat more common in African Americans. Hyperthrophic scars generally develop after thermal or traumatic injury that involves the deep layers of the dermis. Collagen is produced by myofibroblasts, which persist in the lesion through the autocrine production of TGF-β, and the establishment of focal adhesions.[92]
  Exuberant granulation is another deviation in wound healing consisting of the formation of excessive amounts of granulation tissue, which protrudes above the level of the surrounding skin and blocks re-epithelialization (this process has been called, with more literary fervor, *proud flesh*). Excessive granulation must be removed by cautery or surgical excision to permit restoration of the continuity of the epithelium. Finally (fortunately rarely), incisional scars or traumatic injuries may be followed by exuberant proliferation of fibroblasts and other connective tissue elements that may, in fact, recur after excision. Called *desmoids*, or *aggressive fibromatoses*, these lie in the interface between benign proliferations and malignant (though low-grade) tumors. The line between the benign hyperplasias characteristic of repair and neoplasia is frequently finely drawn (Chapter 7).
- *Contraction* in the size of a wound is an important part of the normal healing process. An exaggeration of this process gives rise to *contracture* and results in deformities of the wound and the surrounding tissues. Contractures are particularly prone to develop on the palms, the soles, and the anterior aspect of the thorax. Contractures are commonly seen after serious burns and can compromise the movement of joints (Fig. 3-24).

Fibrosis

Deposition of collagen is part of normal wound healing. However, the term *fibrosis* is used more broadly to denote the excessive deposition of collagen and other ECM components in a tissue. As already mentioned, the terms *scar* and *fibrosis* are used interchangeably, but *fibrosis* most often indicates the deposition of collagen in chronic diseases. The basic mechanisms that occur in the development of fibrosis associated with chronic inflammatory diseases are generally similar to the mechanisms of skin wound healing that have been discussed in this chapter. However, in contrast to the short-lived stimulus that triggers the orderly steps of wound healing in the skin, the injurious stimulus caused by infections, autoimmune reactions, trauma, and other types of tissue injury persists in chronic diseases, causing organ dysfunction and often organ failure.

The persistence of injury leads to chronic inflammation, which is associated with the proliferation and activation of macrophages and lymphocytes, and the production of a plethora of inflammatory and fibrogenic growth factors and cytokines, mentioned earlier and summarized in Figure 3-25 .

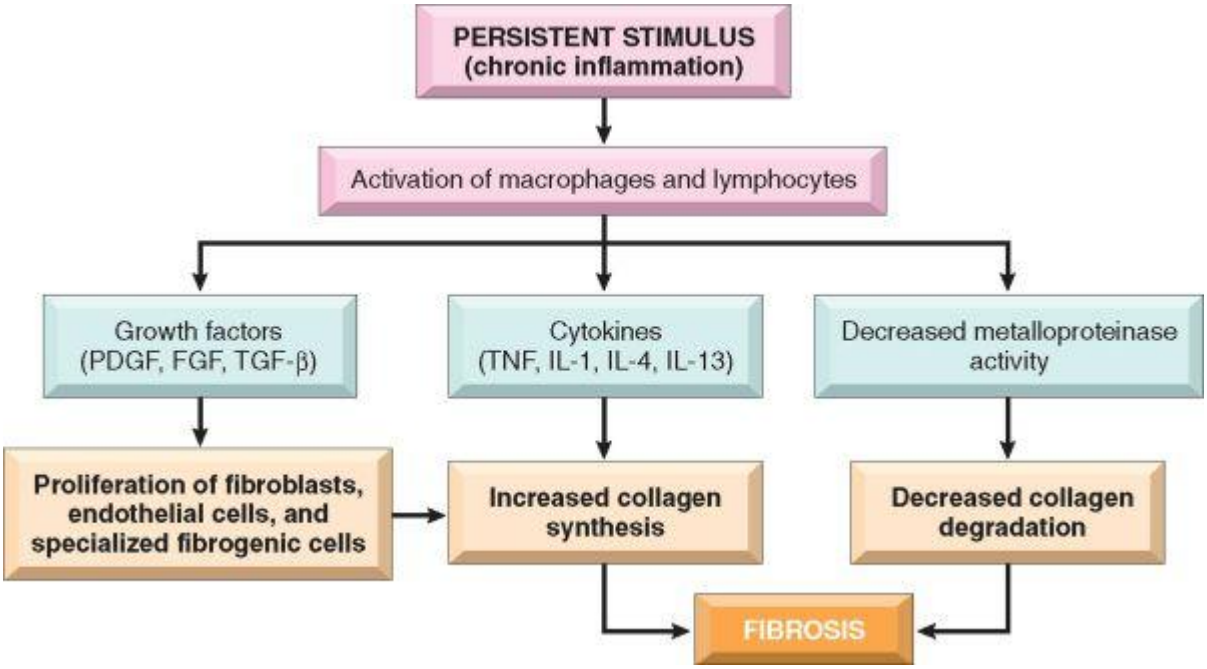

FIGURE 3-25 Development of fibrosis in chronic inflammation. The persistent stimulus of chronic inflammation activates macrophages and lymphocytes, leading to the production of growth factors and cytokines, which increase the synthesis of collagen. Deposition of collagen is enhanced by decreased activity of metalloproteinases.

The host response to harmful stimuli is orchestrated to first clear these stimuli and then heal the damage. As we discussed in Chapter 2 (see Fig. 2-10), the initial wave of the host response to external invaders and tissue injury generates "classically activated macrophages", which are effective in ingesting and destroying microbes and dead tissues. This is followed by the accumulation of "alternatively activated macrophages", which suppress the microbicidal activities and instead function to remodel tissues and promote angiogenesis and scar formation.[93] The cytokines that induce classical macrophage activation are those produced by T_H1 cells, notably IFN-γ and TNF, whereas alternative macrophage activation is best induced by IL-4 and IL-13, cytokines produced by T_H2 cells and other cells including mast cells and eosinophils. Alternatively activated macrophages produce TGF-β and other growth factors that are involved in the repair process.

TGF-β is practically always involved as an important fibrogenic agent (see Table 3-4) in these diseases, regardless of the original cause. It is produced by most of the cells in granulation tissue and causes fibroblast migration and proliferation, increased synthesis of collagen and fibronectin, and decreased degradation of ECM due to inhibition of metalloproteinases. The levels of TGF-β in tissues are not primarily regulated by the transcription of the gene but depend on the post-transcriptional activation of latent TGF-β, the rate of secretion of the active molecule, and factors in the ECM that enhance or diminish TGF-β activity.

The mechanisms that lead to the activation of TGF-β in fibrosis are not precisely known, but cell death by necrosis or apoptosis and the production of reactive oxygen species seem to be important triggers of

the activation, regardless of the tissue. Similarly, the cells that produce collagen under TGF-β stimulation may vary depending on the tissue. In most cases, such as in lung and kidney fibrosis, myofibroblasts (already discussed in this chapter) are the main source of collagen, but stellate cells are the major collagen producers in liver cirrhosis.

Recent studies provide evidence for an important role for osteopontin (OPN) in would healing and fibrosis.[77] OPN is strongly expressed in fibrosis of the heart, lung, liver, kidney and some other tissues. In animal experiments, blockage of OPN expression during wound healing decreases the formation of granulation tissue and scarring.[94] Although the mechanisms by which OPN promotes fibrosis are not completely understood, recent data show that OPN is a mediator of the differentiation of myofibroblasts induced by TGF-β.

In marked contrast to wounds in adults, fetal cutaneous wounds heal without scar formation.[95,][96] Several factors have been proposed to promote scarless healing, including the secretion of non-fibrogenic forms of TGF-β, the lack of osteopontin, and the absence of a T_H2 response, but no definitive results have been obtained. Given the serious organ dysfunction produced by fibrosis, there is a major effort to develop clinically useful antifibrotic agents. Among agents being tested are inhibitors of TGF-β binding or signaling, angiogenesis inhibitors, Toll-like receptors antagonists, and the decoy receptor IL-13Rα2 which blocks IL-13.

Fibrotic disorders include diverse diseases such as liver cirrhosis, systemic sclerosis, fibrosing diseases of the lung (*idiopathic pulmonary fibrosis, pneumoconioses, and drug-, radiation-induced pulmonay fibrosis), chronic pancreatitis, glomerulonephritis, and constrictive pericarditis*. These conditions are discussed in the appropriate chapters throughout the book.

This concludes the discussion, begun in Chapter 1 , of cellular and tissue injury, the inflammatory reaction to such injury (Chapter 2), and tissue healing by regeneration and repair. An overview of the relationships between these processes is illustrated in Fig. 3-26 .

2.4 4. Hemodynamic Disorders, Thromboembolic Disease & Shock

2.4.1 Edema

Richard N. Mitchell

As a group, cardiovascular diseases are the most important cause of morbidity and mortality in Western society. In the year 2005, it was estimated that 81 million people in the United States had one or more forms of cardiovascular disease, which were responsible for 35% to 40% of deaths. Included in this category are diseases that primarily affect one of the three major components of the cardiovascular system: the heart; the blood vessels; and the blood itself, which is composed of water, salts, a wide variety of proteins, elements that regulate clotting (the coagulation factors and platelets), and other formed elements (red cells and white cells). For the sake of simplicity we will consider disorders affecting each component of the cardiovascular system separately, recognizing that disturbances affecting one component often lead to adaptations and abnormalities involving others. Here, we focus on disorders of hemodynamics (edema, congestion, and shock) and hemostasis (hemorrhage and thrombosis), as well as various forms of embolism. Diseases that primarily affect the blood vessels and the heart will be discussed in Chapters 11 and 12 , respectively.

Edema

Approximately 60% of lean body weight is water. Two thirds of the body's water is intracellular, and the remainder is in extracellular compartments, mostly the interstitium (or third space) that lies between

cells; only about 5% of total body water is in blood plasma. The movement of water and low molecular weight solutes such as salts between the intravascular and interstitial spaces is controlled primarily by the opposing effect of vascular hydrostatic pressure and plasma colloid osmotic pressure. Normally the outflow of fluid from the arteriolar end of the microcirculation into the interstitium is nearly balanced by inflow at the venular end; a small residual amount of fluid may be left in the interstitium and is drained by the lymphatic vessels, ultimately returning to the bloodstream via the thoracic duct. *Either increased capillary pressure or diminished colloid osmotic pressure can result in increased interstitial fluid* (Fig. 4-1). If the movement of water into tissues (or body cavities) exceeds lymphatic drainage, fluid accumulates. An abnormal increase in interstitial fluid within tissues is called *edema*, while fluid collections in the different body cavities are variously designated *hydrothorax, hydropericardium, and hydroperitoneum* (the last is more commonly called *ascites*). *Anasarca* is a severe and generalized edema with widespread subcutaneous tissue swelling.

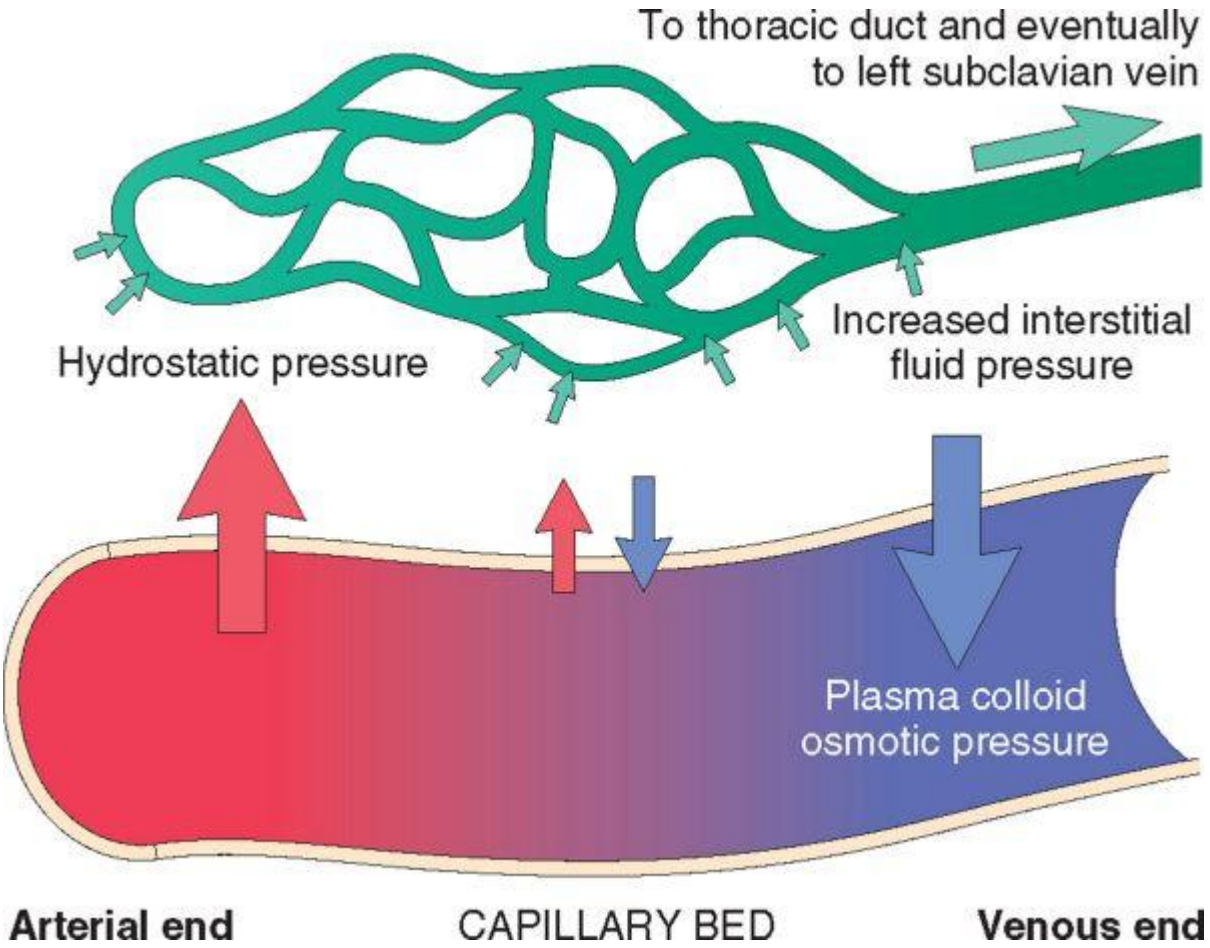

FIGURE 4-1 Factors influencing fluid transit across capillary walls. Capillary hydrostatic and osmotic forces are normally balanced so that there is no *net* loss or gain of fluid across the capillary bed. However, *increased* hydrostatic pressure or *diminished* plasma osmotic pressure will cause extravascular fluid to accumulate. Tissue lymphatics remove much of the excess volume, eventually returning it to the circulation via the thoracic duct; however, if the capacity for lymphatic drainage is exceeded, tissue *edema* results.

There are several pathophysiologic categories of edema (Table 4-1). Edema caused by increased hydrostatic pressure or reduced plasma protein is typically a protein-poor fluid called a *transudate*. Edema fluid of this type is seen in patients suffering from heart failure, renal failure, hepatic failure, and certain forms of malnutrition, as described below and outlined in Figure 4-2 . In contrast, inflammatory

edema is a protein-rich *exudate* that is a result of increased vascular permeability. Edema in inflamed tissues is discussed in Chapter 2 ; *noninflammatory causes of edema* (see Fig. 4-2) are described below.

TABLE 4-1 -- Pathophysiologic Categories of Edema

INCREASED HYDROSTATIC PRESSURE
Impaired venous return
Congestive heart failure
Constrictive pericarditis
Ascites (liver cirrhosis)
Venous obstruction or compression
Thrombosis
External pressure (e.g., mass)
Lower extremity inactivity with prolonged dependency
Arteriolar dilation
Heat
Neurohumoral dysregulation
REDUCED PLASMA OSMOTIC PRESSURE (HYPOPROTEINEMIA)
Protein-losing glomerulopathies (nephrotic syndrome)
Liver cirrhosis (ascites)
Malnutrition
Protein-losing gastroenteropathy
LYMPHATIC OBSTRUCTION
Inflammatory
Neoplastic
Postsurgical
Postirradiation
SODIUM RETENTION
Excessive salt intake with renal insufficiency
Increased tubular reabsorption of sodium
Renal hypoperfusion
Increased renin-angiotensin-aldosterone secretion
INFLAMMATION
Acute inflammation
Chronic inflammation
Angiogenesis

Modified from Leaf A, Cotran RS: Renal Pathophysiology, 3rd ed. New York, Oxford University Press, 1985, p 146.

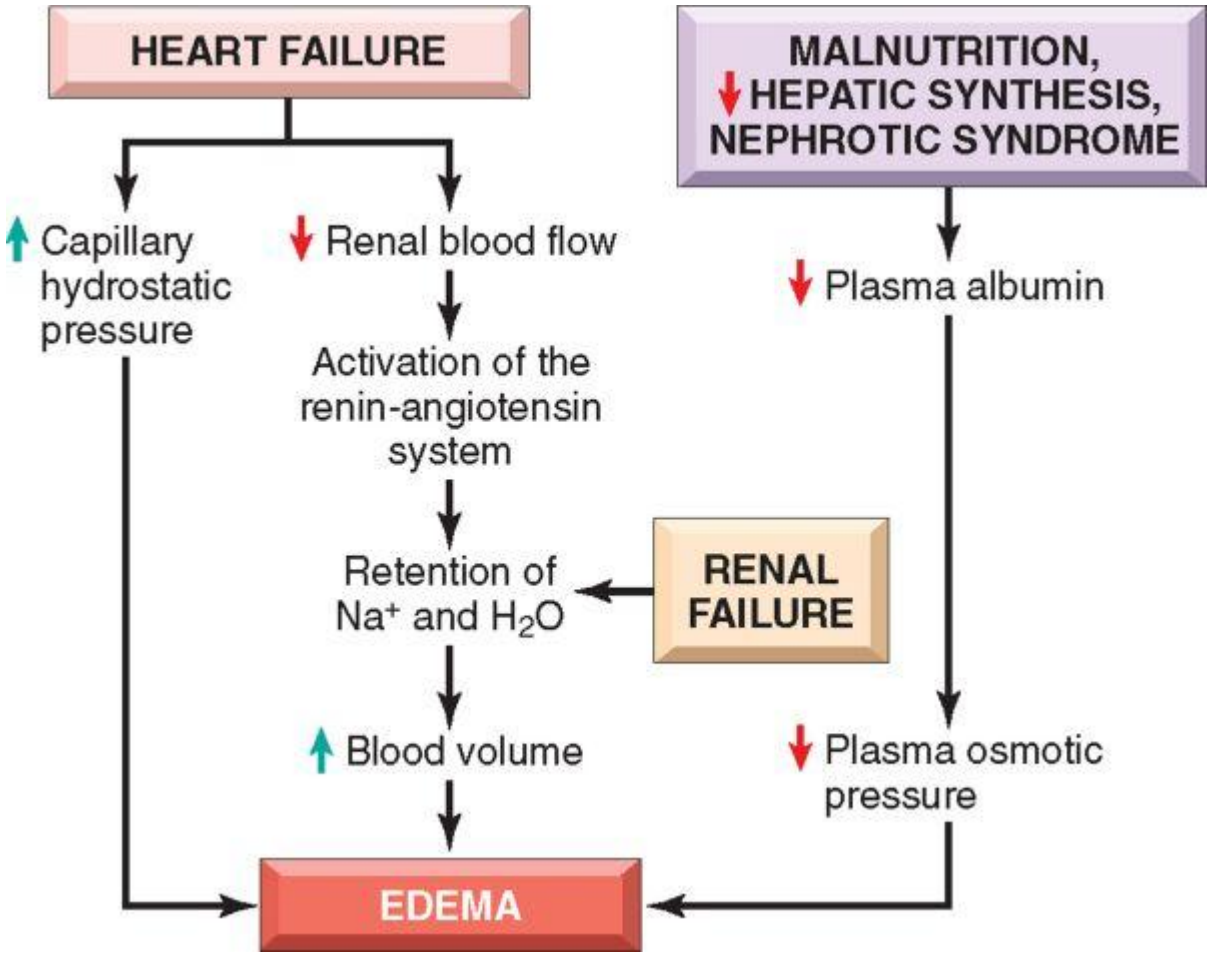

FIGURE 4-2 Pathways leading to systemic edema from primary heart failure, primary renal failure, or reduced plasma osmotic pressure (e.g., from malnutrition, diminished hepatic synthesis, or protein loss from nephrotic syndrome).

Increased Hydrostatic Pressure.

Regional increases in hydrostatic pressure can result from a focal impairment in venous return. Thus, *deep venous thrombosis* in a lower extremity may cause localized edema in the affected leg. On the other hand, *generalized increases* in venous pressure, with resulting systemic edema, occur most commonly in *congestive heart failure* (Chapter 12), where compromised right ventricular function leads to pooling of blood on the venous side of the circulation.

Reduced Plasma Osmotic Pressure.

Reduced plasma osmotic pressure occurs when albumin, the major plasma protein, is not synthesized in adequate amounts or is lost from the circulation. An important cause of albumin loss is the *nephrotic syndrome* (Chapter 20), in which glomerular capillaries become leaky; patients typically present with generalized edema. Reduced albumin synthesis occurs in the setting of severe liver diseases (e.g., cirrhosis, Chapter 18) or protein malnutrition (Chapter 9). In each case, reduced plasma osmotic pressure leads to a net movement of fluid into the interstitial tissues with subsequent plasma volume contraction. The reduced intravascular volume leads to decreased renal perfusion. This triggers increased production of renin, angiotensin, and aldosterone, but the resulting salt and water retention cannot correct the plasma volume deficit because the primary defect of low serum protein persists.

Sodium and Water Retention.

Salt and water retention can also be a primary cause of edema. Increased salt retention—with obligate associated water—causes both increased hydrostatic pressure (due to intravascular fluid volume expansion) and diminished vascular colloid osmotic pressure (due to dilution). Salt retention occurs whenever renal function is compromised, such as in primary disorders of the kidney and disorders that decrease renal perfusion. One of the most important causes of renal hypoperfusion is congestive heart failure, which (like hypoproteinemia) results in the activation of the renin-angiotensin-aldosterone axis. In early heart failure, this response tends to be beneficial, as the retention of sodium and water and other adaptations, including increased vascular tone and elevated levels of antidiuretic hormone (ADH), improve cardiac output and restore normal renal perfusion.[1,][2] However, as heart failure worsens and cardiac output diminishes, the retained fluid merely increases the venous pressure, which (as already mentioned) is a major cause of edema in this disorder. Unless cardiac output is restored or renal sodium and water retention is reduced (e.g., by salt restriction, diuretics, or aldosterone antagonists), a downward spiral of fluid retention and worsening edema ensues. Salt restriction, diuretics, and aldosterone antagonists are also of value in managing generalized edema arising from other causes. Primary retention of water (and modest vasoconstriction) is produced by the release of ADH from the posterior pituitary, which normally occurs in the setting of reduced plasma volumes or increased plasma osmolarity.[2] Inappropriate increases in ADH are seen in association with certain malignancies and lung and pituitary disorders and can lead to hyponatremia and cerebral edema (but interestingly not to peripheral edema).

Lymphatic Obstruction.

Impaired lymphatic drainage results in *lymphedema* that is typically localized; causes include chronic inflammation with fibrosis, invasive malignant tumors, physical disruption, radiation damage, and certain infectious agents. One dramatic example is seen in parasitic *filariasis*, in which lymphatic obstruction due to extensive inguinal lymphatic and lymph node fibrosis can result in edema of the external genitalia and lower limbs that is so massive as to earn the appellation *elephantiasis*. Severe edema of the upper extremity may also complicate surgical removal and/or irradiation of the breast and associated axillary lymph nodes in patients with breast cancer.

Morphology. Edema is easily recognized grossly; microscopically, it is appreciated as clearing and separation of the extracellular matrix and subtle cell swelling. Any organ or tissue can be involved, but edema is most commonly seen in subcutaneous tissues, the lungs, and the brain. **Subcutaneous edema** can be diffuse or more conspicuous in regions with high hydrostatic pressures. In most cases the distribution is influenced by gravity and is termed **dependent edema** (e.g., the legs when standing, the sacrum when recumbent). Finger pressure over substantially edematous subcutaneous tissue displaces the interstitial fluid and leaves a depression, a sign called **pitting edema**.

Edema as a result of **renal dysfunction** can **affect all parts of the body**. It often initially manifests in tissues with loose connective tissue matrix, such as the eyelids; **periorbital edema** is thus a characteristic finding in severe renal disease. With **pulmonary edema**, the lungs are often two to three times their normal weight, and sectioning yields frothy, blood-tinged fluid—a mixture of air, edema, and extravasated red cells. **Brain edema** can be localized or generalized depending on the nature and extent of the pathologic process or injury. With generalized edema the brain is grossly swollen with narrowed sulci; distended gyri show evidence of compression against the unyielding skull (Chapter 28).

Clinical Consequences.

The consequences of edema range from merely annoying to rapidly fatal. Subcutaneous tissue edema is important primarily because it signals potential underlying cardiac or renal disease; however, when significant, it can also impair wound healing or the clearance of infection. Pulmonary edema is a common clinical problem that is most frequently seen in the setting of left ventricular failure; it can also occur with renal failure, acute respiratory distress syndrome (Chapter 15), and pulmonary inflammation or infection. Not only does fluid collect in the alveolar septa around capillaries and impede oxygen diffusion, but edema fluid in the alveolar spaces also creates a favorable environment for bacterial infection. Brain edema is life-threatening; if severe, brain substance can *herniate* (extrude) through the foramen magnum, or the brain stem vascular supply can be compressed. Either condition can injure the medullary centers and cause death (Chapter 28).

2.4.2 Hyperemia & Congestion

Hyperemia and congestion both stem from locally increased blood volumes. *Hyperemia* is an *active process* in which arteriolar dilation (e.g., at sites of inflammation or in skeletal muscle during exercise) leads to increased blood flow. Affected tissues turn red (*erythema*) because of the engorgement of vessels with oxygenated blood. *Congestion* is a *passive process* resulting from reduced outflow of blood from a tissue. It can be systemic, as in cardiac failure, or local, as in isolated venous obstruction. Congested tissues take on a dusky reddish-blue color (*cyanosis*) due to red cell stasis and the accumulation of deoxygenated hemoglobin.

As a result of the increased volumes and pressures, congestion commonly leads to edema. In long-standing *chronic passive congestion*, the lack of blood flow causes chronic hypoxia, potentially resulting in ischemic tissue injury and scarring. Capillary rupture in chronic congestion can also cause small hemorrhagic foci; subsequent catabolism of extravasated red cells can leave residual telltale clusters of hemosiderin-laden macrophages.

Morphology. The cut surfaces of congested tissues are often discolored due to the presence of high levels of poorly oxygenated blood. Microscopically, **acute pulmonary congestion** exhibits engorged alveolar capillaries often with alveolar septal edema and focal intra-alveolar hemorrhage. In **chronic pulmonary congestion** the septa are thickened and fibrotic, and the alveoli often contain numerous hemosiderin-laden macrophages called **heart failure cells**. In **acute hepatic congestion**, the central vein and sinusoids are distended; centrilobular hepatocytes can be frankly ischemic while the periportal hepatocytes—better oxygenated because of proximity to hepatic arterioles—may only develop fatty change. In **chronic passive hepatic congestion** the centrilobular regions are grossly red-brown and slightly depressed (because of cell death) and are accentuated against the surrounding zones of uncongested tan liver **(nutmeg liver)** (Fig. 4-3A). Microscopically, there is centrilobular hemorrhage, hemosiderin-laden macrophages, and degeneration of hepatocytes (Fig. 4-3B). Because the centrilobular area is at the distal end of the blood supply to the liver, it is prone to undergo necrosis whenever the blood supply is compromised.

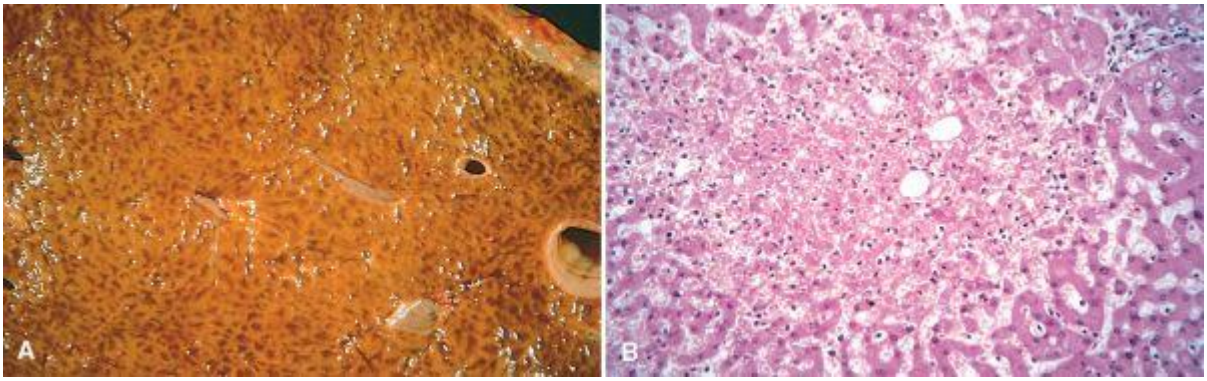

FIGURE 4-3 Liver with chronic passive congestion and hemorrhagic necrosis. **A**, Central areas are red and slightly depressed compared with the surrounding tan viable parenchyma, forming a "nutmeg liver" pattern (so-called because it resembles the cut surface of a nutmeg. **B**, Centrilobular necrosis with degenerating hepatocytes and hemorrhage. *(Courtesy of Dr. James Crawford, Department of Pathology, University of Florida, Gainesville, FL.)*

2.4.3 Hemorrhage

Hemorrhage is defined as the extravasation of blood into the extravascular space. As described above, capillary bleeding can occur under conditions of chronic congestion; an increased tendency to hemorrhage (usually with insignificant injury) also occurs in a variety of clinical disorders that are collectively called *hemorrhagic diatheses*. Rupture of a large artery or vein results in severe hemorrhage and is almost always due to vascular injury, including trauma, atherosclerosis, or inflammatory or neoplastic erosion of the vessel wall.

Tissue hemorrhage can occur in distinct patterns, each with its own clinical implications:

- Hemorrhage may be external or contained within a tissue; any accumulation is called a *hematoma*. Hematomas may be relatively insignificant or so massive that death ensues.
- Minute 1- to 2-mm hemorrhages into skin, mucous membranes, or serosal surfaces are called *petechiae* (Fig. 4-4A). These are most commonly associated with locally increased intravascular pressure, low platelet counts *(thrombocytopenia)*, or defective platelet function (as in uremia).
- Slightly larger (≥3 mm) hemorrhages are called *purpura*. These may be associated with many of the same disorders that cause petechiae or can be secondary to trauma, vascular inflammation *(vasculitis)*, or increased vascular fragility (e.g., in amyloidosis).
- Larger (>1 to 2 cm) subcutaneous hematomas (i.e., bruises) are called *ecchymoses*. The red cells in these lesions are degraded and phagocytized by macrophages; the hemoglobin (red-blue color) is then enzymatically converted into bilirubin (blue-green color) and eventually into hemosiderin (gold-brown color), accounting for the characteristic color changes in a bruise.
- Depending on the location, a large accumulation of blood in a body cavity is denoted as a *hemothorax, hemopericardium, hemoperitoneum*, or *hemarthrosis* (in joints). Patients with extensive bleeding can develop jaundice from the massive breakdown of red cells and hemoglobin.

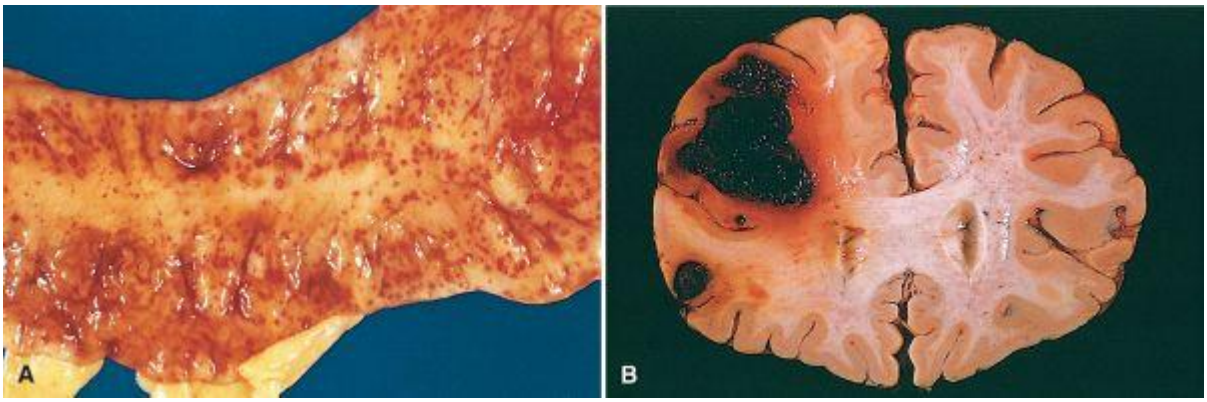

FIGURE 4-4 **A**, Punctate petechial hemorrhages of the colonic mucosa, a consequence of thrombocytopenia. **B**, Fatal intracerebral bleed.

The clinical significance of hemorrhage depends on the volume and rate of bleeding. Rapid loss of up to 20% of the blood volume or slow losses of even larger amounts may have little impact in healthy adults; greater losses, however, can cause *hemorrhagic (hypovolemic) shock* (discussed later). The site of hemorrhage is also important. For example, bleeding that is trivial in the subcutaneous tissues can cause death if located in the brain (Fig. 4-4B); because the skull is unyielding, intracranial hemorrhage can result in an increase in pressure that is sufficient to compromise the blood supply or to cause the herniation of the brainstem (Chapter 28). Finally, chronic or recurrent external blood loss (e.g., peptic ulcer or menstrual bleeding) causes a net loss in iron and can lead to an iron deficiency anemia. In contrast, when red cells are retained (e.g., hemorrhage into body cavities or tissues), iron is recovered and recycled for use in the synthesis of hemoglobin.

2.4.4 Hemostasis & Thrombosis

Normal hemostasis is a consequence of tightly regulated processes that maintain blood in a fluid state in normal vessels, yet also permit the rapid formation of a *hemostatic clot* at the site of a vascular injury. The pathologic counterpart of hemostasis is *thrombosis*; it involves blood clot *(thrombus)* formation within intact vessels. Both hemostasis and thrombosis involve three components: the *vascular wall* (particularly the *endothelium*), *platelets*, and the *coagulation cascade*. We begin the discussion with the normal hemostatic pathway and how it is regulated.

NORMAL HEMOSTASIS

The general sequence of events in hemostasis at a site of vascular injury is shown in Figure 4-5 .[3,][4]

- After initial injury there is a brief period of *arteriolar vasoconstriction* mediated by reflex neurogenic mechanisms and augmented by the local secretion of factors such as *endothelin* (a potent endothelium-derived vasoconstrictor; Fig. 4-5A). The effect is transient, however, and bleeding would resume if not for activation of the platelet and coagulation systems.
- Endothelial injury exposes highly thrombogenic subendothelial extracellular matrix (ECM), facilitating *platelet adherence and activation*. Activation of platelets results in a dramatic shape change (from small rounded discs to flat plates with markedly increased surface area), as well as the release of secretory granules. Within minutes the secreted products recruit additional platelets *(aggregation)* to form a *hemostatic plug*; this process is referred to as *primary hemostasis* (Fig. 4-5B).
- *Tissue factor* is also exposed at the site of injury. Also known as *factor III* and *thromboplastin*, tissue factor is a membrane-bound procoagulant glycoprotein synthesized by endothelial cells. It acts in conjunction with factor VII (see below) as the major in vivo initiator of the coagulation cascade, eventually culminating in

thrombin generation. Thrombin cleaves circulating fibrinogen into insoluble *fibrin*, creating a fibrin meshwork, and also induces additional platelet recruitment and activation. This sequence, *secondary hemostasis*, consolidates the initial platelet plug (Fig. 4-5C).

- Polymerized fibrin and platelet aggregates form a solid, *permanent plug* to prevent any further hemorrhage. At this stage, counter-regulatory mechanisms (e.g., *tissue plasminogen activator, t-PA*) are set into motion to limit the hemostatic plug to the site of injury (Fig. 4-5D).

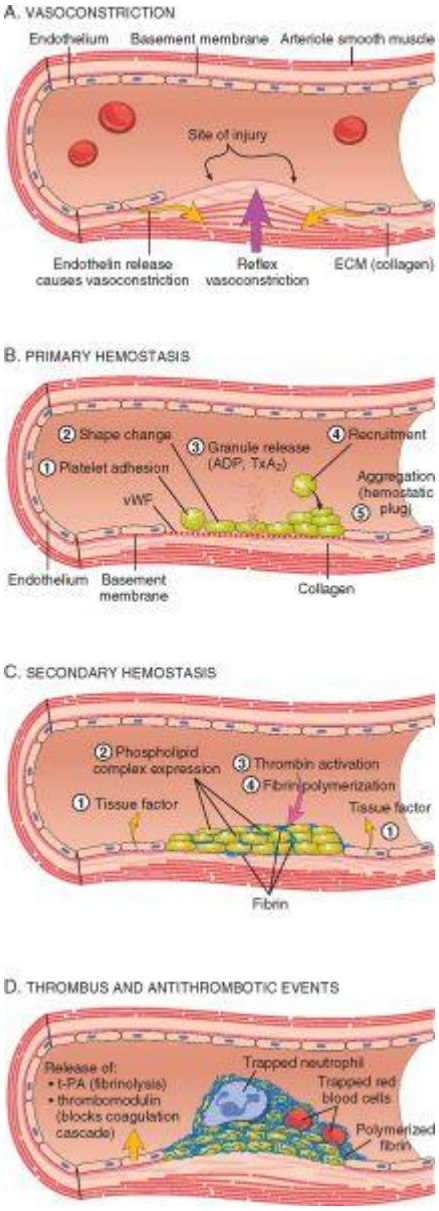

FIGURE 4-5 Normal hemostasis. **A**, After vascular injury local neurohumoral factors induce a transient vasoconstriction. **B**, Platelets bind via glycoprotein Ib (GpIb) receptors to von Willebrand factor (vWF) on exposed extracellular matrix (ECM) and are activated, undergoing a shape change and granule release. Released adenosine diphosphate (ADP) and thromboxane A_2 (TxA_2) induce additional platelet aggregation through platelet GpIIb-IIIa receptor binding to fibrinogen, and form the *primary* hemostatic plug. **C**, Local activation of the coagulation cascade (involving tissue factor and platelet phospholipids) results in fibrin polymerization, "cementing" the platelets into a definitive *secondary* hemostatic plug. **D**, Counter-regulatory mechanisms, mediated by tissue plasminogen activator (t-PA, a fibrinolytic product) and thrombomodulin, confine the hemostatic process to the site of injury.

The following sections discuss the roles of the endothelium, platelets, and the coagulation cascade in greater detail.

Endothelium

Endothelial cells are key players in the regulation of homeostasis, as the balance between the anti- and prothrombotic activities of endothelium determines whether thrombus formation, propagation, or dissolution occurs. [5] [6] [7] Normally, endothelial cells exhibit antiplatelet, anticoagulant, and fibrinolytic properties; however, after injury or activation they acquire numerous *procoagulant* activities (Fig. 4-6). Besides trauma, endothelium can be activated by infectious agents, hemodynamic forces, plasma mediators, and cytokines.

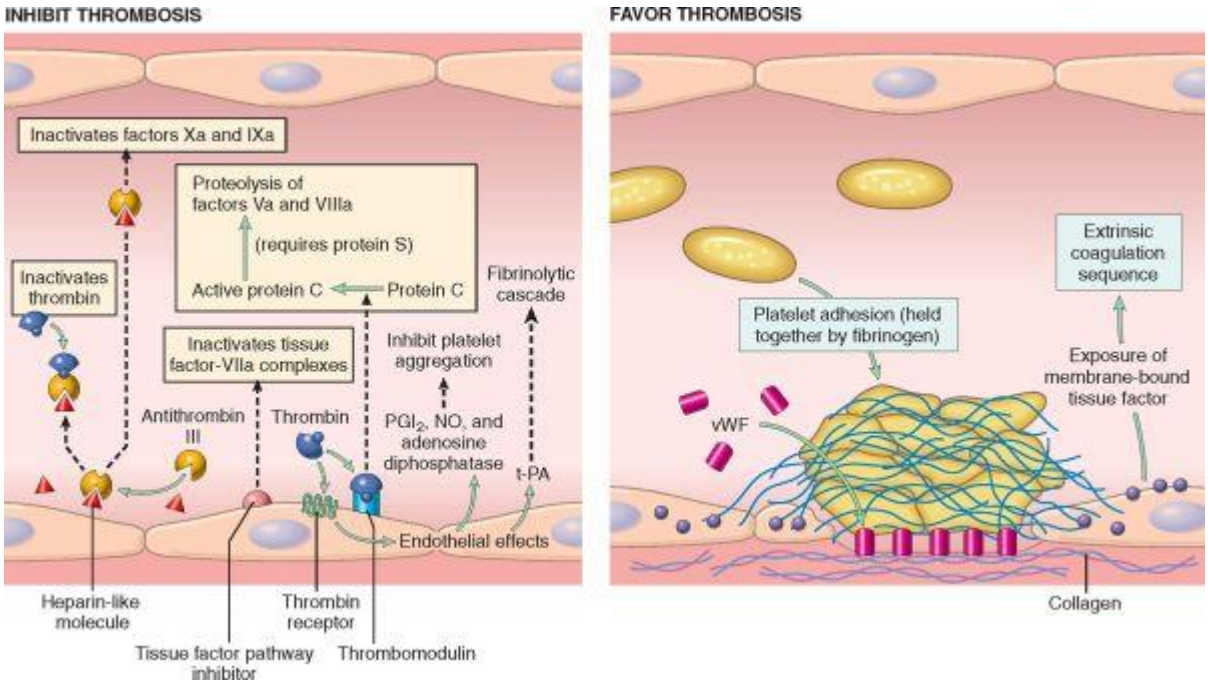

FIGURE 4-6 Anti- and procoagulant activities of endothelium. NO, nitric oxide; PGI_2, prostacyclin; t-PA, tissue plasminogen activator; vWF, von Willebrand factor. The thrombin receptor is also called a protease-activated receptor (PAR).

Antithrombotic Properties

Under normal circumstances endothelial cells actively prevent thrombosis by producing factors that variously block platelet adhesion and aggregation, inhibit coagulation, and lyse clots.

- *Antiplatelet effects*. Intact endothelium prevents platelets (and plasma coagulation factors) from engaging the highly thrombogenic subendothelial ECM. Nonactivated platelets do not adhere to endothelial cells, and even if platelets are activated, prostacyclin (PGI_2) and nitric oxide produced by the endothelial cells impede platelet adhesion. Both of these mediators are potent vasodilators and inhibitors of platelet aggregation; their synthesis by the endothelium is stimulated by several factors produced during coagulation (e.g., thrombin and cytokines). Endothelial cells also elaborate adenosine diphosphatase, which degrades adenosine diphosphate (ADP) and further inhibits platelet aggregation (see below).
- *Anticoagulant effects*.[8] These effects are mediated by endothelial membrane-associated heparin-like molecules, thrombomodulin, and tissue factor pathway inhibitor (see Fig. 4-6). The *heparin-like molecules* act indirectly; they are cofactors that greatly enhance the inactivation of thrombin and several other coagulation factors by the plasma protein *antithrombin III* (see later). *Thrombomodulin* binds to thrombin and

converts it from a procoagulant into an anticoagulant via its ability to activate protein C, which inhibits clotting by inactivating factors Va and VIIIa.[9] Endothelium also produces protein S, a co-factor for protein C, and *tissue factor pathway inhibitor (TFPI)*, a cell surface protein that directly inhibits tissue factor–factor VIIa and factor Xa activities.[10]

- *Fibrinolytic effects*. Endothelial cells synthesize tissue-type plasminogen activator (*t-PA*), a protease that cleaves plasminogen to form plasmin; plasmin, in turn, cleaves fibrin to degrade thrombi.[9]

Prothrombotic Properties

While normal endothelial cells limit clotting, trauma and inflammation of endothelial cells induce a prothrombotic state that alters the activities of platelets, coagulation proteins, and the fibrinolytic system.

- *Platelet effects*. Endothelial injury allows platelets to contact the underlying extracellular matrix; subsequent adhesion occurs through interactions with *von Willebrand factor (vWF)*, which is a product of normal endothelial cells and an essential cofactor for platelet binding to matrix elements (Fig. 4-7).[11]
- *Procoagulant effects*. In response to cytokines (e.g., tumor necrosis factor [TNF] or interleukin-1 [IL-1]) or bacterial endotoxin, endothelial cells synthesize *tissue factor*, the major activator of the extrinsic clotting cascade.[10,][12] In addition, activated endothelial cells augment the catalytic function of activated coagulation factors IXa and Xa.
- *Antifibrinolytic effects*. Endothelial cells secrete inhibitors of plasminogen activator (PAIs), which limit fibrinolysis and tend to favor thrombosis.

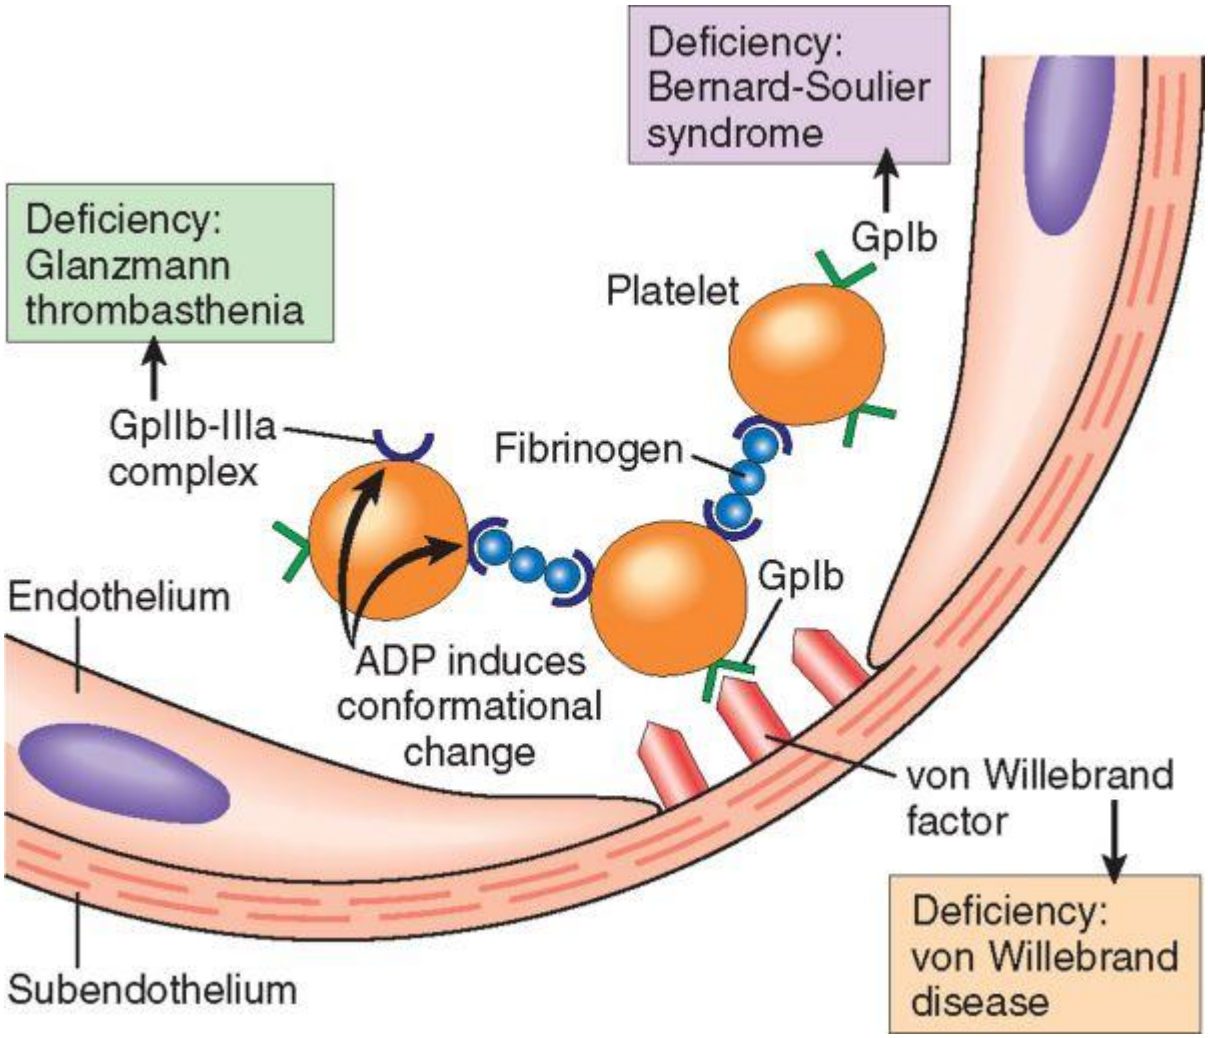

FIGURE 4-7 Platelet adhesion and aggregation. Von Willebrand factor functions as an adhesion bridge between subendothelial collagen and

the glycoprotein Ib (GpIb) platelet receptor. Aggregation is accomplished by fibrinogen bridging GpIIb-IIIa receptors on different platelets. Congenital deficiencies in the various receptors or bridging molecules lead to the diseases indicated in the colored boxes. ADP, adenosine diphosphate.

In summary, intact, nonactivated endothelial cells inhibit platelet adhesion and blood clotting. Endothelial injury or activation, however, results in a procoagulant phenotype that enhances thrombus formation.

Platelets

Platelets are disc-shaped, anucleate cell fragments that are shed from megakaryocytes in the bone marrow into the blood stream. They play a critical role in normal hemostasis,[13] by forming the hemostatic plug that initially seals vascular defects, and by providing a surface that recruits and concentrates activated coagulation factors. Their function depends on several glycoprotein receptors, a contractile cytoskeleton, and two types of cytoplasmic granules. α-*Granules* have the adhesion molecule P-selectin on their membranes (Chapter 2) and contain fibrinogen, fibronectin, factors V and VIII, platelet factor 4 (a heparin-binding chemokine), platelet-derived growth factor (PDGF), and transforming growth factor-β (TGF-β). *Dense (or δ) granules* contain ADP and ATP, ionized calcium, histamine, serotonin, and epinephrine.

After vascular injury, platelets encounter ECM constituents such as collagen and the adhesive glycoprotein vWF. On contact with these proteins, platelets undergo: (1) adhesion and shape change, (2) secretion (release reaction), and (3) aggregation (see Fig. 4-5B).

- *Platelet adhesion* to ECM is mediated largely via interactions with vWF, which acts as a bridge between platelet surface receptors (e.g., glycoprotein Ib [GpIb]) and exposed collagen (Fig. 4-8). Although platelets can also adhere to other components of the ECM (e.g., fibronectin), vWF-GpIb associations are necessary to overcome the high shear forces of flowing blood. Reflecting the importance of these interactions, genetic deficiencies of vWF (von Willebrand disease; Chapter 14) or its receptor (Bernard-Soulier syndrome) result in bleeding disorders.
- *Secretion (release reaction)* of both granule types occurs soon after adhesion. Various agonists can bind platelet surface receptors and initiate an intracellular protein phosphorylation cascade ultimately leading to degranulation. Release of the contents of dense-bodies is especially important, since calcium is required in the coagulation cascade, and ADP is a potent activator of *platelet aggregation*. ADP also begets additional ADP release, amplifying the aggregation process. Finally, platelet activation leads to the appearance of *negatively charged phospholipids* (particularly phosphatidylserine) on their surfaces. These phospholipids bind calcium and serve as critical nucleation sites for the assembly of complexes containing the various coagulation factors.[14,][15]
- *Platelet aggregation* follows adhesion and granule release. In addition to ADP, the vasoconstrictor thromboxane A_2 (TxA_2; Chapter 2) is an important platelet-derived stimulus that amplifies platelet aggregation, which leads to the formation of the primary hemostatic plug. Although this initial wave of aggregation is reversible, concurrent activation of the coagulation cascade generates thrombin, which stabilizes the platelet plug via two mechanisms. First, thrombin binds to a protease-activated receptor (PAR, see below) on the platelet membrane and in concert with ADP and TxA_2 causes further platelet aggregation. This is followed by *platelet contraction*, an event that is dependent on the platelet cytoskeleton that creates an irreversibly fused mass of platelets, which constitutes the definitive *secondary hemostatic plug*. Second, thrombin converts fibrinogen to *fibrin* in the vicinity of the platelet plug, functionally cementing the platelets in place.

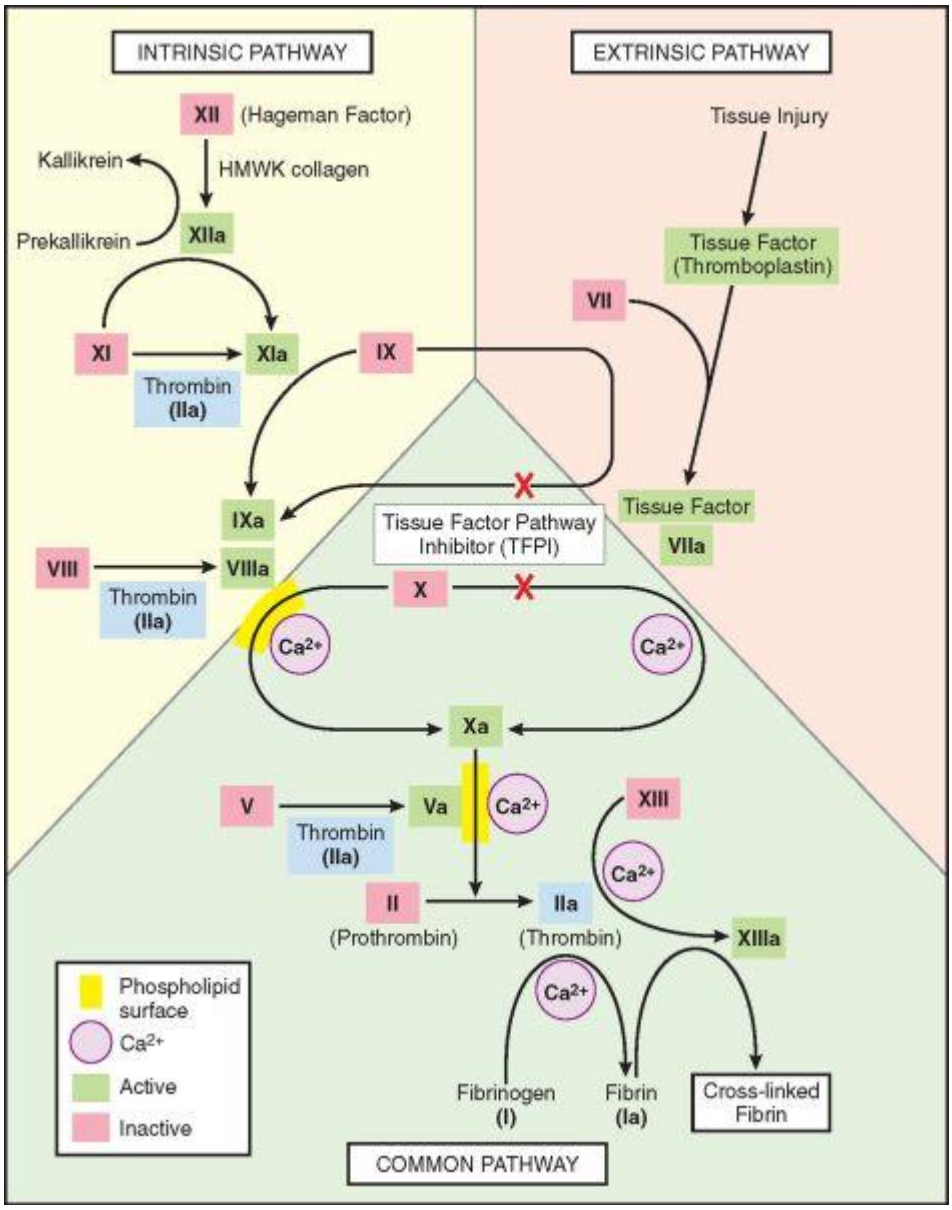

FIGURE 4-8 The coagulation cascade. Factor IX can be activated either by factor XIa or factor VIIa; in lab tests, activation is predominantly dependent on factor XIa of the intrinsic pathway. Factors in red boxes represent inactive molecules; activated factors are indicated with a lower case "a" and a green box. Note also the multiple points where thrombin (factor IIa; light blue boxes) contributes to coagulation through positive feedback loops. The red "X"s denote points of action of tissue factor pathway inhibitor (TFPI), which inhibits the activation of factors X and IX by factor VIIa. PL, phospholipid; HMWK, high-molecular-weight kininogen.

Noncleaved *fibrinogen* is also an important component of platelet aggregation. Platelet activation by ADP triggers a conformational change in the platelet GpIIb-IIIa receptors that induces binding to fibrinogen, a large protein that forms bridging interactions between platelets that promote platelet aggregation (see Fig. 4-7). Predictably, inherited deficiency of GpIIb-IIIa results in a bleeding disorder *(Glanzmann thrombasthenia)*.[16] The recognition of the central role of the various receptors and mediators in platelet cross-linking has led to the development of therapeutic agents that block platelet aggregation—for example, by interfering with thrombin activity,[17] by blocking ADP binding (clopidogrel), or by binding to the GpIIb-IIIa receptors (synthetic antagonists or monoclonal antibodies).[18] Antibodies against GpIb are on the horizon.

Red cells and leukocytes are also found in hemostatic plugs. Leukocytes adhere to platelets via P-selectin and to endothelium using several adhesion receptors (Chapter 2); they contribute to the inflammation that accompanies thrombosis. Thrombin also drives thrombus-associated inflammation by directly stimulating neutrophil and monocyte adhesion and by generating chemotactic *fibrin split products* during fibrinogen cleavage.

Platelet-Endothelial Cell Interactions.

The interplay of platelets and endothelium has a profound impact on clot formation. The endothelial cell-derived prostaglandin PGI_2 (prostacyclin) inhibits platelet aggregation and is a potent vasodilator; conversely, the platelet-derived prostaglandin TxA_2 activates platelet aggregation and is a vasoconstrictor (Chapter 2). Effects mediated by PGI_2 and TxA_2 are exquisitely balanced to effectively modulate platelet and vascular wall function: at baseline, platelet aggregation is prevented, whereas endothelial injury promotes hemostatic plug formation. The clinical utility of aspirin (an irreversible cyclooxygenase inhibitor) in persons at risk for coronary thrombosis resides in its ability to permanently block platelet TxA_2 synthesis. Although endothelial PGI_2 production is also inhibited by aspirin, endothelial cells can resynthesize active cyclooxygenase and thereby overcome the blockade. In a manner similar to PGI_2, endothelial-derived nitric oxide also acts as a vasodilator and inhibitor of platelet aggregation (see Fig. 4-6).

Coagulation Cascade

The coagulation cascade is the third arm of the hemostatic process. The pathways are schematically presented in Figure 4-8 ; only general principles are discussed here.[4,][19]

The coagulation cascade is essentially an amplifying series of enzymatic conversions; each step proteolytically cleaves an inactive proenzyme into an activated enzyme, culminating in *thrombin* formation. Thrombin is the most important coagulation factor, and indeed can act at numerous stages in the process (see blue boxes in Fig. 4-8).[20] At the conclusion of the proteolytic cascade, thrombin converts the soluble plasma protein *fibrinogen* into *fibrin* monomers that polymerize into an insoluble gel. The fibrin gel encases platelets and other circulating cells in the definitive secondary hemostatic plug, and the fibrin polymers are covalently cross-linked and stabilized by factor XIIIa (which itself is activated by thrombin).

Each reaction in the pathway results from the assembly of a complex composed of an *enzyme* (activated coagulation factor), a *substrate* (proenzyme form of coagulation factor), and a *cofactor* (reaction accelerator). These components are typically assembled on a *phospholipid surface* and held together by *calcium ions* (as an aside, the clotting of blood is prevented by the presence of calcium chelators). The requirement that coagulation factors be brought close together ensures that clotting is normally localized to the surface of activated platelets or endothelium;[4] as shown in Figure 4-9 , it can be likened to a "dance" of complexes, in which coagulation factors are passed successfully from one partner to the next. Parenthetically, the binding of coagulation factors II, XII, IX, and X to calcium depends on the addition of γ-carboxyl groups to certain glutamic acid residues on these proteins. This reaction uses vitamin K as a cofactor and is antagonized by drugs such as *coumadin*, which is a widely used anticoagulant.

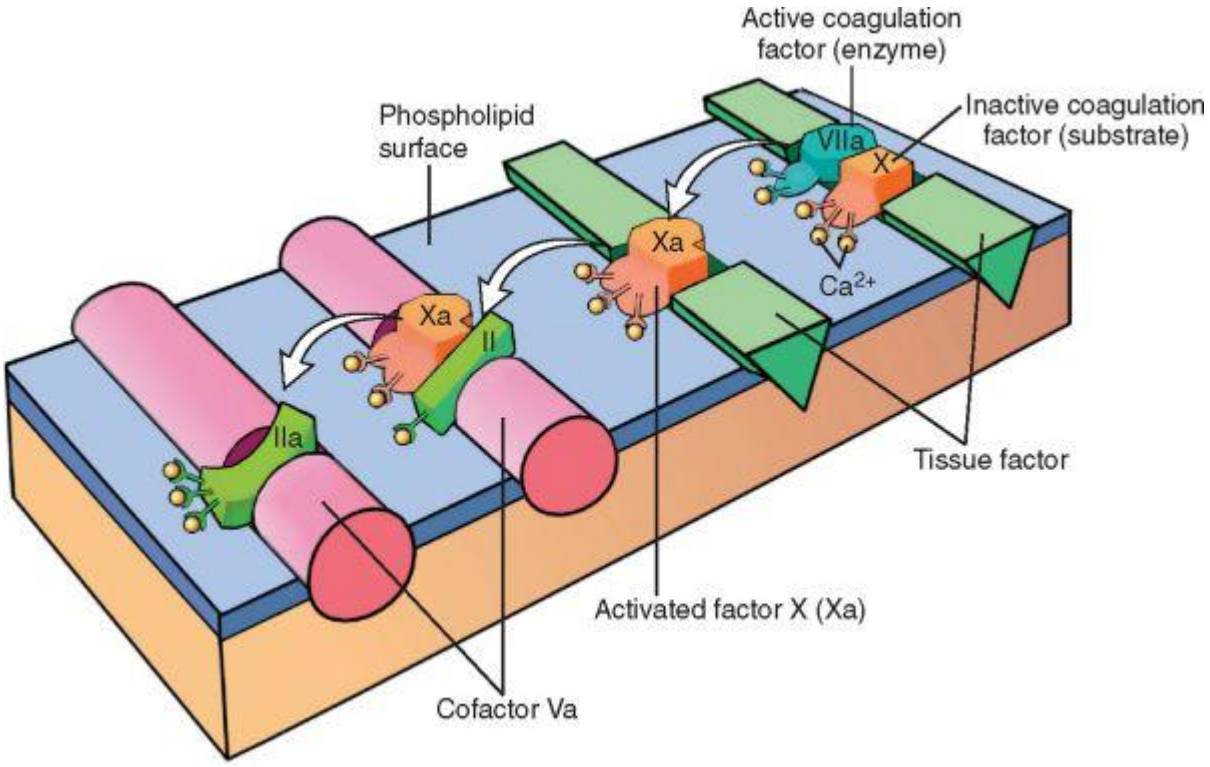

FIGURE 4-9 Schematic illustration of the conversion of factor X to factor Xa via the extrinsic pathway, which in turn converts factor II (prothrombin) to factor IIa (thrombin). The initial reaction complex consists of a proteolytic enzyme (factor VIIa), a substrate (factor X), and a reaction accelerator (tissue factor), all assembled on a platelet phospholipid surface. Calcium ions hold the assembled components together and are essential for the reaction. Activated factor Xa becomes the protease for the second adjacent complex in the coagulation cascade, converting prothrombin substrate (II) to thrombin (IIa) using factor Va as the reaction accelerator.

Blood coagulation is traditionally classified into *extrinsic* and *intrinsic* pathways that converge on the activation of factor X (see Fig. 4-8). The extrinsic pathway was so designated because it required the addition of an exogenous trigger (originally provided by tissue extracts); the intrinsic pathway only required exposing factor XII (Hageman factor) to thrombogenic surfaces (even glass would suffice). However, such a division is largely an artifact of in vitro testing; there are, in fact, several interconnections between the two pathways. Moreover, the extrinsic pathway is the most physiologically relevant pathway for coagulation occurring when vascular damage has occurred; it is activated by *tissue factor* (also known as *thromboplastin* or factor III), a membrane-bound lipoprotein expressed at sites of injury (see Fig. 4-8).[12]

Clinical laboratories assess the function of the two arms of the coagulation pathway through two standard assays: *prothrombin time* (PT) and *partial thromboplastin time* (PTT). The PT assay assesses the function of the proteins in the extrinsic pathway (factors VII, X, II, V, and fibrinogen). This is accomplished by adding tissue factor and phospholipids to citrated plasma (sodium citrate chelates calcium and prevents spontaneous clotting). Coagulation is initiated by the addition of exogenous calcium and the time for a fibrin clot to form is recorded. The *partial thromboplastin time* (PTT) screens for the function of the proteins in the intrinsic pathway (factors XII, XI, IX, VIII, X, V, II, and fibrinogen). In this assay, clotting is initiated through the addition of negative charged particles (e.g., ground glass), which you will recall activates factor XII (Hageman factor), phospholipids, and calcium, and the time to fibrin clot formation is recorded.

In addition to catalyzing the final steps in the coagulation cascade, thrombin exerts a wide variety of proinflammatery effects (Fig. 4-10). Most of these effects of thrombin occur through its activation of a family of protease activated receptors (PARs) that belong to the seven-transmembrane G protein–coupled receptor family[21,][22] (see also Fig. 4-6). PARs are expressed on endothelium, monocytes, dendritic cells, T lymphocytes, and other cell types. Receptor activation is initiated by cleavage of the extracellular end of the PAR; this generates a tethered peptide that binds to the "clipped" receptor, causing a conformational change that triggers signaling.

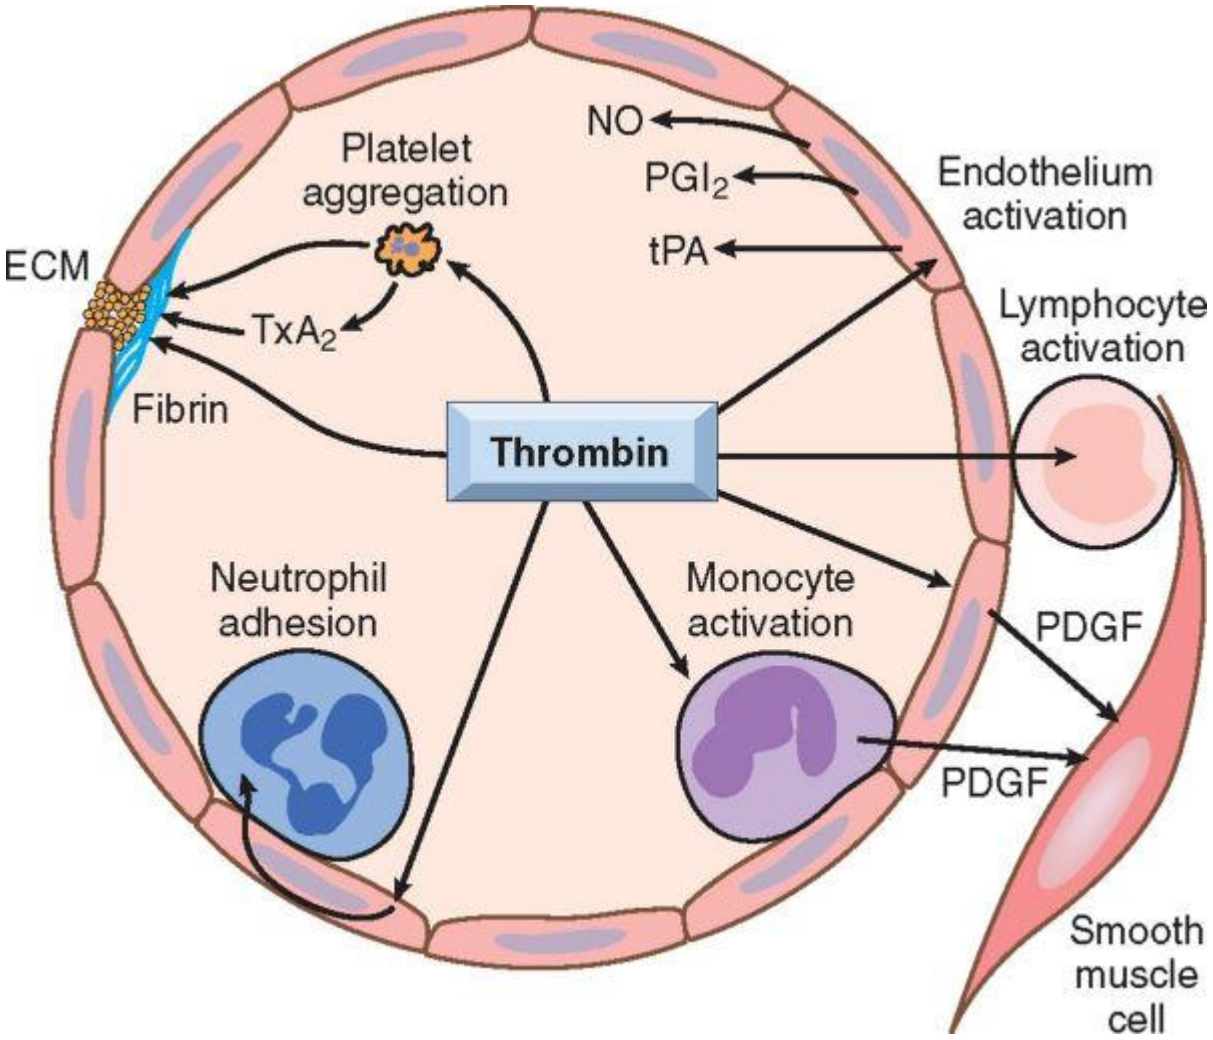

FIGURE 4-10 Role of thrombin in hemostasis and cellular activation. Thrombin plays a critical role in generating cross-linked fibrin (by cleaving fibrinogen to fibrin, and by activating factor XIII), as well as activating several other coagulation factors (see Fig. 4-8). Through protease-activated receptors (PARs, see text), thrombin also modulates several cellular activities. It directly induces platelet aggregation and TxA_2 production, and activates ECs to express adhesion molecules, and a variety of fibrinolytic (t-PA), vasoactive (NO, PGI_2), and cytokine mediators (e.g., PDGF). Thrombin also directly activates leukocytes. ECM, extracellular matrix; NO, nitric oxide; PDGF, platelet-derived growth factor; PGI_2, prostacyclin; TxA_2, thromboxane A_2; t-PA, tissue plasminogen activator. See Figure 4-7 for additional anticoagulant activities mediated by thrombin, including via thrombomodulin. *(Courtesy of Shaun Coughlin, MD, PhD, Cardiovascular Research Institute, University of California at San Francisco; modified with permission.)*

Once activated, the coagulation cascade must be restricted to the site of vascular injury to prevent runaway clotting of the entire vascular tree. Besides restricting factor activation to sites of exposed

phospholipids, three categories of endogenous anticoagulants also control clotting. (1) *Antithrombins* (e.g., antithrombin III) inhibit the activity of thrombin and other serine proteases, including factors IXa, Xa, XIa, and XIIa. Antithrombin III is activated by binding to heparin-like molecules on endothelial cells; hence the clinical usefulness of administering heparin to minimize thrombosis (see Fig. 4-6). (2) *Proteins C and S* are vitamin K–dependent proteins that act in a complex that proteolytically inactivates factors Va and VIIIa. Protein C activation by thrombomodulin was described earlier. (3) *TFPI* is a protein produced by endothelium (and other cell types) that inactivates tissue factor–factor VIIa complexes (see Figs. 4-6 and 4-8).[10]

Activation of the coagulation cascade also sets into motion a *fibrinolytic cascade* that moderates the size of the ultimate clot. Fibrinolysis is largely accomplished through the enzymatic activity of *plasmin*, which breaks down fibrin and interferes with its polymerization (Fig. 4-11).[23] The resulting *fibrin split products* (FSPs or fibrin degradation products) can also act as weak anticoagulants. Elevated levels of FSPs (most notably fibrin-derived *D-dimers*) can be used in diagnosing abnormal thrombotic states including disseminated intravascular coagulation (DIC), deep venous thrombosis, or pulmonary embolism (described later). Plasmin is generated by enzymatic catabolism of the inactive circulating precursor *plasminogen*, either by a factor XII–dependent pathway or by plasminogen activators (PAs; see Fig. 4-11). The most important of the PAs is t-PA; it is synthesized principally by endothelium and is most active when bound to fibrin. The affinity for fibrin makes t-PA a useful therapeutic agent, since it largely confines fibrinolytic activity to sites of recent thrombosis. *Urokinase-like PA (u-PA)* is another PA present in plasma and in various tissues; it can activate plasmin in the fluid phase. Finally, plasminogen can be cleaved to plasmin by the bacterial enzyme *streptokinase*, an activity that may be clinically significant in certain bacterial infections. As with any potent regulator, plasmin activity is tightly restricted. To prevent excess plasmin from lysing thrombi indiscriminately elsewhere in the body, free plasmin is rapidly inactivated by α_2-plasmin inhibitor (see Fig. 4-11).

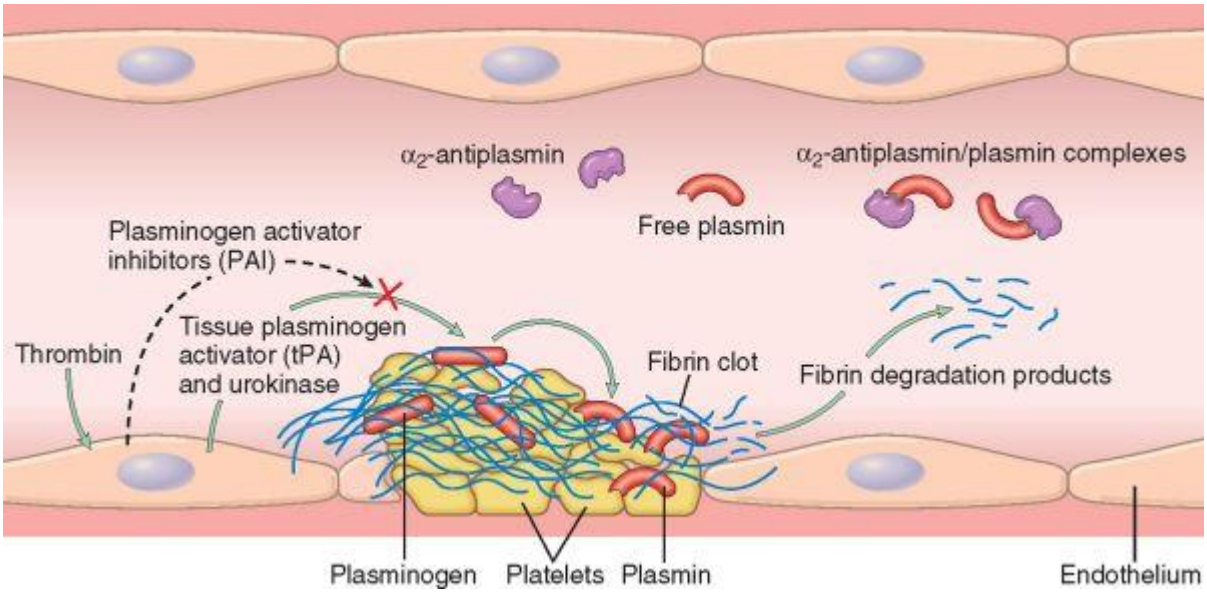

FIGURE 4-11 The fibrinolytic system, illustrating various plasminogen activators and inhibitors (see text).

Endothelial cells also fine-tune the coagulation/anticoagulation balance by releasing plasminogen activator inhibitor (PAI); it blocks fibrinolysis by inhibiting t-PA binding to fibrin and confers an

overall procoagulant effect (see Fig. 4-11). PAI production is increased by thrombin as well as certain cytokines, and probably plays a role in the intravascular thrombosis accompanying severe inflammation.[24]

THROMBOSIS

Having discussed the components of normal hemostasis, we now turn our attention to the three primary *abnormalities that lead to thrombus formation (called Virchow's triad)*: (1) endothelial injury, (2) stasis or turbulent blood flow, and (3) hypercoagulability of the blood (Fig. 4-12).

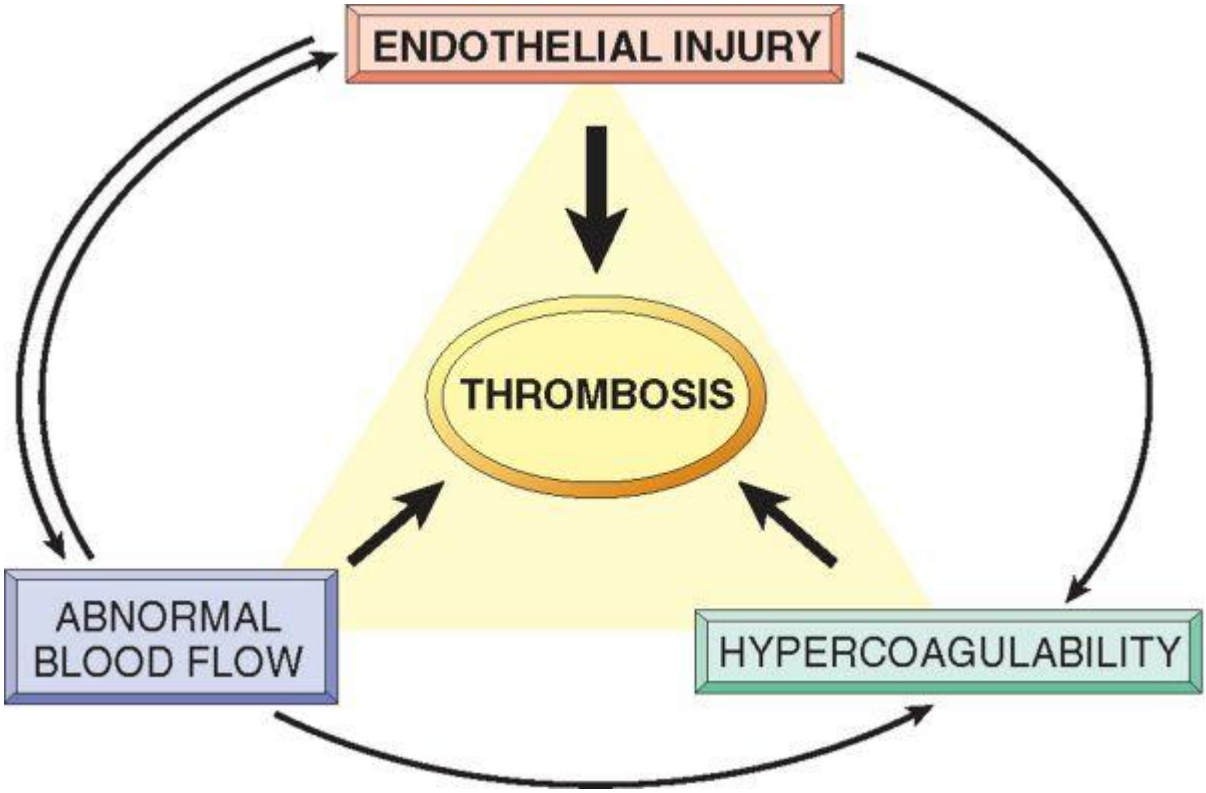

FIGURE 4-12 Virchow's triad in thrombosis. Endothelial integrity is the most important factor. Injury to endothelial cells can alter local blood flow and affect coagulability. Abnormal blood flow (stasis or turbulence), in turn, can cause endothelial injury. The factors promote thrombosis independently or in combination.

Endothelial Injury.

Endothelial injury is particularly important for thrombus formation in the heart or the arterial circulation, where the normally high flow rates might otherwise impede clotting by preventing platelet adhesion and washing out activated coagulation factors. Thus, thrombus formation within cardiac chambers (e.g., after endocardial injury due to myocardial infarction), over ulcerated plaques in atherosclerotic arteries, or at sites of traumatic or inflammatory vascular injury *(vasculitis)* is largely a consequence of endothelial cell injury. Clearly, physical loss of endothelium can lead to exposure of the subendothelial ECM, adhesion of platelets, release of tissue factor, and local depletion of PGI_2 and plasminogen activators. *However, it should be emphasized that endothelium need not be denuded or physically disrupted to contribute to the development of thrombosis; any perturbation in the dynamic balance of the prothombotic and antithrombotic activities of endothelium can influence local clotting events* (see Fig. 4-6). Thus, dysfunctional endothelial cells can produce more procoagulant factors (e.g., platelet

adhesion molecules, tissue factor, PAIs) or may synthesize less anticoagulant effectors (e.g., thrombomodulin, PGI_2, t-PA). Endothelial dysfunction can be induced by a wide variety of insults, including hypertension, turbulent blood flow, bacterial endotoxins, radiation injury, metabolic abnormalities such as homocystinemia or hypercholesterolemia, and toxins absorbed from cigarette smoke.

Alterations in Normal Blood Flow.

Turbulence contributes to arterial and cardiac thrombosis by causing endothelial injury or dysfunction, as well as by forming countercurrents and local pockets of stasis; *stasis* is a major contributor in the development of venous thrombi.[25] Normal blood flow is *laminar* such that the platelets (and other blood cellular elements) flow centrally in the vessel lumen, separated from endothelium by a slower moving layer of plasma. Stasis and turbulence therefore:

- Promote endothelial activation, enhancing procoagulant activity, leukocyte adhesion, etc., in part through flow-induced changes in endothelial cell gene expression.[21]
- Disrupt laminar flow and bring platelets into contact with the endothelium[26]
- Prevent washout and dilution of activated clotting factors by fresh flowing blood and the inflow of clotting factor inhibitors

Turbulence and stasis contribute to thrombosis in several clinical settings. Ulcerated atherosclerotic plaques not only expose subendothelial ECM but also cause turbulence. Aortic and arterial dilations called *aneurysms* result in local stasis and are therefore fertile sites for thrombosis (Chapter 11). Acute myocardial infarctions result in areas of noncontractile myocardium and sometimes cardiac aneurysms; both are associated with stasis and flow abnormalities that promote the formation of cardiac mural thrombi (Chapter 12). Rheumatic mitral valve stenosis results in left atrial dilation; in conjunction with atrial fibrillation, a dilated atrium is a site of profound stasis and a prime location for developing thrombi (Chapter 12). *Hyperviscosity* (such as is seen with polycythemia vera; Chapter 13) increases resistance to flow and causes small vessel stasis; the deformed red cells in *sickle cell anemia* (Chapter 14) cause vascular occlusions, with the resulting stasis also predisposing to thrombosis.

Hypercoagulability.

Hypercoagulability (also called *thrombophilia*) is a less frequent contributor to thrombotic states but is nevertheless an important component in the equation, and in some situations can predominate. It is loosely defined as any alteration of the coagulation pathways that predisposes to thrombosis; it can be divided into *primary* (genetic) and *secondary* (acquired) disorders (Table 4-2). [27] [28] [29] *Of the inherited causes of hypercoagulability, point mutations in the factor V gene and prothrombin gene are the most common*.

- Approximately 2% to 15% of Caucasians carry a single-nucleotide mutation in factor V (called the *Leiden mutation*, after the city in the Netherlands where it was discovered). Among individuals with recurrent deep venous thrombosis the frequency of this mutation is considerably higher, approaching 60%. The mutation results in a glutamine to arginine substitution at position 506 that renders factor V resistant to cleavage by protein C. As a result, an important antithrombotic counter-regulatory pathway is lost (see Fig. 4-6). Indeed, heterozygotes have a five-fold increased relative risk of venous thrombosis, and homozygotes have a 50-fold increase![30]
- A single nucleotide change (G20210A) in the 3′-untranslated region of the *prothrombin gene* is another fairly common mutation in individuals with hypercoagulability (1% to 2% of the population); it is associated with elevated prothrombin levels and an almost threefold increased risk of venous thromboses.[28,][31]
- Elevated levels of *homocysteine* contribute to arterial and venous thrombosis, as well as the development of atherosclerosis (Chapter 11). The prothrombotic effects of homocysteine may be due to thioester linkages

formed between homocysteine metabolites and a variety of proteins, including fibrinogen.[32] Marked elevations of homocysteine may be caused by an inherited deficiency of cystathione βsynthetase. Much more common is a variant form of the enzyme 5,10-methylenetetrahydrofolate reductase that causes mild homocysteinemia in 5% to 15% of Caucasian and eastern Asian populations; this possible etiology for hypercoagulability is therefore as common as factor V Leiden.[27] However, while folic acid, pyridoxine, and/or vitamin B_{12} supplements can reduce plasma homocysteine concentrations (by stimulating its metabolism), they fail to lower the risk of thromboses, raising questions about the significance of modest homocysteinemia.[33]

- Rare inherited causes of primary hypercoagulability include deficiencies of anticoagulants such as antithrombin III, protein C, or protein S; affected individuals typically present with venous thrombosis and recurrent thromboembolism beginning in adolescence or early adulthood.[27] Various polymorphisms in coagulant factor genes can result in increased synthesis and impart an elevated risk of venous thrombosis.[34]

TABLE 4-2 -- Hypercoagulable States

PRIMARY (GENETIC)
Common
Factor V mutation (G1691A mutation; factor V Leiden)
Prothrombin mutation (G20210A variant)
5,10-Methylenetetrahydrofolate reductase (homozygous C677T mutation)
Increased levels of factors VIII, IX, XI, or fibrinogen
Rare
Antithrombin III deficiency
Protein C deficiency
Protein S deficiency
Very Rare
Fibrinolysis defects
Homozygous homocystinuria (deficiency of cystathione β-synthetase)
SECONDARY (ACQUIRED)
High Risk for Thrombosis
Prolonged bedrest or immobilization
Myocardial infarction
Atrial fibrillation
Tissue injury (surgery, fracture, burn)
Cancer
Prosthetic cardiac valves
Disseminated intravascular coagulation
Heparin-induced thrombocytopenia
Antiphospholipid antibody syndrome
Lower Risk for Thrombosis
Cardiomyopathy

Nephrotic syndrome
Hyperestrogenic states (pregnancy and postpartum)
Oral contraceptive use
Sickle cell anemia
Smoking

The most common thrombophilic genotypes found in various populations (heterozygosity for factor V Leiden and heterozygosity for prothrombin) impart only a moderately increased risk of thrombosis; most individuals with these genotypes, when otherwise healthy, are free of thrombotic complications. However, mutations in factor V and prothrombin are frequent enough that homozygosity and compound heterozygosity are not rare, and such genotypes are associated with greater risk.[35] Moreover, individuals with such mutations have a significantly increased frequency of venous thrombosis in the setting of other acquired risk factors (e.g., pregnancy or prolonged bedrest). Thus, factor V Leiden heterozygosity (which by itself has only a modest effect) may trigger deep venous thrombosis when combined with enforced inactivity, such as during prolonged plane travel. Consequently, *inherited causes of hypercoagulability must be considered in patients under the age of 50 who present with thrombosis—even when acquired risk factors are present*.[36,][37]

Unlike hereditary disorders, the pathogenesis of *acquired thrombophilia* is frequently multifactorial (see Table 4-2). In some cases (e.g., cardiac failure or trauma), stasis or vascular injury may be most important. Hypercoagulability due to oral contraceptive use or the hyperestrogenic state of pregnancy is probably caused by increased hepatic synthesis of coagulation factors and reduced anticoagulant synthesis.[38] In disseminated cancers, release of procoagulant tumor products predisposes to thrombosis.[39] The hypercoagulability seen with advancing age may be due to reduced endothelial PGI_2. Smoking and obesity promote hypercoagulability by unknown mechanisms.

Among the acquired thrombophilic states, two that are particularly important clinical problems deserve special mention.

Heparin-induced thrombocytopenia (HIT) syndrome.

HIT occurs following the administration of *unfractionated heparin*, which may induce the appearance of antibodies that recognize complexes of heparin and platelet factor 4 on the surface of platelets (Chapter 14), as well as complexes of heparin-like molecules and platelet factor 4-like proteins on endothelial cells. [40] [41] [42] Binding of these antibodies to platelets results in their activation, aggregation, and consumption (hence the *thrombocytopenia* in the syndrome name). This effect on platelets and endothelial damage combine to produce a *prothrombotic state*, even in the face of heparin administration and low platelet counts. Newer low-molecular weight heparin preparations induce antibody formation less frequently, but still cause thrombosis if antibodies have already formed.[41] Other anticoagulants such as fondaparinux (a pentasaccharide inhibitor of factor X) also cause a HIT-like syndrome on rare occasions.[42]

Antiphospholipid antibody syndrome[43]

(previously called the lupus anticoagulant syndrome). This syndrome has protean clinical manifestations, including recurrent thromboses, repeated miscarriages, cardiac valve vegetations, and thrombocytopenia. Depending on the vascular bed involved, the clinical presentations can include pulmonary embolism (following lower extremity venous thrombosis), pulmonary hypertension (from recurrent subclinical pulmonary emboli), stroke, bowel infarction, or renovascular hypertension. Fetal loss is attributable to

antibody-mediated inhibition of t-PA activity necessary for trophoblastic invasion of the uterus. Antiphospholipid antibody syndrome is also a cause of renal microangiopathy, resulting in renal failure associated with multiple capillary and arterial thromboses (Chapter 20).

The name *antiphospholipid antibody syndrome* is a bit of a misnomer, as it is believed that the most important pathologic effects are mediated through binding of the antibodies to epitopes on plasma proteins (e.g., prothrombin) that are somehow induced or "unveiled" by phospholipids. In vivo, these autoantibodies induce a *hypercoagulable state* by causing endothelial injury, by activating platelets and complement directly, and through interaction with the catalytic domains of certain coagulation factors.[43] However, in vitro (in the absence of platelets and endothelial cells), the autoantibodies interfere with phospholipids and thus inhibit coagulation. The antibodies also frequently give a false-positive serologic test for syphilis because the antigen in the standard assay is embedded in cardiolipin.

Antiphospholipid antibody syndrome has primary and secondary forms. Individuals with a well-defined autoimmune disease, such as systemic lupus erythematosus (Chapter 6), are designated as having *secondary antiphospholipid syndrome* (hence the earlier term *lupus anticoagulant syndrome*). In *primary antiphospholipid syndrome*, patients exhibit only the manifestations of a hypercoagulable state and lack evidence of other autoimmune disorders; occasionally this happens in association with certain drugs or infections. A particularly aggressive form *(catastrophic antiphospholipid syndrome)* characterized by widespread small-vessel thrombi and multi-organ failure has a 50% mortality.[44] The antibodies also make surgical procedures more difficult; for example, nearly 90% of patients with anti-phospholipid antibodies undergoing cardiovascular surgery have complications related to the antibodies.[45] Therapy involves anticoagulation and immunosuppression. Although antiphospholipid antibodies are clearly associated with thrombotic diatheses, they have also been identified in 5% to 15% of apparently normal individuals, implying that they are necessary but not sufficient to cause the full-blown syndrome.

Morphology. Thrombi can develop anywhere in the cardiovascular system (e.g., in cardiac chambers, on valves, or in arteries, veins, or capillaries). The size and shape of thrombi depend on the site of origin and the cause. Arterial or cardiac thrombi usually begin at sites of turbulence or endothelial injury; venous thrombi characteristically occur at sites of stasis. Thrombi are focally attached to the underlying vascular surface; arterial thrombi tend to grow retrograde from the point of attachment, while venous thrombi extend in the direction of blood flow (thus both propagate toward the heart). The propagating portion of a thrombus is often poorly attached and therefore prone to fragmentation and embolization.

Thrombi often have grossly and microscopically apparent laminations called **lines of Zahn**; these represent pale platelet and fibrin deposits alternating with darker red cell–rich layers. Such laminations signify that a thrombus has formed in flowing blood; their presence can therefore distinguish antemortem thrombosis from the bland nonlaminated clots that occur postmortem (see below).

Thrombi occurring in heart chambers or in the aortic lumen are designated **mural thrombi**. Abnormal myocardial contraction (arrhythmias, dilated cardiomyopathy, or myocardial infarction) or endomyocardial injury (myocarditis or catheter trauma) promotes cardiac mural thrombi (Fig. 4-13A), while ulcerated atherosclerotic plaque and aneurysmal dilation are the precursors of aortic thrombus (Fig. 4-13B).

Arterial thrombi are frequently **occlusive**; the most common sites in decreasing order of frequency are the coronary, cerebral, and femoral arteries. They typically cosist of a friable meshwork of

platelets, fibrin, red cells, and degenerating leukocytes. Although these are usually superimposed on a ruptured atherosclerotic plaque, other vascular injuries (vasculitis, trauma) may be the underlying cause.

Venous thrombosis (phlebothrombosis) is almost invariably occlusive, with the thrombus forming a long cast of the lumen. Because these thrombi form in the sluggish venous circulation, they tend to contain more enmeshed red cells (and relatively few platelets) and are therefore known as **red**, or **stasis, thrombi**. The veins of the lower extremities are most commonly involved (90% of cases); however, upper extremities, periprostatic plexus, or the ovarian and periuterine veins can also develop venous thrombi. Under special circumstances, they can also occur in the dural sinuses, portal vein, or hepatic vein.

Postmortem clots can sometimes be mistaken for antemortem venous thrombi. However, postmortem clots are gelatinous with a dark red dependent portion where red cells have settled by gravity and a yellow "chicken fat" upper portion; they are usually not attached to the underlying wall. In comparison, red thrombi are firmer and are focally attached, and sectioning typically reveals gross and/or microscopic lines of Zahn.

Thrombi on heart valves are called **vegetations**. Blood-borne bacteria or fungi can adhere to previously damaged valves (e.g., due to rheumatic heart disease) or can directly cause valve damage; in both cases, endothelial injury and disturbed blood flow can induce the formation of large thrombotic masses (**infective endocarditis**; Chapter 12). Sterile vegetations can also develop on noninfected valves in persons with hypercoagulable states, so-called **nonbacterial thrombotic endocarditis** (Chapter 12). Less commonly, sterile, verrucous endocarditis (**Libman-Sacks endocarditis**) can occur in the setting of systemic lupus erythematosus (Chapter 6).

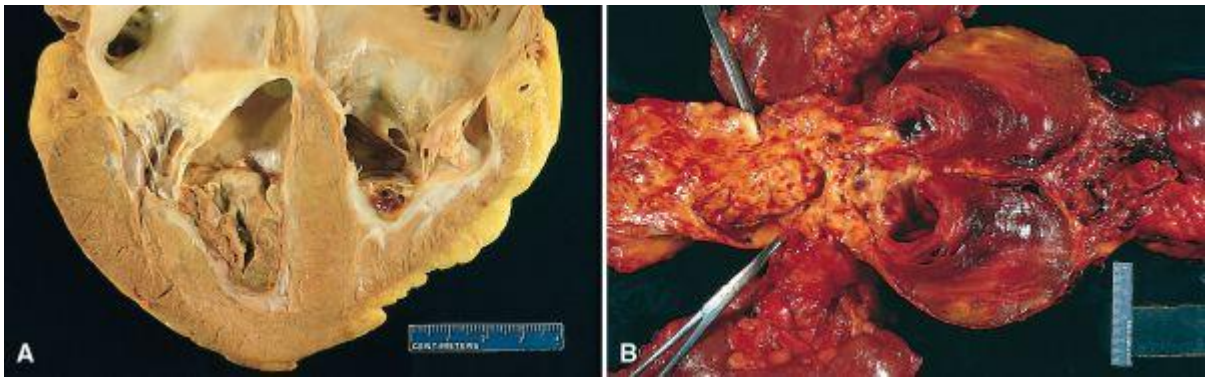

FIGURE 4-13 Mural thrombi. **A**, Thrombus in the left and right ventricular apices, overlying white fibrous scar. **B**, Laminated thrombus in a dilated abdominal aortic aneurysm. Numerous friable mural thrombi are also superimposed on advanced atherosclerotic lesions of the more proximal aorta *(left side of picture)*.

Fate of the Thrombus.

If a patient survives the initial thrombosis, in the ensuing days to weeks thrombi undergo some combination of the following four events:

- *Propagation*. Thrombi accumulate additional platelets and fibrin. This process was discussed earlier.
- *Embolization*. Thrombi dislodge and travel to other sites in the vasculature. This process is described below.

- *Dissolution*. Dissolution is the result of fibrinolysis, which can lead to the rapid shrinkage and total disappearance of recent thrombi. In contrast, the extensive fibrin deposition and crosslinking in older thrombi renders them more resistant to lysis. This distinction explains why therapeutic administration of fibrinolytic agents such as t-PA (e.g., in the setting of acute coronary thrombosis) is generally effective only when given in the first few hours of a thrombotic episode.
- *Organization and recanalization*. Older thrombi become organized by the ingrowth of endothelial cells, smooth muscle cells, and fibroblasts (Fig. 4-14). Capillary channels eventually form that re-establish the continuity of the original lumen, albeit to a variable degree.

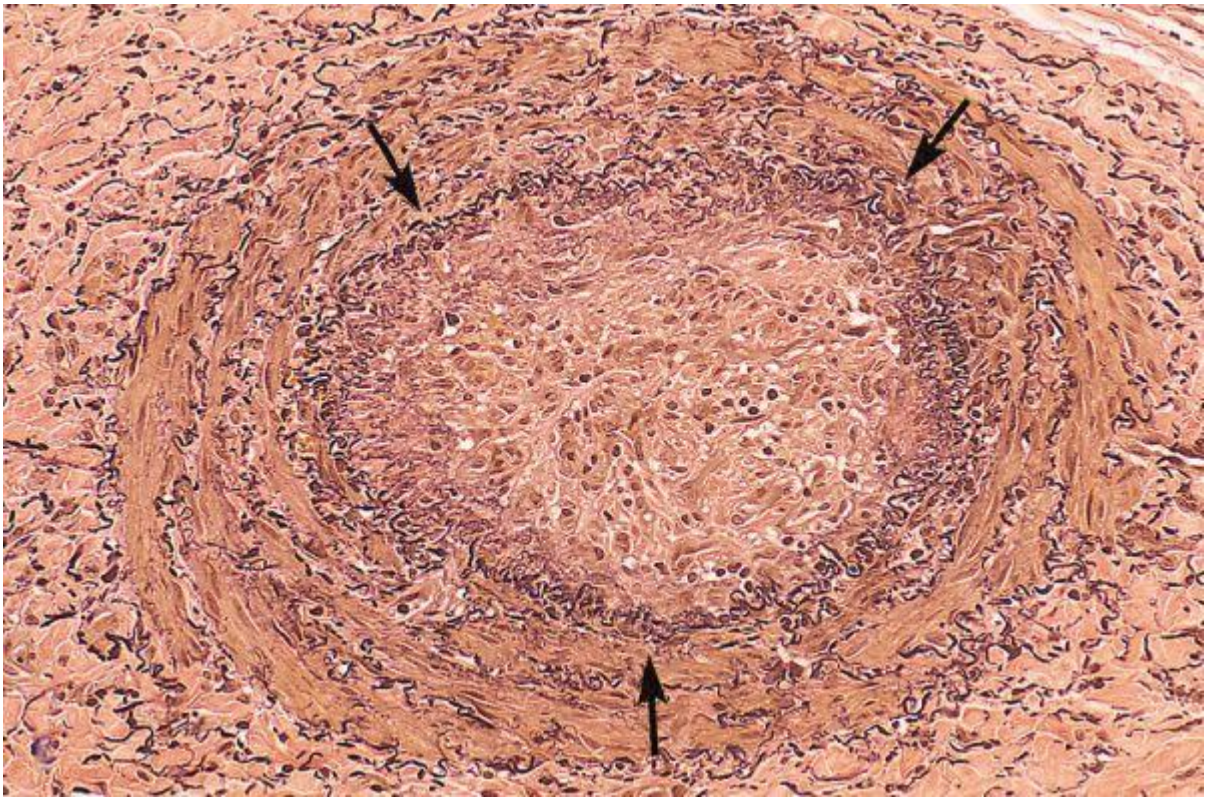

FIGURE 4-14 Low-power view of a thrombosed artery stained for elastic tissue. The original lumen is delineated by the internal elastic lamina *(arrows)* and is totally filled with organized thrombus, now punctuated by several recanalized endothelium-lined channels (white spaces).

Although the earliest capillary channels may not restore significant flow to obstructed vessels, continued recanalization may convert a thrombus into a smaller mass of connective tissue that becomes incorporated into the vessel wall. Eventually, with remodeling and contraction of the mesenchymal elements, only a fibrous lump may remain to mark the original thrombus. Occasionally the centers of thrombi undergo enzymatic digestion, presumably as a result of the release of lysosomal enzymes from trapped leukocytes and platelets. In the setting of bacteremia such thrombi may become infected, producing an inflammatory mass that erodes and weakens the vessel wall. If unchecked, this may result in a mycotic aneurysm (Chapter 11).

Clinical Consequences.

Thrombi are significant because *they cause obstruction of arteries and veins*, and *are sources of emboli*. Which effect predominates depends on the site of the thrombosis. Venous thrombi can cause congestion and edema in vascular beds distal to an obstruction, but they are far more worrisome for their capacity

to embolize to the lungs and cause death (see below). Conversely, although arterial thrombi can embolize and cause downstream infarctions, a thrombotic occlusion at a critical site (e.g., a coronary artery) can have more serious clinical consequences.

Venous Thrombosis (Phlebothrombosis).

Most venous thrombi occur in the superficial or deep veins of the leg.[25] Superficial venous thrombi typically occur in the saphenous veins in the setting of varicosities. Although such thrombi can cause local congestion, swelling, pain, and tenderness, they rarely embolize. Nevertheless, the local edema and impaired venous drainage do predispose the overlying skin to infections from slight trauma and to the development of *varicose ulcers. Deep venous thrombosis (DVT) in the larger leg veins—at or above the knee* (e.g., popliteal, femoral, and iliac veins)—is more serious because such thrombi more often embolize to the lungs and give rise to pulmonary infarction (see below and Chapter 15). Although they can cause local pain and edema, venous obstructions from DVTs can be rapidly offset by collateral channels. Consequently, DVTs are asymptomatic in approximately 50% of affected individuals and are recognized only in retrospect after embolization.

Lower extremity DVTs are associated with hypercoagulable states, as described earlier (see Table 4-2). Common predisposing factors include bed rest and immobilization (because they reduce the milking action of the leg muscles, resulting in reduced venous return), and congestive heart failure (also a cause of impaired venous return). Trauma, surgery, and burns not only immobilize a person but are also associated with vascular insults, procoagulant release from injured tissues, increased hepatic synthesis of coagulation factors, and altered t-PA production. Many elements contribute to the thrombotic diathesis of pregnancy; besides the potential for amniotic fluid infusion into the circulation at the time of delivery, late pregnancy and the postpartum period are also associated with systemic hypercoagulability. Tumor-associated inflammation and coagulation factors (tissue factor, factor VIII) and procoagulants (e.g., mucin) released from tumor cells all contribute to the increased risk of thromboembolism in disseminated cancers, so-called *migratory thrombophlebitis* or *Trousseau syndrome*.[39,][46] Regardless of the specific clinical setting, advanced age also increases the risk of DVT.

Arterial and Cardiac Thrombosis.

Atherosclerosis is a major cause of arterial thromboses, because it is associated with loss of endothelial integrity and with abnormal vascular flow (see Fig. 4-13B). Myocardial infarction can predispose to cardiac mural thrombi by causing dyskinetic myocardial contraction as well as damage to the adjacent endocardium (see Fig. 4-13A), and rheumatic heart disease may engender atrial mural thrombi as discussed above. Besides local obstructive consequences, cardiac and aortic mural thrombi can also embolize peripherally. Although any tissue can be affected, the brain, kidneys, and spleen are particularly likely targets because of their rich blood supply.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Disorders ranging from obstetric complications to advanced malignancy can be complicated by DIC, the sudden or insidious onset of widespread fibrin thrombi in the microcirculation. Although these thrombi are not grossly visible, they are readily apparent microscopically and can cause diffuse circulatory insufficiency, particularly in the brain, lungs, heart, and kidneys. To complicate matters, the widespread microvascular thrombosis results in platelet and coagulation protein consumption (hence the synonym *consumption coagulopathy*), and at the same time, fibrinolytic mechanisms are activated. Thus, an initially thrombotic disorder can evolve into a bleeding catastrophe. *It should be emphasized that DIC is not a primary disease but rather a potential complication of any condition associated with widespread activation of thrombin*.[47] It is discussed in greater detail along with other bleeding diatheses in Chapter 14 .

2.4.5 Embolism

An embolus is a detached intravascular solid, liquid, or gaseous mass that is carried by the blood to a site distant from its point of origin. The term *embolus* was coined by Rudolf Virchow in 1848 to describe objects that lodge in blood vessels and obstruct the flow of blood. Almost all emboli represent some part of a dislodged thrombus, hence the term *thromboembolism*. Rare forms of emboli include fat droplets, nitrogen bubbles, atherosclerotic debris *(cholesterol emboli)*, tumor fragments, bone marrow, or even foreign bodies. However, unless otherwise specified, emboli should be considered thrombotic in origin. Inevitably, emboli lodge in vessels too small to permit further passage, causing partial or complete vascular occlusion; a major consequence is ischemic necrosis *(infarction)* of the downstream tissue. Depending on where they originate, emboli can lodge anywhere in the vascular tree; the clinical outcomes are best understood based on whether emboli lodge in the pulmonary or systemic circulations.

PULMONARY EMBOLISM

Pulmonary embolism (PE) has had a fairly stable incidence since the 1970s of roughly 2 to 4 per 1000 hospitalized patients in the United States, although the numbers vary depending on the mix of patient age and diagnosis (i.e., surgery, pregnancy, and malignancy all increase the risk).[48] While the rate of fatal PEs (as assessed at autopsy) has declined from 6% to 2% over the last quarter century, PE still causes about 200,000 deaths per year in the United States.[49] In more than 95% of cases, PEs originate from leg deep vein thromboses (DVTs), although it is important to realize that DVTs occur roughly two to three times more frequently than PEs.[48]

Fragmented thrombi from DVTs are carried through progressively larger channels and the right side of the heart before slamming into the pulmonary arterial vasculature. Depending on the size of the embolus, it can occlude the main pulmonary artery, straddle the pulmonary artery bifurcation *(saddle embolus)*, or pass out into the smaller, branching arteries (Fig. 4-15). Frequently there are multiple emboli, perhaps sequentially or as a shower of smaller emboli from a single large mass; in general, *the patient who has had one PE is at high risk of having more*. Rarely, an embolus can pass through an interatrial or interventricular defect and gain access to the systemic circulation *(paradoxical embolism)*. A more complete discussion of PEs is presented in Chapter 15 ; an overview is offered here. [49] [50] [51]

- Most pulmonary emboli (60% to 80%) are clinically silent because they are small. With time they become organized and are incorporated into the vascular wall; in some cases organization of the thromboembolus leaves behind a delicate, bridging fibrous *web*.
- Sudden death, right heart failure *(cor pulmonale)*, or cardiovascular collapse occurs when emboli obstruct 60% or more of the pulmonary circulation.
- Embolic obstruction of medium-sized arteries with subsequent vascular rupture can result in pulmonary hemorrhage but usually does not cause pulmonary infarction. This is because the lung has a dual blood supply, and the intact bronchial circulation continues to perfuse the affected area. However, a similar embolus in the setting of left-sided cardiac failure (and compromised bronchial artery flow) can result in infarction.
- Embolic obstruction of small end-arteriolar pulmonary branches usually does result in hemorrhage or infarction.
- Multiple emboli over time may cause pulmonary hypertension and right ventricular failure.

FIGURE 4-15 Embolus from a lower extremity deep venous thrombosis, now impacted in a pulmonary artery branch.

SYSTEMIC THROMBOEMBOLISM

Systemic thromboembolism refers to emboli in the arterial circulation. Most (80%) arise from intracardiac mural thrombi, two thirds of which are associated with left ventricular wall infarcts and another quarter with left atrial dilation and fibrillation. The remainder originate from aortic aneurysms, thrombi on ulcerated atherosclerotic plaques, or fragmentation of a valvular vegetation, with a small fraction due to *paradoxical emboli*; 10% to 15% of systemic emboli are of unknown origin. In contrast to venous emboli, which tend to lodge primarily in one vascular bed (the lung), arterial emboli can travel to a wide variety of sites; the point of arrest depends on the source and the relative amount of blood flow that downstream tissues receive. Major sites for arteriolar embolization are the lower extremities (75%) and the brain (10%), with the intestines, kidneys, spleen, and upper extremities involved to a lesser extent. The consequences of embolization in a tissue depend on its vulnerability to ischemia, the caliber of the occluded vessel, and whether there is a collateral blood supply; in general, arterial emboli cause infarction of the affected tissues.

FAT AND MARROW EMBOLISM

Microscopic fat globules—with or without associated hematopoietic marrow elements—can be found in the circulation and impacted in the pulmonary vasculature after fractures of long bones (which have fatty marrow) or, rarely, in the setting of soft tissue trauma and burns. Fat and associated cells released by marrow or adipose tissue injury may enter the circulation after the rupture of the marrow vascular sinusoids or venules. Fat and marrow PEs are very common incidental findings after vigorous cardiopulmonary resuscitation and are probably of no clinical consequence. Indeed, fat embolism occurs

in some 90% of individuals with severe skeletal injuries (Fig. 4-16), but less than 10% of such patients have any clinical findings.

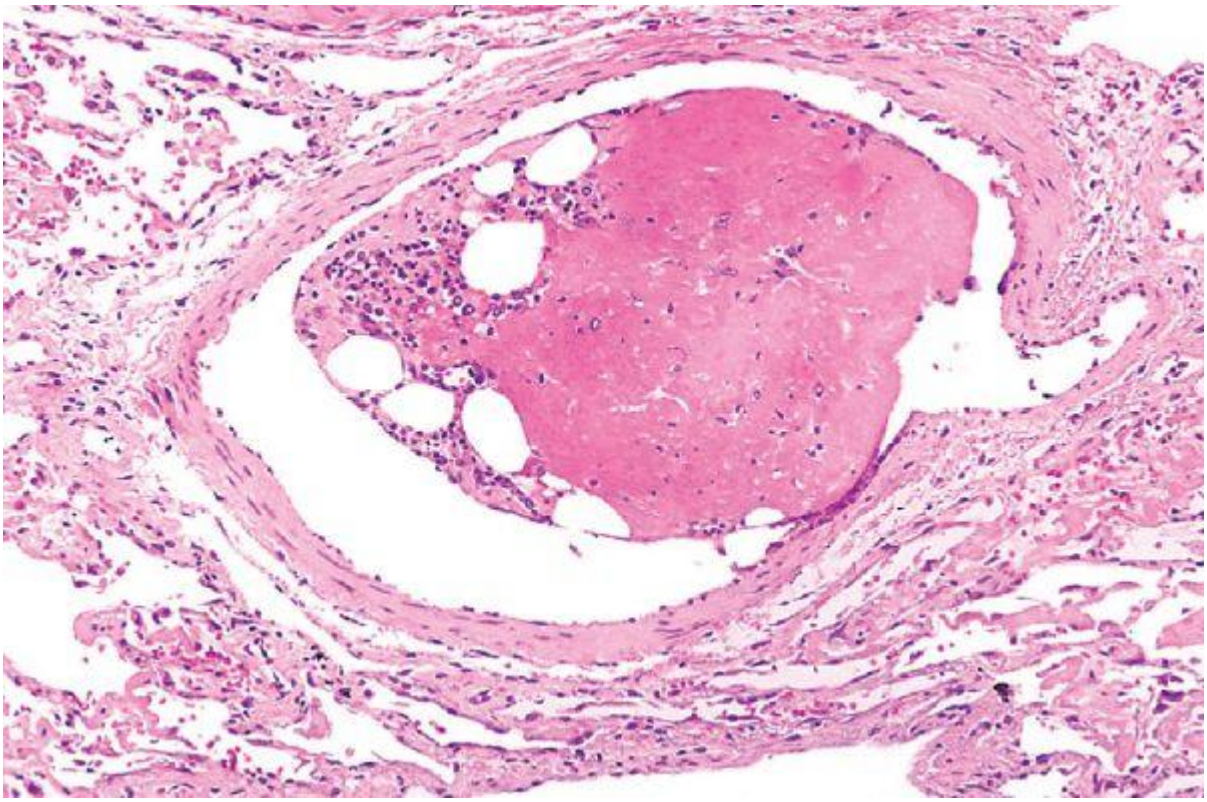

FIGURE 4-16 Bone marrow embolus in the pulmonary circulation. The cellular elements on the left side of the embolus are hematopoietic precursors, while the cleared vacuoles represent marrow fat. The relatively uniform red area on the right of the embolus is an early organizing thrombus.

Fat embolism syndrome is the term applied to the minority of patients who become symptomatic. It is characterized by pulmonary insufficiency, neurologic symptoms, anemia, and thrombocytopenia, and is fatal in about 5% to 15% of cases.[52,][53] Typically, 1 to 3 days after injury there is a sudden onset of tachypnea, dyspnea, and tachycardia; irritability and restlessness can progress to delirium or coma. Thrombocytopenia is attributed to platelet adhesion to fat globules and subsequent aggregation or splenic sequestration; anemia can result from similar red cell aggregation and/or hemolysis. A diffuse petechial rash (seen in 20% to 50% of cases) is related to rapid onset of thrombocytopenia and can be a useful diagnostic feature.

The pathogenesis of fat emboli syndrome probably involves both mechanical obstruction and biochemical injury.[52] Fat microemboli and associated red cell and platelet aggregates can occlude the pulmonary and cerebral microvasculature. Release of free fatty acids from the fat globules exacerbates the situation by causing local toxic injury to endothelium, and platelet activation and granulocyte recruitment (with free radical, protease, and eicosanoid release) complete the vascular assault. Because lipids are dissolved out of tissue preparations by the solvents routinely used in paraffin embedding, the microscopic demonstration of fat microglobules (in the absence of accompanying marrow) typically requires specialized techniques, including frozen sections and stains for fat.

AIR EMBOLISM

Gas bubbles within the circulation can coalesce to form frothy masses that obstruct vascular flow (and cause distal ischemic injury). For example, a very small volume of air trapped in a coronary artery during bypass surgery, or introduced into the cerebral circulation by neurosurgery in the "sitting position," can occlude flow with dire consequences. Generally, more than 100 cc of air are required to have a clinical effect in the pulmonary circulation; however, this volume of air can be inadvertently introduced during obstetric or laparoscopic procedures, or as a consequence of chest wall injury.[54]

A particular form of gas embolism, called *decompression sickness*, occurs when individuals experience sudden decreases in atmospheric pressure.[55] Scuba and deep sea divers, underwater construction workers, and individuals in unpressurized aircraft in rapid ascent are all at risk. When air is breathed at high pressure (e.g., during a deep sea dive), increased amounts of gas (particularly nitrogen) are dissolved in the blood and tissues. If the diver then ascends (depressurizes) too rapidly, the nitrogen comes out of solution in the tissues and the blood.

The rapid formation of gas bubbles within skeletal muscles and supporting tissues in and about joints is responsible for the painful condition called *the bends*. In the lungs, gas bubbles in the vasculature cause edema, hemorrhage, and focal atelectasis or emphysema, leading to a form of respiratory distress called the *chokes*. A more chronic form of decompression sickness is called *caisson disease* (named for the pressurized vessels used in the bridge construction; workers in these vessels suffered both acute and chronic forms of decompression sickness). In caisson disease, persistence of gas emboli in the skeletal system leads to multiple foci of ischemic necrosis; the more common sites are the femoral heads, tibia, and humeri.

Acute decompression sickness is treated by placing the individual in a high pressure chamber, which serves to force the gas bubbles back into solution. Subsequent slow decompression theoretically permits gradual resorption and exhalation of the gases so that obstructive bubbles do not re-form.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism is an ominous complication of labor and the immediate postpartum period. Although the incidence is only approximately 1 in 40,000 deliveries, the mortality rate is up to 80%, making amniotic fluid embolism the fifth most common cause of maternal mortality worldwide; it accounts for roughly 10% of maternal deaths in the United States and results in permanent neurologic deficit in as many as 85% of survivors.[56] The onset is characterized by sudden severe dyspnea, cyanosis, and shock, followed by neurologic impairment ranging from headache to seizures and coma. If the patient survives the initial crisis, pulmonary edema typically develops, along with (in half the patients) DIC, as a result of release of thrombogenic substances from the amniotic fluid.[56]

The underlying cause is the infusion of amniotic fluid or fetal tissue into the maternal circulation via a tear in the placental membranes or rupture of uterine veins. Classic findings include the presence of squamous cells shed from fetal skin, lanugo hair, fat from vernix caseosa, and mucin derived from the fetal respiratory or gastrointestinal tract in the maternal pulmonary microvasculature (Fig. 4-17). Other findings include marked pulmonary edema, *diffuse alveolar damage* (Chapter 15), and the presence of fibrin thrombi in many vascular beds due to DIC.

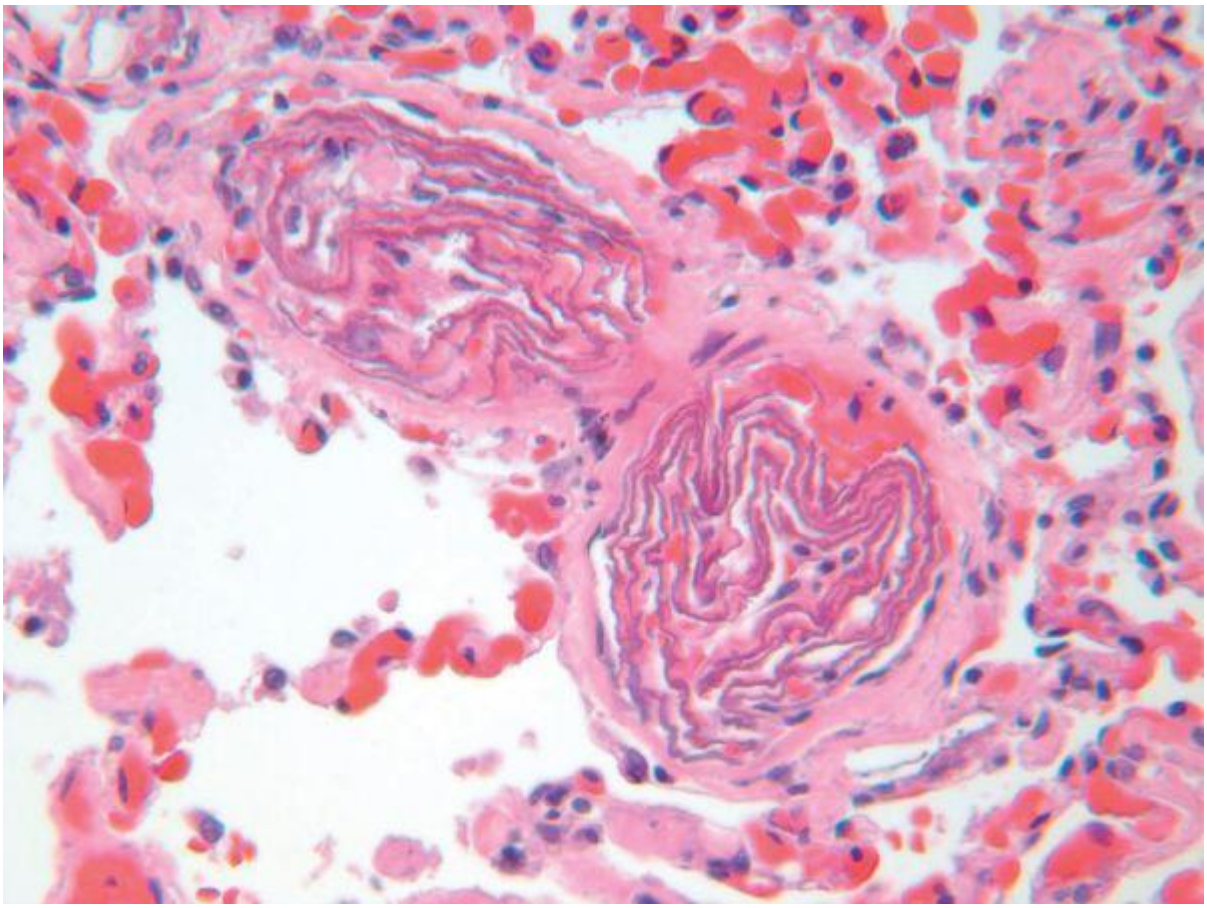

FIGURE 4-17 Amniotic fluid embolism. Two small pulmonary arterioles are packed with laminated swirls of fetal squamous cells. There is marked edema and congestion, and elsewhere in the lung were small organizing thrombi consistent with disseminated intravascular coagulation. *(Courtesy of Dr. Beth Schwartz, Baltimore, MD.)*

2.4.6 Infarction

An infarct is an area of ischemic necrosis caused by occlusion of either the arterial supply or the venous drainage. Tissue infarction is a common and extremely important cause of clinical illness. Roughly 40% of all deaths in the United States are caused by cardiovascular disease, and most of these are attributable to myocardial or cerebral infarction. Pulmonary infarction is also a common complication in many clinical settings, bowel infarction is frequently fatal, and ischemic necrosis of the extremities *(gangrene)* is a serious problem in the diabetic population.

Nearly all infarcts result from thrombotic or embolic arterial occlusions. Occasionally infarctions are caused by other mechanisms, including local vasospasm, hemorrhage into an atheromatous plaque, or extrinsic vessel compression (e.g., by tumor). Rarer causes include torsion of a vessel (e.g., in testicular torsion or bowel volvulus), traumatic rupture, or vascular compromise by edema (e.g., *anterior compartment syndrome*) or by entrapment in a hernia sac. Although venous thrombosis can cause infarction, the more common outcome is just congestion; in this setting, bypass channels rapidly open and permit vascular outflow, which then improves arterial inflow. Infarcts caused by venous thrombosis are thus more likely in organs with a single efferent vein (e.g., testis and ovary).

Morphology. Infarcts are classified according to color and the presence or absence of infection; they are either red (hemorrhagic) or white (anemic) and may be septic or bland.

- **Red infarcts** (Fig. 4-18A) occur (1) with venous occlusions (e.g., ovary), (2) in loose tissues (e.g., lung) where blood can collect in the infarcted zone, (3) in tissues with dual circulations (e.g., lung and small intestine) that allow blood flow from an unobstructed parallel supply into a necrotic zone, (4) in tissues previously congested by sluggish venous outflow, and (5) when flow is re-established to a site of previous arterial occlusion and necrosis (e.g., following angioplasty of an arterial obstruction).
- **White infarcts** (Fig. 4-18B) occur with arterial occlusions in solid organs with end-arterial circulation (e.g., heart, spleen, and kidney), and where tissue density limits the seepage of blood from adjoining capillary beds into the necrotic area.

Infarcts tend to be wedge-shaped, with the occluded vessel at the apex and the periphery of the organ forming the base (see Fig. 4-18); when the base is a serosal surface there can be an overlying fibrinous exudate. Acute infarcts are poorly defined and slightly hemorrhagic. With time the margins tend to become better defined by a narrow rim of congestion attributable to inflammation.

Infarcts resulting from arterial occlusions in organs without a dual blood supply typically become progressively paler and more sharply defined with time (see Fig. 4-18B). By comparison, in the lung hemorrhagic infarcts are the rule (see Fig. 4-18A). Extravasated red cells in hemorrhagic infarcts are phagocytosed by macrophages, which convert heme iron into hemosiderin; small amounts do not grossly impart any appreciable color to the tissue, but extensive hemorrhage can leave a firm, brown residuum.

The dominant histologic characteristic of infarction is **ischemic coagulative necrosis** (Chapter 1). It is important to recall that if the vascular occlusion has occurred shortly (minutes to hours) before the death of the person, no demonstrable histologic changes may be evident; it takes 4 to 12 hours for the tissue to show frank necrosis. Acute inflammation is present along the margins of infarcts within a few hours and is usually well defined within 1 to 2 days. Eventually the inflammatory response is followed by a reparative response beginning in the preserved margins (Chapter 2). In stable or labile tissues, parenchymal regeneration can occur at the periphery where underlying stromal architecture is preserved. However, most infarcts are ultimately replaced by **scar** (Fig. 4-19). The brain is an exception to these generalizations, as central nervous system infarction results in **liquefactive necrosis** (Chapter 1).

Septic infarctions occur when infected cardiac valve vegetations embolize or when microbes seed necrotic tissue. In these cases the infarct is converted into an **abscess**, with a correspondingly greater inflammatory response (Chapter 2). The eventual sequence of organization, however, follows the pattern already described.

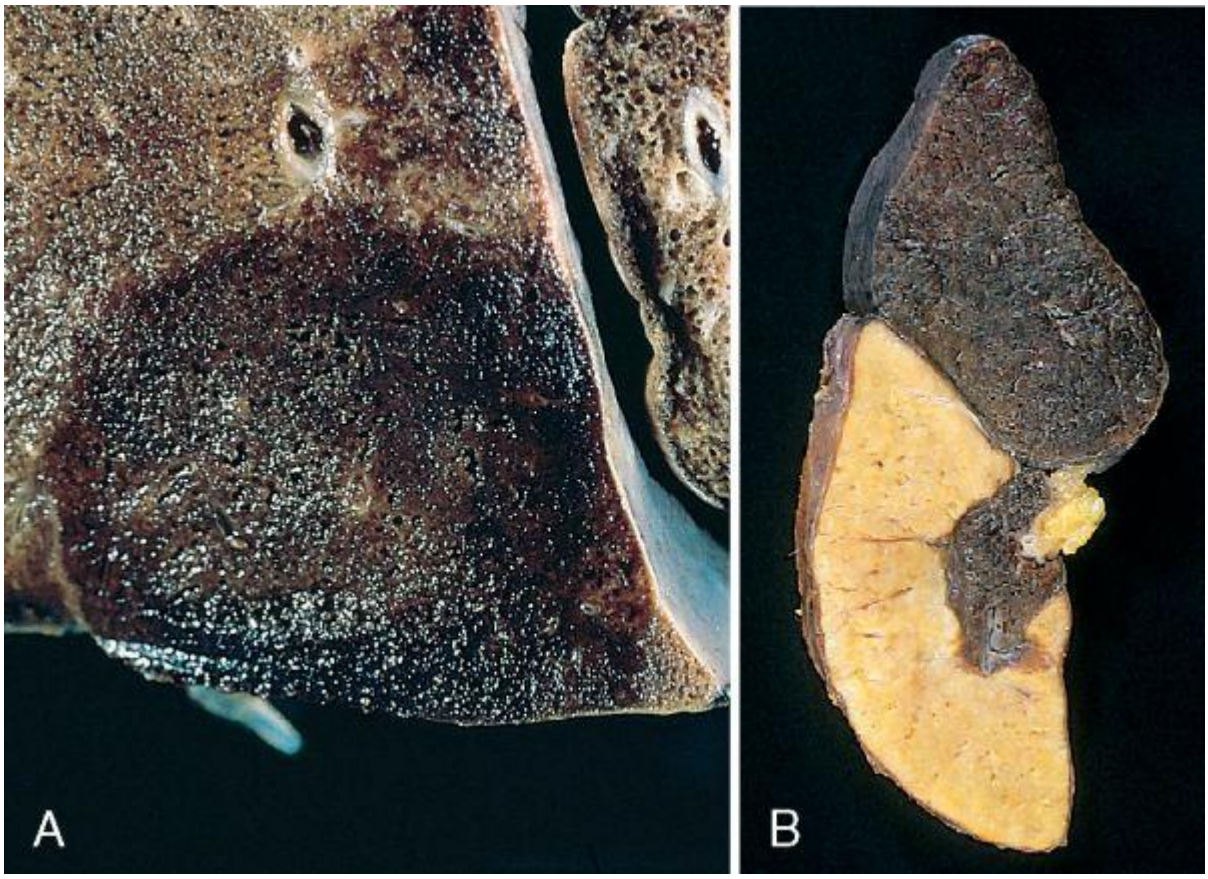

FIGURE 4-18 Red and white infarcts. **A**, Hemorrhagic, roughly wedge-shaped pulmonary *red infarct*. **B**, Sharply demarcated *white infarct* in the spleen.

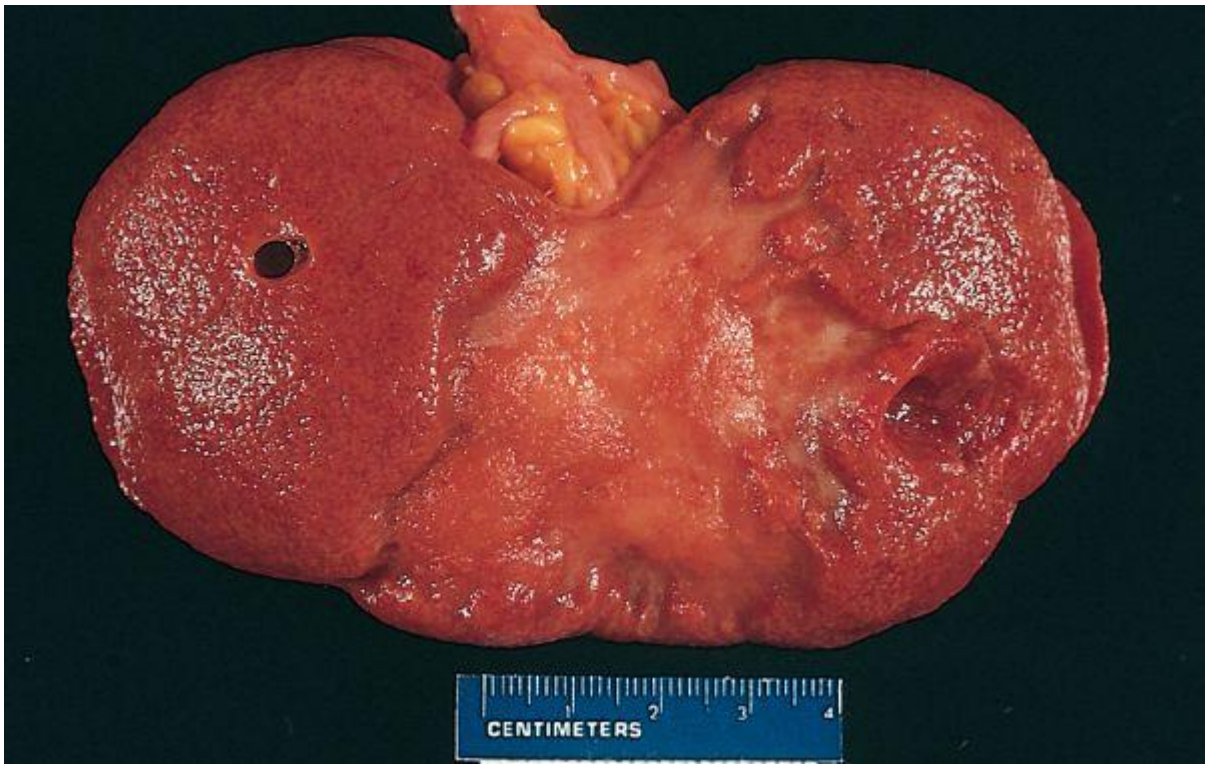

FIGURE 4-19 Remote kidney infarct, now replaced by a large fibrotic scar.

Factors That Influence Development of an Infarct.

The effects of vascular occlusion can range from no or minimal effect to causing the death of a tissue or person. *The major determinants of the eventual outcome are:* (1) *the nature of the vascular supply*, (2) *the rate at which an occlusion develops*, (3) *vulnerability to hypoxia*, and (4) *the oxygen content of the blood*.

- *Nature of the vascular supply*. The availability of an alternative blood supply is the most important determinant of whether vessel occlusion will cause damage. As already mentioned, the lungs have a dual pulmonary and bronchial artery blood supply that provides protection from thromboembolism-induced infarction. Similarly, the liver, with its dual hepatic artery and portal vein circulation, and the hand and forearm, with their dual radial and ulnar arterial supply, are all relatively resistant to infarction. In contrast, renal and splenic circulations are end-arterial, and vascular obstruction generally causes tissue death.
- *Rate of occlusion development*. Slowly developing occlusions are less likely to cause infarction, because they provide time to develop alternate perfusion pathways. For example, small interarteriolar anastomoses—normally with minimal functional flow—interconnect the three major coronary arteries in the heart. If one of the coronaries is only slowly occluded (i.e., by an encroaching atherosclerotic plaque), flow within this *collateral circulation* may increase sufficiently to prevent infarction, even though the larger coronary artery is eventually occluded.
- *Vulnerability to hypoxia*. Neurons undergo irreversible damage when deprived of their blood supply for only 3 to 4 minutes. Myocardial cells, though hardier than neurons, are also quite sensitive and die after only 20 to 30 minutes of ischemia. In contrast, fibroblasts within myocardium remain viable even after many hours of ischemia (Chapter 12).
- *Oxygen content of blood*. A partial obstruction of a small vessel that would be without effect in an otherwise normal individual might cause infarction in an anemic or cyanotic patient.

2.4.7 Shock

Shock is the final common pathway for several potentially lethal clinical events, including severe hemorrhage, extensive trauma or burns, large myocardial infarction, massive pulmonary embolism, and microbial sepsis. *Shock is characterized by systemic hypotension due either to reduced cardiac output or to reduced effective circulating blood volume*. The consequences are *impaired tissue perfusion and cellular hypoxia*. At the outset the cellular injury is reversible; however, prolonged shock eventually leads to irreversible tissue injury that often proves fatal.

The causes of shock fall into three general categories (Table 4-3):

- *Cardiogenic shock* results from low cardiac output due to myocardial pump failure. This can be due to intrinsic myocardial damage (infarction), ventricular arrhythmias, extrinsic compression (cardiac tamponade; Chapter 12), or outflow obstruction (e.g., pulmonary embolism).
- *Hypovolemic shock* results from low cardiac output due to the loss of blood or plasma volume, such as can occur with massive hemorrhage or fluid loss from severe burns.
- *Septic shock* results from vasodilation and peripheral pooling of blood as part of a systemic immune reaction to bacterial or fungal infection. Its complex pathogenesis is discussed in further detail below.

TABLE 4-3 -- Three Major Types of Shock

Type of Shock	Clinical Example	Principal Mechanisms
CARDIOGENIC		
	Myocardial infarction Ventricular rupture Arrhythmia Cardiac tamponade Pulmonary embolism	Failure of myocardial pump resulting from intrinsic myocardial damage, extrinsic pressure, or obstruction to outflow
HYPOVOLEMIC		
	Fluid loss (e.g., hemorrhage, vomiting, diarrhea, burns, or trauma)	Inadequate blood or plasma volume
SEPTIC		
	Overwhelming microbial infections (bacterial and fungal) Superantigens (e.g., toxic shock syndrome)	Peripheral vasodilation and pooling of blood; endothelial activation/injury; leukocyte-induced damage, disseminated intravascular coagulation; activation of cytokine cascades

Less commonly, shock can occur in the setting of anesthetic accident or a spinal cord injury *(neurogenic shock)*, as a result of loss of vascular tone and peripheral pooling of blood. *Anaphylactic shock* denotes systemic vasodilation and increased vascular permeability caused by an IgE–mediated hypersensitivity reaction (Chapter 6). In these situations, acute widespread vasodilation results in tissue hypoperfusion and hypoxia.

PATHOGENESIS OF SEPTIC SHOCK

Septic shock is associated with severe hemodynamic and hemostatic derangements, and therefore merits more detailed consideration here. With a mortality rate near 20%, septic shock ranks first among the causes of death in intensive care units and accounts for over 200,000 lost lives each year in the United States.[57] Its incidence is rising, ironically due to improvements in life support for critically ill patients and the growing ranks of immunocompromised hosts (due to chemotherapy, immunosuppression, or HIV infection). Currently, septic shock is most frequently triggered by gram-positive bacterial infections, followed by gram-negative bacteria and fungi.[57] Hence, the older synonym of "endotoxic shock" is not appropriate.

In septic shock, systemic vasodilation and pooling of blood in the periphery leads to tissue hypoperfusion, even though cardiac output may be preserved or even increased early in the course. This is accompanied by widespread endothelial cell activation and injury, often leading to a hypercoagulable state that can manifest as DIC. In addition, septic shock is associated with changes in metabolism that directly suppress cellular function. The net effect of these abnormalities is hypoperfusion and dysfunction of multiple organs—culminating in the extraordinary morbidity and mortality associated with sepsis.

The ability of diverse microorganisms to cause septic shock (sometimes even when the infection is localized to one area of the body)[58] is consistent with the idea that several microbial constituents can initiate the process. As you will recall from Chapter 2 , macrophages, neutrophils, and other cells of the innate immune system express a number of receptors that respond to a variety of substances derived from microorganisms. Once activated, these cells release inflammatory mediators, as well as a variety of immunosuppressive factors that modify the host response. In addition, microbial constituents also activate humoral elements of innate immunity, particularly the complement and coagulation pathways. These mediators combine with the direct effects of microbial constituents on endothelium in a complex, incompletely understood fashion to produce septic shock (Fig. 4-20). [59] [60] [61] The major factors contributing to its pathophysiology include the following:

- *Inflammatory mediators*. Various microbial cell wall constituents engage receptors on neutrophils, mononuclear inflammatory cells, and endothelial cells, leading to cellular activation. Toll-like receptors (TLRs, Chapter 2) recognize microbial elements and trigger the responses that initiate sepsis. However, mice genetically deficient in TLRs still succumb to sepsis,[59,][60] and it is believed that other pathways are probably also involved in the initiation of sepsis in humans (e.g., G-protein coupled receptors that detect bacterial peptides and nucleotide oligomerization domain proteins 1 and 2 [NOD1, NOD2]).[62] Upon activation, inflammatory cells produce TNF, IL-1, IFN-γ, IL-12, and IL-18, as well as other inflammatory mediators such as high mobility group box 1 protein (HMGB1).[62] Reactive oxygen species and lipid mediators such as prostaglandins and platelet activating factor (PAF) are also elaborated. These effector molecules activate endothelial cells (and other cell types) resulting in adhesion molecule expression, a procoagulant phenotype, and secondary waves of cytokine production.[61] The *complement cascade* is also activated by microbial components, both directly and through the proteolytic activity of plasmin (Chapter 2), resulting in the production of anaphylotoxins (C3a, C5a), chemotactic fragments (C5a), and opsonins (C3b) that contribute to the pro-inflammatory state.[63] In addition, microbial components such as endotoxin can activate coagulation directly through factor XII and indirectly through altered endothelial function (discussed below). The systemic procoagulant state induced by sepsis not only leads to thrombosis, but also augments inflammation through effects mediated by protease-activated receptors (PARs) found on inflammatory cells.
- *Endothelial cell activation and injury*. Endothelial cell activation by microbial constituents or inflammatory mediators produced by leukocytes has three major sequelae: (1) thrombosis; (2) increased vascular permeability; and (3) vasodilation. *The derangement in coagulation is sufficient to produce the fearsome complication of DIC in up to half of septic patients*.[60] Sepsis alters the expression of many factors so as to favor coagulation. Pro-inflammatory cytokines result in increased tissue factor production by endothelial cells (and monocytes as well), while at the same time reining in fibrinolysis by increasing PAI-1 expression (see Fig. 4-6*B* and Fig. 4-8). The production of other endothelial anti-coagulant factors, such as tissue factor pathway inhibitor, thrombomodulin, and protein C (see Fig. 4-6 and Fig. 4-8), are diminished.[60,][61,][64] The procoagulant tendency is further exacerbated by decreased blood flow at the level of small vessels, producing stasis and diminishing the washout of activated coagulation factors. Acting in concert, these

effects promote the deposition of fibrin-rich thrombi in small vessels, often throughout the body, which also contributes to the hypoperfusion of tissues.[60] In full-blown DIC, the consumption of coagulation factors and platelets is so great that deficiencies of these factors appear, leading to concomitant bleeding and hemorrhage (Chapter 14). The increase in vascular permeability leads to exudation of fluid into the interstitium, causing edema and an increase in interstitial fluid pressure that may further impede blood flow into tissues, particularly following resuscitation of the patient with intravenous fluids. The endothelium also increases its expression of inducible nitric oxide synthetase and the production of nitric oxide (NO). These alterations, along with increases in vasoactive inflammatory mediators (e.g., C3a, C5a, and PAF), cause the systemic relaxation of vascular smooth muscle, leading to hypotension and diminished tissue perfusion.

- *Metabolic abnormalities*. Septic patients exhibit insulin resistance and hyperglycemia. Cytokines such as TNF and IL-1, stress-induced hormones (such as glucagon, growth hormone, and glucocorticoids), and catecholamines all drive gluconeogenesis. At the same time, the pro-inflammatory cytokines suppress insulin release while simultaneously promoting insulin resistance in the liver and other tissues, likely by impairing the surface expression of GLUT-4,[65] a glucose transporter. Hyperglycemia decreases neutrophil function—thereby suppressing bactericidal activity—and causes increased adhesion molecule expression on endothelial cells.[65] Although sepsis is initially associated with an acute surge in glucocorticoid production, this phase is frequently followed by adrenal insufficiency and a functional deficit of glucocorticoids. This may stem from depression of the synthetic capacity of intact adrenal glands or frank adrenal necrosis due to DIC (*Waterhouse-Friderichsen syndrome*, Chapter 24).
- *Immune suppression*. The hyperinflammatory state initiated by sepsis can activate counter-regulatory immunosuppressive mechanisms, which may involve both innate and adaptive immunity. [59] [60] [61] Proposed mechanisms for the immune suppression include a shift from pro-inflammatory (T_H1) to anti-inflammatory (T_H2) cytokines (Chapter 6), production of anti-inflammatory mediators (e.g., soluble TNF receptor, IL-1 receptor antagonist, and IL-10), lymphocyte apoptosis, the immunosuppressive effects of apoptotic cells, and the induction of cellular anergy. [59] [60] [61] It is still debated whether immunosuppressive mediators are deleterious or protective in sepsis.[59]
- *Organ dysfunction*. Systemic hypotension, interstitial edema, and small vessel thrombosis all decrease the delivery of oxygen and nutrients to the tissues, which fail to properly utilize those nutrients that are delivered due to changes in cellular metabolism. High levels of cytokines and secondary mediators may diminish myocardial contractility and cardiac output, and increased vascular permeability and endothelial injury can lead to the *adult respiratory distress syndrome* (Chapter 15). Ultimately, these factors may conspire to cause the failure of multiple organs, particularly the kidneys, liver, lungs, and heart, culminating in death.

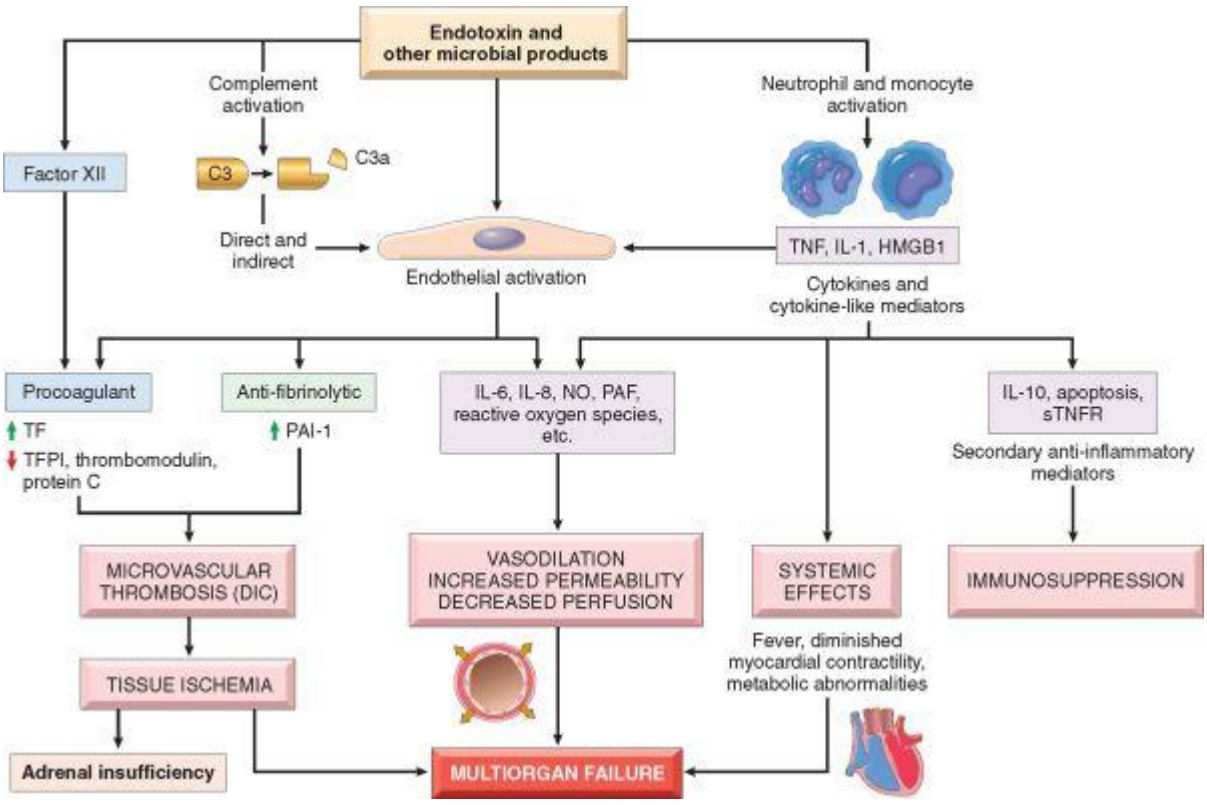

FIGURE 4-20 Major pathogenic pathways in septic shock. Microbial products activate endothelial cells and cellular and humoral elements of the innate immune system, initiating a cascade of events that lead to end-stage multiorgan failure. Additional details are given in the text. DIC, disseminated vascular coagulation; HMGB1, high mobility group box 1 protein; NO, nitric oxide; PAF, platelet activating factor; PAI-1, plasminogen activator inhibitor 1; STNFR, soluble TNF receptor; TF, tissue factor; TFPI, tissue factor pathway inhibitor.

The severity and outcome of septic shock are likely dependent upon the extent and virulence of the infection; the immune status of the host; the presence of other co-morbid conditions; and the pattern and level of mediator production. The multiplicity of factors and the complexity of the interactions that underlie sepsis explain why most attempts to intervene therapeutically with antagonists of specific mediators have been of very modest benefit at best, and may even have had deleterious effects in some cases.[59] The standard of care remains treatment with appropriate antibiotics, intensive insulin therapy for hyperglycemia, fluid resuscitation to maintain systemic pressures, and "physiologic doses" of corticosteroids to correct relative adrenal insufficiency.[59] Administration of activated protein C (to prevent thrombin generation and thereby reduce coagulation and inflammation) may have some benefit in cases of severe sepsis, but this remains controversial. Suffice it to say, even in the best of clinical centers, septic shock remains an obstinate clinical challenge.[58]

It is worth mentioning here that an additional group of secreted bacterial proteins called *superantigens* also cause a syndrome similar to septic shock (e.g., *toxic shock syndrome*). Superantigens are polyclonal T-lymphocyte activators that induce the release of high levels of cytokines that result in a variety of clinical manifestations, ranging from a diffuse rash to vasodilation, hypotension, and death.[66]

STAGES OF SHOCK

Shock is a progressive disorder that, if uncorrected, leads to death. The exact mechanism(s) of death from sepsis are still unclear; aside from increased lymphocyte and enterocyte apoptosis there is only minimal cell death, and patients rarely have refractory hypotension.[61] For hypovolemic and cardiogenic shock, however, the pathways to death are reasonably well understood. Unless the insult is massive and rapidly lethal (e.g., a massive hemorrhage from a ruptured aortic aneurysm), shock in those settings tends to evolve through three general (albeit somewhat artificial) phases:

- An initial *nonprogressive phase* during which reflex compensatory mechanisms are activated and perfusion of vital organs is maintained
- A *progressive stage* characterized by tissue hypoperfusion and onset of worsening circulatory and metabolic imbalances, including acidosis
- An *irreversible stage* that sets in after the body has incurred cellular and tissue injury so severe that even if the hemodynamic defects are corrected, survival is not possible

In the early nonprogressive phase of shock, a variety of *neurohumoral mechanisms* help to maintain cardiac output and blood pressure. These include baroreceptor reflexes, catecholamine release, activation of the renin-angiotensin axis, ADH release, and generalized sympathetic stimulation. The net effect is *tachycardia, peripheral vasoconstriction, and renal conservation of fluid*. Cutaneous vasoconstriction, for example, is responsible for the characteristic coolness and pallor of the skin in well-developed shock (although septic shock can initially cause cutaneous *vasodilation* and thus present with warm, flushed skin). Coronary and cerebral vessels are less sensitive to the sympathetic response and thus maintain relatively normal caliber, blood flow, and oxygen delivery.

If the underlying causes are not corrected, shock passes imperceptibly to the progressive phase, during which there is widespread tissue hypoxia. In the setting of persistent oxygen deficit, intracellular aerobic respiration is replaced by anaerobic glycolysis with excessive production of lactic acid. The resultant metabolic *lactic acidosis lowers the tissue pH and blunts the vasomotor response*; arterioles dilate, and blood begins to pool in the microcirculation. Peripheral pooling not only worsens the cardiac output, but also puts EC at risk for developing anoxic injury with subsequent DIC. With widespread tissue hypoxia, vital organs are affected and begin to fail.

Without intervention, the process eventually enters an irreversible stage. Widespread cell injury is reflected in lysosomal enzyme leakage, further aggravating the shock state. Myocardial contractile function worsens in part because of nitric oxide synthesis. If ischemic bowel allows intestinal flora to enter the circulation, bacteremic shock may be superimposed. At this point the patient has complete renal shutdown as a result of acute tubular necrosis (Chapter 20), and despite heroic measures the downward clinical spiral almost inevitably culminates in death.

Morphology. The cellular and tissue changes induced by cardiogenic or hypovolemic shock are essentially those of hypoxic injury (Chapter 1); changes can manifest in any tissue although they are particularly evident in brain, heart, lungs, kidneys, adrenals, and gastrointestinal tract. The **adrenal** changes in shock are those seen in all forms of stress; essentially there is cortical cell lipid depletion. This does not reflect adrenal exhaustion but rather conversion of the relatively inactive vacuolated cells to metabolically active cells that utilize stored lipids for the synthesis of steroids. The **kidneys** typically exhibit acute tubular necrosis (Chapter 20). The **lungs** are seldom affected in pure hypovolemic shock, because they are somewhat resistant to hypoxic injury. However, when shock is caused by bacterial sepsis or trauma, changes of **diffuse alveolar damage** (Chapter 15) may develop, the so-called shock lung. In septic shock, the development of DIC leads to widespread deposition of fibrin-rich microthrombi, particularly in the brain, heart, lungs, kidney, adrenal glands, and gastrointestinal tract. The consumption of platelets and coagulation factors also often leads to the appearance of petechial hemorrhages on serosal surface and the skin.

With the exception of neuronal and myocyte ischemic loss, virtually all of these tissues may revert to normal if the individual survives. Unfortunately, most patients with irreversible changes due to severe shock die before the tissues can recover.

Clinical Consequences.

The clinical manifestations of shock depend on the precipitating insult. In hypovolemic and cardiogenic shock *the patient presents with hypotension; a weak, rapid pulse; tachypnea; and cool, clammy, cyanotic skin*. In septic shock *the skin may initially be warm and flushed because of peripheral vasodilation*. The initial threat to life stems from the underlying catastrophe that precipitated the shock (e.g., myocardial infarct, severe hemorrhage, or sepsis). Rapidly, however, the cardiac, cerebral, and pulmonary changes secondary to shock worsen the problem. Eventually, electrolyte disturbances and metabolic acidosis also exacerbate the situation. Individuals who survive the initial complications may enter *a second phase dominated by renal insufficiency* and marked by a progressive fall in urine output as well as severe fluid and electrolyte imbalances.

The prognosis varies with the origin of shock and its duration. Thus, greater than 90% of young, otherwise healthy patients with hypovolemic shock survive with appropriate management; in comparison, septic shock, or cardiogenic shock associated with extensive myocardial infarction, can have substantially worse mortality rates, even with optimal care.

2.5 5. Genetic Disorders

2.5.1 Human Genetic Architecture

* The assistance of Dr. A. John Iafrate (Massachusetts General Hospital, Boston, MA) in the revision of the section on molecular diagnosis is greatly appreciated.

Human Genetic Architecture

The sequence of the human genome is complete, and much has been learned about the "genetic architecture" of humans.[1] Some of what has been revealed was quite unexpected. For example, we now know that less than 2% of the human genome encodes proteins, whereas more than one half represents blocks of repetitive DNA sequences whose functions remain mysterious. What was totally unexpected was that humans have a mere 20,000 to 25,000 genes that code for proteins rather than the 100,000 predicted. Quite remarkably, this figure is about the same as that of the mustard plant, with 26,000 genes! However, it is also known that by alternative splicing, the 25,000 human genes can give rise to greater than 100,000 proteins. Humans are not so poor, after all. With the completion of the Human Genome Project, a new term, *genomics*, has been added to the medical vocabulary. Whereas genetics is the study of single or a few genes and their phenotypic effects, genomics is the study of all the genes in the genome and their interactions.[2] DNA microarray analysis of tumors (Chapter 7) is an excellent example of genomics in current clinical use.

Another surprising revelation from the recent progress in genomics is that, on average, any two individuals share greater than 99.5% of their DNA sequences.[3] Thus, the remarkable diversity of humans is encoded in less than 0.5% of our DNA. The secrets to disease predisposition and response to environmental agents and drugs must therefore reside within these variations. Though small when compared to the total nucleotide sequences, this 0.5% represents about 15 million base pairs. The two most common forms of DNA variations in the human genome are *single-nucleotide polymorphisms (SNPs)* and *copy number variations (CNVs)*. SNPs represent variation at single isolated nucleotide positions and are almost always biallelic (i.e., one of only two choices exist at a given site within the population, such as A or T). Much effort has been devoted to making SNP maps of the human genome. These efforts have identified over 6 million SNPs in the human population, many of which show wide variation in frequency in different populations. SNPs may occur anywhere in the genome—within exons, introns, or intergenic regions, but less than 1% of SNPs occur in coding regions. These coding sequence variations are important, since they could of course alter the gene product and predispose to a phenotypic difference or to a disease. Much more commonly, however, the SNP is just a marker that is co-inherited with a disease-associated gene as a result of physical proximity. Another way of expressing this is to say that the SNP and the causative genetic factor are in *linkage disequilibrium*. There is optimism that groups of SNPs could serve as reliable markers of risk for multigenic complex diseases such as type II diabetes and hypertension, and that by identifying such variants strategies for disease prevention could be developed (discussed later).

CNVs are a recently identified form of genetic variation consisting of different numbers of large contiguous stretches of DNA from 1000 base pairs to millions of base pairs.[4,][5] In some instances these loci are, like SNPs, biallelic and simply duplicated or deleted in a subset of the population. In other instances there are complex rearrangements of genomic material, with multiple alleles in the human population. Current estimates are that CNVs are responsible for between 5 and 24 million base pairs of sequence difference between any two individuals.[6] Approximately 50% of CNVs involve gene-coding sequences; thus, CNVs may underlie a large portion of human phenotypic diversity. There is a significant over-representation of certain gene families in regions affected by CNVs; these include genes involved in the immune system and in the nervous system. It is assumed that copy number diversity in such gene families has been subject to strong evolutionary selection, since they would enhance human adaptation to changing environmental factors. We currently know much less about CNVs than SNPs, therefore their influence on disease susceptibility is less established, though predicted to be substantial.

It should be pointed out that despite all these advances in the understanding of human variations, it is clear that alterations in DNA sequence cannot by themselves explain the diversity of phenotypes in human populations. Nor can classic genetics explain how monozygotic twins can have differing phenotypes.[7] The answer must lie in *epigenetics*, which is defined as heritable changes in gene expression that are not caused by alterations in DNA sequence. Epigenetic changes are involved in tissue-specific expression of genes and genomic imprinting. The biochemical basis of epigenetic changes and its detection are discussed under “Molecular Diagnosis.”

Just as genomics involves the study of all the DNA sequences, *proteomics* concerns itself with the measurement of all proteins expressed in a cell or tissue. To simultaneously analyze patterns of expression involving thousands of genes and proteins has required the parallel development of computer-based techniques that can manage vast collections of data. In response to this, an exciting new discipline called *bioinformatics* has sprouted.[8]

It is worth noting that until recently the major focus of gene hunting has been discovery of structural genes whose products encode proteins. Recent studies indicate, however, that a very large number of genes do not encode proteins. Instead, their products play important regulatory functions. The most

recently discovered among this class of genes are those that encode small RNA molecules, so-called microRNAs (miRNAs). miRNAs, unlike other RNAs, do not encode proteins but instead inhibit gene expression. Silencing of gene expression by miRNA is preserved in all living forms from plants to humans and therefore must be a fundamental mechanism of gene regulation. Because of their profound influence on gene regulation, miRNAs are assuming central importance in understanding normal developmental pathways, as well as pathologic conditions, such as cancer.[9] Such is the importance of the discovery of gene silencing by miRNAs that Andrew Fire and Craig Mello were awarded the Nobel Prize in physiology or medicine in 2006, a mere 8 years after they published their initial work.

By current estimates there are approximately 1000 genes in humans that encode miRNAs, accounting for about 5% of the human genome. Transcription of miRNA genes produces primary miRNA transcripts, which is processed within the nucleus to form another structure, called pre-miRNA (Fig. 5-1). With the help of specific transporter proteins, pre-miRNA is exported to the cytoplasm. Additional "cutting" by an enzyme, appropriately called Dicer, generates mature miRNAs that are about 21 to 30 nucleotides in length (hence the name "micro"). At this stage the miRNA is still double-stranded. Next, the miRNA unwinds, and single strands of this duplex are incorporated into a multiprotein complex called RNA-induced silencing complex (RISC). Base-pairing between the miRNA strand and its target messenger RNA (mRNA) directs the RISC to either cause mRNA cleavage or repress its translation. In this way, the gene from which the target mRNA was derived is silenced (at a post-transcriptional level).[10] Given that the numbers of miRNA genes are far fewer than those that encode proteins, it follows that a given miRNA can silence many target genes. The precise mechanism by which the target specificity of miRNA is determined remains to be fully elucidated.

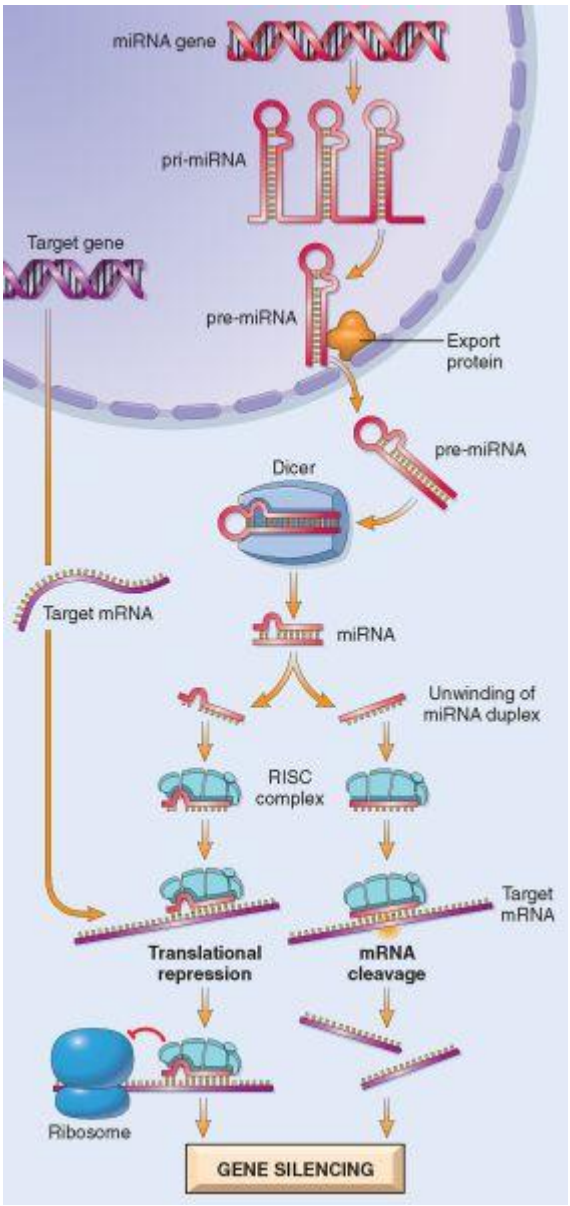

FIGURE 5-1 Generation of microRNAs and their mode of action in regulating gene function. Pri-miRNA, primary microRNA transcript; pre-miRNA, precursor microRNA; RISC, RNA-induced silencing complex.

Another species of gene-silencing RNA, called *small interfering RNAs* (siRNAs), works in a manner quite similar to that of miRNA. Unlike miRNA, however, siRNA precursors are introduced by investigators into the cell. Their processing by Dicer and functioning via RISC are essentially similar to that described for miRNA. siRNAs are becoming powerful tools for studying gene function and may in the future be used therapeutically to silence specific genes, such as oncogenes, whose products are involved in neoplastic transformation.

2.5.2 Genes & Human Diseases

Genetic disorders are far more common than is widely appreciated. The lifetime frequency of genetic diseases is estimated to be 670 per 1000.[11] Furthermore, the genetic diseases encountered in medical

practice represent only the tip of the iceberg, that is, those with less extreme genotypic errors permitting full embryonic development and live birth. It is estimated that 50% of spontaneous abortuses during the early months of gestation have a demonstrable chromosomal abnormality; there are, in addition, numerous smaller detectable errors and many others still beyond our range of identification. About 1% of all newborn infants possess a gross chromosomal abnormality, and approximately 5% of individuals under age 25 develop a serious disease with a significant genetic component. How many more mutations remain hidden?

Before discussing specific aberrations that may cause genetic diseases, it is useful to summarize the genetic contribution to human disease. Human genetic disorders can be broadly classified into three categories

- *Disorders related to mutations in single genes with large effects*. These mutations cause the disease or predispose to the disease and are typically not present in normal population. Such mutations and their associated disorders are highly penetrant, meaning that the presence of the mutation is associated with the disease in a large proportion of individuals. Because these diseases are caused by single gene mutations, they usually follow the classic Mendelian pattern of inheritance and are also referred to as Mendelian disorders. A few important exceptions to this rule are noted later.
  Study of single genes and mutations with large effects has been extremely informative in medicine since a great deal of what we know about several physiologic pathways (such as cholesterol transport, chloride secretion) has been learned from analysis of single gene disorders. Although informative, these disorders are generally rare unless they are maintained in a population by strong selective forces (e.g., sickle cell anemia in areas where malaria is endemic, Chapter 14).
- *Chromosomal disorders*. These arise from structural or numerical alteration in the autosomes and sex chromosomes. Like monogenic disease they are uncommon but associated with high penetrance.
- *Complex multigenic disorders*. These are far more common than the previous two categories. They are caused by interactions between multiple variant forms of genes and environmental factors. Such variations in genes are common within the population and are also called *polymorphisms*. Each such variant gene confers a small increase in disease risk, and no single susceptibility gene is necessary or sufficient to produce the disease. It is only when several such polymorphisms are present in an individual that disease occurs, hence the term *multigenic* or *polygenic*. Thus, unlike mutant genes with large effects that are highly penetrant and give rise to Mendelian disorders, each polymorphism has a small effect and is of low penetrance. Since environmental interactions are important in the pathogenesis of these diseases, they are also called multifactorial disorders. In this category are some of the most common diseases that afflict humans, including atherosclerosis, diabetes mellitus, hypertension, and autoimmune diseases. Even normal traits such as height and weight are governed by polymorphisms in several genes.
  Since complex traits do not follow a Mendelian pattern of inheritance, the genes and polymorphisms that contribute to such diseases have been very difficult to discern. However, recent progress in genomics and high throughput sequencing technology has made possible genome wide association studies (GWAS), a systematic method of identifying disease-associated polymorphisms that is beginning to unravel the molecular basis of complex disorders. We will discuss the principle of GWAS later in the chapter.

We begin our discussion with a description of mutations that affect single genes, since they underlie Mendelian disorders. We follow with transmission patterns and selected samples of single gene disorders.

MUTATIONS

A *mutation* is defined as a permanent change in the DNA. Mutations that affect germ cells are transmitted to the progeny and can give rise to inherited diseases. Mutations that arise in somatic cells understandably do not cause hereditary diseases but are important in the genesis of cancers and some congenital malformations.

Mutations may result in partial or complete deletion of a gene or, more often, affect a single base. For example, a single nucleotide base may be *substituted* by a different base, resulting in a *point mutation*.

Less commonly, one or two base pairs may be *inserted* into or *deleted* from the DNA, leading to alterations in the reading frame of the DNA strand; hence these are referred to as *frameshift* mutations (Figs. 5-2 and 5-3). Next we briefly review some general principles relating to the effects of gene mutations.

- *Point mutations within coding sequences:* A point mutation may alter the code in a triplet of bases and lead to the replacement of one amino acid by another in the gene product. Because these mutations alter the meaning of the sequence of the encoded protein, they are often termed *missense mutations*. If the substituted amino acid causes little change in the function of the protein, the mutation is called a "conservative" missense mutation. On the other hand, a "nonconservative" missense mutation replaces the normal amino acid with a very different one. An excellent example of this type is the sickle mutation affecting the β-globin chain of hemoglobin (Chapter 14). Here the nucleotide triplet CTC (or GAG in mRNA), which encodes glutamic acid, is changed to CAC (or GUG in mRNA), which encodes valine. This single amino acid substitution alters the physicochemical properties of hemoglobin, giving rise to sickle cell anemia. Besides producing an amino acid substitution, a point mutation may change an amino acid codon to a chain terminator, or *stop codon (nonsense mutation)*. Taking again the example of β-globin, a point mutation affecting the codon for glutamine (CAG) creates a stop codon (UAG) if U is substituted for C (Fig. 5-4). This change leads to premature termination of β-globin gene translation, and the short peptide that is produced is rapidly degraded. The resulting deficiency of β-globin chains can give rise to a severe form of anemia called β^0-thalassemia (Chapter 14).
- *Mutations within noncoding sequences:* Deleterious effects may also result from mutations that do not involve the exons. Recall that transcription of DNA is initiated and regulated by promoter and enhancer sequences. Point mutations or deletions involving these regulatory sequences may interfere with binding of transcription factors and thus lead to a marked reduction in or total lack of transcription. Such is the case in certain forms of hereditary anemias. In addition, point mutations within introns may lead to defective splicing of intervening sequences. This, in turn, interferes with normal processing of the initial mRNA transcripts and results in a failure to form mature mRNA. Therefore, translation cannot take place, and the gene product is not synthesized.
- *Deletions and insertions:* Small deletions or insertions involving the coding sequence lead to alterations in the reading frame of the DNA strand; hence, they are referred to as *frameshift mutations* (see Figs. 5-2 and 5-3). If the number of base pairs involved is three or a multiple of three, frameshift does not occur (Fig. 5-5); instead an abnormal protein lacking or gaining one or more amino acids is synthesized.
- *Trinucleotide-repeat mutations:* Trinucleotide-repeat mutations belong to a special category of genetic anomaly. These mutations are characterized by amplification of a sequence of three nucleotides. Although the specific nucleotide sequence that undergoes amplification differs in various disorders, almost all affected sequences share the nucleotides guanine (G) and cytosine (C). For example, in fragile-X syndrome, prototypical of this category of disorders, there are 250 to 4000 tandem repeats of the sequence CGG within a gene called familial mental retardation 1 (*FMR1*). In normal populations the number of repeats is small, averaging 29. Such expansions of the trinucleotide sequences prevent normal expression of the *FMR1* gene, thus giving rise to mental retardation. Another *distinguishing feature of trinucleotide-repeat mutations is that they are dynamic* (i.e., the degree of amplification increases during gametogenesis). These features, discussed in greater detail later, influence the pattern of inheritance and the phenotypic manifestations of the diseases caused by this class of mutation.

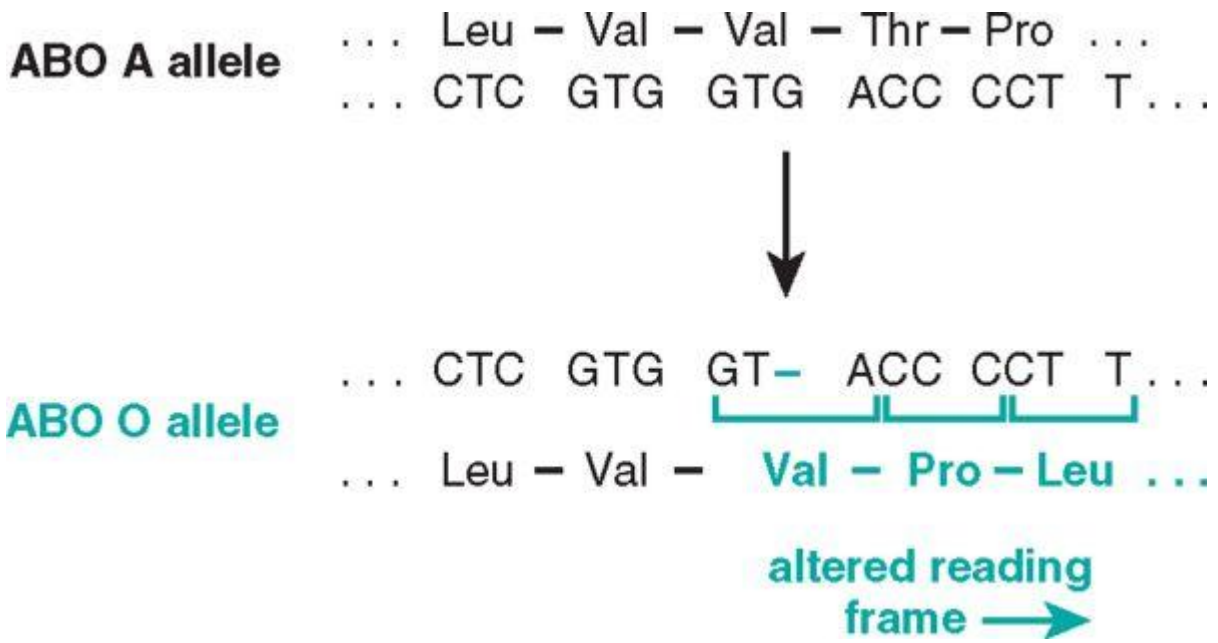

FIGURE 5-2 Single-base deletion at the ABO (glycosyltransferase) locus, leading to a frameshift mutation responsible for the O allele. *(From Thompson MW et al.: Thompson and Thompson Genetics in Medicine, 5th ed. Philadelphia, WB Saunders, 1991, p 134.)*

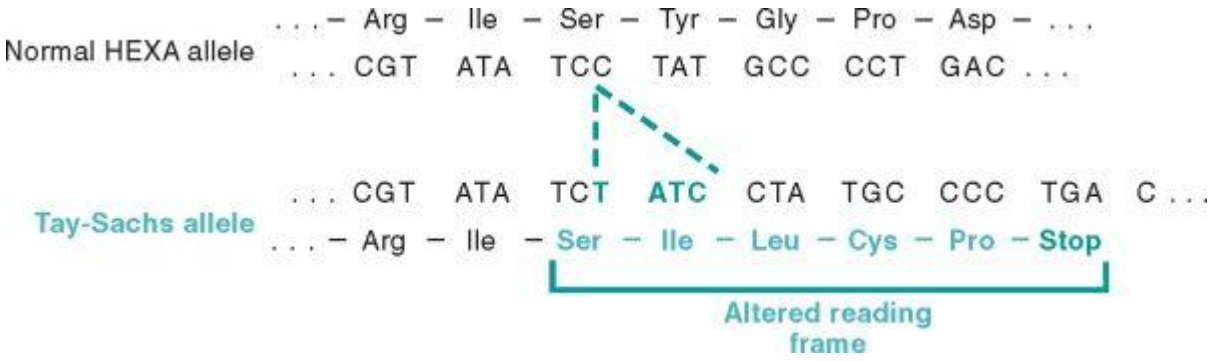

FIGURE 5-3 Four-base insertion in the hexosaminidase A gene, leading to a frameshift mutation. This mutation is the major cause of Tay-Sachs disease in Ashkenazi Jews. *(From Nussbaum RL et al.: Thompson and Thompson Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001, p 212.)*

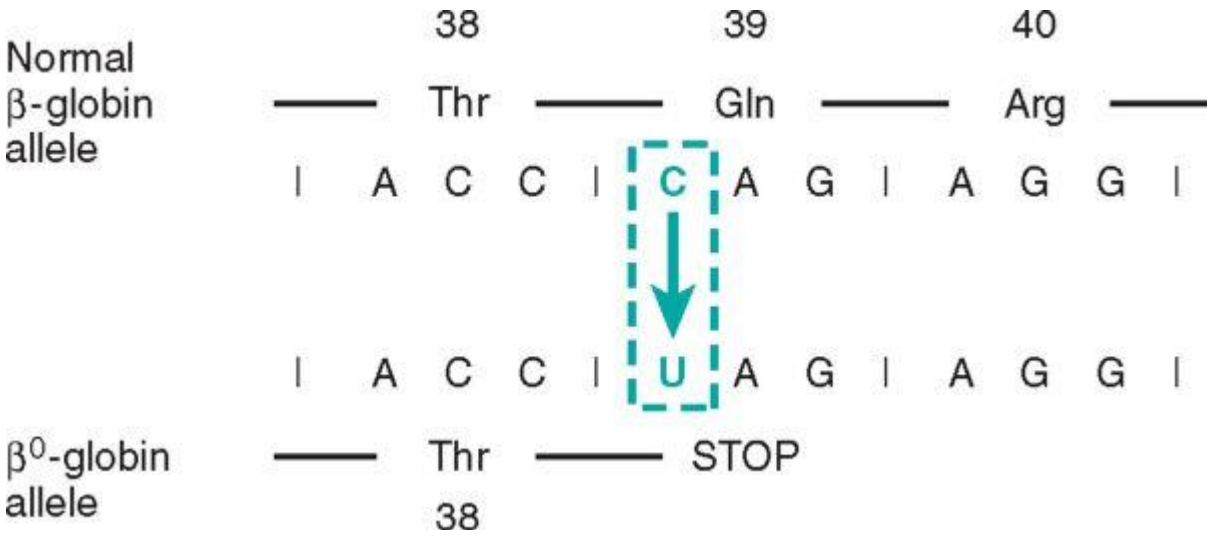

FIGURE 5-4 Point mutation leading to premature chain termination. Partial mRNA sequence of the β-globin chain of hemoglobin showing codons for amino acids 38 to 40. A point mutation (C → U) in codon 39 changes glutamine (Gln) codon to a stop codon, and hence protein synthesis stops at amino acid 38.

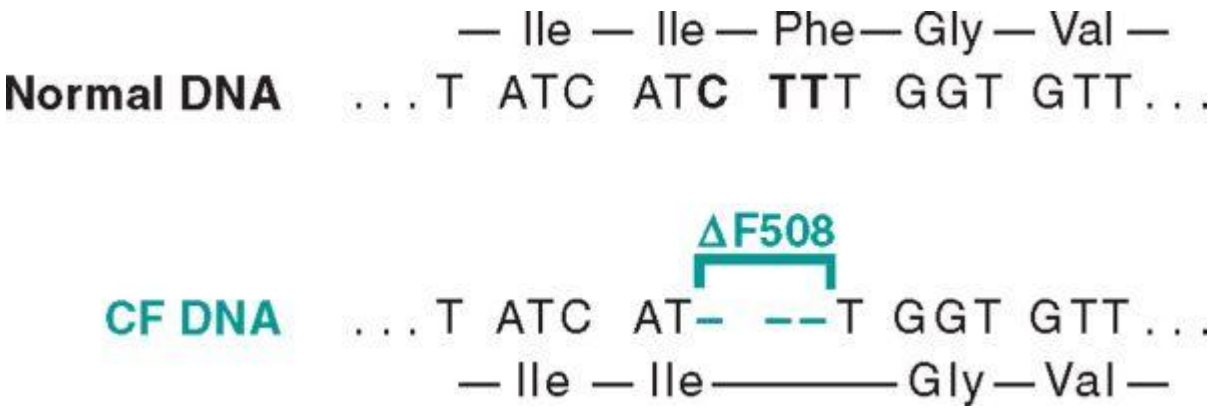

FIGURE 5-5 Three-base deletion in the common cystic fibrosis (CF) allele results in synthesis of a protein that lacks amino acid 508 (phenylalanine). Because the deletion is a multiple of three, this is not a frameshift mutation. *(From Thompson MW et al.: Thompson and Thompson Genetics in Medicine, 5th ed. Philadelphia, WB Saunders, 1991, p 135.)*

To summarize, mutations can interfere with protein synthesis at various levels. Transcription may be suppressed with gene deletions and point mutations involving promoter sequences. Abnormal mRNA processing may result from mutations affecting introns or splice junctions or both. Translation is affected if a stop codon (chain termination mutation) is created within an exon. Finally, some point mutations may lead to the formation of an abnormal protein without impairing any step in protein synthesis.

In closing, it should be noted that, uncommonly, mutations are beneficial. As will be discussed in Chapter 6 , the human immunodeficiency virus (HIV) uses a chemokine receptor, CCR5, to enter cells; a deletion in the *CCR5* gene thus protects from HIV infection.

Against this background, we now turn our attention to the three major categories of genetic disorders: (1) disorders related to mutant genes of large effect, (2) diseases with multifactorial inheritance, and (3) chromosomal disorders. To these three well-known categories must be added a heterogeneous group of *single-gene disorders with nonclassic patterns of inheritance*. This group includes disorders resulting from triplet-repeat mutations, those arising from mutations in mitochondrial DNA (mtDNA), and those in which the transmission is influenced by genomic imprinting or gonadal mosaicism. Diseases within this group are caused by mutations in single genes, but they do not follow the mendelian pattern of inheritance. These are discussed later in this chapter.

It is beyond the scope of this book to review normal human genetics. It is, however, important to clarify several commonly used terms—*hereditary*, *familial*, and *congenital*. Hereditary disorders, by definition, are derived from one's parents and are transmitted in the germ line through the generations and therefore are familial. The term *congenital* simply implies "born with." Some congenital diseases are not genetic; for example, congenital syphilis. Not all genetic diseases are congenital; individuals with Huntington disease, for example, begin to manifest their condition only after their 20s or 30s.

2.5.3 Mendelian Disorders

All mendelian disorders are the result of mutations in single genes that have large effects. It is not necessary to detail Mendel's laws here, since every student in biology, and possibly every garden pea, has learned about them at an early age. Only some comments of medical relevance are made.

It is estimated that every individual is a carrier of five to eight deleterious genes. Most of these are recessive and therefore do not have serious phenotypic effects. About 80% to 85% of these mutations are familial. The remainder represent new mutations acquired de novo by an affected individual.

Some autosomal mutations produce partial expression in the heterozygote and full expression in the homozygote. Sickle cell anemia is caused by substitution of normal hemoglobin (HbA) by hemoglobin S (HbS). When an individual is homozygous for the mutant gene, all the hemoglobin is of the abnormal, HbS, type, and even with normal saturation of oxygen the disorder is fully expressed (i.e., sickling deformity of all red cells and hemolytic anemia). In the heterozygote, only a proportion of the hemoglobin is HbS (the remainder being HbA), and therefore red cell sickling occurs only when there is exposure to lowered oxygen tension. This is referred to as the *sickle cell trait* to differentiate it from full-blown sickle cell anemia.

Although gene expression and mendelian traits are usually described as dominant or recessive, in some cases both of the alleles of a gene pair contribute to the phenotype—a condition called *codominance*. Histocompatibility and blood group antigens are good examples of codominant inheritance.

A single mutant gene may lead to many end effects, termed *pleiotropism*; conversely, mutations at several genetic loci may produce the same trait *(genetic heterogeneity)*. Sickle cell anemia is an example of pleiotropism. In this hereditary disorder not only does the point mutation in the gene give rise to HbS, which predisposes the red cells to hemolysis, but also the abnormal red cells tend to cause a logjam in small vessels, inducing, for example, splenic fibrosis, organ infarcts, and bone changes. The numerous differing end-organ derangements are all related to the primary defect in hemoglobin synthesis. On the other hand, profound childhood deafness, an apparently homogeneous clinical entity, results from many different types of autosomal recessive mutations. Recognition of genetic heterogeneity not only is important in genetic counseling but also is relevant in the understanding of the pathogenesis of some common disorders, such as diabetes mellitus.

TRANSMISSION PATTERNS OF SINGLE-GENE DISORDERS

Mutations involving single genes typically follow one of three patterns of inheritance: autosomal dominant, autosomal recessive, and X-linked. The general rules that govern the transmission of single-gene disorders are well known; only a few salient features are summarized.[12] Single-gene disorders with nonclassic patterns of inheritance are described later.

Autosomal Dominant Disorders

Autosomal dominant disorders are manifested in the heterozygous state, so at least one parent of an index case is usually affected; both males and females are affected, and both can transmit the condition. When an affected person marries an unaffected one, every child has one chance in two of having the disease. In addition to these basic rules, autosomal dominant conditions are characterized by the following:

- With every autosomal dominant disorder, some proportion of patients do not have affected parents. Such patients owe their disorder to new mutations involving either the egg or the sperm from which they were derived. Their siblings are neither affected nor at increased risk for developing the disease. The proportion of patients who develop the disease as a result of a new mutation is related to the effect of the disease on reproductive capability. If a disease markedly reduces reproductive fitness, most cases would be expected to result from new mutations. Many new mutations seem to occur in germ cells of relatively older fathers.
- Clinical features can be modified by variations in penetrance and expressivity. Some individuals inherit the mutant gene but are phenotypically normal. This is referred to as *incomplete penetrance*. Penetrance is expressed in mathematical terms. Thus, 50% penetrance indicates that 50% of those who carry the gene express the trait. In contrast to penetrance, if a trait is seen in all individuals carrying the mutant gene but is expressed differently among individuals, the phenomenon is called *variable expressivity*. For example, manifestations of neurofibromatosis type 1 range from brownish spots on the skin to multiple skin tumors and skeletal deformities. The mechanisms underlying incomplete penetrance and variable expressivity are not fully understood, but they most likely result from effects of other genes or environmental factors that modify the phenotypic expression of the mutant allele. For example, the phenotype of a patient with sickle cell anemia (resulting from mutation at the β-globin locus) is influenced by the genotype at the α-globin locus, because the latter influences the total amount of hemoglobin made (Chapter 14). The influence of environmental factors is exemplified by familial hypercholesterolemia. The expression of the disease in the form of atherosclerosis is conditioned by the dietary intake of lipids.
- In many conditions the age at onset is delayed: symptoms and signs may not appear until adulthood (as in Huntington disease).

The biochemical mechanisms of autosomal dominant disorders are best considered in the context of the nature of the mutation and the type of protein affected. Most mutations lead to the reduced production of a gene product or give rise to an inactive protein. The effect of such *loss-of-function mutations* depends on the nature of the protein affected. If the mutation affects an enzyme protein the heterozygotes are usually normal. Because up to 50% loss of enzyme activity can be compensated for, mutation in genes that encode enzymes do not manifest an autosomal dominant pattern of inheritance. By contrast, two major categories of nonenzyme proteins are affected in autosomal dominant disorders:

1. Those involved in regulation of complex metabolic pathways that are subject to feedback inhibition: Membrane receptors such as the low-density lipoprotein (LDL) receptor provide one such example; in familial hypercholesterolemia, discussed in detail later, a 50% loss of LDL receptors results in a secondary elevation of cholesterol that, in turn, predisposes to atherosclerosis in affected heterozygotes.
2. Key structural proteins, such as collagen and cytoskeletal elements of the red cell membrane (e.g., spectrin): The biochemical mechanisms by which a 50% reduction in the amounts of such proteins results in an abnormal phenotype are not fully understood. In some cases, especially when the gene encodes one subunit of a multimeric protein, the product of the mutant allele can interfere with the assembly of a functionally normal multimer. For example, the collagen molecule is a trimer in which the three collagen chains are arranged in a helical configuration. Each of the three collagen chains in the helix must be normal for the assembly and stability of the collagen molecule. Even with a single mutant collagen chain, normal

collagen trimers cannot be formed, and hence there is a marked deficiency of collagen. In this instance the mutant allele is called *dominant negative*, because it impairs the function of a normal allele. This effect is illustrated by some forms of osteogenesis imperfecta, characterized by marked deficiency of collagen and severe skeletal abnormalities (Chapter 26).

Less common than loss-of-function mutations are *gain-of-function* mutations. As the name indicates, in this type of mutation the protein product of the mutant allele acquires new properties not normally associated with the wild-type protein. The transmission of disorders produced by gain-of-function mutations is almost always autosomal dominant, as illustrated by Huntington disease (Chapter 28). In this disease the trinucleotide-repeat mutation affecting the Huntington gene (see later) gives rise to an abnormal protein, called huntingtin, that is toxic to neurons, and hence even heterozygotes develop a neurologic deficit.

To summarize, two types of mutations and two categories of proteins are involved in the pathogenesis of autosomal dominant diseases. The more common loss-of-function mutations affect regulatory proteins and subunits of multimeric proteins, the latter acting through a dominant-negative effect. Gain-of-function mutations are less common; they often endow normal proteins with toxic properties, or more rarely increase a normal activity (e.g., activating mutation in the erythropoetin receptor associated with a pathologic increase in red cell production).

Table 5-1 lists common autosomal dominant disorders. Many are discussed more logically in other chapters. A few conditions not considered elsewhere are discussed later in this chapter to illustrate important principles.

TABLE 5-1 -- Autosomal Dominant Disorders

System	Disorder
Nervous	Huntington disease
	Neurofibromatosis
	Myotonic dystrophy
	Tuberous sclerosis
Urinary	Polycystic kidney disease
Gastrointestinal	Familial polyposis coli
Hematopoietic	Hereditary spherocytosis von Willebrand disease
Skeletal	Marfan syndrome[*]
	Ehlers-Danlos syndrome (some variants)[*]
	Osteogenesis imperfecta
	Achondroplasia
Metabolic	Familial hypercholesterolemia[*]
	Acute intermittent porphyria

[*] Discussed in this chapter. Other disorders listed are discussed in appropriate chapters in the book.

Autosomal Recessive Disorders

Autosomal recessive traits make up the largest category of mendelian disorders. Because autosomal recessive disorders result only when both alleles at a given gene locus are mutated, such disorders are characterized by the following features: (1) The trait does not usually affect the parents of the affected individual, but siblings may show the disease; (2) siblings have one chance in four of having the trait

(i.e., the recurrence risk is 25% for each birth); and (3) if the mutant gene occurs with a low frequency in the population, there is a strong likelihood that the affected individual (proband) is the product of a consanguineous marriage. The following features generally apply to most autosomal recessive disorders and distinguish them from autosomal dominant diseases:

- The expression of the defect tends to be more uniform than in autosomal dominant disorders.
- Complete penetrance is common.
- Onset is frequently early in life.
- Although new mutations associated with recessive disorders do occur, they are rarely detected clinically. Since the individual with a new mutation is an asymptomatic heterozygote, several generations may pass before the descendants of such a person mate with other heterozygotes and produce affected offspring.
- Many of the mutated genes encode enzymes. In heterozygotes, equal amounts of normal and defective enzyme are synthesized. Usually the natural “margin of safety” ensures that cells with half the usual complement of the enzyme function normally.

Autosomal recessive disorders include almost all inborn errors of metabolism. The various consequences of enzyme deficiencies are discussed later. The more common of these conditions are listed in Table 5-2 . Most are presented elsewhere; a few prototypes are discussed later in this chapter.

TABLE 5-2 -- Autosomal Recessive Disorders

System	Disorder
Metabolic	Cystic fibrosis
	Phenylketonuria
	Galactosemia
	Homocystinuria
	Lysosomal storage diseases[*]
	α_1-Antitrypsin deficiency
	Wilson disease
	Hemochromatosis
	Glycogen storage diseases[*]
Hematopoietic	Sickle cell anemia
	Thalassemias
Endocrine	Congenital adrenal hyperplasia
Skeletal	Ehlers-Danlos syndrome (some variants)[*]
	Alkaptonuria[*]
Nervous	Neurogenic muscular atrophies
	Friedreich ataxia
	Spinal muscular atrophy

[*] Discussed in this chapter. Many others are discussed elsewhere in the text.

X-Linked Disorders

All sex-linked disorders are X-linked, and almost all are recessive. Several genes are located in the “male-specific region of Y”; all of these are related to spermatogenesis.[13] Males with mutations

affecting the Y-linked genes are usually infertile, and hence there is no Y-linked inheritance. As discussed later, a few additional genes with homologues on the X chromosome have been mapped to the Y chromosome, but no disorders resulting from mutations in such genes have been described.

X-linked recessive inheritance accounts for a small number of well-defined clinical conditions. The Y chromosome, for the most part, is not homologous to the X, and so mutant genes on the X do not have corresponding alleles on the Y. Thus, the male is said to be *hemizygous* for X-linked mutant genes, so these disorders are expressed in the male. Other features that characterize these disorders are as follows:

- An affected male does not transmit the disorder to his sons, but all daughters are carriers. Sons of heterozygous women have, of course, one chance in two of receiving the mutant gene.
- The heterozygous female usually does not express the full phenotypic change because of the paired normal allele. Because of the random inactivation of one of the X chromosomes in the female, however, females have a variable proportion of cells in which the mutant X chromosome is active. Thus, it is remotely possible for the normal allele to be inactivated in most cells, permitting full expression of heterozygous X-linked conditions in the female. Much more commonly, the normal allele is inactivated in only some of the cells, and thus the heterozygous female expresses the disorder partially. An illustrative condition is *glucose-6-phosphate dehydrogenase (G6PD) deficiency*. Transmitted on the X chromosome, this enzyme deficiency, which predisposes to red cell hemolysis in patients receiving certain types of drugs (Chapter 14), is expressed principally in males. In the female, a proportion of the red cells may be derived from marrow cells with inactivation of the normal allele. Such red cells are at the same risk for undergoing hemolysis as are the red cells in the hemizygous male. Thus, the female is not only a carrier of this trait but also is susceptible to drug-induced hemolytic reactions. Because the proportion of defective red cells in heterozygous females depends on the random inactivation of one of the X chromosomes, however, the severity of the hemolytic reaction is almost always less in heterozygous women than in hemizygous men. Most of the X-linked conditions listed in Table 5-3 are covered elsewhere in the text.

TABLE 5-3 -- X-Linked Recessive Disorders

System	Disease
Musculoskeletal	Duchenne muscular dystrophy
Blood	Hemophilia A and B
	Chronic granulomatous disease
	Glucose-6-phosphate dehydrogenase deficiency
Immune	Agammaglobulinemia
	Wiskott-Aldrich syndrome
Metabolic	Diabetes insipidus
	Lesch-Nyhan syndrome
Nervous	Fragile-X syndrome[*]

[*] Discussed in this chapter. Others are discussed in appropriate chapters in the text.

There are only a few *X-linked dominant* conditions. They are caused by dominant disease-associated alleles on the X chromosome. These disorders are transmitted by an affected heterozygous female to half her sons and half her daughters and by an affected male parent to all his daughters but none of his sons, if the female parent is unaffected. Vitamin D–resistant rickets is an example of this type of inheritance.

BIOCHEMICAL AND MOLECULAR BASIS OF SINGLE-GENE (MENDELIAN) DISORDERS

Mendelian disorders result from alterations involving single genes. The genetic defect may lead to the formation of an abnormal protein or a reduction in the output of the gene product. Virtually any type of protein may be affected in single-gene disorders and by a variety of mechanisms (Table 5-4). To some extent the pattern of inheritance of the disease is related to the kind of protein affected by the mutation, as was discussed earlier and is reiterated subsequently. For the purposes of this discussion, the mechanisms involved in single-gene disorders can be classified into four categories: (1) *enzyme defects and their consequences*; (2) *defects in membrane receptors and transport systems*; (3) *alterations in the structure, function, or quantity of nonenzyme proteins*; and (4) *mutations resulting in unusual reactions to drugs*.

TABLE 5-4 -- Biochemical and Molecular Basis of Some Mendelian Disorders

Protein Type/Function	Example	Molecular Lesion	Disease
ENZYME	Phenylalanine hydroxylase	Splice-site mutation: reduced amount	Phenylketonuria
	Hexosaminidase	Splice-site mutation or frameshift mutation with stop codon: reduced amount	Tay-Sachs disease
	Adenosine deaminase	Point mutations: abnormal protein with reduced activity	Severe combined immunodeficiency
ENZYME INHIBITOR	α_1-Antitrypsin	Missense mutations: impaired secretion from liver to serum	Emphysema and liver disease
RECEPTOR	Low-density lipoprotein receptor	Deletions, point mutations: reduction of synthesis, transport to cell surface, or binding to low-density lipoprotein	Familial hypercholesterolemia
	Vitamin D receptor	Point mutations: failure of normal signaling	Vitamin D–resistant rickets
TRANSPORT			
Oxygen	Hemoglobin	Deletions: reduced amount	α-Thalassemia
		Defective mRNA processing: reduced amount	β-Thalassemia
		Point mutations: abnormal structure	Sickle cell anemia
Ions	Cystic fibrosis transmembrane conductance regulator	Deletions and other mutations: nonfunctional or misfolded proteins	Cystic fibrosis
STRUCTURAL			
Extracellular	Collagen	Deletions or point mutations cause reduced amount of normal collagen or normal amounts of defective collagen	Osteogenesis imperfecta; Ehlers-Danlos syndromes
	Fibrillin	Missense mutations	Marfan syndrome
Cell membrane	Dystrophin	Deletion with reduced synthesis	Duchenne/Becker muscular dystrophy
	Spectrin, ankyrin, or protein 4.1	Heterogeneous	Hereditary spherocytosis
HEMOSTASIS	Factor VIII	Deletions, insertions, nonsense mutations, and others: reduced synthesis or abnormal factor VIII	Hemophilia A
GROWTH REGULATION	Rb protein	Deletions	Hereditary retinoblastoma
	Neurofibromin	Heterogeneous	Neurofibromatosis type 1

Enzyme Defects and Their Consequences

Mutations may result in the synthesis of a defective enzyme with reduced activity or in a reduced amount of a normal enzyme. In either case, the consequence is a metabolic block. Figure 5-6 provides an example of an enzyme reaction in which the substrate is converted by intracellular enzymes, denoted as 1, 2, and 3, into an end product through intermediates 1 and 2. In this model the final product exerts feedback control on enzyme 1. A minor pathway producing small quantities of M1 and M2 also exists. The biochemical consequences of an enzyme defect in such a reaction may lead to three major consequences:

1. *Accumulation of the substrate*, depending on the site of block, may be accompanied by accumulation of one or both intermediates. Moreover, an increased concentration of intermediate 2 may stimulate the minor pathway and thus lead to an excess of M1 and M2. Under these conditions tissue injury may result if the precursor, the intermediates, or the products of alternative minor pathways are toxic in high concentrations. For example, in galactosemia, the deficiency of galactose-1-phosphate uridyltransferase (Chapter 10) leads to the accumulation of galactose and consequent tissue damage. Excessive accumulation of complex substrates within the lysosomes as a result of deficiency of degradative enzymes is responsible for a group of diseases generally referred to as *lysosomal storage diseases*.
2. *An enzyme defect can lead to a metabolic block and a decreased amount of end product* that may be necessary for normal function. For example, a deficiency of melanin may result from lack of tyrosinase, which is necessary for the biosynthesis of melanin from its precursor, tyrosine. This results in the clinical condition called *albinism*. If the end product is a feedback inhibitor of the enzymes involved in the early reactions (in Fig. 5-6 it is shown that the product inhibits enzyme 1), the deficiency of the end product may permit overproduction of intermediates and their catabolic products, some of which may be injurious at high concentrations. A prime example of a disease with such an underlying mechanism is the Lesch-Nyhan syndrome (Chapter 26).
3. *Failure to inactivate a tissue-damaging substrate* is best exemplified by α_1-antitrypsin deficiency. Individuals who have an inherited deficiency of serum α_1-antitrypsin are unable to inactivate neutrophil elastase in their lungs. Unchecked activity of this protease leads to destruction of elastin in the walls of lung alveoli, leading eventually to pulmonary emphysema (Chapter 15).

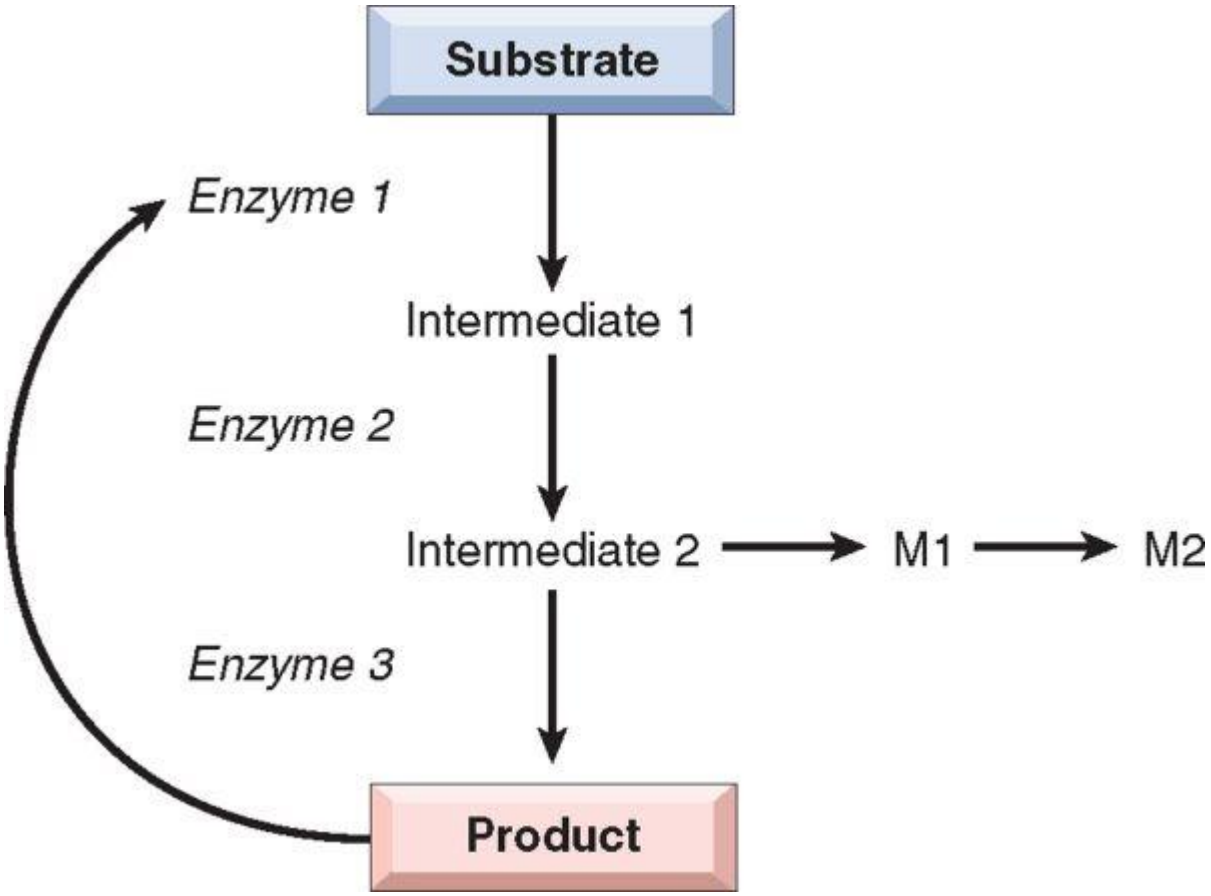

FIGURE 5-6 A possible metabolic pathway in which a substrate is converted to an end product by a series of enzyme reactions. M1, M2, products of a minor pathway.

Defects in Receptors and Transport Systems

Many biologically active substances have to be actively transported across the cell membrane. This transport is generally achieved by one of two mechanisms—through receptormediated endocytosis or by a transport protein. A genetic defect in a receptor-mediated transport system is exemplified by familial hypercholesterolemia, in which reduced synthesis or function of LDL receptors leads to defective transport of LDL into the cells and secondarily to excessive cholesterol synthesis by complex intermediary mechanisms. In cystic fibrosis the transport system for chloride ions in exocrine glands, sweat ducts, lungs, and pancreas is defective. By mechanisms not fully understood, impaired chloride transport leads to serious injury to the lungs and pancreas (Chapter 10).

Alterations in Structure, Function, or Quantity of Nonenzyme Proteins

Genetic defects resulting in alterations of nonenzyme proteins often have widespread secondary effects, as exemplified by sickle cell disease. The hemoglobinopathies, sickle cell disease being one, all of which are characterized by defects in the structure of the globin molecule, best exemplify this category. In contrast to the hemoglobinopathies, the thalassemias result from mutations in globin genes that affect the amount of globin chains synthesized. Thalassemias are associated with reduced amounts of structurally normal α-globin or β-globin chains (Chapter 14). Other examples of genetically defective structural proteins include collagen, spectrin, and dystrophin, giving rise to osteogenesis imperfecta

(Chapter 26), heredit-ary spherocytosis (Chapter 14), and muscular dystrophies (Chapter 27), respectively.

Genetically Determined Adverse Reactions to Drugs

Certain genetically determined enzyme deficiencies are unmasked only after exposure of the affected individual to certain drugs. This special area of genetics, called *pharmacogenetics*, is of considerable clinical importance.[14] The classic example of drug-induced injury in the genetically susceptible individual is associated with a deficiency of the enzyme G6PD. Under normal conditions glucose-6 phosphatedehydrogenase (G6PD) deficiency does not result in disease, but on administration, for example, of the antimalarial drug primaquine, a severe hemolytic anemia results (Chapter 14). In recent years an increasing number of polymorphisms of genes encoding drug-metabolizing enzymes, transporters, and receptors are being identified. In some cases these genetic factors have major impact on drug sensitivity and adverse reactions. It is expected that advances in pharmacogenetics will lead to patient-tailored therapy, or "personalized medicine."

With this overview of the biochemical basis of single-gene disorders, we now consider selected examples grouped according to the underlying defect.

DISORDERS ASSOCIATED WITH DEFECTS IN STRUCTURAL PROTEINS

Several diseases caused by mutations in genes that encode structural proteins are listed in Table 5-4 . Many are discussed elsewhere in the text. Only Marfan syndrome and Ehlers-Danlos syndromes (EDSs) are discussed here, because they affect connective tissue and hence involve multiple organ systems.

Marfan Syndrome

Marfan syndrome is a disorder of connective tissues, manifested principally by changes in the skeleton, eyes, and cardiovascular system.[15] Its prevalence is estimated to be 1 in 5000. Approximately 70% to 85% of cases are familial and transmitted by autosomal dominant inheritance. The remainder are sporadic and arise from new mutations.

Pathogenesis.

Marfan syndrome results from an inherited defect in an extracellular glycoprotein called *fibrillin-1*. As alluded to in Chapter 3 , fibrillin is the major component of microfibrils found in the extracellular matrix. These fibrils provide a scaffolding on which tropoelastin is deposited to form elastic fibers. Although microfibrils are widely distributed in the body, they are particularly abundant in the aorta, ligaments, and the ciliary zonules that support the lens; these tissues are prominently affected in Marfan syndrome.

Fibrillin occurs in two homologous forms, fibrillin-1 and fibrillin-2, encoded by two separate genes, *FBN1* and *FBN2*, mapped on chromosomes 15q21.1 and 5q23.31, respectively. Mutations of *FBN1* underlie Marfan syndrome; mutations of the related *FBN2* gene are less common, and they give rise to *congenital contractural arachnodactyly*, an autosomal dominant disorder characterized by skeletal abnormalities. Mutational analysis has revealed more than 600 distinct mutations of the *FBN1* gene in individuals with Marfan syndrome. Most of these are missense mutations that give rise to abnormal fibrillin-1. While many clinical manifestations of Marfan syndrome can be explained by changes in the mechanical properties of the extracellular matrix resulting from abnormalities of fibrillin, several others such as bone overgrowth cannot be attributed to changes in tissue elasticity. Recent studies indicate that loss of microfibrils gives rise to abnormal and excessive activation of transforming growth factor β (TGF-β), since normal microfibrils sequester TGF-β and thus control the bioavailability of this cytokine. Excessive TGF-β signaling has deleterious effects on vascular smooth muscle development and the

integrity of extracellular matrix. This hypothesis is supported by two sets of observations. First, in a small number of individuals with clinical features of Marfan syndrome (MFS2) there are no mutations in *FBN1* but mutations in genes that encode TGF-β receptors. Second, in mouse models of Marfan syndrome generated by mutations in *Fbn1*, administration of antibodies to TGF-β prevents alterations in the aorta and mitral valves.[16] Human trials with a similar strategy seem to be promising.

Morphology. Skeletal abnormalities are the most striking feature of Marfan syndrome. Typically the patient is unusually tall with exceptionally long extremities and long, tapering fingers and toes. The joint ligaments in the hands and feet are lax, suggesting that the patient is double-jointed; typically the thumb can be hyperextended back to the wrist. The head is commonly dolichocephalic (long-headed) with bossing of the frontal eminences and prominent supraorbital ridges. A variety of spinal deformities may appear, including kyphosis, scoliosis, or rotation or slipping of the dorsal or lumbar vertebrae. The chest is classically deformed, presenting either pectus excavatum (deeply depressed sternum) or a pigeon-breast deformity.

The **ocular changes** take many forms. Most characteristic is bilateral subluxation or dislocation (usually outward and upward) of the lens, referred to as ectopia lentis. This abnormality is so uncommon in persons who do not have this genetic disease that the finding of bilateral ectopia lentis should raise the suspicion of Marfan syndrome.

Cardiovascular lesions are the most life-threatening features of this disorder. The two most common lesions are mitral valve prolapse and, of greater importance, dilation of the ascending aorta due to cystic medionecrosis. Histologically the changes in the media are virtually identical to those found in cystic medionecrosis not related to Marfan syndrome (see Chapter 12). Loss of medial support results in progressive dilation of the aortic valve ring and the root of the aorta, giving rise to severe aortic incompetence. In addition, excessive TGF-β signaling in the adventia also probably contributes to aortic dilation. Weakening of the media predisposes to an intimal tear, which may initiate an intramural hematoma that cleaves the layers of the media to produce aortic dissection. After cleaving the aortic layers for considerable distances, sometimes back to the root of the aorta or down to the iliac arteries, the hemorrhage often ruptures through the aortic wall. Such a calamity is the cause of death in 30% to 45% of these individuals.

Clinical Features

Although mitral valve lesions are more frequent, they are clinically less important than aortic lesions. Loss of connective tissue support in the mitral valve leaflets makes them soft and billowy, creating the so-called floppy valve (Chapter 12). Valvular lesions, along with lengthening of the chordae tendineae, frequently give rise to mitral regurgitation. Similar changes may affect the tricuspid and, rarely, the aortic valves. Echocardiography greatly enhances the ability to detect the cardiovascular abnormalities and is therefore extremely valuable in the diagnosis of Marfan syndrome. The great majority of deaths are caused by rupture of aortic dissections, followed in importance by cardiac failure.

While the lesions just described typify Marfan syndrome, it must be emphasized that there is great variation in the clinical expression of this genetic disorder. Patients with prominent eye or cardiovascular changes may have few skeletal abnormalities, whereas others with striking changes in body habitus have no eye changes. Although variability in clinical expression may be seen within a family, interfamilial variability is much more common and extensive. Because of such variations, the clinical diagnosis of Marfan syndrome must be based on major involvement of two of the four organ systems (skeletal, cardiovascular, ocular, and skin) and minor involvement of another organ.

To account for the variable expression of the Marfan defect, it has been hypothesized that Marfan syndrome is genetically heterogeneous. With one exception, however, all studies thus far point to mutations in the *FBN1* gene, on chromosome 15q21.1, as the cause of this disease.[15] Thus, variable expressivity is best explained on the basis of allelic mutations within the same locus. Because the *FBN1* gene is large and many different mutations have been identified, direct diagnosis by DNA sequencing is not currently feasible, but this may change in the near future as new technologies are being developed.

Ehlers-Danlos Syndromes (EDS)

EDSs comprise a clinically and genetically heterogeneous group of disorders that result from some defect in the synthesis or structure of fibrillar collagen. Other disorders resulting from mutations affecting collagen synthesis include osteogenesis imperfecta (Chapter 26), Alport syndrome (Chapter 20), and epidermolysis bullosa (Chapter 25).

Biosynthesis of collagen is a complex process that can be disturbed by genetic errors that may affect any one of the numerous structural collagen genes or enzymes necessary for post-transcriptional modifications of collagen. Hence, the mode of inheritance of EDS encompasses all three mendelian patterns. On the basis of clinical and molecular characteristics, six variants of EDS have been recognized.[17] These are listed in Table 5-5 . It is beyond the scope of this book to discuss each variant individually; instead, we first summarize the important clinical features that are common to most variants and then correlate some of the clinical manifestations with the underlying molecular defects in collagen synthesis or structure.

TABLE 5-5 -- Classification of Ehlers-Danlos Syndromes

EDS Type[*]	Clinical Findings	Inheritance	Gene Defects
Classical (I/II)	Skin and joint hypermobility, atrophic scars, easy bruising	Autosomal dominant	*COL5A1*, *COL5A2*
Hypermobility (III)	Joint hypermobility, pain, dislocations	Autosomal dominant	Unknown
Vascular (IV)	Thin skin, arterial or uterine rupture, bruising, small joint hyperextensibility	Autosomal dominant	*COL3A1*
Kyphoscoliosis (VI)	Hypotonia, joint laxity, congenital scoliosis, ocular fragility	Autosomal recessive	Lysyl hydroxylase
Arthrochalasia (VIIa, b)	Severe joint hypermobility, skin changes (mild), scoliosis, bruising	Autosomal dominant	*COL1A1*, *COL1A2*
Dermatosparaxsis (VIIc)	Severe skin fragility, cutis laxa, bruising	Autosomal recessive	Procollagen *N*-peptidase

[*] EDS types were previously classified by Roman numerals. Parentheses show previous numerical equivalents.

As might be expected, tissues rich in collagen, such as skin, ligaments, and joints, are frequently involved in most variants of EDS. Because the abnormal collagen fibers lack adequate tensile strength, *skin is hyperextensible, and the joints are hypermobile*. These features permit grotesque contortions, such as bending the thumb backward to touch the forearm and bending the knee forward to create almost a right angle. It is believed that most contortionists have one of the EDSs. A predisposition to joint dislocation, however, is one of the prices paid for this virtuosity. *The skin is extraordinarily stretchable, extremely fragile, and vulnerable to trauma*. Minor injuries produce gaping defects, and surgical repair or intervention is accomplished with great difficulty because of the lack of normal tensile strength. *The basic defect in connective tissue may lead to serious internal complications*. These include

rupture of the colon and large arteries (vascular EDS), ocular fragility with rupture of cornea and retinal detachment (kyphoscoliosis EDS), and diaphragmatic hernia (classical EDS).

The biochemical and molecular bases of these abnormalities are known in several forms of EDS. These are described briefly, because they offer some insights into the perplexing clinical heterogeneity of EDS. Perhaps the best characterized is the *kyphoscoliosis type, the most common autosomal recessive form of EDS*. It results from mutations in the gene encoding lysyl hydroxylase, an enzyme necessary for hydroxylation of lysine residues during collagen synthesis.[18] Affected patients have markedly reduced levels of this enzyme. Because hydroxylysine is essential for the cross-linking of collagen fibers, a deficiency of lysyl hydroxylase results in the synthesis of collagen that lacks normal structural stability.

The *vascular type of EDS results from abnormalities of type III collagen*.[19] This form is genetically heterogeneous, because at least three distinct types of mutations affecting the *COL3A1* gene encoding collagen type III can give rise to this variant. Some affect the rate of synthesis of pro α1 (III) chains, others affect the secretion of type III procollagen, and still others lead to the synthesis of structurally abnormal type III collagen. Some mutant alleles behave as dominant negatives (see discussion under "Autosomal Dominant Disorders") and thus produce severe phenotypic effects. These molecular studies provide a rational basis for the pattern of transmission and clinical features that are characteristic of this variant. First, because vascular-type EDS results from mutations involving a structural protein (rather than an enzyme protein), an autosomal dominant pattern of inheritance would be expected. Second, because blood vessels and intestines are known to be rich in collagen type III, an abnormality of this collagen is consistent with severe defects (e.g., spontaneous rupture) in these organs.

In two forms of EDS—arthrochalasia type and dermatosparaxis type—the fundamental defect is in the conversion of type I procollagen to collagen. This step in collagen synthesis involves cleavage of noncollagen peptides at the N terminus and C terminus of the procollagen molecule. This is accomplished by N terminal–specific and C terminal–specific peptidases. *The defect in the conversion of procollagen to collagen in the arthrochalasia type has been traced to mutations that affect one of the two type I collagen genes, COL1A1 and COL1A2*. As a result, structurally abnormal pro α1 (I) or pro α2 (I) chains that resist cleavage of N-terminal peptides are formed. In patients with a single mutant allele, only 50% of the type I collagen chains are abnormal, but because these chains interfere with the formation of normal collagen helices, heterozygotes manifest the disease. By contrast, the related dermatosparaxis type is caused by mutations in the procollagen-N-peptidase genes, essential for the cleavage of collagens. In this case the enzyme deficiency leads to an autosomal recessive form of inheritance.

Finally, the *classical type of EDS* is worthy of brief mention, since molecular analysis of this variant suggests that genes other than collagen genes may be involved in the pathogenesis of EDS. In 30% to 50% of these cases, mutations in the genes for type V collagen (*COL5A1* and *COL5A2*) have been detected.[20] Surprisingly, despite a phenotype typical of EDS, no other collagen gene abnormalities have been found in the remaining cases.

To summarize, the common thread in EDS is some abnormality of collagen. These disorders, however, are extremely heterogeneous. At the molecular level, a variety of defects, varying from mutations involving structural genes for collagen to those involving enzymes that are responsible for post-transcriptional modifications of mRNA, have been detected. Such molecular heterogeneity results in the expression of EDS as a clinically variable disorder with several patterns of inheritance.

DISORDERS ASSOCIATED WITH DEFECTS IN RECEPTOR PROTEINS

Familial Hypercholesterolemia

Familial hypercholesterolemia is a “receptor disease” that is the consequence of *a mutation in the gene encoding the receptor for LDL, which is involved in the transport and metabolism of cholesterol*. As a consequence of receptor abnormalities there is a loss of feedback control and elevated levels of cholesterol that induce premature atherosclerosis, leading to a greatly increased risk of myocardial infarction.[21]

Familial hypercholesterolemia is one of the most frequently occurring mendelian disorders. Heterozygotes with one mutant gene, representing about 1 in 500 individuals, have from birth a two-fold to three-fold elevation of plasma cholesterol level, leading to tendinous xanthomas and premature atherosclerosis in adult life (Chapter 11). Homozygotes, having a double dose of the mutant gene, are much more severely affected, and may have five-fold to six-fold elevations in plasma cholesterol levels. These individuals develop skin xanthomas and coronary, cerebral, and peripheral vascular atherosclerosis at an early age. Myocardial infarction may develop before age 20. Large-scale studies have found that familial hypercholesterolemia is present in 3% to 6% of survivors of myocardial infarction.

An understanding of this disorder requires that we briefly review the normal process of cholesterol metabolism and transport. Approximately 7% of the body's cholesterol circulates in the plasma, predominantly in the form of LDL. As might be expected, the amount of plasma cholesterol is influenced by its synthesis and catabolism, and the liver plays a crucial role in both these processes (Fig. 5-7). The first step in this complex sequence is the secretion of very-low-density lipoproteins (VLDLs) by the liver into the bloodstream. VLDL particles are rich in triglycerides, but they contain lesser amounts of cholesteryl esters. When a VLDL particle reaches the capillaries of adipose tissue or muscle, it is cleaved by lipoprotein lipase, a process that extracts most of the triglycerides. The resulting molecule, called *intermediate-density lipoprotein (IDL)*, is reduced in triglyceride content and enriched in cholesteryl esters, but it retains two of the three apoproteins (B-100 and E) present in the parent VLDL particle (see Fig. 5-7). After release from the capillary endothelium, the IDL particles have one of two fates. Approximately 50% of newly formed IDL is rapidly taken up by the liver by receptor-mediated transport. The receptor responsible for the binding of IDL to the liver cell membrane recognizes both apoprotein B-100 and apoprotein E. It is called the *LDL receptor*, however, because it is also involved in the hepatic clearance of LDL, as described later. In the liver cells, IDL is recycled to generate VLDL. The IDL particles not taken up by the liver are subjected to further metabolic processing that removes most of the remaining triglycerides and apoprotein E, yielding cholesterol-rich LDL particles. *It should be emphasized that IDL is the immediate and major source of plasma LDL*. There seem to be two mechanisms for removal of LDL from plasma, one mediated by an LDL receptor and the other by a receptor for oxidized LDL (scavenger receptor), described later. Although many cell types, including fibroblasts, lymphocytes, smooth muscle cells, hepatocytes, and adrenocortical cells, possess high-affinity LDL receptors, approximately 70% of the plasma LDL seems to be cleared by the liver, using a quite sophisticated transport process (Fig. 5-8). The first step involves binding of LDL to cell surface receptors, which are clustered in specialized regions of the plasma membrane called *coated pits*. After binding, the coated pits containing the receptor-bound LDL are internalized by invagination to form coated vesicles, after which they migrate within the cell to fuse with the lysosomes. Here the LDL dissociates from the receptor, which is recycled to the surface. In the lysosomes the LDL molecule is enzymatically degraded; the apoprotein part is hydrolyzed to amino acids, whereas the cholesteryl esters are broken down to free cholesterol. This free cholesterol, in turn, crosses the lysosomal membrane to enter the cytoplasm, where it is used for membrane synthesis and as a regulator of cholesterol homeostasis. The exit of cholesterol from the lysosomes requires the action of two proteins called NPC1 and NPC2 (see “Niemann-Pick Disease, Type C”). Three separate processes are affected by the released intracellular cholesterol, as follows:

- Cholesterol *suppresses* cholesterol synthesis within the cell by inhibiting the activity of the enzyme 3-

hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase, which is the rate-limiting enzyme in the synthetic pathway.

- Cholesterol *activates* the enzyme acyl-coenzyme A : cholesterol acyltransferase, favoring esterification and storage of excess cholesterol.
- Cholesterol *suppresses* the synthesis of LDL receptors, thus protecting the cells from excessive accumulation of cholesterol.

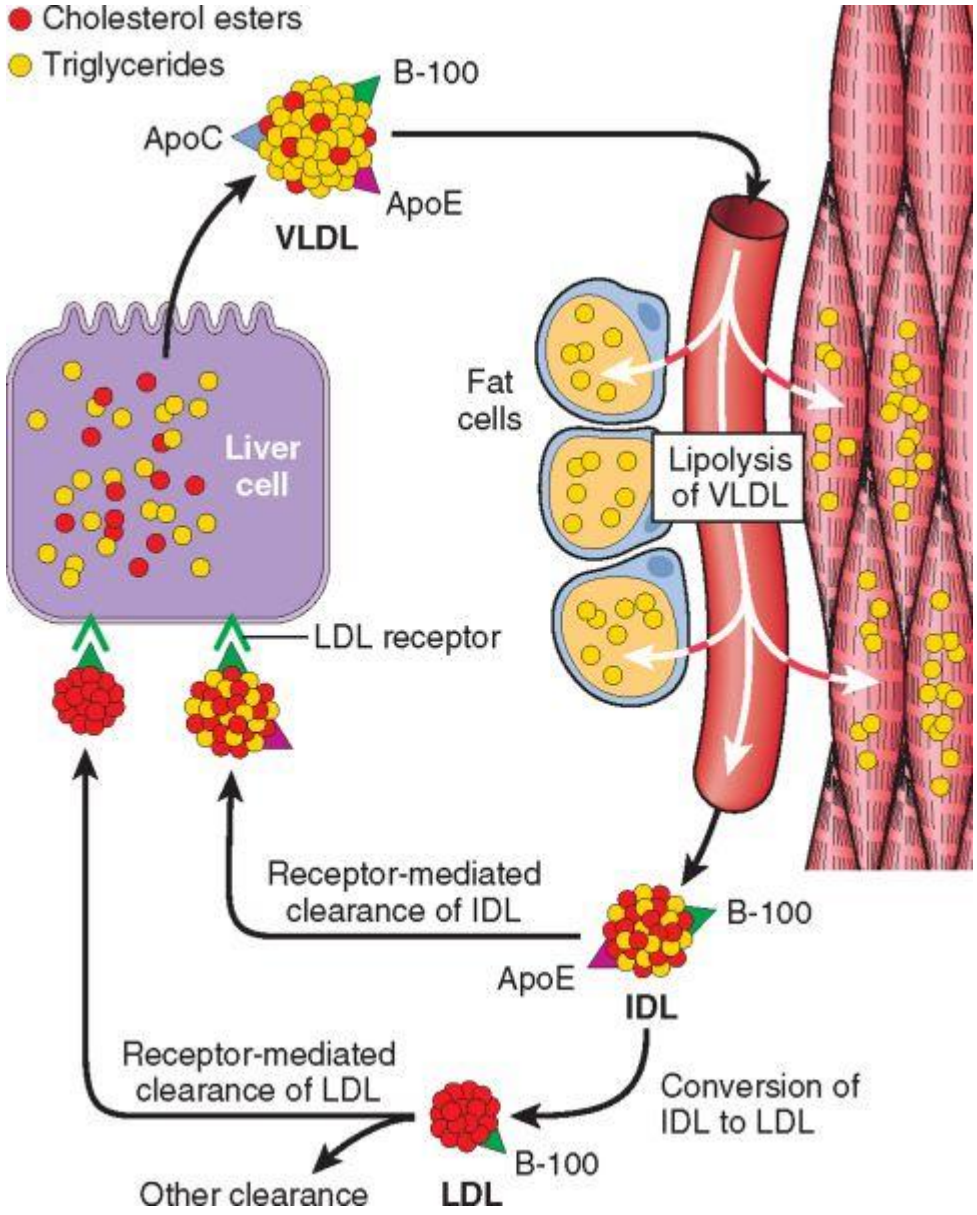

FIGURE 5-7 Low-density lipoprotein (LDL) metabolism and the role of the liver in its synthesis and clearance. Lipolysis of very-low-density lipoprotein (VLDL) by lipoprotein lipase in the capillaries releases triglycerides, which are then stored in fat cells and used as a source of energy in skeletal muscles. See text for explanation of abbreviations used.

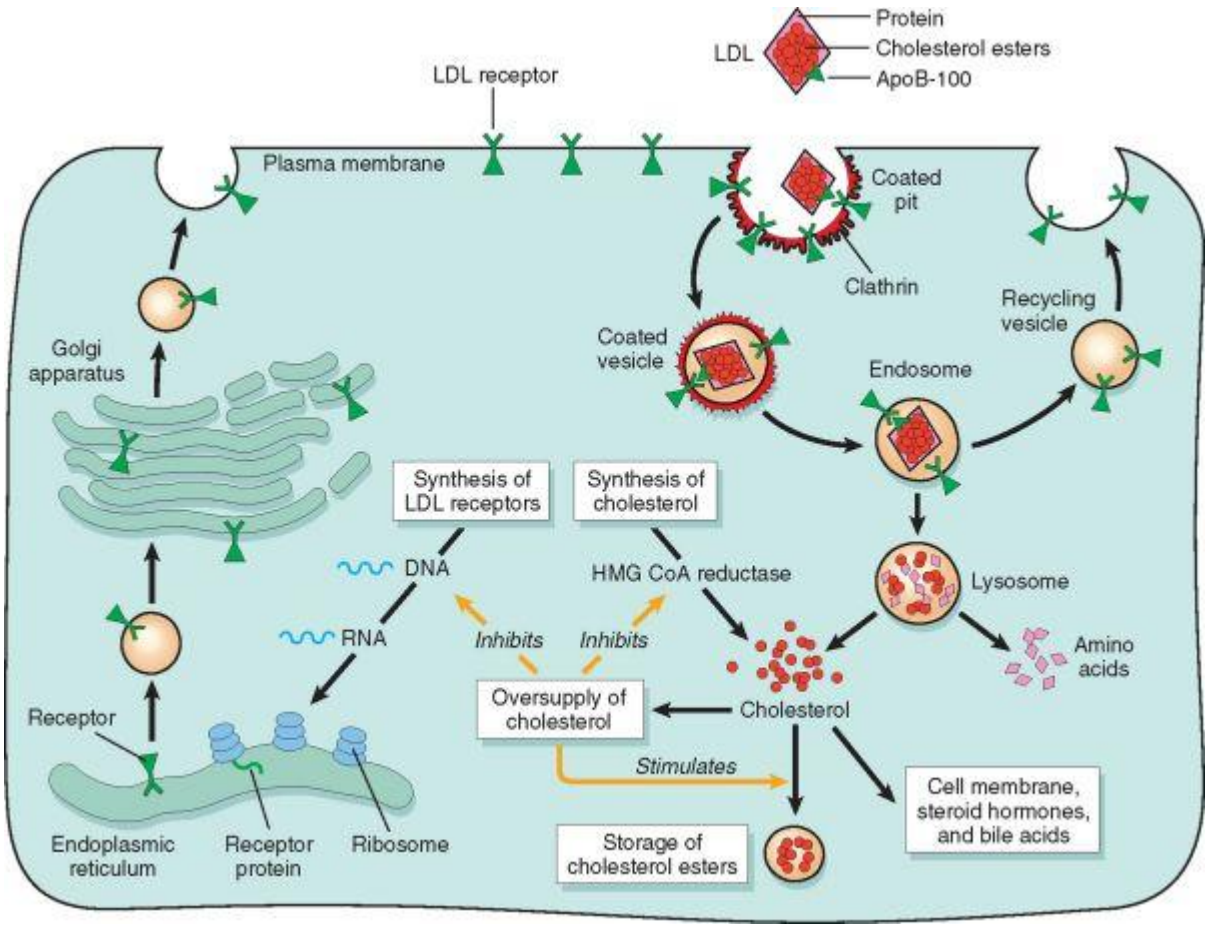

FIGURE 5-8 The LDL receptor pathway and regulation of cholesterol metabolism.

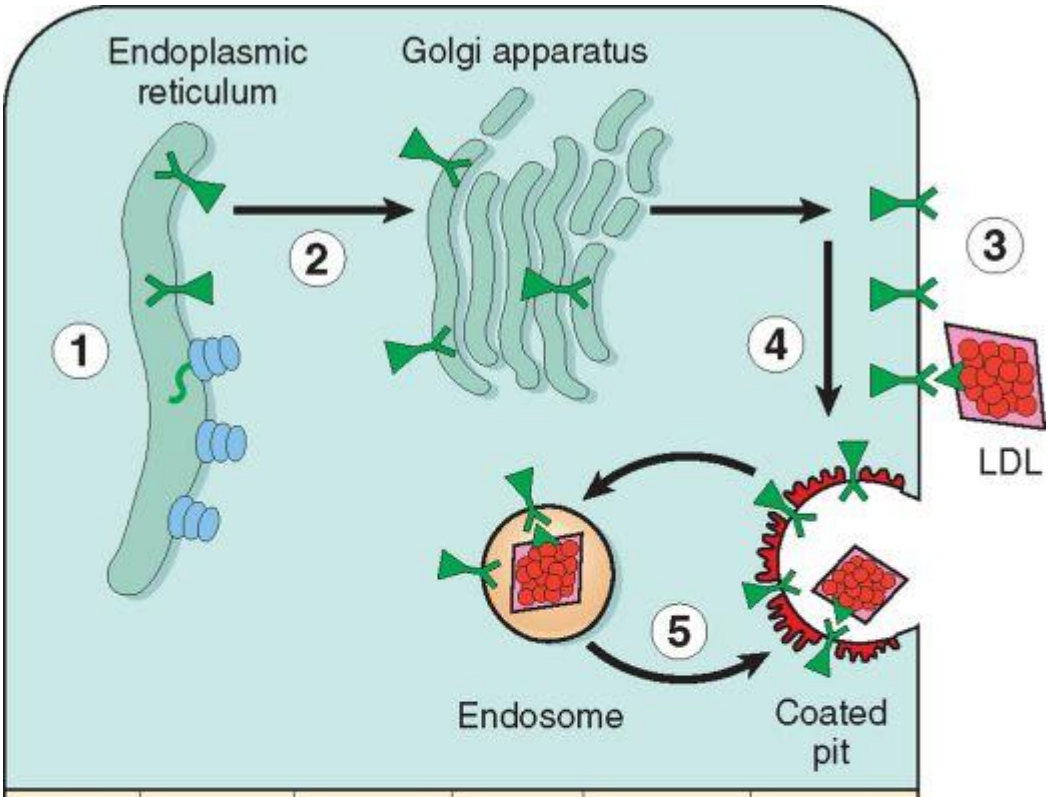
As mentioned earlier, familial hypercholesterolemia results from mutations in the gene specifying the receptor for LDL. Heterozygotes with familial hypercholesterolemia possess only 50% of the normal number of high-affinity LDL receptors, because they have only one normal gene. As a result of this defect in transport, the catabolism of LDL by the receptor-dependent pathways is impaired, and the plasma level of LDL increases approximately two-fold. Homozygotes have virtually no normal LDL receptors in their cells and have much higher levels of circulating LDL. In addition to defective LDL clearance, both the homozygotes and heterozygotes have increased synthesis of LDL. The mechanism of increased synthesis that contributes to hypercholesterolemia also results from a lack of LDL receptors (see Fig. 5-7). Recall that IDL, the immediate precursor of plasma LDL, also uses hepatic LDL receptors (apoprotein B-100 and E receptors) for its transport into the liver. In familial hypercholesterolemia, impaired IDL transport into the liver secondarily diverts a greater proportion of plasma IDL into the precursor pool for plasma LDL.

The transport of LDL via the scavenger receptor seems to occur at least in part into the cells of the mononuclear phagocyte system. Monocytes and macrophages have receptors for chemically altered (e.g., acetylated or oxidized) LDL. Normally the amount of LDL transported along this scavenger receptor pathway is less than that mediated by the LDL receptor–dependent mechanisms. In the face of hypercholesterolemia, however, there is a marked increase in the scavenger receptor–mediated traffic of LDL cholesterol into the cells of the mononuclear phagocyte system and possibly the vascular walls

(Chapter 11). This increase is responsible for the appearance of xanthomas and contributes to the pathogenesis of premature atherosclerosis.

The molecular genetics of familial hypercholesterolemia is extremely complex. More than 900 mutations, including insertions, deletions, and missense and nonsense mutations, involving the LDL receptor gene have been identified. These can be classified into five groups (Fig. 5-9): *Class I mutations* are relatively uncommon, and they lead to a complete failure of synthesis of the receptor protein (null allele). *Class II mutations* are fairly common; they encode receptor proteins that accumulate in the endoplasmic reticulum because their folding defects make it impossible for them to be transported to the Golgi complex. *Class III mutations* affect the LDL-binding domain of the receptor; the encoded proteins reach the cell surface but fail to bind LDL or do so poorly. *Class IV mutations* encode proteins that are synthesized and transported to the cell surface efficiently. They bind LDL normally, but they fail to localize in coated pits, and hence the bound LDL is not internalized. *Class V mutations* encode proteins that are expressed on the cell surface, can bind LDL, and can be internalized; however, the pH-dependent dissociation of the receptor and the bound LDL fails to occur. Such receptors are trapped in the endosome, where they are degraded, and hence they fail to recycle to the cell surface.



Mutation class	Synthesis	Transport	Binding	Clustering	Recycling
I	X				
II	→	X			
III	→	→	X		
IV	→	→	→	X	
V	→	→	→	→	X

FIGURE 5-9 Classification of LDL receptor mutations based on abnormal function of the mutant protein. These mutations disrupt the receptor's synthesis in the endoplasmic reticulum, transport to the Golgi complex, binding of apoprotein ligands, clustering in coated pits, and recycling in endosomes. Each class is heterogeneous at the DNA level. *(Modified with permission from Hobbs HH et al.: The LDL receptor locus in familial hypercholesterolemia: mutational analysis of a membrane protein. Annu Rev Genet 24:133–170, 1990. © 1990 by Annual Reviews.)*

The discovery of the critical role of LDL receptors in cholesterol homeostasis has led to the rational design of drugs that lower plasma cholesterol by increasing the number of LDL receptors. One strategy is based on the ability of certain drugs (statins) to suppress intracellular cholesterol synthesis by inhibiting the enzyme HMG CoA reductase. This, in turn, allows greater synthesis of LDL receptors (see Fig. 5-8).

DISORDERS ASSOCIATED WITH DEFECTS IN ENZYMES

Lysosomal Storage Diseases

Lysosomes are key components of the "intracellular digestive tract." They contain a battery of hydrolytic enzymes, which have two special properties. First, they function in the acidic milieu of the lysosomes. Second, these enzymes constitute a special category of secretory proteins that are destined not for the extracellular fluids but for intracellular organelles. This latter characteristic requires special processing within the Golgi apparatus, which is reviewed briefly. Similar to all other secretory proteins, lysosomal enzymes (or acid hydrolases, as they are sometimes called) are synthesized in the endoplasmic reticulum and transported to the Golgi apparatus. Within the Golgi complex they undergo a variety of post-translational modifications, of which one is worthy of special note. This modification involves the attachment of terminal mannose6-phosphate groups to some of the oligosaccharide side chains. The phosphorylated mannose residues serve as an "address label" that is recognized by specific receptors found on the inner surface of the Golgi membrane. Lysosomal enzymes bind these receptors and are thereby segregated from the numerous other secretory proteins within the Golgi. Subsequently, small transport vesicles containing the receptor-bound enzymes are pinched off from the Golgi and proceed to fuse with the lysosomes. Thus, the enzymes are targeted to their intracellular abode, and the vesicles are shuttled back to the Golgi (Fig. 5-10). As indicated later, genetically determined errors in this remarkable sorting mechanism may give rise to one form of lysosomal storage disease.[22]

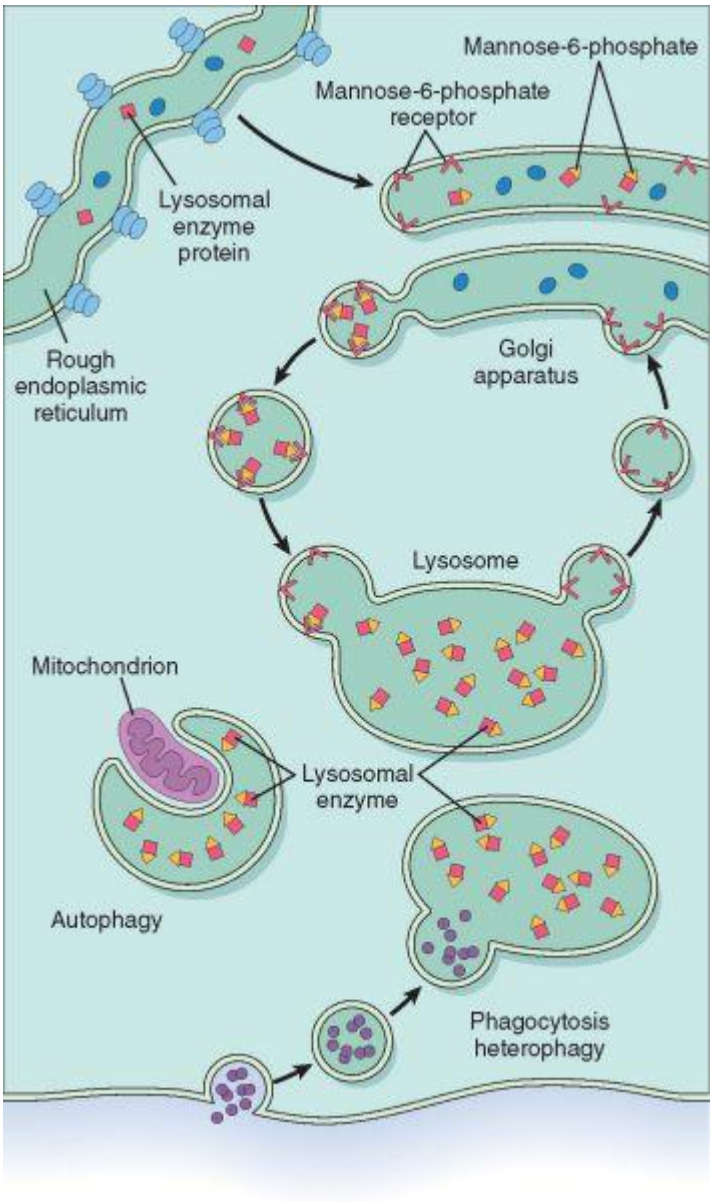


FIGURE 5-10 Synthesis and intracellular transport of lysosomal enzymes.

The lysosomal acid hydrolases catalyze the breakdown of a variety of complex macromolecules. These large molecules may be derived from the metabolic turnover of intracellular organelles (autophagy), or they may be acquired from outside the cells by phagocytosis (heterophagy). With an inherited deficiency of a functional lysosomal enzyme, catabolism of its substrate remains incomplete, leading to the accumulation of the partially degraded insoluble metabolite within the lysosomes. Stuffed with incompletely digested macromolecules, these organelles become large and numerous enough to interfere with normal cell functions, giving rise to the so-called *lysosomal storage disorders* (Fig. 5-11). In addition to "missing enzymes," lysosomal storage diseases can result from lack of any protein essential for normal function of lysosomes. Examples are:

- Lack of an enzyme activator or protector protein.

- Lack of a substrate activator protein. In some instances, proteins that react with the substrate to facilitate its hydrolysis may be missing or defective.
- Lack of a transport protein required for egress of the digested material from the lysosomes.

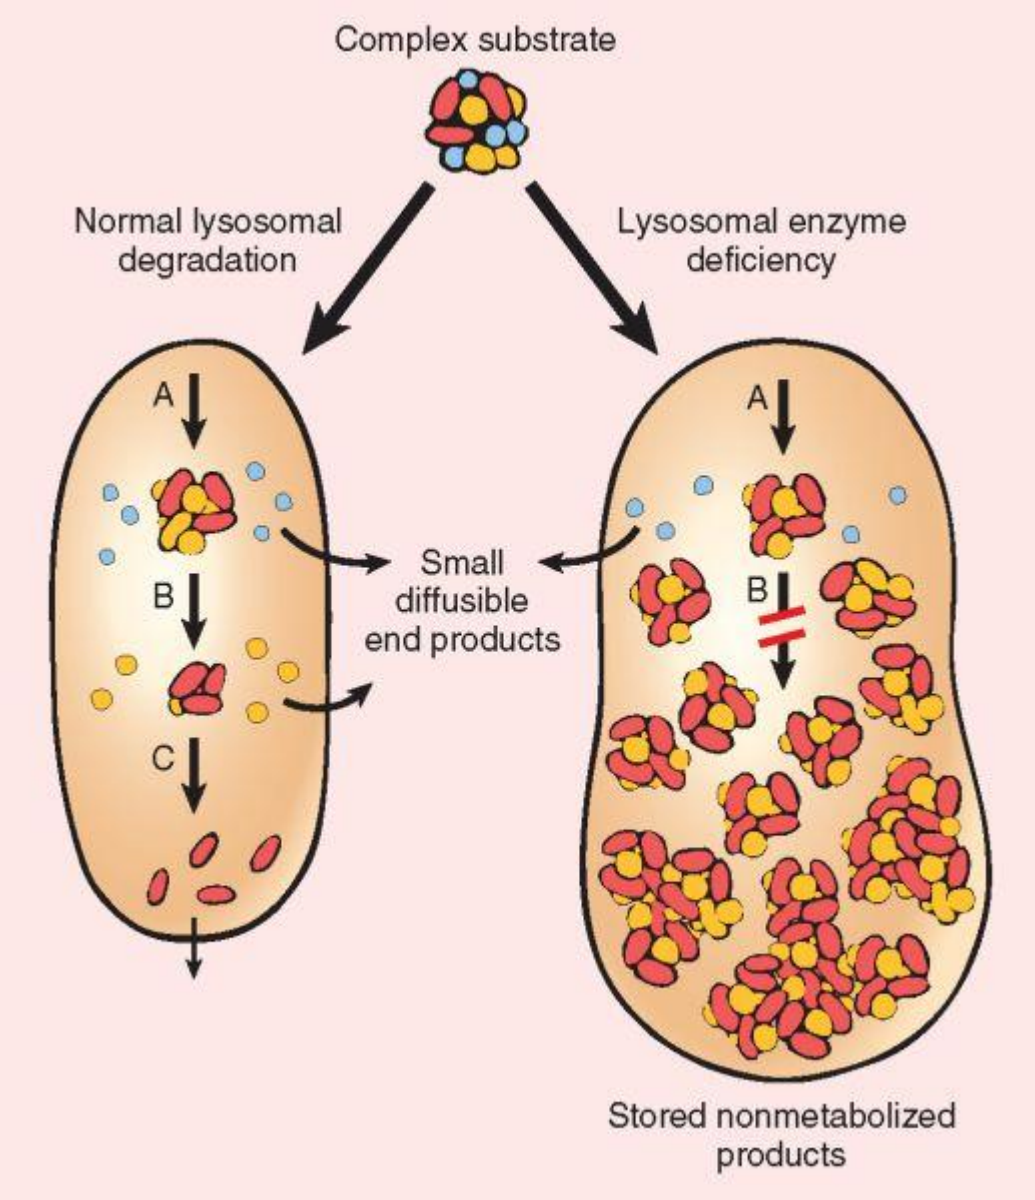

FIGURE 5-11 Pathogenesis of lysosomal storage diseases. In the example shown a complex substrate is normally degraded by a series of lysosomal enzymes (A, B, and C) into soluble end products. If there is a deficiency or malfunction of one of the enzymes (e.g., B), catabolism is incomplete and insoluble intermediates accumulate in the lysosomes.

There are three general approaches to the treatment of lysosomal storage diseases. The most obvious is enzyme replacement therapy, currently in use for several lysosomal storage diseases. Another approach, the "substrate reduction therapy," is based on the premise that if the substrate to be degraded by the lysosomal enzyme can be reduced, the residual enzyme activity may be sufficient to catabolize it and prevent accumulation. A more recent strategy is based on the understanding of the molecular basis of enzyme deficiency. In many disorders, exemplified by Gaucher disease, the enzyme activity is low because the mutant proteins are unstable and prone to misfolding, and hence degraded in the

endoplasmic reticulum. In such diseases an exogenous competitive inhibitor of the enzyme can, paradoxically, bind to the mutant enzyme and act as the "folding template" that assists proper folding of the enzyme and thus prevents its degradation. Such *molecular chaperone therapy* is under active investigation.[23]

Several distinctive and separable conditions are included among the lysosomal storage diseases (Table 5-6). In general, the distribution of the stored material, and hence the organs affected, is determined by two interrelated factors: (1) the tissue where most of the material to be degraded is found and (2) the location where most of the degradation normally occurs. *For example, brain is rich in gangliosides, and hence defective hydrolysis of gangliosides, as occurs in G_{M1} and G_{M2} gangliosidoses, results primarily in accumulation within neurons and consequent neurologic symptoms*. Defects in degradation of mucopolysaccharides affect virtually every organ, because mucopolysaccharides are widely distributed in the body. Because cells of the mononuclear phagocyte system are especially rich in lysosomes and are involved in the degradation of a variety of substrates, organs rich in phagocytic cells, such as the spleen and liver, are frequently enlarged in several forms of lysosomal storage disorders. The ever-expanding number of lysosomal storage diseases can be divided into rational categories based on the biochemical nature of the accumulated metabolite, thus creating such subgroups as the *glycogenoses*, *sphingolipidoses (lipidoses)*, *mucopolysaccharidoses (MPSs)*, and *mucolipidoses* (see Table 5-6). Only the most common disorders among the remaining groups are considered here.

TABLE 5-6 -- Lysosomal Storage Diseases

Disease	Enzyme Deficiency	Major Accumulating Metabolites
GLYCOGENOSIS		
Type 2—Pompe disease	α-1,4-Glucosidase (lysosomal glucosidase)	Glycogen
SPHINGOLIPIDOSES		
G_{M1} gangliosidosis	G_{M1} ganglioside β-galactosidase	G_{M1} ganglioside, galactose-containing oligosaccharides
Type 1—infantile, generalized		
Type 2—juvenile		
G_{M2} gangliosidosis		
Tay-Sachs disease	Hexosaminidase, α subunit	G_{M2} ganglioside
Sandhoff disease	Hexosaminidase, β subunit	G_{M2} ganglioside, globoside
G_{M2} gangliosidosis variant AB	Ganglioside activator protein	G_{M2} ganglioside
SULFATIDOSES		
Metachromatic leukodystrophy	Arylsulfatase A	Sulfatide
Multiple sulfatase deficiency	Arylsulfatase A, B, C; steroid sulfatase; iduronate sulfatase; heparan *N*-sulfatase	Sulfatide, steroid sulfate, heparan sulfate, dermatan sulfate
Krabbe disease	Galactosylceramidase	Galactocerebroside
Fabry disease	α-Galactosidase A	Ceramide trihexoside
Gaucher disease	Glucocerebrosidase	Glucocerebroside
Niemann-Pick disease: types A and B	Sphingomyelinase	Sphingomyelin

Disease	Enzyme Deficiency	Major Accumulating Metabolites
MUCOPOLYSACCHARIDOSES (MPSS)		
MPS I H (Hurler)	α-L-Iduronidase	Dermatan sulfate, heparan sulfate
MPS II (Hunter)	L-Iduronosulfate sulfatase	
MUCOLIPIDOSES (MLS)		
I-cell disease (ML II) and pseudo-Hurler polydystrophy	Deficiency of phosphorylating enzymes essential for the formation of mannose-6-phosphate recognition marker; acid hydrolases lacking the recognition marker cannot be targeted to the lysosomes but are secreted extracellularly	Mucopolysaccharide, glycolipid
OTHER DISEASES OF COMPLEX CARBOHYDRATES		
Fucosidosis	α-Fucosidase	Fucose-containing sphingolipids and glycoprotein fragments
Mannosidosis	α-Mannosidase	Mannose-containing oligosaccharides
Aspartylglycosaminuria	Aspartylglycosamine amide hydrolase	Aspartyl-2-deoxy-2-acetamido-glycosylamine
OTHER LYSOSOMAL STORAGE DISEASES		
Wolman disease	Acid lipase	Cholesterol esters, triglycerides
Acid phosphate deficiency	Lysosomal acid phosphatase	Phosphate esters

Tay-Sachs Disease (G_{M2} Gangliosidosis: Hexosaminidase α-Subunit Deficiency)

G_{M2} gangliosidoses are a group of three lysosomal storage diseases caused by an inability to catabolize G_{M2} gangliosides. Degradation of G_{M2} gangliosides requires three polypeptides encoded by three distinct genes. The phenotypic effects of mutations affecting these genes are fairly similar, because they result from accumulation of G_{M2} gangliosides.[24] The underlying enzyme defect, however, is different for each. Tay-Sachs disease, the most common form of G_{M2} gangliosidosis, results from mutations in the α-subunit locus on chromosome 15 that cause a severe deficiency of hexosaminidase A. This disease is especially prevalent among Jews, particularly among those of Eastern European (Ashkenazic) origin, in whom a carrier rate of 1 in 30 has been reported.

Morphology. The hexosaminidase A is absent from virtually all the tissues, so G_{M2} ganglioside accumulates in many tissues (e.g., heart, liver, spleen), but the **involvement of neurons in the central and autonomic nervous systems and retina dominates the clinical picture**. On histologic examination, the neurons are ballooned with cytoplasmic vacuoles, each representing a markedly distended lysosome filled with gangliosides (Fig. 5-12A). Stains for fat such as oil red O and Sudan black B are positive. With the electron microscope, several types of cytoplasmic inclusions can be visualized, the most prominent being whorled configurations within lysosomes composed of onion-skin layers of membranes (Fig. 5-12B). In time there is progressive destruction of neurons, proliferation of microglia, and accumulation of complex lipids in phagocytes within the brain substance. A similar process occurs in the cerebellum as well as in neurons throughout the basal ganglia, brain stem, spinal cord, and dorsal root ganglia and in the neurons of the autonomic nervous system. The ganglion cells in the retina are similarly swollen with G_{M2} ganglioside, particularly at the

margins of the macula. A **cherry-red spot** thus appears in the macula, representing accentuation of the normal color of the macular choroid contrasted with the pallor produced by the swollen ganglion cells in the remainder of the retina (Chapter 29). This finding is characteristic of Tay-Sachs disease and other storage disorders affecting the neurons.

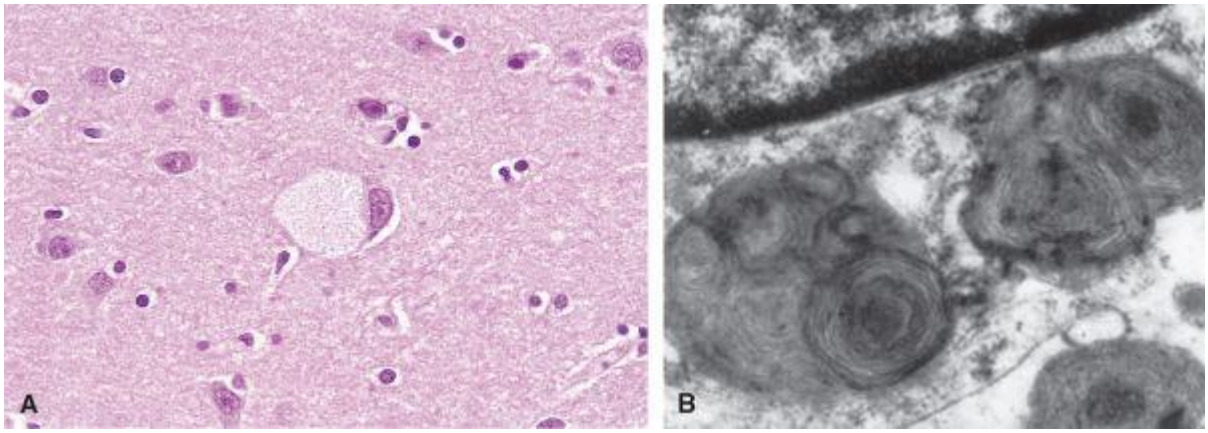

FIGURE 5-12 Ganglion cells in Tay-Sachs disease. **A**, Under the light microscope a large neuron has obvious lipid vacuolation. **B**, A portion of a neuron under the electron microscope shows prominent lysosomes with whorled configurations. Part of the nucleus is shown above. *(**A**, courtesy of Dr. Arthur Weinberg, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX; **B**, electron micrograph courtesy of Dr. Joe Rutledge, University of Texas Southwestern Medical Center, Dallas, TX.)*

Clinical Features

The affected infants appear normal at birth but begin to manifest signs and symptoms at about age 6 months. There is relentless motor and mental deterioration, beginning with motor incoordination, mental obtundation leading to muscular flaccidity, blindness, and increasing dementia. Sometime during the early course of the disease, the characteristic, but not pathognomonic, cherry-red spot appears in the macula of the eye in almost all patients. Over the span of 1 or 2 years a complete vegetative state is reached, followed by death at age 2 to 3 years. More than 100 mutations have been described in the α-subunit gene; most affect protein folding. Such misfolded proteins trigger the "unfolded protein" response (Chapter 1) leading to apoptosis. These findings have given rise to the possibility of chaperone therapy of Tay-Sachs disease.

Antenatal diagnosis and carrier detection are possible by enzyme assays and DNA-based analysis. The clinical features of the two other forms of G_{M2} gangliosidosis, Sandhoff disease, resulting from β-subunit defect, and G_{M2} activator deficiency, are similar to those of Tay-Sachs disease.

Niemann-Pick Disease, Types A and B

Niemann-Pick disease types A and B refers to two related disorders that are characterized by lysosomal accumulation of sphingomyelin due to an inherited deficiency of sphingomyelinase.[25] *Type A is a severe infantile form with extensive neurologic involvement, marked visceral accumulations of sphingomyelin, and progressive wasting and early death within the first 3 years of life*. In contrast, type B disease patients have organomegaly but generally no central nervous system involvement. They usually survive into adulthood. As with Tay-Sachs disease, Niemann-Pick disease types A and B are common in Ashkenazi Jews. The acid sphingomyelinase gene maps to chromosome 11p15.4 and is one of the imprinted genes that is preferentially expressed from the maternal chromosome as a result of

epigenetic silencing of the paternal gene (discussed later). More than 100 mutations have been found in the acid sphingomyelinase gene and there seems to be a correlation between the type of mutation, the severity of enzyme deficiency, and the phenotype.

Morphology. In the classic infantile type A variant, a missense mutation causes almost complete deficiency of sphingomyelinase. Sphingomyelin is a ubiquitous component of cellular (including organellar) membranes, and so the enzyme deficiency blocks degradation of the lipid, resulting in its progressive accumulation within lysosomes, particularly within cells of the mononuclear phagocyte system. Affected cells become enlarged, sometimes to 90 μm in diameter, due to the distention of lysosomes with sphingomyelin and cholesterol. Innumerable small vacuoles of relatively uniform size are created, imparting foaminess to the cytoplasm (Fig. 5-13). In frozen sections of fresh tissue, the vacuoles stain for fat. Electron microscopy confirms that the vacuoles are engorged secondary lysosomes that often contain membranous cytoplasmic bodies resembling concentric lamellated myelin figures, sometimes called "zebra" bodies.

The lipid-laden phagocytic foam cells are widely distributed in the spleen, liver, lymph nodes, bone marrow, tonsils, gastrointestinal tract, and lungs. **The involvement of the spleen generally produces massive enlargement**, sometimes to ten times its normal weight, but the hepatomegaly is usually not quite so striking. The lymph nodes are generally moderately to markedly enlarged throughout the body.

Involvement of the brain and eye deserves special mention. In the brain the gyri are shrunken and the sulci widened. The neuronal involvement is diffuse, affecting all parts of the nervous system. Vacuolation and ballooning of neurons constitute the dominant histologic change, which in time leads to cell death and loss of brain substance. A retinal cherry-red spot similar to that seen in Tay-Sachs disease is present in about one third to one half of affected individuals.

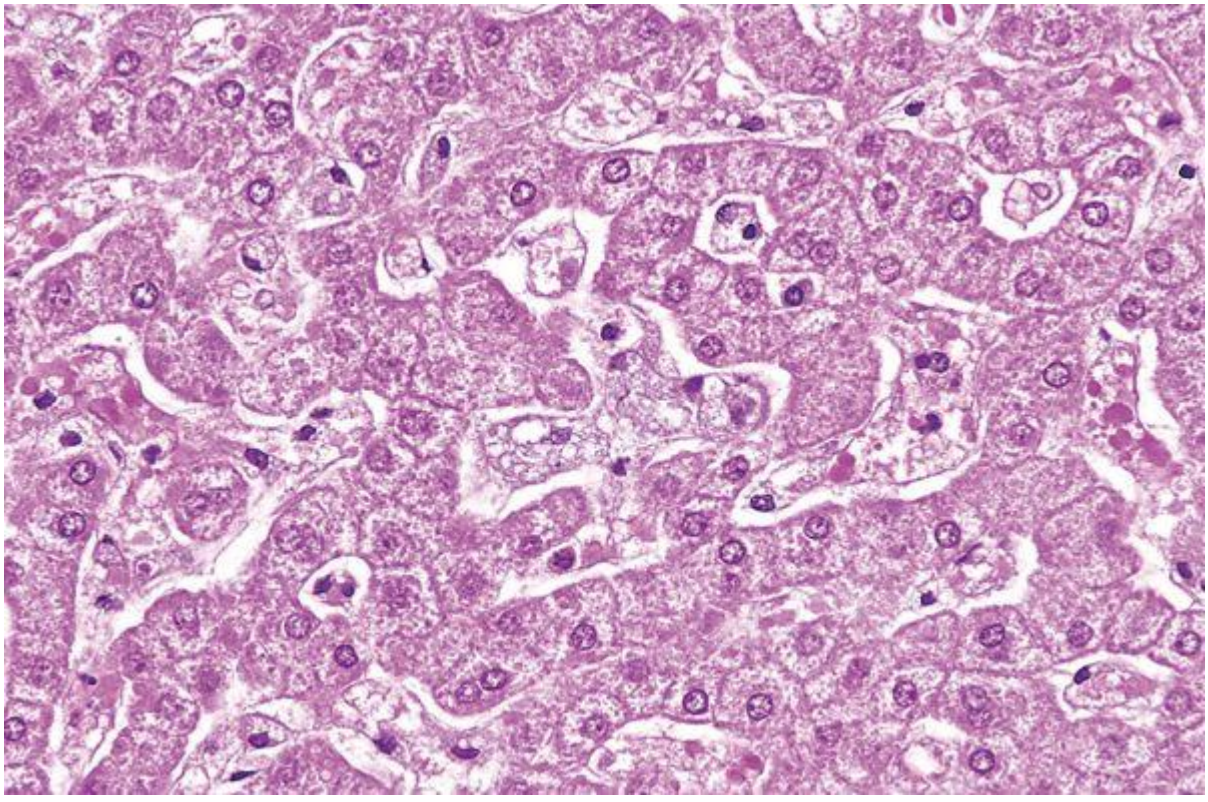

FIGURE 5-13 Niemann-Pick disease in liver. The hepatocytes and Kupffer cells have a foamy, vacuolated appearance due to deposition of lipids. *(Courtesy of Dr. Arthur Weinberg, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)*

Clinical manifestations in type A disease may be present at birth and almost invariably become evident by age 6 months. Infants typically have a protuberant abdomen because of the hepatosplenomegaly. Once the manifestations appear, they are followed by progressive failure to thrive, vomiting, fever, and generalized lymphadenopathy as well as progressive deterioration of psychomotor function. Death comes, usually within the first or second year of life.

The diagnosis is established by biochemical assays for sphingomyelinase activity in liver or bone marrow biopsy. Individuals affected with types A and B as well as carriers can be detected by DNA analysis.

Niemann-Pick Disease, Type C (NPC)

Although previously considered to be related to types A and B, Niemann-Pick disease type C (NPC) is quite distinct at the biochemical and molecular levels and is more common than types A and B combined. Mutations in two related genes, *NPC1* and *NPC2*, can give rise to it, with *NPC1* being responsible for 95% of cases. Unlike most other lysosomal storage diseases, NPC is due to a primary defect in lipid transport. Affected cells accumulate cholesterol as well as gangliosides such as G_{M1} and G_{M2}. Both NPC1 and NPC2 are involved in the transport of free cholesterol from the lysosomes to the cytoplasm.[26] NPC is clinically heterogeneous. It may present as hydrops fetalis and stillbirth, as neonatal hepatitis, or as a chronic form characterized by progressive neurologic damage. The most common form presents in childhood and is marked by ataxia, vertical supranuclear gaze palsy, dystonia, dysarthria, and psychomotor regression.

Gaucher Disease

Gaucher disease refers to a cluster of autosomal recessive disorders resulting from mutations in the gene encoding glucocerebrosidase.[27] This disease is the most common lysosomal storage disorder. The affected gene encodes glucocerebrosidase, an enzyme that normally cleaves the glucose residue from ceramide. As a result of the enzyme defect, glucocerebroside accumulates principally in phagocytes but in some subtypes also in the central nervous system. Glucocerebrosides are continually formed from the catabolism of glycolipids derived mainly from the cell membranes of senescent leukocytes and erythrocytes. It is clear now that the pathologic changes in Gaucher disease are caused not just by the burden of storage material but also by activation of macrophages and the consequent secretion of cytokines such as IL-1, IL-6, and tumor necrosis factor (TNF). Three clinical subtypes of Gaucher disease have been distinguished. The most common, accounting for 99% of cases, is called *type I*, or the chronic non-neuronopathic form. In this type, *storage of glucocerebrosides is limited to the mononuclear phagocytes throughout the body without involving the brain. Splenic and skeletal involvements dominate this pattern of the disease*. It is found principally in Jews of European stock. Individuals with this disorder have reduced but detectable levels of glucocerebrosidase activity. Longevity is shortened but not markedly. *Type II*, or acute neuronopathic Gaucher disease, is the *infantile acute cerebral pattern. This form has no predilection for Jews. In these patients there is virtually no detectable glucocerebrosidase activity in the tissues*. Hepatosplenomegaly is also seen in this form of Gaucher disease, but the clinical picture is dominated by progressive central nervous system involvement, leading to death at an early age. A third pattern, type III, is intermediate between

types I and II. These patients have the systemic involvement characteristic of type I but have progressive central nervous system disease that usually begins in adolescence or early adulthood.

Morphology. Glucocerebrosides accumulate in massive amounts within phagocytic cells throughout the body in all forms of Gaucher disease. The distended phagocytic cells, known as **Gaucher cells**, are found in the spleen, liver, bone marrow, lymph nodes, tonsils, thymus, and Peyer's patches. Similar cells may be found in both the alveolar septa and the air spaces in the lung. In contrast to other lipid storage diseases, Gaucher cells rarely appear vacuolated but instead have a fibrillary type of cytoplasm likened to crumpled tissue paper (Fig. 5-14). Gaucher cells are often enlarged, sometimes up to 100 μm in diameter, and have one or more dark, eccentrically placed nuclei. Periodic acid–Schiff staining is usually intensely positive. With the electron microscope the fibrillary cytoplasm can be resolved as elongated, distended lysosomes, containing the stored lipid in stacks of bilayers.

In type I disease, the spleen is enlarged, sometimes up to 10 kg. The lymphadenopathy is mild to moderate and is body-wide. The accumulation of Gaucher cells in the bone marrow occurs in 70% to 100% of cases of type I Gaucher disease. It produces areas of bone erosion that are sometimes small but in other cases sufficiently large to give rise to pathologic fractures. Bone destruction occurs due to the secretion of cytokines by activated macrophages. In patients with cerebral involvement, Gaucher cells are seen in the Virchow-Robin spaces, and arterioles are surrounded by swollen adventitial cells. There is no storage of lipids in the neurons, yet neurons appear shriveled and are progressively destroyed. It is suspected that the lipids that accumulate in the phagocytic cells around blood vessels secrete cytokines that damage nearby neurons.

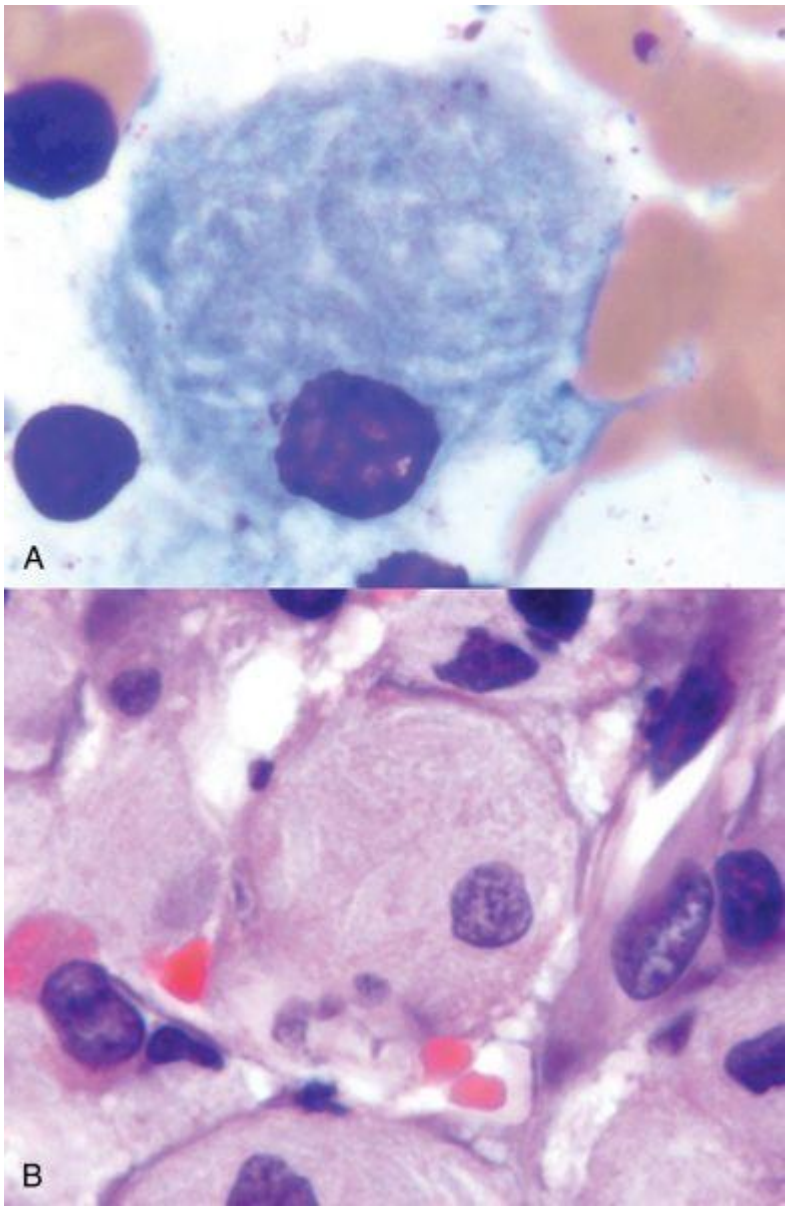

FIGURE 5-14 Gaucher disease involving the bone marrow. Gaucher cells (**A**, H&E; **B**, Wright stain) are plump macrophages that characteristically have the appearance in the cytoplasm of crumpled tissue paper (**B**), due to accumulation of glucocerebroside. *(Courtesy of Dr. John Anastasi, Department of Pathology, University of Chicago, Chicago, IL.)*

Clinical Features

The clinical course of Gaucher disease depends on the clinical subtype. In type I, symptoms and signs first appear in adult life and are related to splenomegaly or bone involvement. Most commonly there is pancytopenia or thrombocytopenia secondary to hypersplenism. Pathologic fractures and bone pain occur if there has been extensive expansion of the marrow space. Although the disease is progressive in the adult, it is compatible with long life. In types II and III, central nervous system dysfunction, convulsions, and progressive mental deterioration dominate, although organs such as the liver, spleen, and lymph nodes are also affected.

The diagnosis of homozygotes can be made by measurement of glucocerebrosidase activity in peripheral blood leukocytes or in extracts of cultured skin fibroblasts. In principle, heterozygotes can be identified by detection of mutations. However, because more than 150 mutations in the glucocerebroside gene can cause Gaucher disease, it is not possible to use a single genetic test.

Replacement therapy with recombinant enzymes is the mainstay for treatment of Gaucher disease; it is effective, and those with type I disease can expect normal life expectancy with this form of treatment. However, such therapy is extremely expensive. Because the fundamental defect resides in mononuclear phagocytic cells originating from marrow stem cells, bone marrow transplantation has been attempted. Other work is directed toward correction of the enzyme defect by transfer of the normal glucocerebrosidase gene into the patient's bone marrow cells. Substrate reduction therapy with inhibitors of glucosylceramide synthetase is also being evaluated.

Mucopolysaccharidoses

The MPSs are a group of closely related syndromes that result from genetically determined deficiencies of lysosomal enzymes involved in the degradation of mucopolysaccharides (glycosaminoglycans). Chemically, mucopolysaccharides are long-chain complex carbohydrates that are linked with proteins to form proteoglycans. They are abundant in the ground substance of connective tissue. The glycosaminoglycans that accumulate in MPSs are dermatan sulfate, heparan sulfate, keratan sulfate, and chondroitin sulfate. The enzymes involved in the degradation of these molecules cleave terminal sugars from the polysaccharide chains disposed along a polypeptide or core protein. In the absence of enzymes, these chains accumulate within lysosomes in various tissues and organs of the body.

Several clinical variants of MPS, classified numerically from MPS I to MPS VII, have been described, each resulting from the deficiency of one specific enzyme. All the MPSs except one are inherited as autosomal recessive traits; the exception, called *Hunter syndrome*, is an X-linked recessive trait. Within a given group (e.g., MPS I, characterized by a deficiency of α-l-iduronidase), subgroups exist that result from different mutant alleles at the same genetic locus. Thus, the severity of enzyme deficiency and the clinical picture even within subgroups are often different.

In general, MPSs are progressive disorders, characterized by *coarse facial features*, *clouding of the cornea, joint stiffness*, and *mental retardation*. Urinary excretion of the accumulated mucopolysaccharides is often increased.

Morphology. The accumulated mucopolysaccharides are generally found in mononuclear phagocytic cells, endothelial cells, intimal smooth muscle cells, and fibroblasts throughout the body. Common sites of involvement are thus the spleen, liver, bone marrow, lymph nodes, blood vessels, and heart.

Microscopically, affected cells are distended and have apparent clearing of the cytoplasm to create so-called balloon cells. Under the electron microscope, the clear cytoplasm can be resolved as numerous minute vacuoles. These are swollen lysosomes containing a finely granular periodic acid–Schiff–positive material that can be identified biochemically as mucopolysaccharide. Similar lysosomal changes are found in the neurons of those syndromes characterized by central nervous system involvement. In addition, however, some of the lysosomes in neurons are replaced by lamellated zebra bodies similar to those seen in Niemann-Pick disease. **Hepatosplenomegaly, skeletal deformities, valvular lesions, and subendothelial arterial deposits, particularly in the coronary arteries, and lesions in the brain, are common threads that run through all of the MPSs**. In many of the more protracted syndromes, coronary subendothelial lesions lead to myocardial ischemia.

Thus, myocardial infarction and cardiac decompensation are important causes of death.

Clinical Features

Of the seven recognized variants, only two well-characterized syndromes are described briefly here. *Hurler syndrome*, also called MPS I-H, results from a deficiency of α-l-iduronidase.[28] It is one of the most severe forms of MPS. Affected children appear normal at birth but develop hepatosplenomegaly by age 6 to 24 months. Their growth is retarded, and, as in other forms of MPS, they develop coarse facial features and skeletal deformities. Death occurs by age 6 to 10 years and is often due to cardiovascular complications. *Hunter syndrome*, also called MPS II, differs from Hurler syndrome in mode of inheritance (X-linked), absence of corneal clouding, and milder clinical course.[29]

Glycogen Storage Diseases (Glycogenoses)

The *glycogen storage diseases* result from a hereditary deficiency of one of the enzymes involved in the synthesis or sequential degradation of glycogen. Depending on the tissue or organ distribution of the specific enzyme in the normal state, *glycogen storage in these disorders may be limited to a few tissues, may be more widespread while not affecting all tissues, or may be systemic in distribution*.[30]

The significance of a specific enzyme deficiency is best understood from the perspective of the normal metabolism of glycogen (Fig. 5-15). Glycogen is a storage form of glucose. Glycogen synthesis begins with the conversion of glucose to glucose-6-phosphate by the action of a hexokinase (glucokinase). A phosphoglucomutase then transforms the glucose-6-phosphate to glucose-1-phosphate, which, in turn, is converted to uridine diphosphoglucose. A highly branched, large polymer is then built (molecular weight as high as 100 million), containing as many as 10,000 glucose molecules linked together by α-1,4-glucoside bonds. The glycogen chain and branches continue to be elongated by the addition of glucose molecules mediated by glycogen synthetases. During degradation, distinct phosphorylases in the liver and muscle split glucose-1-phosphate from the glycogen until about four glucose residues remain on each branch, leaving a branched oligosaccharide called *limit dextrin*. This can be further degraded only by the debranching enzyme. In addition to these major pathways, glycogen is also degraded in the lysosomes by acid maltase. If the lysosomes are deficient in this enzyme, the glycogen contained within them is not accessible to degradation by cytoplasmic enzymes such as phosphorylases.

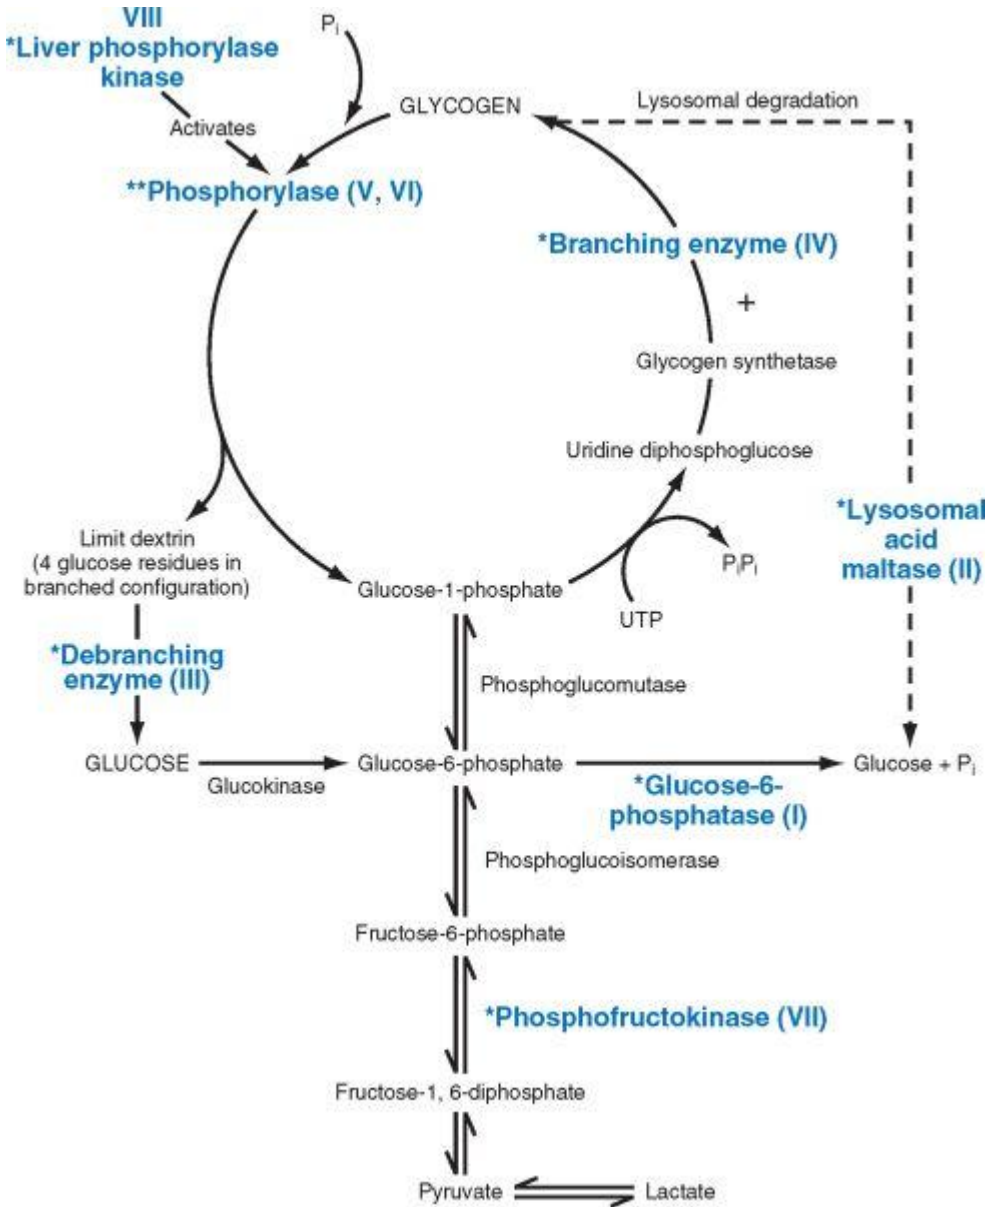

FIGURE 5-15 Pathways of glycogen metabolism. Asterisks mark the enzyme deficiencies associated with glycogen storage diseases. Roman numerals indicate the type of glycogen storage disease associated with the given enzyme deficiency. Types V and VI result from deficiencies of muscle and liver phosphorylases, respectively. *(Modified from Hers H et al.: Glycogen storage diseases. In Scriver CR et al. [eds]: The Metabolic Basis of Inherited Disease, 6th ed. New York, McGraw-Hill, 1989, p 425.)*

On the basis of specific enzyme deficiencies and the resultant clinical pictures, glycogenoses have traditionally been divided into a dozen or so syndromes designated by roman numerals, and the list continues to grow.[31] On the basis of pathophysiology glycogenoses can be divided into three major subgroups (Table 5-7).

- *Hepatic forms:* The liver is a key player in glycogen metabolism. It contains enzymes that synthesize glycogen for storage and ultimately break it down into free glucose, which is then released into the blood. An inherited deficiency of hepatic enzymes that are involved in glycogen degradation therefore leads not only to the storage of glycogen in the liver but also to a reduction in blood glucose concentrations (hypoglycemia)

(Fig. 5-16). Deficiency of the enzyme glucose-6-phosphatase (von Gierke disease, or type I glycogenosis) is a prime example of the hepatic-hypoglycemic form of glycogen storage disease (see Table 5-7). Other examples include deficiencies of liver phosphorylase and debranching enzyme, both involved in the breakdown of glycogen (see Fig. 5-15). In all these disorders glycogen is stored in many organs, but *hepatic enlargement and hypoglycemia dominate the clinical picture*.[32]

- *Myopathic forms:* In the skeletal muscles, as opposed to the liver, glycogen is used predominantly as a source of energy during physical activity. ATP is generated by glycolysis, which leads ultimately to the formation of lactate (see Fig. 5-16). If the enzymes that fuel the glycolytic pathway are deficient, glycogen storage occurs in the muscles and is associated with muscular weakness due to impaired energy production. Examples in this category include deficiencies of muscle phosphorylase (McArdle disease, or type V glycogenosis), muscle phosphofructokinase (type VII glycogen storage disease), and several others. *Typically, individuals with the myopathic forms present with muscle cramps after exercise and lactate levels in the blood fail to rise after exercise due to a block in glycolysis*.[33]
- Glycogen storage diseases associated with (1) deficiency of α-glucosidase (acid maltase) and (2) lack of branching enzyme do not fit into the hepatic or myopathic categories. They are associated with glycogen storage in many organs and death early in life. Acid maltase is a lysosomal enzyme, and hence its deficiency leads to lysosomal storage of glycogen (type II glycogenosis, or Pompe disease) in all organs, but cardiomegaly is the most prominent feature[34] (Fig. 5-17).

TABLE 5-7 -- Principal Subgroups of Glycogenoses

Clinicopathologic Category	Specific Type	Enzyme Deficiency	Morphologic Changes	Clinical Features
Hepatic type	Hepatorenal—von Gierke disease (type I)	Glucose-6-phosphatase	Hepatomegaly—intracytoplasmic accumulations of glycogen and small amounts of lipid; intranuclear glycogen Renomegaly—intracytoplasmic accumulations of glycogen in cortical tubular epithelial cells	*In untreated patients*: Failure to thrive, stunted growth, hepatomegaly, and renomegaly Hypoglycemia due to failure of glucose mobilization, often leading to convulsions Hyperlipidemia and hyperuricemia resulting from deranged glucose metabolism; many patients develop gout and skin xanthomas Bleeding tendency due to platelet dysfunction *With treatment:* Most survive and develop late complications (e.g., hepatic adenomas)
Myopathic type	McArdle syndrome (type V)	Muscle phosphorylase	Skeletal muscle only—accumulations of glycogen predominant in subsarcolemmal location	Painful cramps associated with strenuous exercise; myoglobinuria occurs in 50% of cases; onset in adulthood (>20 years); muscular exercise fails to raise lactate level in venous blood; serum creatine kinase always elevated; compatible with normal longevity
Miscellaneous types	Generalized glycogenosis—Pompe disease	Lysosomal glucosidase (acid maltase)	Mild hepatomegaly—ballooning of	Massive cardiomegaly, muscle hypotonia, and cardiorespiratory failure within 2 years; a milder

Clinicopathologic Category	Specific Type	Enzyme Deficiency	Morphologic Changes	Clinical Features
	(type II)		lysosomes with glycogen, creating lacy cytoplasmic pattern Cardiomegaly—glycogen within sarcoplasm as well as membrane-bound Skeletal muscle—similar to changes in heart	adult form with only skeletal muscle involvement, presenting with chronic myopathy

Alkaptonuria (Ochronosis)

Alkaptonuria, the first human inborn error of metabolism to be discovered, is an autosomal recessive disorder in which *there is lack of homogentisic oxidase, an enzyme that converts homogentisic acid to methylacetoacetic acid in the tyrosine degradation pathway*.[35] Thus, homogentisic acid accumulates in the body. A large amount is excreted, imparting a black color to the urine if allowed to stand and undergo oxidation.

Morphology. The retained homogentisic acid binds to collagen in connective tissues, tendons, and cartilage, imparting to these tissues a blue-black pigmentation **(ochronosis)** most evident in the ears, nose, and cheeks. **The most serious consequences of ochronosis, however, stem from deposits of the pigment in the articular cartilages of the joints**. The pigment accumulation causes the cartilage to lose its normal resiliency and become brittle and fibrillated. Wear-and-tear erosion of this abnormal cartilage leads to denudation of the subchondral bone, and often tiny fragments of the fibrillated cartilage are driven into the underlying bone, worsening the damage. The vertebral column, particularly the intervertebral disc, is the prime site of attack, but later the knees, shoulders, and hips may be affected. The small joints of the hands and feet are usually spared.

Clinical Features

The metabolic defect is present from birth, but the degenerative arthropathy develops slowly and usually does not become clinically evident until the 30s. Although it is not life-threatening, it may be severely crippling. The arthropathy may be as extreme as that encountered in the severe forms of osteoarthritis (Chapter 26) of the elderly, but it occurs at a much earlier age.

DISORDERS ASSOCIATED WITH DEFECTS IN PROTEINS THAT REGULATE CELL GROWTH

Normal growth and differentiation of cells are regulated by two classes of genes; proto-oncogenes and tumor suppressor genes, whose products promote or restrain cell growth (Chapter 7). It is now well established that mutations in these two classes of genes are important in the pathogenesis of tumors. In the vast majority of cases, cancer-causing mutations affect somatic cells and hence are not passed in the germ line. In approximately 5% of all cancers, however, mutations transmitted through the germ line contribute to the development of cancer. Most familial cancers are inherited in an autosomal dominant fashion, but a few recessive disorders have also been described. This subject is discussed in Chapter 7 . Specific forms of familial tumors are described in various chapters.

2.5.4 Complex Multigenic Disorders

As discussed previously, such disorders are caused by interactions between variant forms of genes and environmental factors. A genetic variant that has at least two alleles and occurs in at least 1% of the population is called a polymorphism. According to the common disease/common variant hypothesis, complex genetic disorders occur when many polymorphisms, each with a modest effect and low penetrance, are inherited.[36] Two additional facts that have emerged from studies of common complex disorders, such as type I diabetes, are:

- While complex disorders result from the collective inheritance of many polymorphisms, different polymorphisms vary in significance. For example, of the 20–30 genes implicated in type I diabetes, 6–7 are most important, and a few HLA-alleles contribute >50% of the risk (Chapter 24).
- Some polymorphisms are common to multiple diseases of the same type, while others are disease specific. This is best illustrated in immune-mediated inflammatory diseases (Chapter 6).

Several normal phenotypic characteristics are governed by multifactorial inheritance, such as hair color, eye color, skin color, height, and intelligence. These characteristics show a continuous variation in population groups, producing the standard bell-shaped curve of distribution. Environmental influences, however, significantly modify the phenotypic expression of complex traits. For example, type II diabetes mellitus has many of the features of a multifactorial disorder. It is well recognized clinically that individuals often first manifest this disease after weight gain. Thus, obesity as well as other environmental influences unmasks the diabetic genetic trait. Nutritional influences may cause even monozygous twins to achieve different heights. The culturally deprived child cannot achieve his or her full intellectual capacity.

Assigning a disease to this mode of inheritance must be done with caution. It depends on many factors but first on familial clustering and the exclusion of mendelian and chromosomal modes of transmission. A range of levels of severity of a disease is suggestive of a complex multigenic disorder, but, as pointed out earlier, variable expressivity and reduced penetrance of single mutant genes may also account for this phenomenon. Because of these problems, sometimes it is difficult to distinguish between mendelian and multifactorial disease.

2.5.5 Chromosomal Disorders

NORMAL KARYOTYPE

As is well known, human somatic cells contain 46 chromosomes; these comprise 22 homologous pairs of autosomes and two sex chromosomes, XX in the female and XY in the male. The study of chromosomes—*karyotyping*—is the basic tool of the cytogeneticist. The usual procedure to examine chromosomes is to arrest dividing cells in metaphase with mitotic spindle inhibitors (e.g., *N*-deacetyl-*N*-methylcolchicine [Colcemid]) and then to stain the chromosomes. In a metaphase spread, the individual chromosomes take the form of two chromatids connected at the centromere. A karyotype is obtained by arranging each pair of autosomes according to length, followed by sex chromosomes.

A variety of staining methods have been developed that allow identification of individual chromosomes on the basis of a distinctive and reliable pattern of alternating light and dark bands. The one most commonly used involves a Giemsa stain and is hence called *G banding*. A normal male karyotype with G banding is illustrated in Figure 5-18 . With standard G banding, approximately 400 to 800 bands per haploid set can be detected. The resolution obtained by banding can be markedly improved by obtaining the cells in prophase. The individual chromosomes appear markedly elongated, and as many as 1500 bands per karyotype can be recognized. The use of these banding techniques permits certain identification of each chromosome and roughly delineates breakpoints and other gross alterations, to be described later.

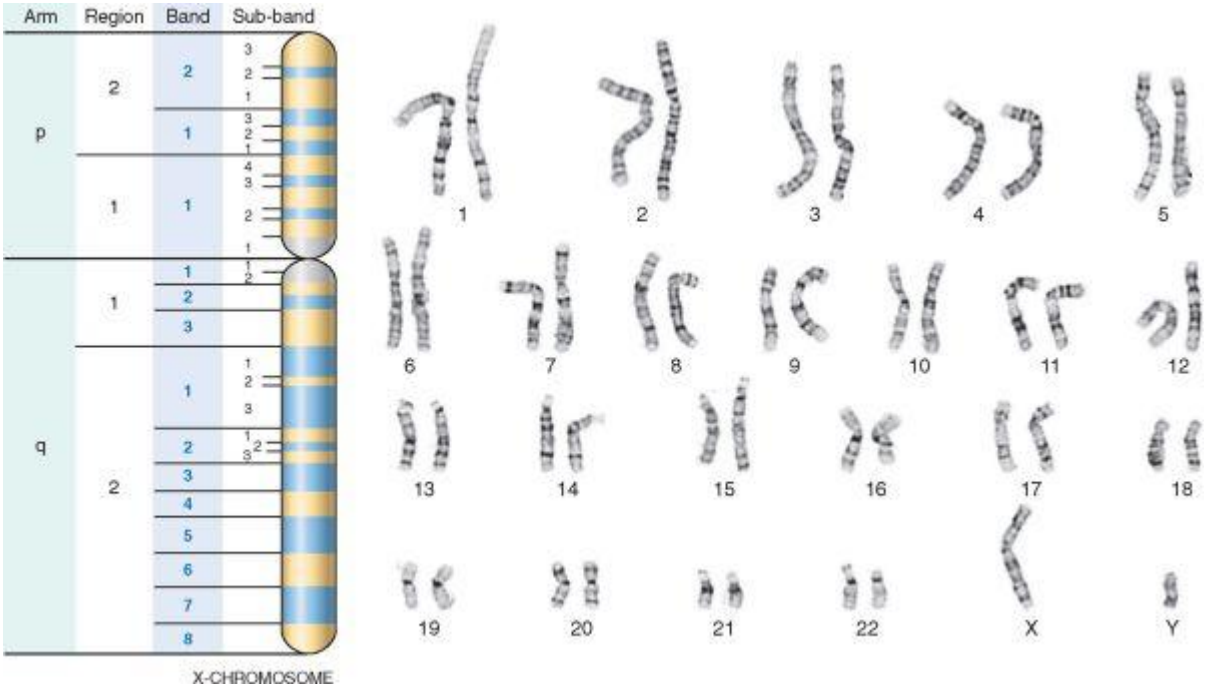

FIGURE 5-18 G-banded karyotype from a normal male (46,XY). Also shown is the banding pattern of the X-chromosome with nomenclature of arms, regions, bands, and sub-bands. *(Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)*

Before this discussion of the normal karyotype is concluded, reference must be made to commonly used cytogenetic terminology. Karyotypes are usually described using a shorthand system of notations. The following order is used: Total number of chromosomes is given first, followed by the sex chromosome complement, and finally the description of abnormalities in ascending numerical order. For example, a male with trisomy 21 is designated *47,XY,+21*. Some of the notations denoting structural alterations of chromosomes are described along with the abnormalities in a later section. Here we should mention that the short arm of a chromosome is designated *p* (for petit), and the long arm is referred to as *q* (the next letter of the alphabet). In a banded karyotype, each arm of the chromosome is divided into two or more regions bordered by prominent bands. The regions are numbered (e.g., 1, 2, 3) from the centromere outward. Each region is further subdivided into bands and sub-bands, and these are ordered numerically as well (see Fig. 5-18). Thus, the notation *Xp21.2* refers to a chromosomal segment located on the short arm of the X chromosome, in region 2, band 1, and sub-band 2.

STRUCTURAL ABNORMALITIES OF CHROMOSOMES

The aberrations underlying cytogenetic disorders may take the form of an abnormal number of chromosomes or alterations in the structure of one or more chromosomes. The normal chromosome complement is expressed as 46,XX for the female and 46,XY for the male. Any exact multiple of the haploid number is called *euploid*. If an error occurs in meiosis or mitosis and a cell acquires a chromosome complement that is not an exact multiple of 23, it is referred to as *aneuploidy*. The usual causes for aneuploidy are *nondisjunction* and *anaphase lag*. When nondisjunction occurs during gametogenesis, the gametes formed have either an extra chromosome (n + 1) or one less chromosome (n - 1). Fertilization of such gametes by normal gametes results in two types of zygotes—trisomic (2n + 1) or monosomic (2n - 1). In anaphase lag, one homologous chromosome in meiosis or one chromatid in mitosis lags behind and is left out of the cell nucleus. The result is one normal cell and one cell with monosomy. As seen subsequently, monosomy or trisomy involving the sex chromosomes, or even more bizarre aberrations, are compatible with life and are usually associated with variable degrees of phenotypic abnormalities. *Monosomy involving an autosome generally causes loss of too much genetic information to permit live birth or even embryogenesis, but several autosomal trisomies do permit survival*. With the exception of trisomy 21, all yield severely handicapped infants who almost invariably die at an early age.

Occasionally, *mitotic errors in early development give rise to two or more populations of cells with different chromosomal complement, in the same individual*, a condition referred to as *mosaicism*. Mosaicism can result from mitotic errors during the cleavage of the fertilized ovum or in somatic cells. Mosaicism affecting the sex chromosomes is relatively common. In the division of the fertilized ovum, an error may lead to one of the daughter cells receiving three sex chromosomes, whereas the other receives only one, yielding, for example, a 45,X/47,XXX mosaic. All descendent cells derived from each of these precursors thus have either a 47,XXX complement or a 45,X complement. Such a patient is a mosaic variant of Turner syndrome, with the extent of phenotypic expression dependent on the number and distribution of the 45,X cells.

Autosomal mosaicism seems to be much less common than that involving the sex chromosomes. An error in an early mitotic division affecting the autosomes usually leads to a nonviable mosaic due to autosomal monosomy. Rarely, the nonviable cell population is lost during embryogenesis, yielding a viable mosaic (e.g., 46,XY/47,XY,+21). Such a patient is a trisomy 21 mosaic with variable expression of Down syndrome, depending on the proportion of cells containing the trisomy.

A second category of chromosomal aberrations is associated with changes in the structure of chromosomes. To be visible by routine banding techniques, a fairly large amount of DNA (approximately 2–4 million base pairs), containing many genes, must be involved. The resolution is much higher with fluorescence in situ hybridization (FISH), which can detect changes as small as kilobases. Structural changes in chromosomes usually result from chromosome breakage followed by loss or rearrangement of material. Such alterations occur spontaneously at a low rate that is increased by exposure to environmental mutagens, such as chemicals and ionizing radiation. In the next section we briefly review the more common forms of alterations in chromosome structure and the notations used to signify them.

Deletion refers to loss of a portion of a chromosome (Fig. 5-19). Most deletions are interstitial, but rarely terminal deletions may occur. Interstitial deletions occur when there are two breaks within a chromosome arm, followed by loss of the chromosomal material between the breaks and fusion of the broken ends. One can specify in which region(s) and at what bands the breaks have occurred. For example, *46,XY, del(16) (p11.2p13.1)* describes breakpoints in the short arm of chromosome 16 at 16p11.2 and 16p13.1 with loss of material between breaks. Terminal deletions result from a single break in a chromosome arm, producing a fragment with no centromere, which is then lost at the next cell

division, and a chromosome bearing a deletion. The end of the chromosome is protected by acquiring telomeric sequences.

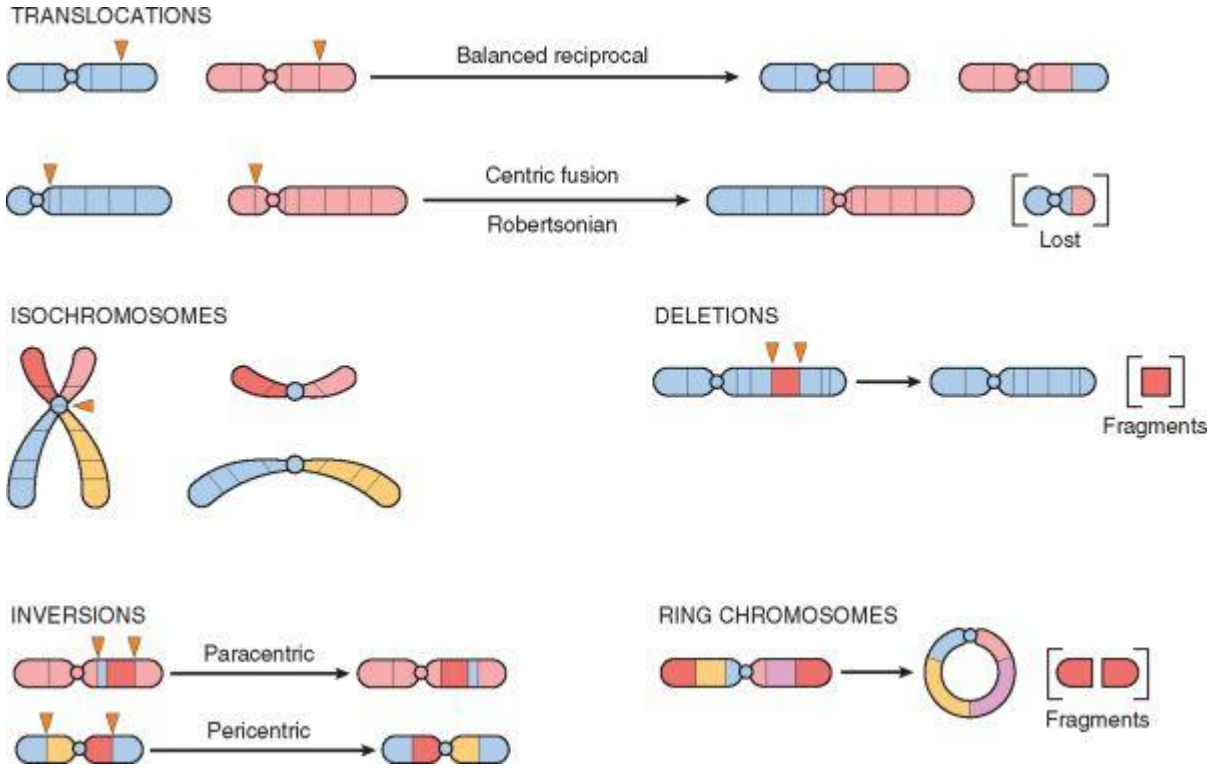

FIGURE 5-19 Types of chromosomal rearrangements.

A *ring chromosome* is a special form of deletion. It is produced when a break occurs at both ends of a chromosome with fusion of the damaged ends (see Fig. 5-19). If significant genetic material is lost, phenotypic abnormalities result. This might be expressed as *46,XY,r(14)*. Ring chromosomes do not behave normally in meiosis or mitosis and usually result in serious consequences.

Inversion refers to a rearrangement that involves two breaks within a single chromosome with reincorporation of the inverted, intervening segment (see Fig. 5-19). An inversion involving only one arm of the chromosome is known as *paracentric*. If the breaks are on opposite sides of the centromere, it is known as *pericentric*. Inversions are often fully compatible with normal development.

Isochromosome formation results when one arm of a chromosome is lost and the remaining arm is duplicated, resulting in a chromosome consisting of two short arms only or of two long arms (see Fig. 5-19). An isochromosome has morphologically identical genetic information in both arms. The most common isochromosome present in live births involves the long arm of the X and is designated *i(X)(q10)*. The Xq isochromosome is associated with monosomy for genes on the short arm of X and with trisomy for genes on the long arm of X.

In a *translocation*, a segment of one chromosome is transferred to another (see Fig. 5-19). In one form, called *balanced reciprocal translocation*, there are single breaks in each of two chromosomes, with exchange of material. A balanced reciprocal translocation between the long arm of chromosome 2 and the short arm of chromosome 5 would be written *46,XX,t(2;5)(q31;p14)*. This individual has 46

chromosomes with altered morphology of one of the chromosomes 2 and one of the chromosomes 5. Because there has been no loss of genetic material, the individual is likely to be phenotypically normal. A balanced translocation carrier, however, is at increased risk for producing abnormal gametes. For example, in the case cited above, a gamete containing one normal chromosome 2 and a translocated chromosome 5 may be formed. Such a gamete would be unbalanced because it would not contain the normal complement of genetic material. Subsequent fertilization by a normal gamete would lead to the formation of an abnormal (unbalanced) zygote, resulting in spontaneous abortion or birth of a malformed child. The other important pattern of translocation is called a *robertsonian translocation* (or centric fusion), a translocation between two acrocentric chromosomes. Typically the breaks occur close to the centromeres of each chromosome. Transfer of the segments then leads to one very large chromosome and one extremely small one. Usually the small product is lost (see Fig. 5-19); however, because it carries only highly redundant genes (e.g., ribosomal RNA genes), this loss is compatible with a normal phenotype. Robertsonian translocation between two chromosomes is encountered in 1 in 1000 apparently normal individuals. The significance of this form of translocation also lies in the production of abnormal progeny, as discussed later with Down syndrome.

Many more numerical and structural chromosomal aberrations are described in specialized texts, and more and more abnormal karyotypes are being identified in disease. As pointed out earlier, the clinically detected chromosome disorders represent only the "tip of the iceberg." It is estimated that approximately 7.5% of all conceptions have a chromosomal abnormality, most of which are not compatible with survival or live birth. Even in live-born infants the frequency is approximately 0.5% to 1.0%. It is beyond the scope of this book to discuss most of the clinically recognizable chromosomal disorders. Hence, we focus attention on those few that are most common.

CYTOGENETIC DISORDERS INVOLVING AUTOSOMES

Trisomy 21 (Down Syndrome)

Down syndrome is the most common of the chromosomal disorders and is a *major cause of mental retardation*. In the United States the incidence in newborns is about 1 in 700. Approximately 95% of affected individuals have trisomy 21, so their chromosome count is 47. FISH with chromosome 21–specific probes reveals the extra copy of chromosome 21 in such cases (Fig. 5-20). Most others have normal chromosome numbers, but the extra chromosomal material is present as a translocation. As mentioned earlier, the most common cause of trisomy and therefore of Down syndrome is meiotic nondisjunction. The parents of such children have a normal karyotype and are normal in all respects.

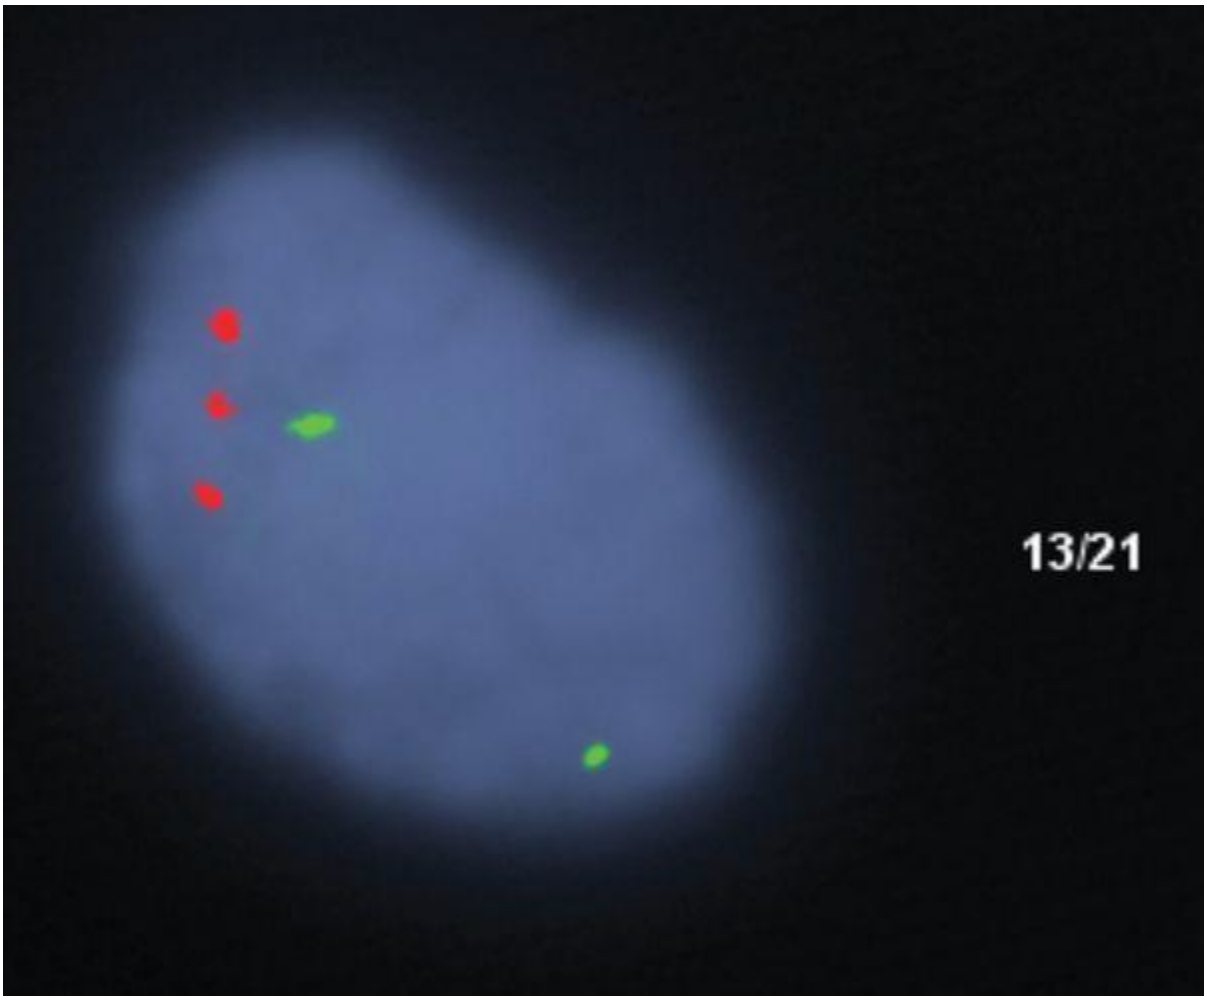

FIGURE 5-20 FISH analysis of an interphase nucleus, using locus-specific probes to chromosome 13 (green) and chromosome 21 (red), revealing three red signals consistent with trisomy 21. *(Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)*

Maternal age has a strong influence on the incidence of trisomy 21. It occurs once in 1550 live births in women under age 20, in contrast to 1 in 25 live births for mothers over age 45. The correlation with maternal age suggests that in most cases the meiotic nondisjunction of chromosome 21 occurs in the ovum. Studies in which DNA polymorphisms were used to trace the parental origin of chromosome 21 have revealed that in 95% of the cases with trisomy 21 the extra chromosome is of maternal origin. Although many hypotheses have been advanced, the reason for the increased susceptibility of the ovum to nondisjunction remains unknown.

In about 4% of cases of Down syndrome, the extra chromosomal material derives from the presence of a robertsonian translocation of the long arm of chromosome 21 to another acrocentric chromosome (e.g., 22 or 14). Because the fertilized ovum already possesses two normal autosomes 21, the translocated material provides the same triple gene dosage as in trisomy 21. Such cases are frequently (but not always) familial, and the translocated chromosome is inherited from one of the parents (usually the mother), who is a carrier of a robertsonian translocation, for example, a mother with karyotype 45,XX,der(14;21)(q10;q10).

Approximately 1% of Down syndrome patients are mosaics, usually having a mixture of cells with 46 and 47 chromosomes. This mosaicism results from mitotic nondisjunction of chromosome 21 during an early stage of embryogenesis. Symptoms in such cases are variable and milder, depending on the proportion of abnormal cells. Clearly, *in cases of translocation or mosaic Down syndrome, maternal age is of no importance*.

The diagnostic clinical features of this condition—flat facial profile, oblique palpebral fissures, and epicanthic folds (Fig. 5-21)—are usually readily evident, even at birth.[37] Down syndrome is a leading cause of severe mental retardation; approximately 80% of those afflicted have an IQ of 25 to 50. Ironically, these severely disadvantaged children may have a gentle, shy manner and may be more easily directed than their more fortunate normal siblings. It should be pointed out that some mosaics with Down syndrome have mild phenotypic changes and often even have normal or near-normal intelligence. In addition to the phenotypic abnormalities and the mental retardation already noted, some other clinical features are worthy of note.

- Approximately 40% of the patients have congenital heart disease, most commonly defects of the endocardial cushion, including ostium primum, atrial septal defects, atrioventricular valve malformations, and ventricular septal defects. Cardiac problems are responsible for the majority of the deaths in infancy and early childhood. Several other congenital malformations, including atresias of the esophagus and small bowel, are also common.
- Children with trisomy 21 have a 10-fold to 20-fold increased risk of developing acute leukemia. Both acute lymphoblastic leukemias and acute myeloid leukemias occur. The latter, most commonly, is acute megakaryoblastic leukemia.[38]
- Virtually all patients with trisomy 21 older than age 40 develop neuropathologic changes characteristic of Alzheimer disease, a degenerative disorder of the brain.
- Patients with Down syndrome have abnormal immune responses that predispose them to serious infections, particularly of the lungs, and to thyroid autoimmunity. Although several abnormalities, affecting mainly T-cell functions, have been reported, the basis of immunological disturbances is not clear.

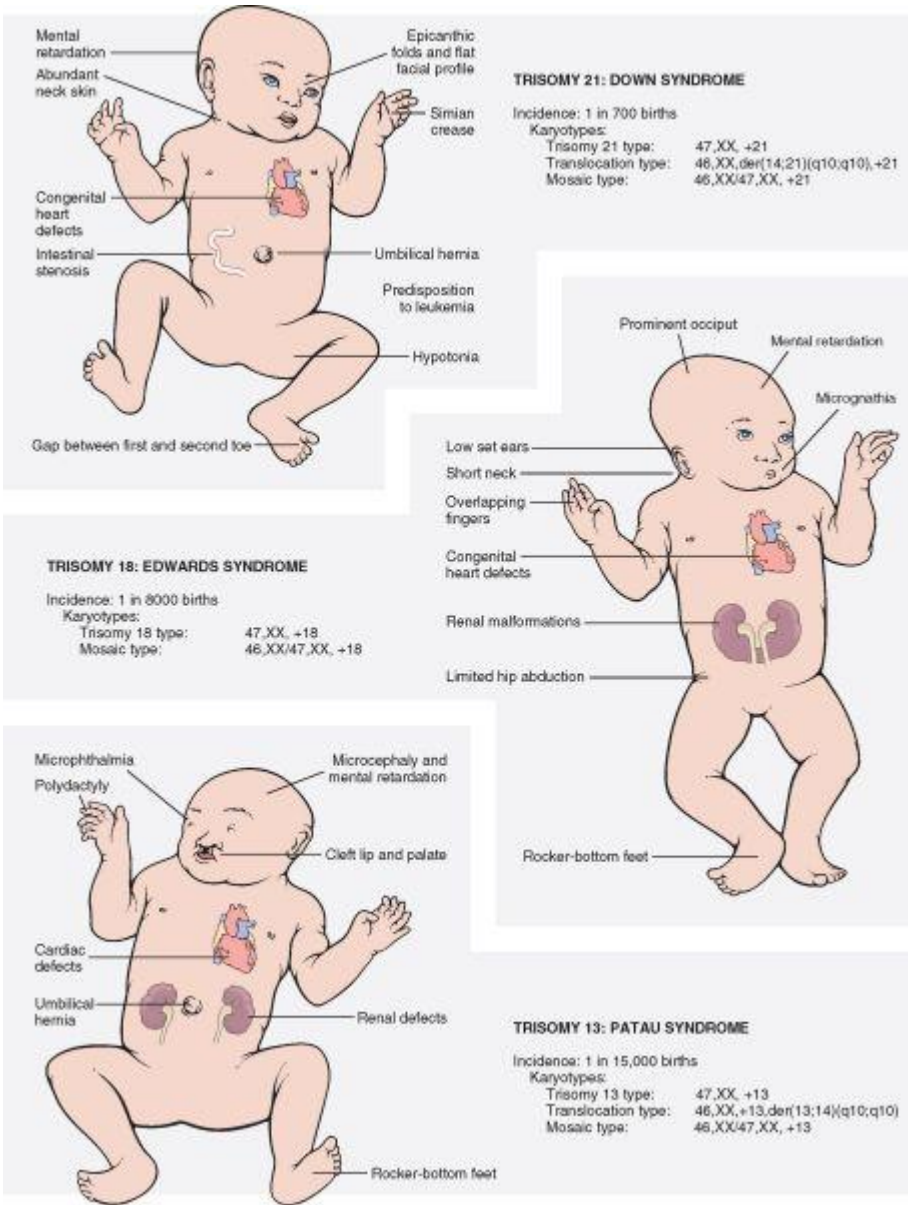

FIGURE 5-21 Clinical features and karyotypes of selected autosomal trisomies.

Despite all these problems, improved medical care has increased the longevity of individuals with trisomy 21. Currently the median age at death is 47 years (up from 25 years in 1983).

Although the karyotype and clinical features of trisomy 21 have been known for decades, little is known about the molecular basis of Down syndrome. Chromosome 21 contains approximately 430 genes. Interestingly, there are several gene clusters, each of which is predicted to participate in the same biologic pathway. For example, there are 16 genes that are involved in the mitochondrial energy pathway, several that are likely to influence central nervous system development, and a group that is involved in folate metabolism. It is not known how each of these groups of genes is related to Down syndrome. The gene dosage hypothesis assumes that the phenotypic features of the trisomy 21 are related to overexpression of genes. In reality only about 37% of the genes on chromosomes 21 are overexpressed by 150%, whereas others have variable degrees of changes in expression. Further

complexity in defining the specific genes involved in the pathogenesis of Down syndrome is related to the presence of several miRNA genes on chromosome 21 that can shut down translation of genes that map elsewhere in the genome.[39] Thus, despite the availability of the gene map of chromosome 21, the progress in understanding the molecular basis of Down syndrome remains slow.[40]

Other Trisomies

A variety of other trisomies, involving chromosomes 8, 9, 13, 18, and 22, have been described. Only trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome) are common enough to merit brief mention here. As noted in Figure 5-21 , they share several karyotypic and clinical features with trisomy 21. Thus, most cases result from meiotic nondisjunction and therefore carry a complete extra copy of chromosome 18 or 13. As in Down syndrome, an association with increased maternal age is also noted. In contrast to trisomy 21, however, the malformations are much more severe and wide-ranging. As a result, only rarely do these infants survive beyond the first year of life. Most succumb within a few weeks to months.

Chromosome 22q11.2 Deletion Syndrome

Chromosome 22q11.2 deletion syndrome encompasses a spectrum of disorders that result from a small deletion of band q11.2 on the long arm of chromosome 22.[41] The syndrome is fairly common, occurring in as many as 1 in 4000 births, but it is often missed because of variable clinical features. These include congenital heart defects, abnormalities of the palate, facial dysmorphism, developmental delay, and variable degrees of T-cell immunodeficiency and hypocalcemia. Previously, these clinical features were considered to represent two different disorders—*DiGeorge syndrome* and *velocardiofacial syndrome*. Patients with DiGeorge syndrome have thymic hypoplasia, with resultant T-cell immunodeficiency (Chapter 6), parathyroid hypoplasia giving rise to hypocalcemia, a variety of cardiac malformations affecting the outflow tract, and mild facial anomalies. The clinical features of the so-called velocardiofacial syndrome include facial dysmorphism (prominent nose, retrognathia), cleft palate, cardiovascular anomalies, and learning disabilities. Less frequently, these patients also have immunodeficiency. Until recently the overlapping clinical features of these two conditions (e.g., cardiac malformations, facial dysmorphology) were not appreciated; it was only after these two apparently unrelated syndromes were found to be associated with a similar cytogenetic abnormality that the clinical overlap came into focus. Recent studies indicate that in addition to the numerous structural malformations, individuals with the 22q11.2 deletion syndrome are at a particularly high risk for psychotic illnesses, such as schizophrenia and bipolar disorders.[42] In fact, it is estimated that approximately 25% of adults with this syndrome develop schizophrenia. Conversely, deletions of the region can be found in 2% to 3% of individuals with childhood-onset schizophrenia. In addition, attention deficit hyperactivity disorder is seen in 30% to 35% of affected children.

The diagnosis of this condition may be suspected on clinical grounds but can be established only by detection of the deletion by FISH (Fig. 5-22). By this test, approximately 90% of those previously diagnosed as having DiGeorge syndrome and 80% of those with the velocardiofacial syndrome have a deletion of 22q11.2. Thirty percent of individuals with conotruncal cardiac defects but no other features of this syndrome also reveal deletions of the same chromosomal region.

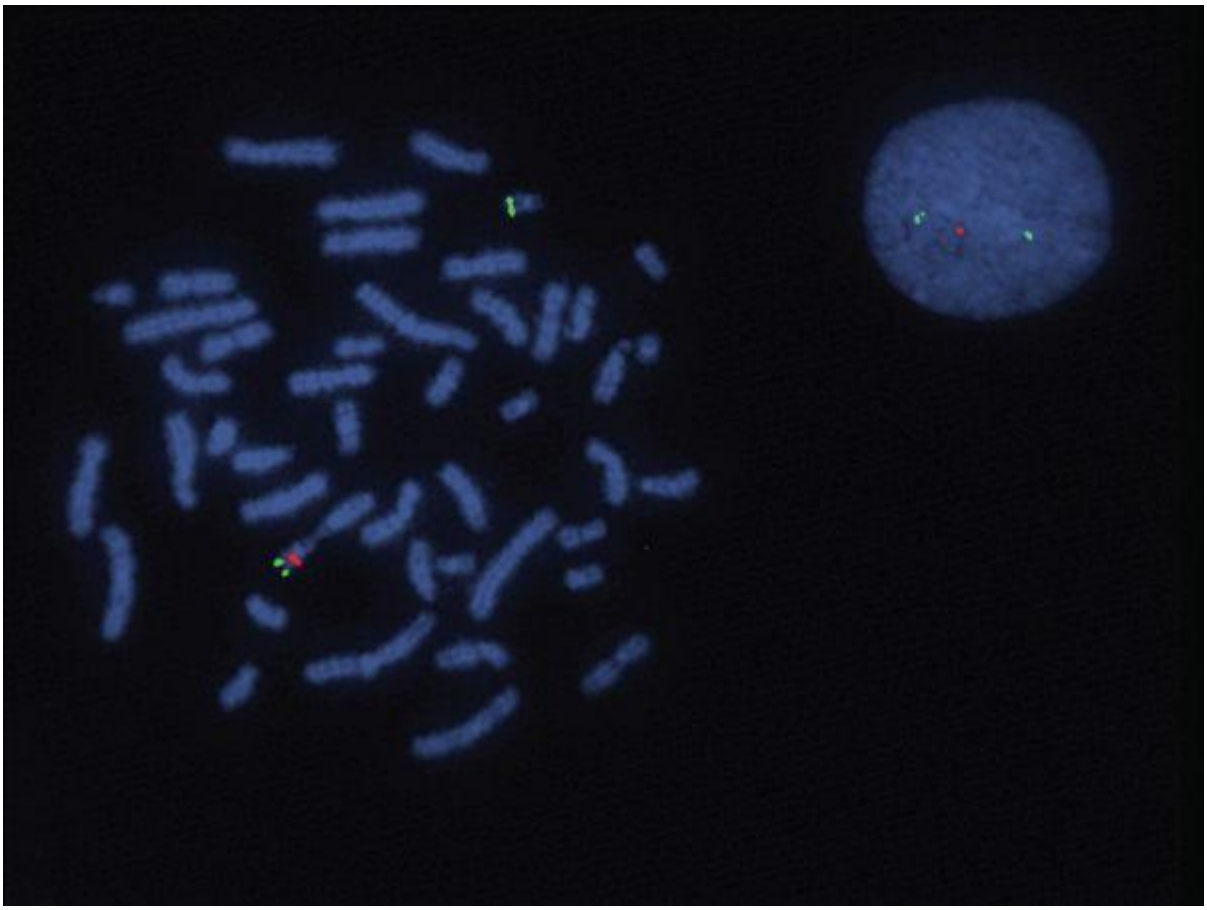

FIGURE 5-22 FISH on both metaphase chromosomes and an interphase cell from a patient with Di George syndrome demonstrating the deletion of the *TUPLE1* probe (official name *HIRA*) localized to chromosome 22q11.2. The *TUPLE1* probe is in red, and the control probe, localized to 22q, is in green. The metaphase spread shows one chromosome 22 with both a green signal (control probe) and a red signal (from the *TUPLE1* probe). The other chromosome 22 shows only hybridization with the control probe (green), but no red signal since there is a deletion on this chromosome. The interphase cell shows two areas of hybridization with the control probe (in green) but also only one area of hybridization with the *TUPLE1* probe (in red), illustrating a deletion of chromosome 22q11.2. *(Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)*

The molecular basis of this syndrome is not fully understood. The deleted region is large (approximately 1.5 megabases) and includes many genes. The clinical heterogeneity, with predominant immunodeficiency in some cases (DiGeorge syndrome) and predominant dysmorphology and cardiac malformations in other cases, probably reflects the variable position and size of the deleted segment from this genetic region. Approximately 30 candidate genes have been mapped to the deleted region. Among these, *TBX1*, a T-box transcription factor is most closely associated with the phenotypic features of this syndrome.[41] This gene is expressed in the pharyngeal mesenchyme and endodermal pouch from which facial structures, thymus, and parathyroid are derived. The targets of *TBX1* include *PAX9*, a gene that controls the development of the palate, parathyroids, and thymus. Clearly there are other genes that contribute to the behavioral and psychiatric disorders that remain to be identified.

CYTOGENETIC DISORDERS INVOLVING SEX CHROMOSOMES

Genetic diseases associated with changes involving the sex chromosomes are far more common than those related to autosomal aberrations. Furthermore, imbalances (excess or loss) of sex chromosomes

are much better tolerated than are similar imbalances of autosomes. In large part, this latitude relates to two factors that are peculiar to the sex chromosomes: (1) lyonization or inactivation of all but one X chromosome and (2) the modest amount of genetic material carried by the Y chromosome.[43] We discuss these features briefly to aid our understanding of sex chromosomal disorders.

In 1961, Lyon[44] outlined the idea of X-inactivation, now commonly known as the Lyon hypothesis. It states that (1) *only one of the X chromosomes is genetically active*, (2) *the other X of either maternal or paternal origin undergoes heteropyknosis and is rendered inactive*, (3) *inactivation of either the maternal or paternal X occurs at random among all the cells of the blastocyst on or about day 16 of embryonic life*, and (4) *inactivation of the same X chromosome persists in all the cells derived from each precursor cell*. Thus, the great preponderance of normal females are in reality mosaics and have two populations of cells, one with an inactivated maternal X and the other with an inactivated paternal X. Herein lies the explanation of why females have the same dosage of X-linked active genes as have males. The inactive X can be seen in the interphase nucleus as a darkly staining small mass in contact with the nuclear membrane known as the Barr body, or X chromatin. The molecular basis of X inactivation involves a unique gene called *XIST*, whose product is a noncoding RNA that is retained in the nucleus, where it "coats" the X chromosome that it is transcribed from and initiates a gene-silencing process by chromatin modification and DNA methylation. The *XIST* allele is switched off in the active X.[45]

Although it was initially thought that all the genes on the inactive X are "switched off," more recent studies have revealed that many genes escape X inactivation. Molecular studies suggest that 21% of genes on Xp, and a smaller number (3%) on Xq escape X inactivation. At least some of the genes that are expressed from both X chromosomes are important for normal growth and development.[46] This notion is supported by the fact that patients with monosomy of the X chromosome (Turner syndrome: 45,X) have severe somatic and gonadal abnormalities. If a single dose of X-linked genes were sufficient, no detrimental effect would be expected in such cases. Furthermore, although one X chromosome is inactivated in all cells during embryogenesis, it is selectively reactivated in oogonia before the first meiotic division. Thus, it seems that both X chromosomes are required for normal oogenesis.

With respect to the Y chromosome, it is well known that this chromosome is both necessary and sufficient for male development. *Regardless of the number of X chromosomes, the presence of a single Y determines the male sex*. The gene that dictates testicular development (*SRY*: sex-determining region Y gene) has been located on its distal short arm. For quite some time this was considered to be the only gene of significance on the Y chromosome. Recent studies of the Y chromosome, however, have yielded a rich harvest of gene families in the so-called "male-specific Y," or MSY region.[47] All of these are believed to be testes-specific genes involved in spermatogenesis. With this background, we review some features that are common to all sex chromosome disorders.

- In general, they cause subtle, chronic problems relating to sexual development and fertility.
- They are often difficult to diagnose at birth, and many are first recognized at the time of puberty.
- In general, the higher the number of X chromosomes, in both male and female, the greater the likelihood of mental retardation.

The most important disorders arising in aberrations of sex chromosomes are described briefly here.

Klinefelter Syndrome

Klinefelter syndrome is best defined as male hypogonadism that occurs when there are two or more X chromosomes and one or more Y chromosomes.[48] It is one of the most frequent forms of genetic disease involving the sex chromosomes as well as one of the most common causes of hypogonadism in

the male. The incidence of this condition is approximately 1 in 660 live male births.[49] It can rarely be diagnosed before puberty, particularly because the testicular abnormality does not develop before early puberty. Most patients have a distinctive body habitus with an increase in length between the soles and the pubic bone, which creates the appearance of an elongated body. Also characteristic are eunuchoid body habitus with abnormally long legs; small atrophic testes often associated with a small penis; and lack of such secondary male characteristics as deep voice, beard, and male distribution of pubic hair. Gynecomastia may be present. The mean IQ is somewhat lower than normal, but mental retardation is uncommon. There is increased incidence of type 2 diabetes and the metabolic syndrome; and curiously, mitral valve prolapse is seen in about 50% of adults with Klinefelter syndrome. It should be evident that the clinical features of this condition are variable, the only consistent finding being hypogonadism. Plasma gonadotropin concentrations, particularly follicle-stimulating hormone, are consistently elevated, whereas testosterone levels are variably reduced. Mean plasma estradiol levels are elevated by an as yet unknown mechanism. The ratio of estrogens and testosterone determines the degree of feminization in individual cases.

Klinefelter syndrome is an important genetic cause of reduced spermatogenesis and male infertility.[50] In some patients the testicular tubules are totally atrophied and replaced by pink, hyaline, collagenous ghosts. In others, apparently normal tubules are interspersed with atrophic tubules. In some patients all tubules are primitive and appear embryonic, consisting of cords of cells that never developed a lumen or progressed to mature spermatogenesis. Leydig cells appear prominent, as a result of the atrophy and crowding of tubules and elevation of gonadotropin concentrations.

Patients with Klinefelter syndrome have a higher risk for breast cancer (20 times more common than in normal males), extragonadal germ cell tumors, and autoimmune diseases such as systemic lupus erythematosus.

The classic pattern of Klinefelter syndrome is associated with a 47,XXY karyotype (90% of cases). This complement of chromosomes results from nondisjunction during the meiotic divisions in one of the parents. Maternal and paternal nondisjunction at the first meiotic division are roughly equally involved. There is no phenotypic difference between those who receive the extra X chromosome from their father and those who receive it from their mother. Maternal age is increased in the cases associated with errors in oogenesis. In addition to this classic karyotype, approximately 15% of patients with Klinefelter syndrome have been found to have a variety of mosaic patterns, most of them being 46,XY/47,XXY. Other patterns are 47,XXY/48,XXXY and variations on this theme. As is the case with normal females, all but one X undergoes inactivation in patients with Klinefelter syndrome. Why then, do the patients with this disorder have hypogonadism and associated features? The explanation of this lies in the pattern of X inactivation. The gene encoding the androgen receptor, through which testosterone mediates its effects, maps on the X chromosome. The androgen receptor gene contains highly polymorphic CAG (trinucleotide) repeats. The functional response to androgens is dictated, in part, by the number of CAG repeats. With shorter CAG repeats, the effect of androgens is more pronounced. In persons with Klinefelter syndrome the X chromosome, bearing androgen receptor with the shortest CAG repeat, is preferentially inactivated. Such nonrandom X inactivation leaves the allele with the longest CAG repeat active, thus accounting for hypogonadism.

Turner Syndrome

Turner syndrome results from complete or partial monosomy of the X chromosome and is characterized primarily by hypogonadism in phenotypic females.[51] It is the most common sex chromosome abnormality in females, affecting about 1 in 2000 live-born females.

With routine cytogenetic methods, three types of karyotypic abnormalities are seen in individuals with Turner syndrome. Approximately 57% are missing an entire X chromosome, resulting in a 45,X

karyotype. Of the remaining 43%, approximately one third (approximately 14%) have structural abnormalities of the X chromosomes, and two thirds (approximately 29%) are mosaics. The common feature of the structural abnormalities is to produce partial monosomy of the X chromosome. In order of frequency, the structural abnormalities of the X chromosome include (1) an isochromosome of the long arm, 46,X,i(X)(q10) resulting in the loss of the short arm; (2) deletion of portions of both long and short arms, resulting in the formation of a ring chromosome, 46,X,r(X); and (3) deletion of portions of the short or long arm, 46X,del(Xq) or 46X,del(Xp). The mosaic patients have a 45,X cell population along with one or more karyotypically normal or abnormal cell types. Examples of karyotypes that mosaic Turner females may have are the following: (1) 45,X/46,XX; (2) 45,X/46,XY; (3) 45,X/47,XXX; or (4) 45,X/46,X,i(X)(q10). Studies suggest that the prevalence of mosaicism in Turner syndrome may be much higher than the 30% detected by conventional cytogenetic studies. With the use of more sensitive techniques, including FISH (discussed later) and polymerase chain reaction (PCR), and analysis of more than one cell type (e.g., peripheral blood and fibroblasts), the prevalence of mosaic Turner syndrome increases to 75%. Because 99% of 45,X conceptuses are nonviable, many authorities believe that there are no truly nonmosaic Turner syndrome patients. While this issue remains controversial, it is important to appreciate the karyotypic heterogeneity associated with Turner syndrome, because it is responsible for significant variations in phenotype. In patients who are truly 45,X, or in whom the proportion of 45,X cells is high, the phenotypic changes are more severe than in those who have readily detectable mosaicism. The latter may have an almost normal appearance and may present only with primary amenorrhea. Similarly, those with a Y chromosome–containing population (e.g., 45,X/46,XY karyotype) may be at risk of developing a gonadal tumor (gonadoblastoma).

The most severely affected patients generally present during infancy with edema of the dorsum of the hand and foot due to lymph stasis, and sometimes *swelling of the nape of the neck*. The latter is related to markedly distended lymphatic channels, producing a so-called cystic hygroma (Chapter 10). As these infants develop, the swellings subside but often leave bilateral *neck webbing* and persistent looseness of skin on the back of the neck. *Congenital heart disease* is also common, affecting 25% to 50% of patients. Left-sided cardiovascular abnormalities, particularly preductal coarctation of the aorta and bicuspid aortic valve, are seen most frequently. Cardiovascular abnormalities are the most important cause of increased mortality in children with Turner syndrome.[52]

The principal clinical features in the adolescent and adult are illustrated in Figure 5-23 . At puberty there is *failure to develop normal secondary sex characteristics*. The genitalia remain infantile, breast development is inadequate, and there is little pubic hair. The mental status of these patients is usually normal, but subtle defects in nonverbal, visual-spatial information processing have been noted. Of particular importance in establishing the diagnosis in the adult is the shortness of stature (rarely exceeding 150 cm in height) and amenorrhea. *Turner syndrome is the single most important cause of primary amenorrhea*, accounting for approximately one third of the cases. For reasons not quite clear, approximately 50% of patients develop autoantibodies that react with the thyroid gland, and up to half of these develop clinically manifest hypothyroidism. Equally mysterious is the presence of glucose intolerance, obesity, and insulin resistance in a minority of patients. The last mentioned is significant, because therapy with growth hormone, commonly used in these patients, worsens insulin resistance.

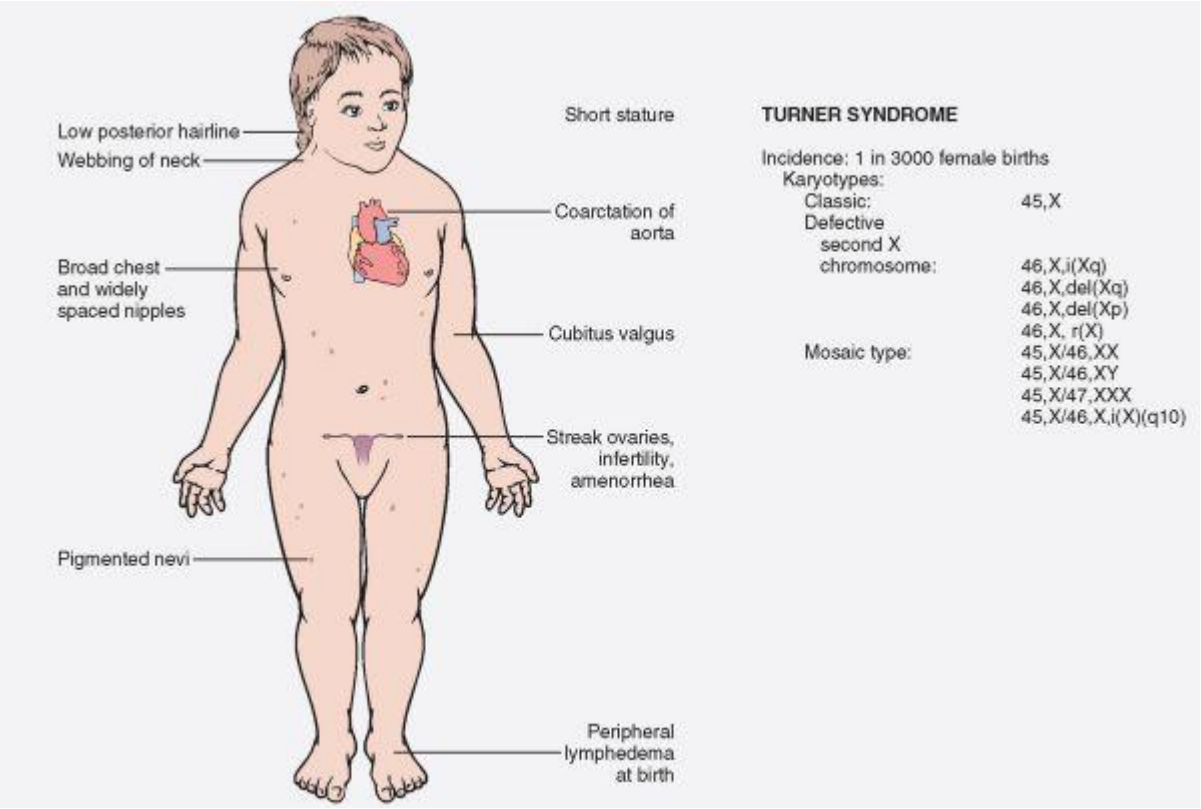

FIGURE 5-23 Clinical features and karyotypes of Turner syndrome.

The molecular pathogenesis of Turner syndrome is not completely understood, but studies have begun to shed some light.[53] As mentioned earlier, both X chromosomes are active during oogenesis and are essential for normal development of the ovaries. During normal fetal development, ovaries contain as many as 7 million oocytes. The oocytes gradually disappear so that by menarche their numbers have dwindled to a mere 400,000, and when menopause occurs fewer than 10,000 remain. In Turner syndrome, fetal ovaries develop normally early in embryogenesis, but the absence of the second X chromosome leads to an accelerated loss of oocytes, which is complete by age 2 years. In a sense, therefore, "menopause occurs before menarche," and the ovaries are reduced to atrophic fibrous strands, devoid of ova and follicles *(streak ovaries)*. Because patients with Turner syndrome also have other (nongonadal) abnormalities, it follows that some genes for normal growth and development of somatic tissues must also reside on the X chromosome. Among the genes involved in the Turner phenotype is the short stature homeobox (*SHOX*) gene at Xp22.33. This is one of several genes that remain active in both X chromosomes and has an active homologue on the short arm of the Y chromosome. Thus, both normal males and females have two copies of this gene. Haploinsufficiency of *SHOX* gives rise to short stature. Indeed, deletions of the *SHOX* gene are noted in 2% to 5% of otherwise normal children with short stature. In keeping with its role as a critical regulator of growth, the *SHOX* gene is expressed during fetal life in the growth plates of several long bones including the radius, ulna, tibia, and fibula. It is also expressed in the first and second pharyngeal arches. Just as the loss of *SHOX* is always associated with short stature, excess copies of this gene are associated with tall stature. Whereas haploinsufficiency of *SHOX* can explain growth deficit in Turner syndrome, it cannot explain other important clinical features such as cardiac malformations and endocrine abnormalities. Clearly several other genes located on the X chromosome are also involved.

The problem of sexual ambiguity is exceedingly complex, and only limited observations are possible here; for more details, reference should be made to specialized sources.[54] It will be no surprise to medical students that the sex of an individual can be defined on several levels. *Genetic sex* is determined by the presence or absence of a Y chromosome. No matter how many X chromosomes are present, a single Y chromosome dictates testicular development and the genetic male gender. The initially indifferent gonads of both the male and the female embryos have an inherent tendency to feminize, unless influenced by Y chromosome–dependent masculinizing factors. *Gonadal sex* is based on the histologic characteristics of the gonads. *Ductal sex* depends on the presence of derivatives of the müllerian or wolffian ducts. *Phenotypic*, or *genital*, *sex* is based on the appearance of the external genitalia. Sexual ambiguity is present whenever there is disagreement among these various criteria for determining sex.

The term true hermaphrodite implies the presence of both ovarian and testicular tissue. In contrast, a pseudohermaphrodite represents a disagreement between the phenotypic and gonadal sex (i.e., a female pseudohermaphrodite has ovaries but male external genitalia; a male pseudohermaphrodite has testicular tissue but female-type genitalia).

True hermaphroditism, implying the presence of both ovarian and testicular tissue, is an extremely rare condition. In some cases there is a testis on one side and an ovary on the other, whereas in other cases there may be combined ovarian and testicular tissue, referred to as ovotestes. The karyotype is 46,XX in 50% of patients; of the remaining, most are mosaics with a 46,XX/46,XY karyotype. Only rarely is the chromosomal constitution 46,XY. The presence of testes implies that those with the 46,XX karyotype might possess Y-chromosomal material, in particular, the *SRY* gene, which dictates testicular differentiation. Indeed, molecular analysis has revealed *SRY* gene expression in the ovotestis of 46,XX true hermaphrodites, indicating either cryptic chimerism localized to the gonads or possibly a Y-to-autosome translocation.[55]

Female pseudohermaphroditism is much less complex. The genetic sex in all cases is XX, and the development of the gonads (ovaries) and internal genitalia is normal. Only the external genitalia are ambiguous or virilized. The basis of female pseudohermaphroditism is excessive and inappropriate exposure to androgenic steroids during the early part of gestation. Such steroids are most commonly derived from the fetal adrenal affected by congenital adrenal hyperplasia, which is transmitted as an autosomal recessive trait. Biosynthetic defects in the pathway of cortisol synthesis are present in these patients, which lead secondarily to excessive synthesis of androgenic steroids by the fetal adrenal cortex (Chapter 24).

Male pseudohermaphroditism represents the most complex of all disorders of sexual differentiation. These individuals possess a Y chromosome, and thus their gonads are exclusively testes, but the genital ducts or the external genitalia are incompletely differentiated along the male phenotype. Their external genitalia are either ambiguous or completely female. Male pseudohermaphroditism is extremely heterogeneous, with a multiplicity of causes. Common to all is defective virilization of the male embryo, which usually results from genetically determined defects in androgen synthesis or action or both. The most common form, called *complete androgen insensitivity syndrome (testicular feminization)*, results from mutations in the gene encoding the androgen receptor.[56] This gene is located at Xq12, and hence this disorder is inherited as an X-linked recessive.

2.5.6 Single-Gene Disorders with Nonclassic Inheritance

It has become increasingly evident that transmission of certain single-gene disorders does not follow classic mendelian principles. This group of disorders can be classified into four categories:

- Diseases caused by trinucleotide-repeat mutations
- Disorders caused by mutations in mitochondrial genes
- Disorders associated with genomic imprinting
- Disorders associated with gonadal mosaicism

Clinical and molecular features of some single-gene diseases that exemplify nonclassic patterns of inheritance are described next.

DISEASES CAUSED BY TRINUCLEOTIDE-REPEAT MUTATIONS

The discovery in 1991 of expanding trinucleotide repeats as a cause of fragile-X syndrome was a landmark in human genetics. Since then the origins of about 40 human diseases (Table 5-8) have been traced to unstable nucleotide repeats,[57] and the number continues to grow. Some general principles that apply to these diseases are as follows:

- The causative mutations are associated with the expansion of a stretch of trinucleotides that usually share the nucleotides G and C. In all cases the DNA is unstable, and an expansion of the repeats above a certain threshold impairs gene function in various ways, discussed below.
- The proclivity to expand depends strongly on the sex of the transmitting parent. In the fragile-X syndrome, expansions occur during oogenesis, whereas in Huntington disease they occur during spermatogenesis.
- From a mechanistic standpoint, the mutations can be divided into two groups. In the first group of disorders, exemplified by fragile-X syndrome and myotonic dystrophy, the repeat expansions occur in noncoding regions, whereas in other disorders, such as Huntington disease, expansions occur in the coding regions (Fig. 5-24).

TABLE 5-8 -- Examples of Trinucleotide-Repeat Disorders

					No. of Repeats	
Disease	**Gene**	**Locus**	**Protein**	**Repeat**	**Normal**	**Disease**
EXPANSIONS AFFECTING NONCODING REGIONS						
Fragile-X syndrome	*FMRI (FRAXA)*	Xq27.3	FMR-1 protein (FMRP)	CGG	6–53	60–200 (pre); >230 (full)
Friedreich ataxia	*FXN*	9q21.1	Frataxin	GAA	7–34	34–80 (pre); >100 (full)
Myotonic dystrophy	*DMPK*	19q13.3	Myotonic dystrophy protein kinase (DMPK)	CTG	5–37	34–80 (pre); >100 (full)
EXPANSIONS AFFECTING CODING REGIONS						
Spinobulbar muscular atrophy (Kennedy disease)	*AR*	Xq12	Androgen receptor (AR)	CAG	9–36	38–62
Huntington disease	*HTT*	4p16.3	Huntingtin	CAG	6–35	36–121
Dentatorubral-pallidoluysian atrophy (Haw River syndrome)	*ATNL*	12p13.31	Atrophin-1	CAG	6–35	49–88
Spinocerebellar ataxia type 1	*ATXN1*	6p23	Ataxin-1	CAG	6–44	39–82
Spinocerebellar ataxia type 2	*ATXN2*	12q24.1	Ataxin-2	CAG	15–31	36–63
Spinocerebellar ataxia type 3 (Machado-Joseph disease)	*ATXN3*	14q21	Ataxin-3	CAG	12–40	55–84
Spinocerebellar ataxia type 6	*CACNA2A*	19p13.3	α_{1A}-Voltage-dependent calcium channel subunit	CAG	4–18	21–33

					No. of Repeats	
Disease	**Gene**	**Locus**	**Protein**	**Repeat**	**Normal**	**Disease**
Spinocerebellar ataxia type 7	*ATXN7*	3p14.1	Ataxin-7	CAG	4–35	37–306

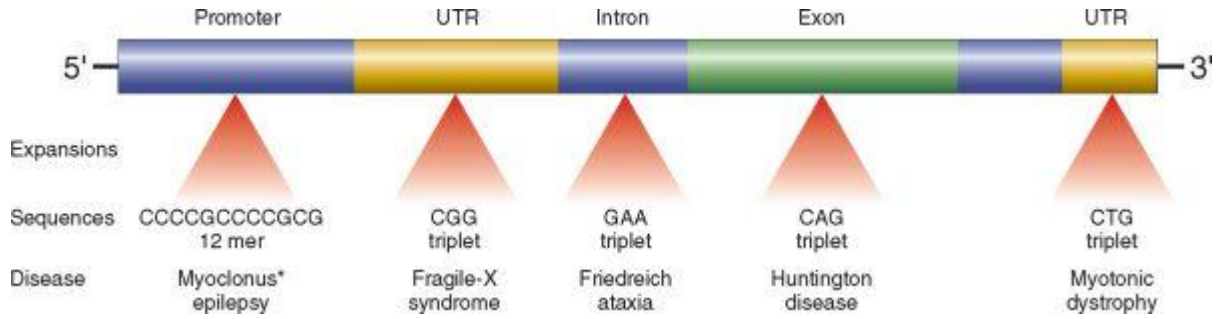

FIGURE 5-24 Sites of expansion and the affected sequence in selected diseases caused by nucleotide-repeat mutations. UTR, untranslated region. *Though not strictly a trinucleotide-repeat disease, progressive myoclonus epilepsy is caused, like others in this group, by a heritable DNA expansion. The expanded segment is in the promoter region of the gene.

The pathogenetic mechanisms underlying disorders caused by mutations that affect coding regions seem to be distinct from those in which the expansions affect noncoding regions.[58] The former usually involve CAG repeats coding for polyglutamine tracts in the corresponding proteins. Such "polyglutamine diseases" are characterized by progressive neurodegeneration, typically striking in midlife. Polyglutamine expansions lead to toxic gain of function, whereby the abnormal protein interferes with the function of the normal protein.[59] The precise mechanisms by which expanded polyglutamine proteins cause disease is not fully understood. However, some general features have emerged. In most cases the proteins are misfolded and tend to aggregate; the aggregates may suppress transcription of other genes, cause mitochondrial dysfunction, or trigger the unfolded-protein stress response and apoptosis (Chapter 1). A morphologic hallmark of these diseases is the accumulation of aggregated mutant proteins in large intranuclear inclusions. By contrast, when expansions affect noncoding regions the resulting mutations are loss-of-function type, since protein synthesis (e.g., FMRP) is suppressed. Typically, such disorders affect many systems. Finally, many noncoding repeat disorders are characterized by intermediate-size expansions, or premutations, that expand to full mutations in germ cells.

Fragile-X Syndrome

Fragile-X syndrome is the prototype of diseases in which the mutation is characterized by a long repeating sequence of three nucleotides. Although the specific nucleotide sequence that undergoes amplification differs in the 20 or so disorders included in this group, in most cases the affected sequences share the nucleotides guanine (G) and cytosine (C). In the ensuing discussion we consider the clinical features and inheritance pattern of the fragile-X syndrome, to be followed by the causative molecular lesion. The remaining disorders in this group are discussed later, in this chapter and elsewhere in the book.

With a frequency of 1 in 1550 for affected males and 1 in 8000 for affected females, *fragile-X syndrome is the second most common genetic cause of mental retardation, after Down syndrome*. It is an X-linked disorder characterized by an inducible cytogenetic abnormality in the X chromosome and an unusual mutation within the familial mental retardation-1 (*FMR1*) gene. The cytogenetic alteration is seen as a

discontinuity of staining or as a constriction in the long arm of the X chromosome when cells are cultured in a folate-deficient medium. Because it appears that the chromosome is “broken” at this locale, it is referred to as a *fragile site* (Fig. 5-25). It should be noted that more than 100 “fragile sites” have been found in the human genome.[60] Many, like the one seen in fragile-X syndrome, are sensitive to lack of folate in the medium, whereas others require different culture conditions. The significance of most fragile sites is unknown, since many are present in normal individuals.

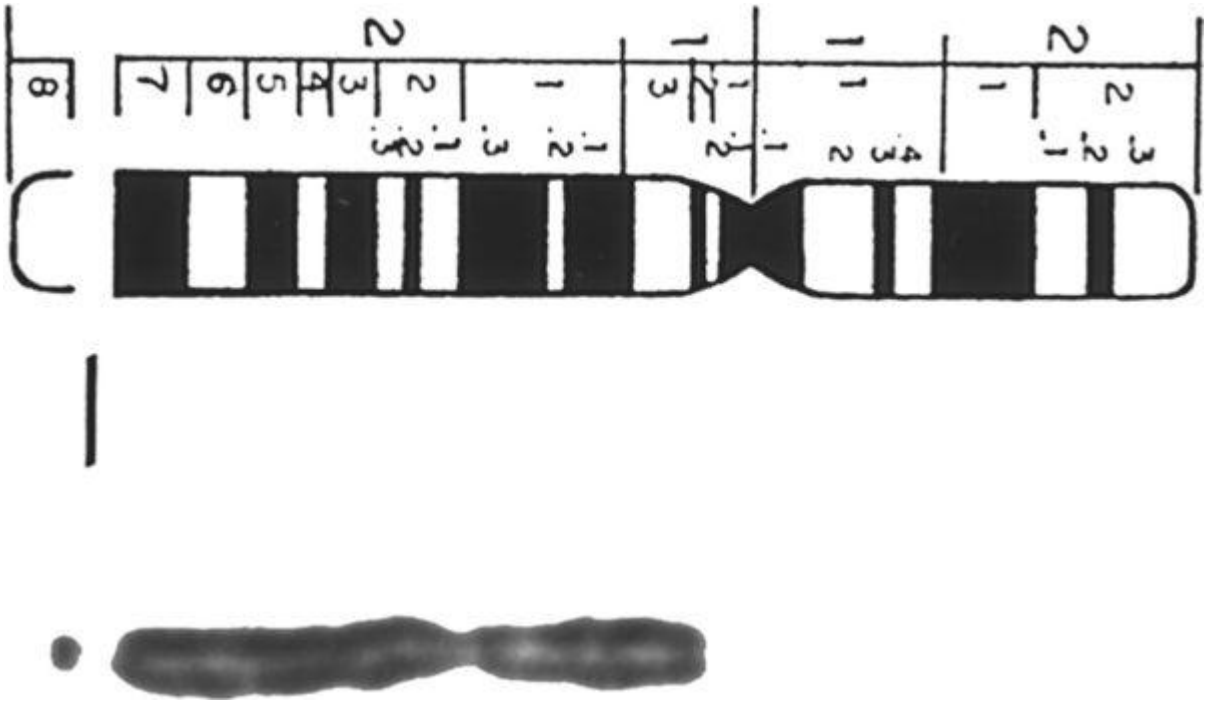

FIGURE 5-25 Fragile X, seen as discontinuity of staining. *(Courtesy of Dr. Patricia Howard-Peebles, University of Texas Southwestern Medical Center, Dallas, TX.)*

In fragile-X syndrome, the affected males are *mentally retarded*, with an IQ in the range of 20 to 60. They express a characteristic physical phenotype that includes a *long face with a large mandible, large everted ears*, and *large testicles (macro-orchidism)*. Hyperextensible joints, a high arched palate, and mitral valve prolapse noted in some patients mimic a connective tissue disorder. These and other physical abnormalities described in this condition, however, are not always present and, in some cases, are quite subtle. *The most distinctive feature is macro-orchidism, which is observed in at least 90% of postpubertal males*.

As with all X-linked diseases, fragile-X syndrome affects males. Analysis of several pedigrees, however, reveals some patterns of transmission not typically associated with other X-linked recessive disorders (Fig. 5-26). These include the following[61]:

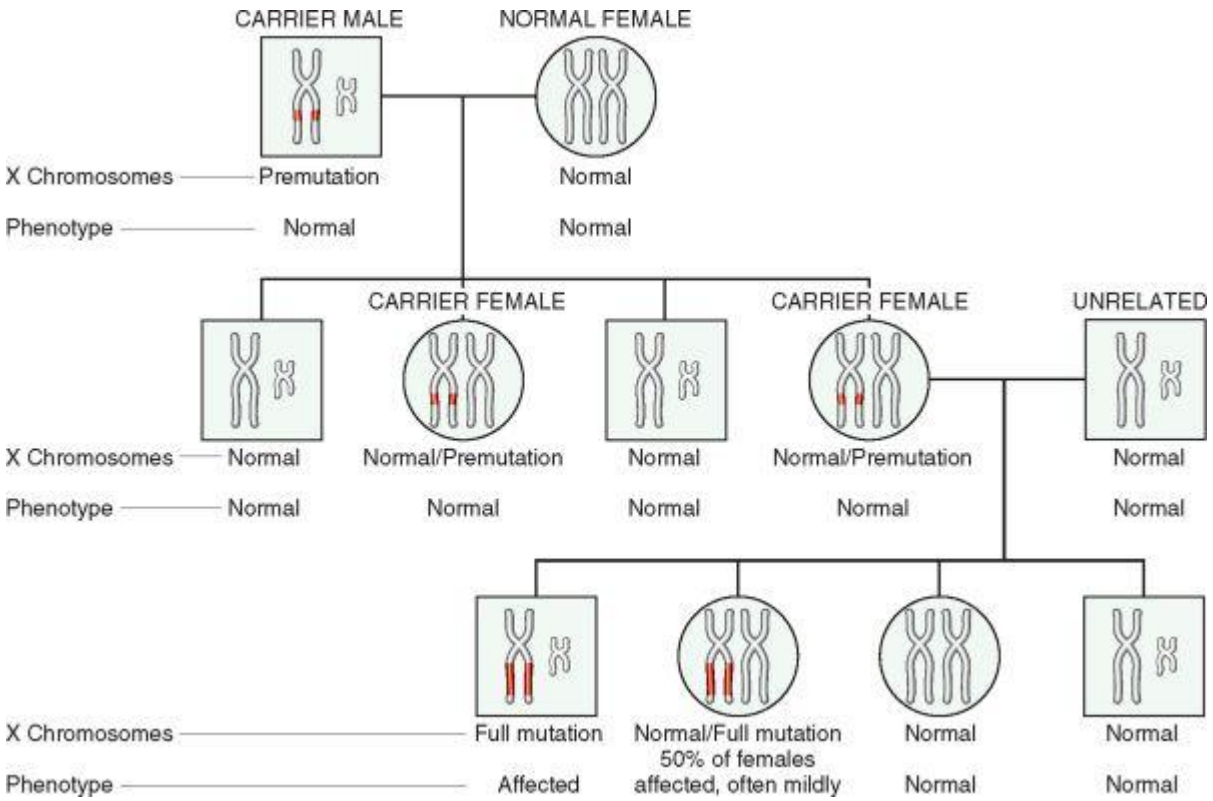

FIGURE 5-26 Fragile-X pedigree. Note that in the first generation all sons are normal and all females are carriers. During oogenesis in the carrier female, premutation expands to full mutation; hence, in the next generation all males who inherit the X with full mutation are affected. However, only 50% of females who inherit the full mutation are affected, and only mildly. *(Courtesy of Dr. Nancy Schneider, Department of Pathology, University of Texas Southwestern Medical Center, Dallas, TX.)*

- *Carrier males:* Approximately 20% of males who, by pedigree analysis and by molecular tests, are known to carry a fragile-X mutation are clinically and cytogenetically normal. Because carrier males transmit the trait through all their daughters (phenotypically normal) to affected grandchildren, they are called *normal transmitting males*.
- *Affected females:* 30% to 50% of carrier females are affected (i.e., mentally retarded), a number much higher than that in other X-linked recessive disorders.
- *Risk of phenotypic effects:* Risk depends on the position of the individual in the pedigree. For example, brothers of transmitting males are at a 9% risk of having mental retardation, whereas grandsons of transmitting males incur a 40% risk.
- *Anticipation:* This refers to the observation that clinical features of fragile-X syndrome worsen with each successive generation, as if the mutation becomes increasingly deleterious as it is transmitted from a man to his grandsons and great-grandsons.

These unusual patterns perplexed geneticists for years, but molecular studies have begun to unravel the complexities of this condition.[62,][63] The first breakthrough came when linkage studies localized the mutation responsible for this disease to Xq27.3, within the cytogenetically abnormal region. Within this region lies the *FMR1* gene, characterized by multiple tandem repeats of the nucleotide sequence CGG in its 5′ untranslated region. In the normal population, the number of CGG repeats is small, ranging from 6 to 55 (average, 29). The presence of clinical symptoms and a cytogenetically detectable fragile site is related to the amplification of the CGG repeats. Thus, normal transmitting males and carrier females carry 55 to 200 CGG repeats. Expansions of this size are called *premutations*. In contrast, affected

individuals have an extremely large expansion of the repeat region (200–4000 repeats, or *full mutations*). Full mutations are believed to arise by further amplification of the CGG repeats seen in premutations. How this process takes place is quite peculiar. Carrier males transmit the repeats to their progeny with small changes in repeat number. When the premutation is passed on by a carrier female, however, there is a high probability of a dramatic amplification of the CGG repeats, leading to mental retardation in most male offspring and 50% of female offspring. Thus, *it seems that during the process of oogenesis, but not spermatogenesis, premutations can be converted to mutations by triplet-repeat amplification*. This explains the unusual inheritance pattern; that is, the likelihood of mental retardation is much higher in grandsons than in brothers of transmitting males because grandsons incur the risk of inheriting a premutation from their grandfather that is amplified to a "full mutation" in their mothers' ova. By comparison, brothers of transmitting males, being "higher up" in the pedigree, are less likely to have a full mutation. These molecular details also provide a satisfactory explanation of anticipation—a phenomenon observed by clinical geneticists but not believed by molecular geneticists until triplet-repeat mutations were identified. Why only 50% of the females with the full mutation are clinically affected is not clear. Presumably in those that are clinically affected there is unfavorable lyonization (i.e., there is a higher frequency of cells in which the X chromosome carrying the mutation is active). Recent studies indicate that premutations are not so benign after all. *Approximately 30% of females carrying the premutation have premature ovarian failure (before the age of 40 years), and about one third of premutation-carrying males exhibit a progressive neurodegenerative syndrome starting in their sixth decade*. This syndrome, referred to as fragile X–associated tremor/ataxia, is characterized by intention tremors and cerebellar ataxia and may progress to parkinsonism. However, it is clear that the abnormalities in premutation carriers are milder and occur later in life.

The molecular basis of mental retardation and other somatic changes is related to a loss of function of the familial mental retardation protein (FMRP). As mentioned earlier, the normal *FMR1* gene contains up to 46 CGG repeats in its 5′ untranslated region. When the trinucleotide repeats in the *FMR1* gene exceed approximately 230, the DNA of the entire 5′ region of the gene becomes abnormally methylated. Methylation also extends upstream into the promoter region of the gene, resulting in transcriptional suppression of *FMR1*. The resulting absence of FMRP is believed to cause the phenotypic changes.

FMRP is a widely expressed cytoplasmic protein, most abundant in the brain and testis, the two organs most affected in this disease. The function of FMRP in the brain is beginning to be unraveled.[64] FMRP is an RNA-binding protein associated with polysomes. Unlike other cells, in neurons protein synthesis occurs both in the perinuclear cytoplasm and in dendritic spines. According to current understanding, FMRP is first transported from the cytoplasm to the nucleus, where it assembles into a complex containing specific mRNA transcripts. The assembled complex is then exported to the cytoplasm. From here the FMRP-mRNA complex is transported to the dendrites close to the synapse (Fig. 5-27). Not all species of mRNA are transported by FMRP to the dendrites. Only those that encode proteins that regulate synaptic function are so shuttled by FMRP. At the synaptic junctions, FMRP suppresses protein synthesis from the bound mRNAs in response to signaling through group I metabotropic glutamate receptors (mGlu-R). In fragile-X syndrome a reduction in FMRP results in increased translation of the bound mRNAs at the synaptic junctions. Such imbalance in turn causes permanent changes in synaptic activity and ultimately mental retardation.

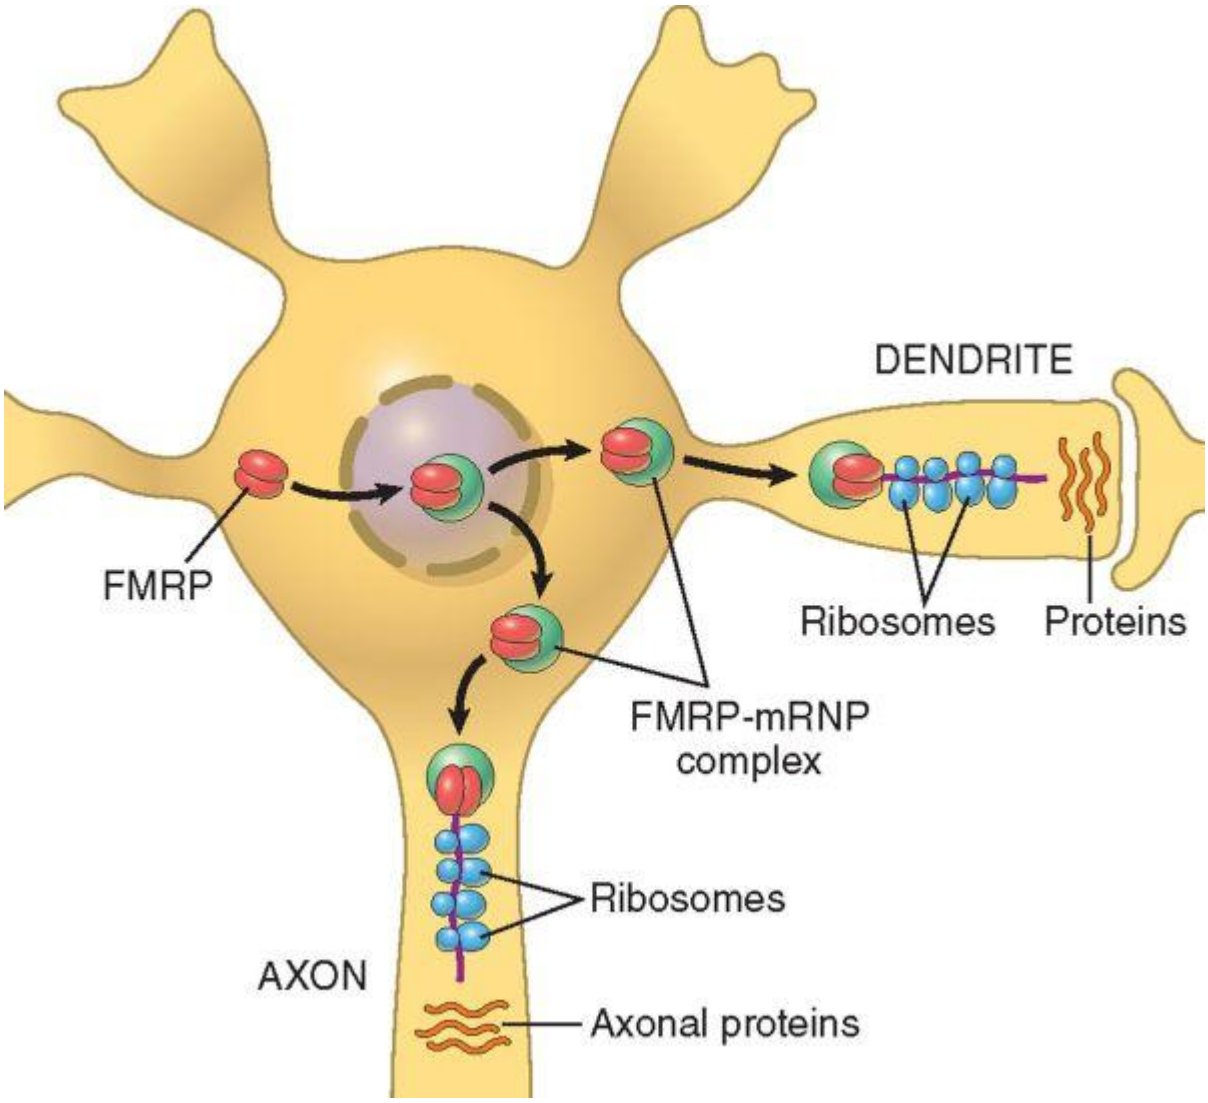

FIGURE 5-27 A model for the action of familial mental retardation protein (FMRP) in neurons. *(Adapted from Hin P, Warren ST: New insights into fragile X syndrome: from molecules to neurobehavior. Trends Biochem Sci 28:152, 2003.)*

Although demonstration of an abnormal karyotype led to the identification of this disorder, PCR-based detection of the repeats is now the method of choice for diagnosis. With Southern blot analysis, distinction between premutations and mutations can be made prenatally as well as postnatally. Hence, this technique is valuable not only for establishing the diagnosis, but also for guiding genetic counseling. These techniques are described later.

MUTATIONS IN MITOCHONDRIAL GENES—LEBER HEREDITARY OPTIC NEUROPATHY

The vast majority of genes are located on chromosomes in the cell nucleus and are inherited in classical Mendelian fashion. There exist several mitochondrial genes, however, that are inherited in quite a different manner. *A feature unique to mtDNA is maternal inheritance*. This peculiarity exists because ova contain numerous mitochondria within their abundant cytoplasm, whereas spermatozoa contain few, if any. Hence, the mtDNA complement of the zygote is derived entirely from the ovum. Thus, mothers

transmit mtDNA to all their offspring, male and female; however, daughters but not sons transmit the DNA further to their progeny (Fig. 5-28). Several other features apply to mitochondrial inheritance.[65,][66] They are as follows:

- Human mtDNA contains 37 genes, of which 22 are transcribed into transfer RNAs and two into ribosomal RNAs. The remaining 13 genes encode subunits of the respiratory chain enzymes. Because mtDNA encodes enzymes involved in oxidative phosphorylation, mutations affecting these genes exert their deleterious effects primarily on the organs most dependent on oxidative phosphorylation such as the central nervous system, skeletal muscle, cardiac muscle, liver, and kidneys.
- Each mitochondrion contains thousands of copies of mtDNA, and, typically, deleterious mutations of mtDNA affect some but not all of these copies. Thus, tissues and, indeed, whole individuals may harbor both wild-type and mutant mtDNA, a situation called *heteroplasmy*. It should be evident that a minimum number of mutant mtDNA must be present in a cell or tissue before oxidative dysfunction gives rise to disease. This is called the “threshold effect.” Not surprisingly, the threshold is reached most easily in the metabolically active tissues listed earlier.[67]
- During cell division, mitochondria and their contained DNA are randomly distributed to the daughter cells. Thus, when a cell containing normal and mutant mtDNA divides, the proportion of the normal and mutant mtDNA in daughter cells is extremely variable. Therefore, the expression of disorders resulting from mutations in mtDNA is quite variable.

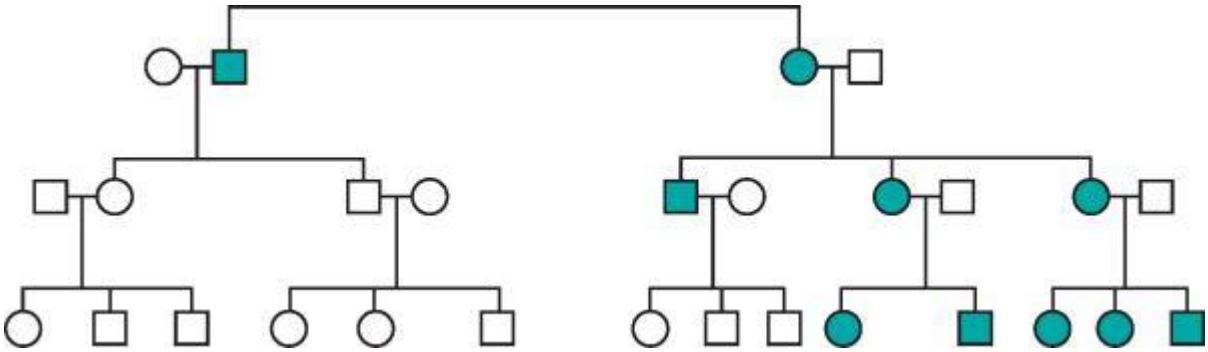

FIGURE 5-28 Pedigree of Leber hereditary optic neuropathy, a disorder caused by mutation in mitochondrial DNA. Note that all progeny of an affected male (shaded squares) are normal, but all children, male and female, of the affected female (shaded circles) manifest disease.

Diseases associated with mitochondrial inheritance are rare and, as mentioned earlier, many of them affect the neuromuscular system. *Leber hereditary optic neuropathy* is a prototype of this type of disorder. It is a neurodegenerative disease that manifests as a progressive bilateral loss of central vision. Visual impairment is first noted between ages 15 and 35, and it leads eventually to blindness. Cardiac conduction defects and minor neurologic manifestations have also been observed in some families.[68]

GENOMIC IMPRINTING

We all inherit two copies of each autosomal gene, carried on homologous maternal and paternal chromosomes. In the past, it had been assumed that there is no functional difference between the alleles derived from the mother or the father. Studies over the past two decades have provided definite evidence that, at least with respect to some genes, important functional differences exist between the paternal allele and the maternal allele. These differences result from an epigenetic process (discussed later), called *imprinting*. In most cases, *imprinting selectively inactivates either the maternal or paternal allele*. Thus, *maternal imprinting* refers to transcriptional silencing of the maternal allele, whereas *paternal imprinting* implies that the paternal allele is inactivated. Imprinting occurs in the ovum or the sperm, before fertilization, and then is stably transmitted to all somatic cells through mitosis.[69] As with

other instances of epigenetic regulation, imprinting is associated with differential patterns of DNA methylation at CG nucleotides. Other mechanisms include histone H4 deacetylation and methylation. Regardless of the mechanism, it is believed that such marking of paternal and maternal chromosomes occurs during gametogenesis, and thus it seems that from the moment of conception some chromosomes remember where they came from. The exact number of imprinted genes is not known; estimates range from 200 to 600. Although imprinted genes may occur in isolation, more commonly they are found in groups that are regulated by common *cis*-acting elements called imprinting control regions. As is often the case in medicine, genomic imprinting is best illustrated by considering two uncommon genetic disorders: Prader-Willi syndrome and Angelman syndrome.

Prader-Willi Syndrome and Angelman Syndrome

Prader-Willi syndrome is characterized by mental retardation, short stature, hypotonia, profound hyperphagia, obesity, small hands and feet, and hypogonadism.[70] In 65% to 70% of cases, an interstitial deletion of band q12 in the long arm of chromosome 15, del(15)(q11.2q13), can be detected. In most cases the breakpoints are the same, causing a 5-Mb deletion. *It is striking that in all cases the deletion affects the paternally derived chromosome 15*. In contrast with the Prader-Willi syndrome, patients with the phenotypically distinct Angelman syndrome are *born with a deletion of the same chromosomal region derived from their mothers*. Patients with Angelman syndrome are also mentally retarded, but in addition they present with ataxic gait, seizures, and inappropriate laughter. Because of their laughter and ataxia they have been referred to as "happy puppets."[71] A comparison of these two syndromes clearly demonstrates the *parent-of-origin* effects on gene function.

The molecular basis of these two syndromes lies in the genomic imprinting (Fig. 5-29). It is known that a gene or set of genes on maternal chromosome 15q12 is imprinted (and hence silenced), and thus the only functional allele(s) are provided by the paternal chromosome. When these are lost as a result of a deletion, the person develops Prader-Willi syndrome. Conversely, a distinct gene that also maps to the same region of chromosome 15 is imprinted on the paternal chromosome. Only the maternally derived allele of this gene is normally active. Deletion of this maternal gene on chromosome 15 gives rise to the Angelman syndrome. Molecular studies of cytogenetically normal patients with the Prader-Willi syndrome (i.e., those without the deletion) have revealed that they have two maternal copies of chromosome 15. Inheritance of both chromosomes of a pair from one parent is called *uniparental disomy*. The net effect is the same (i.e., the person does not have a functional set of genes from the [nonimprinted] paternal chromosomes 15). Angelman syndrome, as might be expected, can also result from uniparental disomy of paternal chromosome 15.

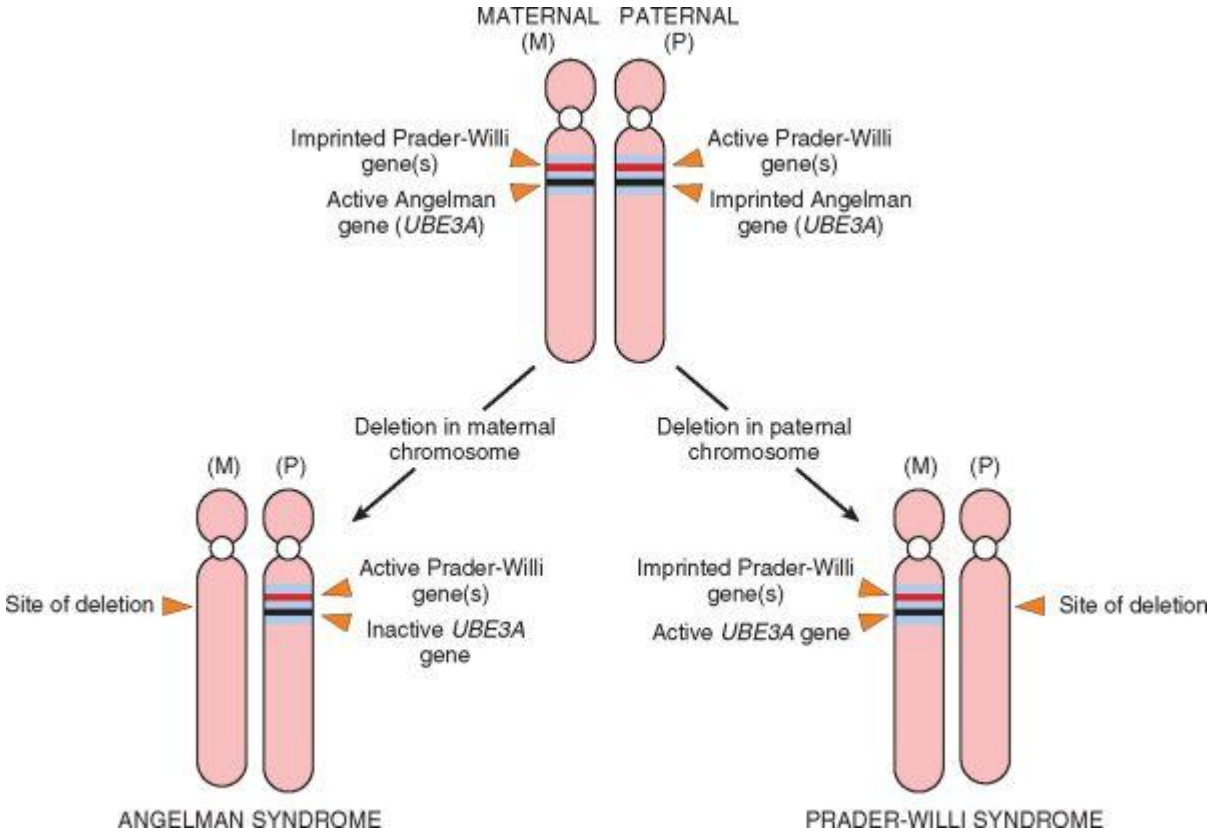

FIGURE 5-29 Diagrammatic representation of Prader-Willi and Angelman syndromes.

The genetic basis of these two imprinting disorders is now being unraveled. In the Angelman syndrome, the affected gene is a ubiquitin ligase that is involved in catalyzing the transfer of activated ubiquitin to target protein substrates. The gene, called *UBE3A*, maps within the 15q12 region, is imprinted on the paternal chromosome, and is expressed from the maternal allele primarily in specific regions of the brain.[72] The imprinting is tissue-specific in that *UBE3A* is expressed from both alleles in most tissues. In approximately 10% of cases, Angelman syndrome occurs not as a result of imprinting but of a point mutation in the maternal allele, thus establishing a firm link between the *UBE3A* gene and Angelman syndrome. In contrast to Angelman syndrome, no single gene has been implicated in Prader-Willi syndrome. Instead, a series of genes located in the 15q11.2–q13 interval (which are imprinted on the maternal chromosome and expressed from the paternal chromosome) are believed to be involved. These include a gene that encodes small nuclear riboprotein N, which controls gene splicing and is expressed highly in the brain and heart. Loss of small nuclear riboprotein N function is believed to contribute to Prader-Willi syndrome. Molecular diagnosis (see later) of these syndromes is based on assessment of methylation status of marker genes and FISH.

The importance of imprinting is not restricted to rare chromosomal disorders. Parent-of-origin effects have been identified in a variety of inherited diseases, such as Huntington disease and myotonic dystrophy and in tumorigenesis.

GONADAL MOSAICISM

It was mentioned earlier that with every autosomal dominant disorder some patients do not have affected parents. In such patients the disorder results from a new mutation in the egg or the sperm from which they were derived; as such, their siblings are neither affected nor at increased risk of developing the disease. This is not always the case, however. In some autosomal dominant disorders, exemplified by osteogenesis imperfecta, phenotypically normal parents have more than one affected child. This clearly violates the laws of mendelian inheritance. Studies indicate that gonadal mosaicism may be responsible for such unusual pedigrees.[73] Gonadal mosaicism results from a mutation that occurs postzygotically during early (embryonic) development. If the mutation affects only cells destined to form the gonads, the gametes carry the mutation, but the somatic cells of the individual are completely normal. Such an individual is said to exhibit *germ line* or *gonadal mosaicism*. A phenotypically normal parent who has germ line mosaicism can transmit the disease-causing mutation to the offspring through the mutant gamete. Because the progenitor cells of the gametes carry the mutation, there is a definite possibility that more than one child of such a parent would be affected. Obviously the likelihood of such an occurrence depends on the proportion of germ cells carrying the mutation.

2.5.7 Molecular Diagnosis of Genetic Diseases

Medical applications of recombinant DNA technology have come of age. With the completion of the Human Genome Project, DNA-based analysis has become a powerful tool for the diagnosis of human disease, both genetic and acquired. Molecular diagnostic techniques have found application in virtually all areas of medicine. In the era predating the ready availability of molecular diagnostic assays, assays for single-gene ("mendelian") disorders depended on the identification of abnormal gene products (e.g., mutant hemoglobin or abnormal metabolites) or their clinical effects, such as mental retardation (e.g., in phenylketonuria). Now, it is possible to identify mutations at the DNA level and offer diagnostic tests for an increasing number of genetic disorders. In addition, molecular tools have become extremely important in discovery of the genetic basis of common complex disorders such as diabetes mellitus, atherosclerosis, and cancer. The molecular diagnosis of inherited diseases at the nucleic acid level has distinct advantages over other surrogate techniques:

- Molecular assays are remarkably sensitive. For example, the use of PCR allows several million-fold amplification of DNA or RNA, making it possible to use as few as 1 or 100 cells for analysis. 0.1µl of blood or cells scraped from buccal mucosa can supply sufficient DNA for PCR amplification.
- DNA-based tests are not dependent on a gene product that may be produced only in certain specialized cells (e.g., brain) or expression of a gene that may occur late in life. Because the defective gene responsible for inherited genetic disorders is present in germ line samples, every postzygotic cell carries the mutation.

INDICATIONS FOR ANALYSIS OF GERM LINE GENETIC ALTERATIONS

While many techniques are available today for the diagnosis of genetic diseases, to judiciously use these methods it is important to ascertain which individuals require genetic testing. In general, testing for alterations inherited in the germ line can be divided into prenatal and postnatal analysis. It may involve conventional cytogenetics, fluorescent in situ hybridization (FISH), other molecular diagnostic assays, or a combination of these techniques.

Prenatal genetic analysis should be offered to all patients who are at risk of having cytogenetically abnormal progeny. It can be performed on cells obtained by amniocentesis, on chorionic villus biopsy material, or on umbilical cord blood. Some important indications are as follows[74]:

- A mother of advanced age (>35 years) because of greater risk of trisomies
- A parent who is a carrier of a balanced reciprocal translocation, robertsonian translocation, or inversion (in these cases the gametes may be unbalanced, and hence the progeny would be at risk for chromosomal disorders)

- A parent with a previous child with a chromosomal abnormality
- A fetus with ultrasound-detected abnormalities
- A parent who is a carrier of an X-linked genetic disorder (to determine fetal sex)
- Abnormal levels of AFP, βHCG, and estriol performed as the triple test.

Postnatal genetic analysis is usually performed on peripheral blood lymphocytes. Indications are as follows:

- Multiple congenital anomalies
- Unexplained mental retardation and/or developmental delay
- Suspected aneuploidy (e.g., features of Down syndrome)
- Suspected unbalanced autosome (e.g., Prader-Willi syndrome)
- Suspected sex chromosomal abnormality (e.g., Turner syndrome)
- Suspected fragile-X syndrome
- Infertility (to rule out sex chromosomal abnormality)
- Multiple spontaneous abortions (to rule out the parents as carriers of balanced translocation; both partners should be evaluated)

INDICATIONS FOR ANALYSIS OF ACQUIRED GENETIC ALTERATIONS

In this era of molecularly targeted therapies it is becoming increasingly important to identify specific molecular genetic signatures for acquired diseases (i.e., cancer and infectious disease), which were formerly diagnosed and managed with nonmolecular clinicopathologic data. The technical approaches are the same as those used for germ line mendelian disorders, and the common indications include:

Diagnosis and management of cancer (see also Chapter 7)

- Detection of tumor-specific acquired mutations and cytogenetic alterations that are the hallmarks of specific tumors (e.g., *BCR-ABL1* in chronic myeloid leukemia or CML)
- Determination of clonality as an indicator of a neoplastic (i.e., nonreactive) condition
- The identification of specific genetic alterations that can direct therapeutic choices (e.g., *HER2/Neu* [official name *ERBB2*] in breast cancer or *EGFR* mutations in lung cancer)
- Determination of treatment efficacy (e.g., minimal residual disease detection of BCR-ABL1 by PCR in CML)
- Detection of Gleevec-resistant forms of chronic myeloid leukemia and gastrointestinal stromal tumors

Diagnosis and management of infectious disease (see also Chapter 8)

- Detection of microorganism-specific genetic material for definitive diagnosis (e.g., HIV, mycobacteria, human papillomavirus, herpesvirus in central nervous system)
- The identification of specific genetic alterations in the genomes of microbes that are associated with drug resistance
- Determination of treatment efficacy (e.g., assessment of viral loads in HIV and hepatitis C virus infection)

PCR AND DETECTION OF DNA SEQUENCE ALTERATIONS

PCR analysis, which involves exponential amplification of DNA, has revolutionized molecular biology and is now widely used in the molecular diagnosis of human disease. By using appropriate DNA polymerases and thermal cycling, the target DNA is greatly amplified, producing millions of copies of the DNA sequence between the two primer sites. The subsequent identification of an abnormal

sequence can then be performed using an ever-increasing number of assays. Direct sequence analysis of PCR products is currently the most straightforward method.

Direct Detection of DNA Sequence Alterations by DNA Sequencing

DNA can be sequenced to obtain a readout of the order of nucleotides, and by comparison with a normal (wild-type) sequence, mutations can be identified. The ready availability of Sanger di-deoxynucleotide sequencing and automated capillary electrophoresis allows thousands of base pairs of genomic DNA to be routinely sequenced in a matter of hours.[75] The genes mutated in hundreds of mendelian disorders have been identified, and definitive diagnosis is possible by direct sequencing in most of them. Some disorders, most with recessive inheritance, are associated with a limited number of recurrent mutations, such as cystic fibrosis. Many others, especially those with dominant inheritance, can have mutations throughout the gene-coding region. Challenges to sole use of gene sequencing for the diagnosis of such diseases include the difficulty and high cost of analyzing large genes. For example, the gene associated with Duchenne muscular dystrophy possesses 79 exons, and the *FBN1* gene mutated in Marfan syndrome possesses 65 exons; the sequencing of these genes in their entirety can be prohibitively expensive with current methodologies. Among other difficulties, it is not uncommon to detect sequence alterations of unknown significance, which cannot be definitively determined to be pathogenic in the absence of any functional data.

However, this picture is changing with remarkable speed. Rapidly advancing technology will make large-scale germ line sequencing applications feasible and may lead in the not distant future to the routine sequencing of entire individual human genomes. One high-throughput technology uses gene chips (microarrays) to sequence genes or portions of genes.[76] Short sequences of DNA (oligonucleotides) that are complementary to the wild-type sequence and to known mutations are "tiled" adjacent to each other on the gene chip, and the DNA sample to be tested is hybridized to the array (Fig. 5-30). Before hybridization the sample is labeled with fluorescent dyes. The hybridization (and consequently, the fluorescent signal emitted) will be strongest at the oligonucleotide that is complementary to wild-type sequence if no mutations are present, while the presence of a mutation will cause hybridization to occur at the complementary mutant oligonucleotide. Computerized algorithms can then rapidly "decode" the DNA sequence for hundreds of thousands of base pairs of sequence from the fluorescent hybridization pattern on the chip, and identify potential mutations. Perhaps the most exciting recent advance is technology termed "next-generation" sequencing, which involves PCR performed in an oil emulsion that allows over one million individual PCR reactions at once.[77] While at present very costly, over one billion nucleotides (one third of the human genome!) can be sequenced per run. Bioinformatics challenges of handling and interpreting such massive amounts of data are currently staggering, and much effort is devoted to such analysis.

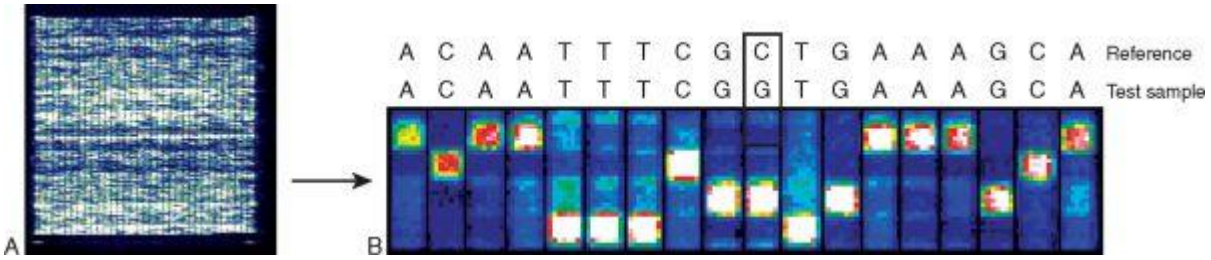

FIGURE 5-30 Microarray-based DNA sequencing. **A**, A low-power digitized scan of a "gene chip" that is no larger than a nickel in size but is capable of sequencing thousands of base pairs of DNA. High-throughput microarrays have been used for sequencing whole organisms (such as viruses), organelles (such as mitochondria), and entire human chromosomes. **B**, A high-resolution view of the gene chip illustrates hybridization patterns corresponding to a stretch of DNA sequence. Typically, a computerized algorithm is available that can convert the individual hybridization patterns across the entire chip into actual sequence data within a matter of minutes ("conventional" sequencing technologies would require days to weeks for such analysis). Here, the upper sequence is the reference (wild-type) sequence, while the lower

one corresponds to the test sample sequence. As shown, the computerized algorithm has identified a C→G mutation in the test sample. *(Adapted from Maitra A et al.: The Human MitoChip: a high-throughput sequencing microarray for the mitochondrial mutation detection. Genome Res 14:812, 2004.)*

Detection of DNA Mutations by Indirect Methods

There are a large number of molecular techniques that detect DNA mutations without direct sequencing. Their development is driven by lower costs and higher throughput.

- One simple approach takes advantage of the digestion of DNA with enzymes known as restriction enzymes that recognize, and then cut, DNA at specific sequences. If the specific mutation is known to affect a restriction site, then the amplified DNA can be digested. Because the mutation affects a restriction site, the mutant and normal alleles give rise to PCR products of different sizes. These would appear as different bands on agarose gel electrophoresis. Needless to say, this approach is considerably less comprehensive than direct sequencing but remains useful for molecular diagnosis when the causal mutation always occurs at an invariant nucleotide position.
- Another approach for identifying mutations at a specific nucleotide position (say, a codon 12 mutation in the *KRAS* oncogene that converts glycine [GGT] to aspartic acid [GAT]) would be to add fluorescently labeled nucleotides C and T to the PCR mixture, which are complementary to either the wild-type (G) or mutant (A) sequence, respectively. Since these two nucleotides are labeled with different fluorophores, the fluorescence emitted by the resulting PCR product can be of one or another color, depending on whether a "C" or a "T" becomes incorporated in the process of primer extension (Fig. 5-31). The advantage of this "allele-specific extension" strategy is that it can detect the presence of mutant DNA even in heterogeneous mixtures of normal and abnormal cells (for example, in clinical specimens obtained from individuals with a suspected malignancy).
- A variety of PCR-based technologies that use fluorophore indicators can detect the presence or absence of mutations in "real time" (i.e., during the exponential phase of DNA amplification). This has significantly reduced the time required for mutation detection by removing the restriction digestion and electrophoresis steps used in conventional PCR assays.
- Mutations that affect the length of DNA (e.g., deletions or expansions) can also be detected by PCR analysis. As discussed earlier, several diseases, such as the fragile-X syndrome, are associated with trinucleotide repeats. Figure 5-32 reveals how PCR analysis can be used to detect this mutation. Two primers that flank the region affected by trinucleotide repeats at the 5′ end of the *FMR1* gene are used to amplify the intervening sequences. Because there are large differences in the number of repeats, the size of the PCR products obtained from the DNA of normal individuals, or those with premutation, is quite different. These size differences are revealed by differential migration of the amplified DNA products on a gel. At this point the full mutation cannot be detected by PCR analysis, because the affected segment of DNA is too large for conventional PCR. In such cases, a Southern blot analysis of genomic DNA must be performed (see "Southern Blotting").

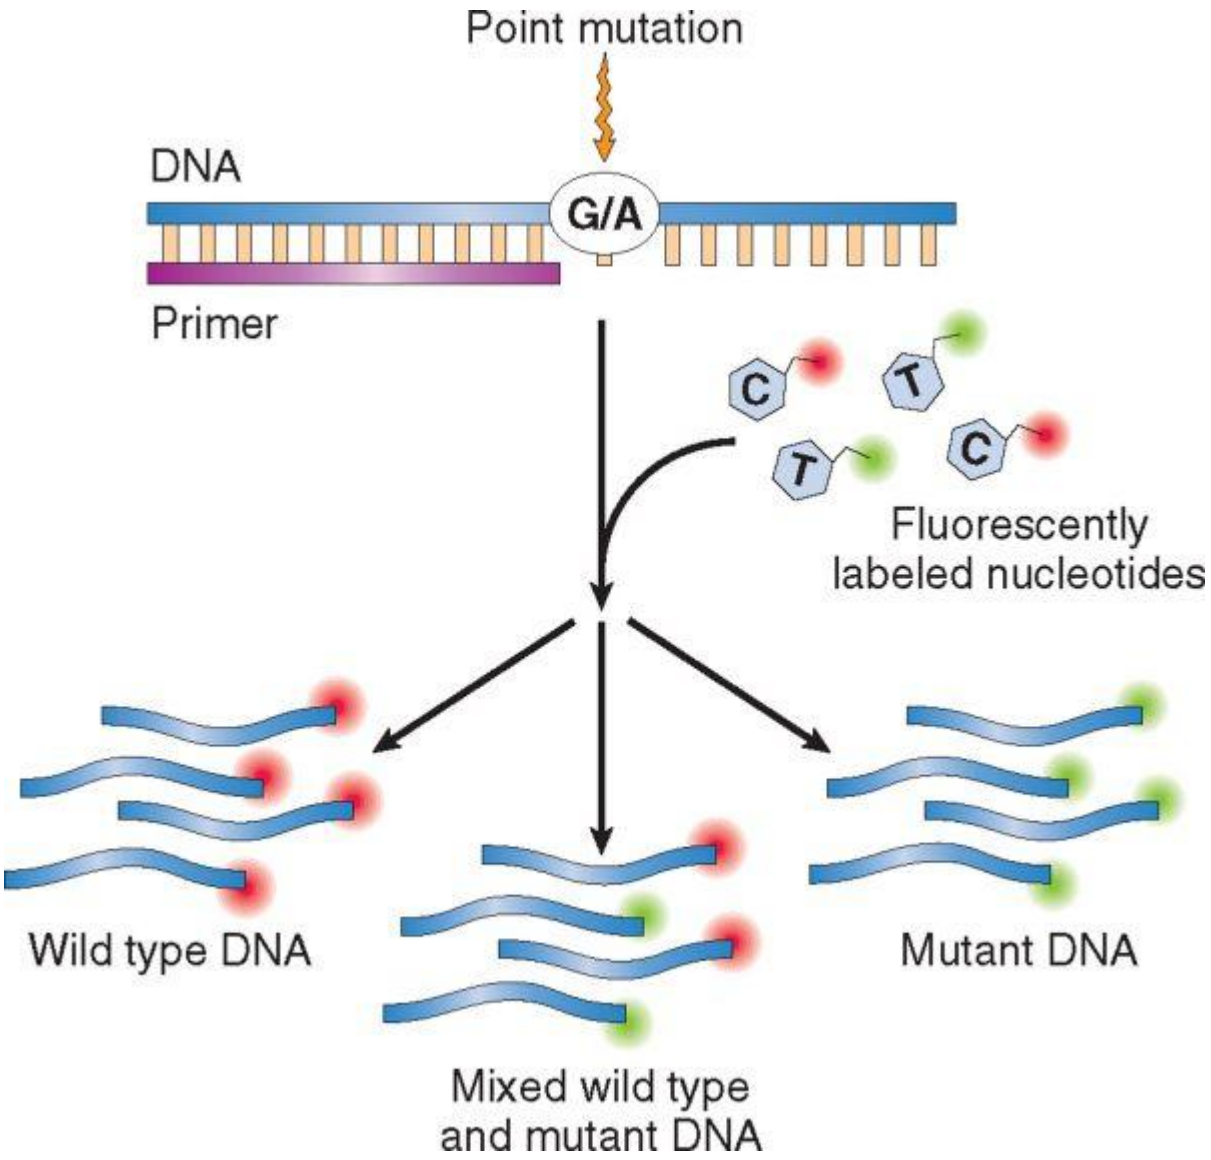

FIGURE 5-31 Allele-specific PCR for mutation detection in a heterogeneous sample containing an admixture of normal and mutant DNA. Nucleotides complementary to the mutant and wild-type nucleotides at the queried base position are labeled with different fluorophores, such that incorporation into the resulting PCR product yields fluorescent signals of varying intensity based on the ratio of mutant to wild-type DNA present.

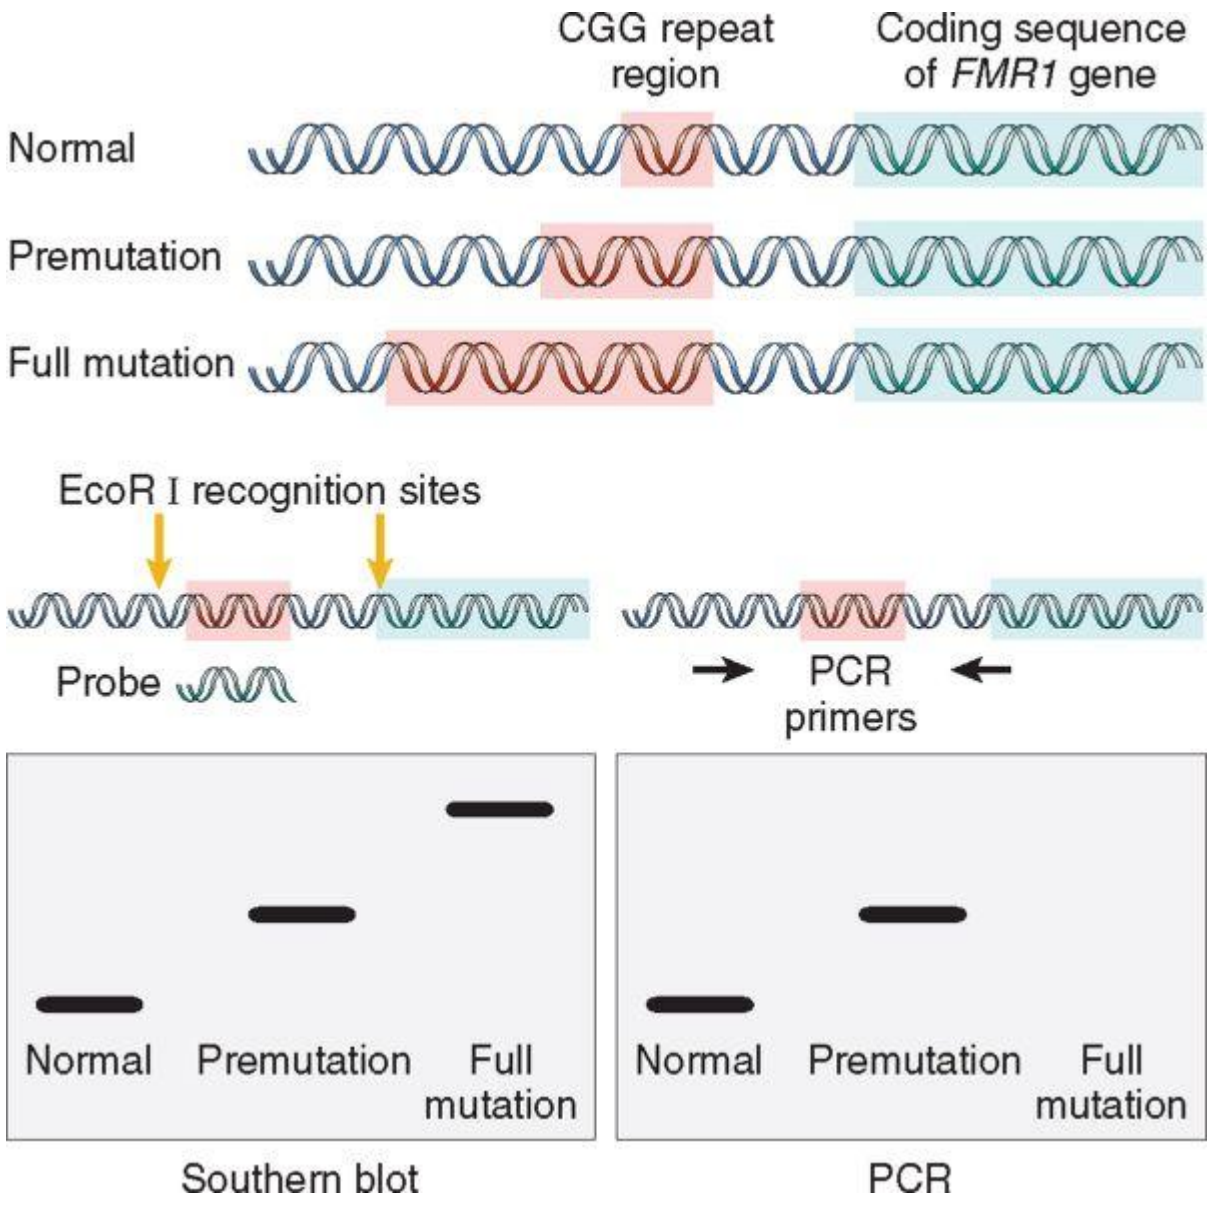

FIGURE 5-32 Diagnostic application of PCR and Southern blot analysis in fragile-X syndrome. With PCR the differences in the size of CGG repeats between normal and premutation give rise to products of different sizes and mobility. With a full mutation, the region between the primers is too large to be amplified by conventional PCR. In Southern blot analysis the DNA is cut by enzymes that flank the CGG repeat region, and is then probed with a complementary DNA that binds to the affected part of the gene. A single small band is seen in normal males, a band of higher molecular weight in males with premutation, and a very large (usually diffuse) band in those with the full mutation.

POLYMORPHIC MARKERS AND MOLECULAR DIAGNOSIS

Detection of mutations by the methods outlined above is possible only if the gene responsible for a genetic disorder is known and its sequence has been identified. In some diseases that have a genetic basis such approaches are not possible, either because the causal gene has not been identified or because the disease is multifactorial and no single gene is involved. In such cases, surrogate markers in the genome, also known as marker loci, can be used to localize the chromosomal regions of interest, on the basis of their linkage to one or more putative disease-causing genes. *Linkage analysis* deals with assessing these marker loci in family members having the disease or trait of interest, with the assumption that marker loci very close to the disease allele are transmitted through pedigrees (linkage

disequilibrium). With time it becomes possible to define a "disease haplotype" based on a panel of marker loci, all of which co-segregate with the putative disease allele. Eventually, linkage analysis facilitates localization and cloning of the disease allele. The marker loci used in linkage studies are naturally occurring variations in DNA sequences known as *polymorphisms*. Two types of genetic polymorphism are most useful for linkage analysis. They are SNPs (including small insertion-deletion polymorphisms) and repeat-length polymorphisms known as minisatellite and microsatellite repeats. Each of the two types is described next.

SNPs occur at a frequency of approximately one nucleotide in every stretch of approximately 1000 base pairs and are found throughout the genome (e.g., in exons and introns and in regulatory sequences). They serve both as a physical landmark within the genome and as a genetic marker whose transmission can be followed from parent to child. Because of their prevalence throughout the genome and relative stability, SNPs can be used in linkage analysis for identifying haplotypes associated with disease.

Human DNA contains short repetitive sequences of DNA giving rise to what are called *repeat-length polymorphisms*. These polymorphisms are often subdivided on the basis of their length into microsatellite repeats and minisatellite repeats. Microsatellites are usually less than 1 kilobase and are characterized by a repeat size of 2 to 6 base pairs. Minisatellite repeats, by comparison, are larger (1–3 kilobases), and the repeat motif is usually 15 to 70 base pairs. It is important to note that the number of repeats, both in microsatellites and minisatellites, is extremely variable within a given population, and hence these stretches of DNA can be used quite effectively to establish genetic identity for linkage analysis. Microsatellites and the smaller minisatellites can be readily distinguished by utilizing PCR primers that flank the repeat region (Fig. 5-33A). Note that in the example given in Figure 5-33 , three different alleles generate PCR products of different lengths (hence the name "length polymorphism").

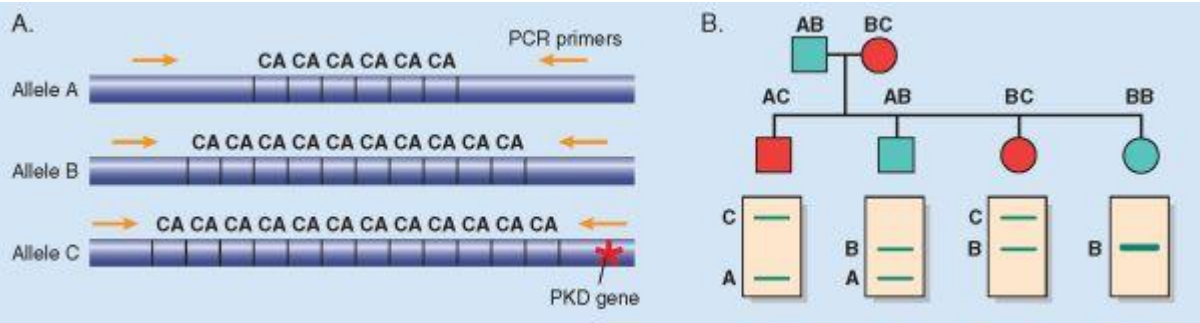

FIGURE 5-33 DNA polymorphisms resulting from a variable number of CA repeats. The three alleles produce PCR products of different sizes, thus identifying their origins from specific chromosomes. In the example depicted, allele C is linked to a mutation responsible for autosomal-dominant polycystic kidney disease (PKD). Application of this to detect progeny carrying the disease-related gene (red symbols) is illustrated in one hypothetical pedigree. Males (squares); females (circles).

Linkage analysis can be been useful in the antenatal or presymptomatic diagnosis of disorders such as Huntington disease and autosomal dominant polycystic kidney disease, even though the disease-associated gene is known in each of these conditions. In general, when the disease-associated gene is known, detection of the causative mutation by direct sequencing is the method of choice. However, if the disease originates from several different mutations in a given gene (e.g., *fibrillin-1*; see earlier), and gene sequencing is either not practical or negative but there is very strong clinical suspicion, linkage analysis can be useful. Figure 5-33B illustrates how microsatellite polymorphisms can be used to track the inheritance of autosomal-dominant polycystic kidney disease. In this case allele C, which produces a

larger PCR product than allele A or B, carries the disease-related gene. Hence all individuals who carry the C allele are affected.

Assays to detect genetic polymorphisms are also important in many other areas of medicine, including in the determination of relatedness and identity in transplantation, cancer genetics, paternity testing, and forensic medicine. Since microsatellite markers are scattered throughout the human genome and have such a high level of polymorphism, they are ideal for differentiating two individuals and to follow transmission of the marker from parent to child. Panels of microsatellite marker PCR assays have been extensively validated and are now routinely used for determining paternity and for criminal investigations. Since PCR can be performed even with highly degraded biologic samples, DNA technology is critical in forensic identifications. The same assays have been applied to the detection and quantification of transplant chimerism in allogeneic bone marrow transplants.

Polymorphisms and Genome-Wide Analyses

As described earlier, linkage analysis utilizing DNA of affected families has been used to detect the presence of genes with large effects and high penetrance, the kind that give rise to Mendelian diseases. Similar analyses of complex (multifactorial) disorders, however, have been unsuccessful since conventional linkage studies lack the statistical power to detect variants with small effects and low penetrance, which are typical of the genes that contribute to complex disorders.

These limitations appear to have been overcome through genome-wide association studies (GWAS), a powerful method of identifying genetic variants that are associated with an increased risk of developing a particular disease.[78] Such variants may themselves be causative, or may be in *linkage disequilibrium* with other genetic variants that are responsible for the increased risk. In GWAS large cohorts of patients with and without a disease (rather than families) are examined across the entire genome for genetic variants or polymorphisms that are over-represented in patients with the disease. This identifies regions of the genome that contain a variant gene or genes that confer disease susceptibility. The causal variant within the region is then provisionally identified using a "candidate gene" approach, in which genes are selected based on how tightly they are associated with the disease and whether their biologic function seems likely to be involved in the disease under study. For example, a variant in a gene whose product regulates vascular smooth muscle tone (e.g., angiotensinogen) is a strong candidate to influence the risk of hypertension. As might be imagined, however, some linked genes would not have been expected to be associated with particular diseases based on prior knowledge; such surprises are one of the benefits of the unbiased, systematic nature of GWAS.

GWAS have been enabled by two major technological breakthroughs. First is the completion of the so-called "HapMap" project, which has provided more complete linkage disequilibrium patterns in three major ethno-racial groups, based on genome-wide single nucleotide polymorphism (SNP) mapping. The entire human genome can now be divided into blocks known as "haplotypes," which contain varying numbers of contiguous SNPs on the same chromosome that are in linkage disequilibrium and hence inherited together as a cluster. As a result, rather than querying every single SNP in the human genome, it is possible to glean comparable information about shared DNA by simply looking for shared haplotypes, using single or a small number of SNPs that "tag" or identify a specific haplotype. Second, it is now possible to simultaneously genotype hundreds of thousands to a million SNPs at one time, in a cost-effective way, using high-density SNP-chip technology. Figure 5-34 demonstrates how information from the publicly available "HapMap" is utilized to manufacture SNP chips that can query genome-wide haplotypes in an unbiased manner. Thereafter, DNA from a cohort of individuals with a defined trait (say, hypertension) is analyzed using SNP chips for haplotypes that are overrepresented compared to individuals without the trait (i.e., in controls). This is followed by the "candidate gene" approach

described above to further localize the causal gene (and in some instances, the functional polymorphism within that gene), associated with the trait.

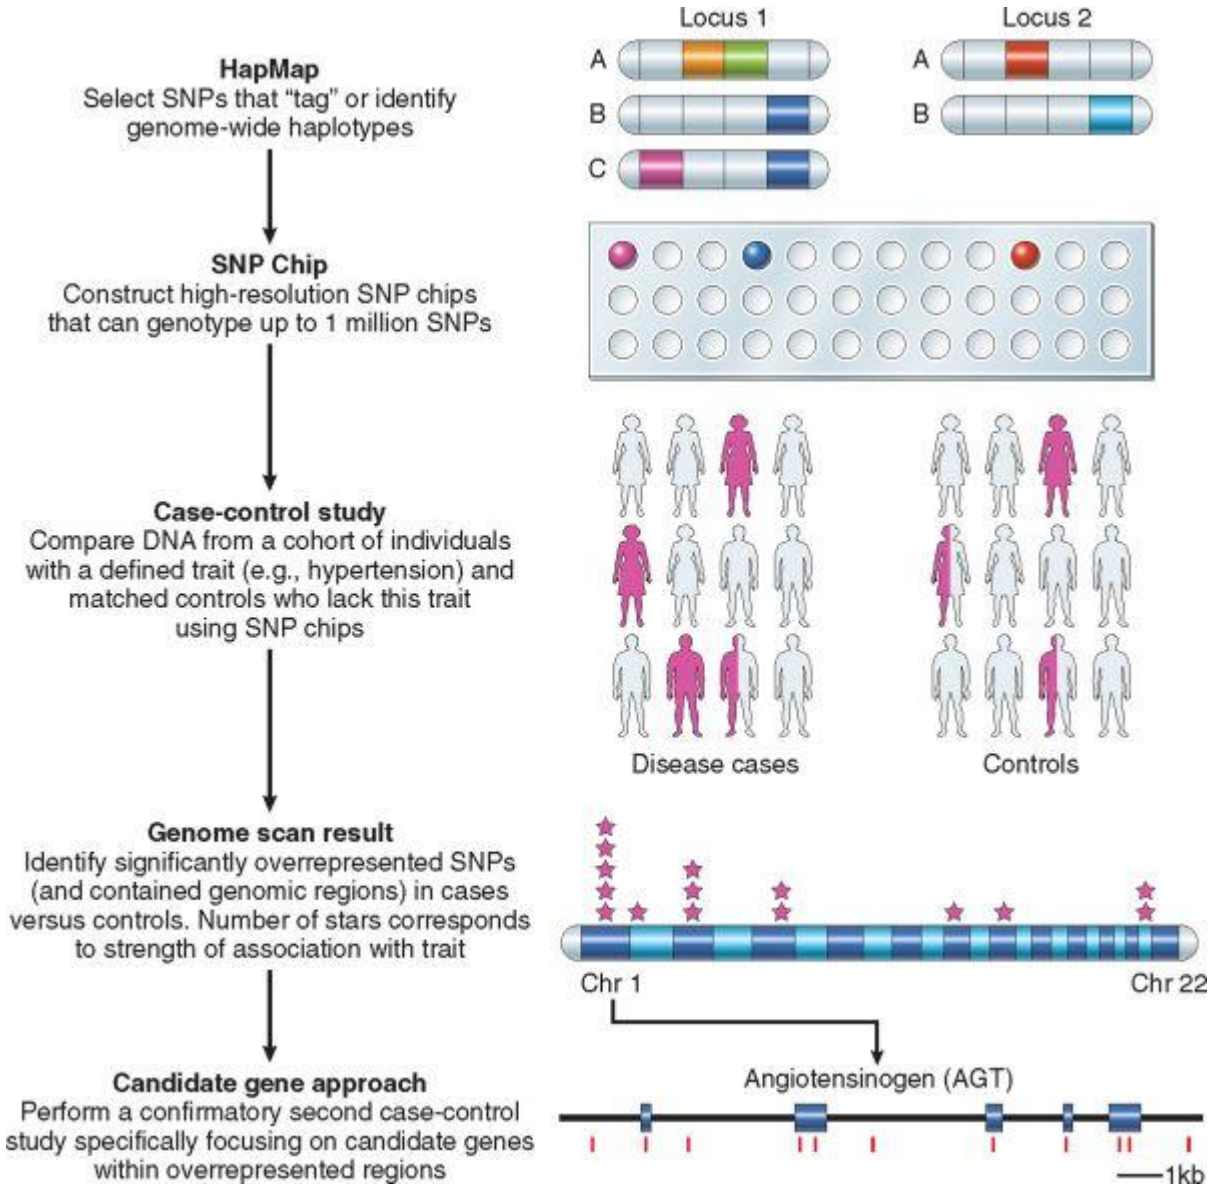

FIGURE 5-34 General scheme for conducting a genome wide association study (GWAS). Using the publicly available "HapMap" data, the human genome is divided into "haplotypes" or regions of contiguous DNA inherited as a block, each identified by one or a few "tag" SNPs that identify the haplotype. In the example shown, locus 1 contains three haplotypes defined by different combinations of SNPs, where white signifies the more common "normal" sequence and each color designates a different SNP; thus, these haplotypes can be distinguished by assaying for only the blue and purple "tag" SNPs. Thereafter, high density SNP chips are constructed that contain these "tag" SNPs, in order to enable an unbiased genome-wide assessment of shared haplotypes between disease and control populations. Of note, "disease" refers to any defined phenotype, and could pertain to an actual disease entity like hypertension, or simply a quantitative trait like hair or eye color. Next, DNA obtained from the two cohorts is analyzed for overrepresented SNPs in the disease population ("cases") *versus* the control samples—this is known as a case-control study. The most significant shared genomic regions of interest are then examined for candidate genes of interest—an example shown here in a search for loci associated with hypertension is *angiotensinogen*, a gene on chromosome 1 whose product regulates vascular smooth muscle tone. The final step is to perform a second case control study, this time using SNPs located within the gene of interest in order to confirm or refute the association with the trait, often in an independent population from the one in which the initial GWAS was conducted. In this example, individual SNPs within angiotensinogen gene are denoted as red vertical bars, and these SNPs will be tested in the second round of case-control study. *(Modified from Mathew CG: New links to the pathogenesis of Crohn disease provided by genome-wide association scans. Nat Rev Genet 9(1):9–14, 2008.)*

In addition to shedding light on some of the most frequent human ailments such as diabetes, hypertension, coronary artery disease, schizophrenia and other mental disorders, and asthma, GWAS have also led to the identification of genetic loci that modulate common quantitative traits in humans, such as height, body mass, hair and eye color, and bone density. An updated catalog of published GWAS is maintained by the National Human Genome Research Institute (www.genome.gov), with the list currently at >200 studies and growing. The power of GWAS is underscored by the fact that within a very short time, nearly a dozen genes that confer risk for type 2 diabetes have been identified, of which one in particular, *TCF7L2*, has emerged as a strong candidate gene (see Chapter 24 for a detailed discussion).

With the incrementally lowered costs for genotyping individual patients for SNPs that might render them “at-risk” for a variety of multifactorial disease over their lifetime, there is emerging concern in the biomedical community that such information would be utilized for discrimination in the workplace or by healthcare agencies. In the United States, a law was passed in 2008 that explicitly prohibits discrimination based on an individual's genetic makeup.

MOLECULAR ANALYSIS OF GENOMIC ALTERATIONS

A significant number of genetic lesions involve large deletions, duplications, or more complex rearrangements that are not easily assayed using PCR methods or sequence analysis. Such “genomic” alterations can be studied using a variety of hybridization-based techniques.

Southern Blotting

Changes in the structure of specific loci can be detected by Southern blotting, which involves hybridization of radiolabeled sequence-specific probes to genomic DNA that has been first digested with a restriction enzyme and separated by gel electrophoresis. The probe usually detects one germ line band in normal individuals. Importantly, a normal DNA sample is required to compare the pattern of the DNA in question. With the advent of FISH and microarray technology, Southern blotting is rarely used but remains useful in the detection of large-trinucleotide-expansion diseases including the fragile-X syndrome (see Fig. 5-32), and in detection of clonal immunoglobulin gene rearrangements in the diagnosis of lymphoma. The latter is being replaced by PCR-based methods.

Fluorescence in Situ Hybridization

FISH uses DNA probes that recognize sequences specific to particular chromosomal regions. As part of the Human Genome Project, large libraries of bacterial artificial chromosomes that span the entire human genome were created. The human DNA insert in these clones is on the order of 100,000–200,000 base pairs, which defines the limit of resolution of FISH for identifying chromosomal changes. These DNA clones are labeled with fluorescent dyes and applied to metaphase spreads or interphase nuclei. The probe hybridizes to its homologous genomic sequence and thus labels a specific chromosomal region that can be visualized under a fluorescent microscope. The ability of FISH to circumvent the need for dividing cells is invaluable when a rapid diagnosis is warranted (e.g., when deciding to treat a patient with acute myeloid leukemia with retinoic acid, which is only effective in a particular subtype with a chromosomal translocation involving the retinoic acid receptor gene [Chapter 14]). FISH can be performed on prenatal samples (e.g., cells obtained by amniocentesis, chorionic villus biopsy, or umbilical cord blood), peripheral blood lymphocytes, touch preparations from cancer biopsies, and even archival tissue sections. FISH has been used for detection of numeric abnormalities of chromosomes (aneuploidy) (see Fig. 5-20); for the demonstration of subtle microdeletions (see Fig.

5-22) or complex translocations not detectable by routine karyotyping; for analysis of gene amplification (e.g., *HER2/NEU* in breast cancer or *N-MYC* amplification in neuroblastomas); and for mapping newly isolated genes of interest to their chromosomal loci. Chromosome painting is an extension of FISH, whereby probes are prepared for entire chromosomes. The number of chromosomes that can be *detected simultaneously* by chromosome painting is limited by the availability of fluorescent dyes that emit different wavelengths of visible light. This limitation has been overcome by the introduction of spectral karyotyping (also called multicolor FISH). By using a combination of five fluorochromes and appropriate computer-generated signals, the entire human genome can be visualized (Fig. 5-35). So powerful is spectral karyotyping that it might well be called "spectacular karyotyping."

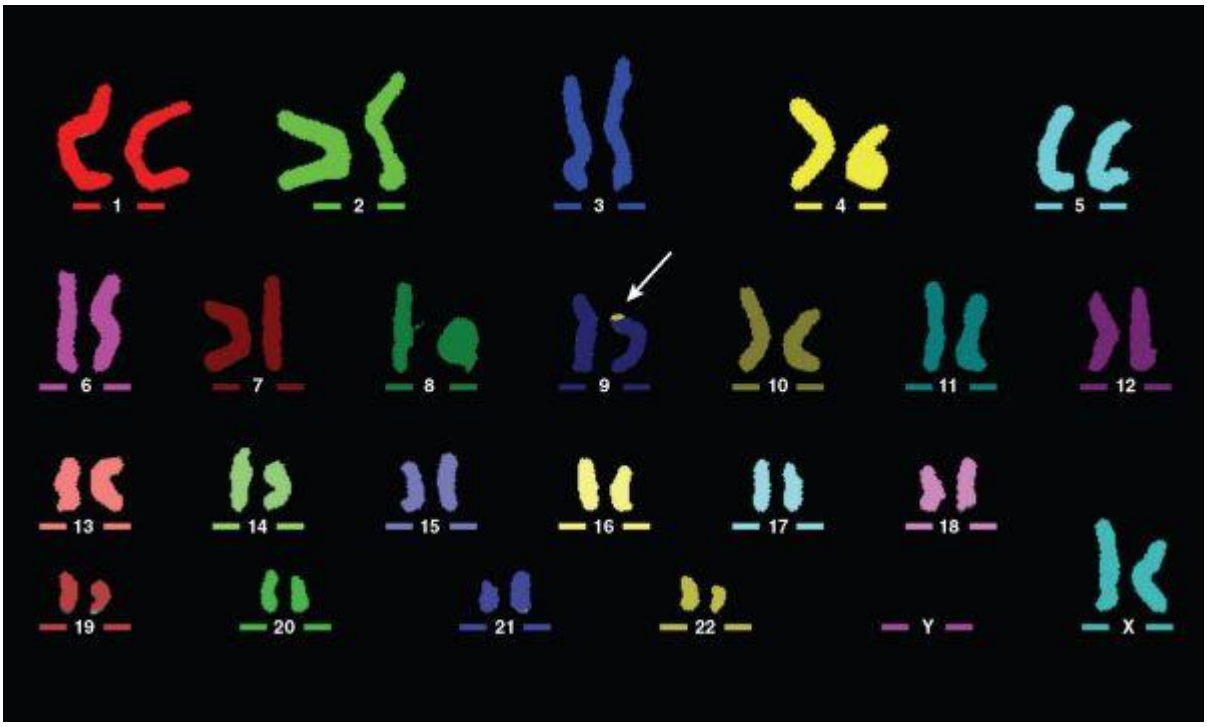

FIGURE 5-35 FISH studies using multicolor FISH in a child with an undetermined abnormality. This technique uses ratio-labeled probes labeled with 23 distinct mixtures of 5 fluorophores to create a unique "color" for each chromosome. This analysis revealed a derivative chromosome 9, with 9p containing additional material from 22q. *(Courtesy of Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)*

Array-Based Comparative Genomic Hybridization (Array CGH)

It is obvious from the preceding discussion that FISH requires prior knowledge of the one or few specific chromosomal regions suspected of being altered in the test sample. However, genomic abnormalities can also be detected without prior knowledge of what these aberrations may be, using a global strategy such as array CGH. In array CGH the test DNA and a reference (normal) DNA are labeled with two different fluorescent dyes (most commonly Cy5 and Cy3, which fluoresce red and green, respectively) (Fig. 5-36). The differentially labeled samples are then hybridized to a glass slide spotted with DNA probes that span the human genome at regularly spaced intervals, and usually cover all 22 autosomes and the X chromosome. If the contributions of both samples are equal for a given chromosomal region (i.e., the test sample is diploid), then all spots on the array will fluoresce yellow (the result of an equal admixture of green and red dyes). In contrast, if the test sample shows an excess of DNA at any given chromosomal region (such as resulting from an amplification), there will be a

corresponding excess of signal from the dye with which this sample was labeled. The reverse will be true in the event of a deletion, with an excess of the signal used for labeling the reference sample. Amplifications and deletions in the test sample can now be significantly better localized, often down to a few thousand base pairs. Newer arrays provide even higher resolution with more than 100,000 probes per array, and are at present being used to uncover copy number abnormalities in a variety of diseases, from cancer to autism. Array CGH is regularly performed in cases of mental retardation–developmental delay of unknown etiology or in children with dysmorphic features with negative karyotypes.

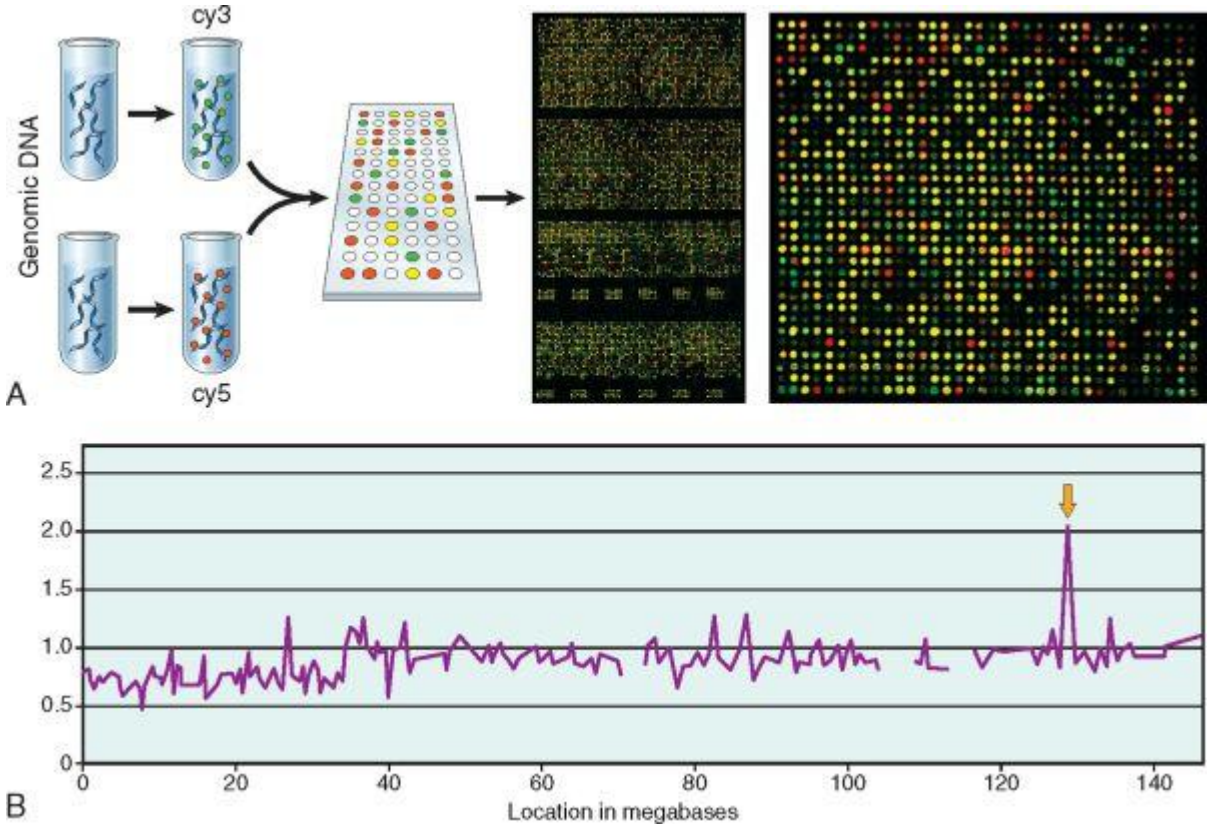

FIGURE 5-36 **A**, Array CGH is performed by hybridization of fluorescently labeled "test" DNA and "control" DNA on a slide that contains thousands of probes corresponding to defined chromosomal regions across the human genome. The resolution of most currently available array CGH assays is in the order of about 200 to 500 kilobases. Higher power view of the array demonstrates copy number aberrations in the "test" sample (Cy5, red), including regions of amplification (spots with excess of red signal) and deletion (spots with excess of green signal); yellow spots correspond to regions of normal (diploid) copy number. **B**, The hybridization signals are digitized, resulting in a virtual karyotype of the genome of the "test" sample. In the illustrated example, array CGH of a cancer cell line identifies an amplification on the distal long arm of chromosome 8, which corresponds to increased number of the oncogenic *MYC*. *(**A**, From Snijders AM et al.: Assembly of microarrays for genome-wide measurement of DNA copy number. Nat Genet 29:263, 2001. Web Figure A, Copyright 2001. Reprinted by permission from Macmillan Publishers Ltd.)*

As discussed earlier in the chapter, CNVs are a recently discovered source of genetic polymorphism, which was uncovered using array CGH technology. While intriguing in terms of understanding the marked differences between individual genomes, they can be problematic in the clinical interpretation of array CGH data.[79] There are usually many CNVs observed when comparing any two genomes encompassing millions of bases of DNA. Deciding whether a specific change is a benign polymorphism or a critical disease-causing duplication or deletion can be difficult. Databases of CNVs now exist that are very helpful guides in deciding on the relevance of questionable CNVs. Another limitation of

existing array CGH platforms is that they cannot detect balanced translocations, since there is a rearrangement but no genetic material is gained or lost. Nonetheless, the vastly superior sensitivity of molecular approaches should make assays such as array CGH first-line genomic diagnostic tests that have the potential of replacing traditional karyotyping.

EPIGENETIC ALTERATIONS

Epigenetics is defined as the study of heritable chemical modification of DNA or chromatin that does not alter the DNA sequence itself. Examples of such modification include the methylation of DNA, and the methylation and acetylation of histones. Our understanding of these types of molecular alterations is rapidly growing, and it is clear that epigenetic modifications are critical for normal human development—including the regulation of tissue-specific gene expression, X chromosome inactivation, and imprinting, as well as for understanding of the cellular perturbations in the aging process and cancer.[80,][81]

Gene expression frequently correlates with the level of methylation of DNA, usually of cytosines specifically in the CG dinucleotide-rich promoter regions known as CpG islands. As discussed earlier in the section on genomic imprinting, increased methylation of these loci is associated with decreased gene expression and is accompanied by concomitant specific patterns of histone methylation and acetylation. An ever-increasing number of disease states warrant analysis of promoter methylation—for example, in the diagnosis of fragile-X syndrome, in which hypermethylation results in *FMR1* silencing. Methylation analysis is also essential in the diagnosis of Prader-Willi and Angelman syndromes.

Since traditional Sanger sequencing alone cannot detect DNA methylation, other techniques have been developed to uncover these chemical modifications. One common approach is to treat genomic DNA with sodium bisulfite, a chemical that converts unmethylated cytosines to uracil, while methylated cytosines are protected from modification. An assay termed methylation-specific PCR uses two PCR primer sets to analyze single DNA loci: one to detect a DNA sequence with unmethylated cytosines (which are converted to uracils after bisulfite treatment) and the other to detect DNA sequences with methylated cytosines (which remain cytosines after bisulfite treatment).[82] Additional techniques are evolving that provide a genome-wide snapshot of epigenetically altered DNA. These techniques are based on the ability to detect histone modifications such as methylation and acetylation (which, like DNA methylation, are important regulators of gene expression) by using antibodies against specifically modified histones. Such antibodies can be used to pull down bound DNA sequences, a method termed chromatin immunoprecipitation (ChIP). These pulled-down sequences can be amplified and analyzed by hybridizing to microarrays (“ChIP on Chip”) or sequencing (“ChIP-Seq”) to map epigenetically modified genes throughout the genome.[83,][84]

RNA ANALYSIS

Changes in DNA lead to alterations in mRNA expression; hence in principle it should be possible to use mRNA expression analysis in the diagnosis of genetic diseases. From a practical standpoint, however, DNA-based diagnosis is much preferred, since DNA is much more stable. Nonetheless, RNA analysis is critical in several areas of molecular diagnostics. The most important application is the detection and quantification of RNA viruses such as HIV and hepatitis C virus. Furthermore, mRNA expression profiling (described in Chapters 7 and 23 is rapidly becoming an important tool for molecular stratification of tumors. In some instances cancer cells bearing particular chromosomal translocations are detected with greater sensitivity by analyzing mRNA (e.g., *BCR-ABL* fusion in CML). The principal reason for this is that most translocations occur in scattered locations within particular introns, which can be very large, beyond the capacity of conventional PCR amplification. Since introns are removed by splicing during the formation of mRNA, PCR analysis is possible if RNA is first converted to cDNA by

reverse transcriptase. PCR performed on cDNA is the method of choice for detection of minimal residual disease in patients with chronic myeloid leukemia (Chapter 13).

In closing, it should be pointed out that the progress in unraveling the genetic basis of human disease promises to be breathtaking in the coming years. An entirely new field of personalized and genomic medicine is waiting to be developed.

2.6 6. Diseases of the Immune System

2.6.1 The Normal Immune Response

The immune system is vital for survival, because our environment is teeming with potentially deadly microbes and the immune system protects us from infectious pathogens. Predictably, immune deficiencies render individuals easy prey to infections. But the immune system is similar to the proverbial double-edged sword. Although it normally defends us against infections, a hyperactive immune system may cause diseases that can sometimes be fatal. Examples of disorders caused by immune responses include allergic reactions and reactions against an individual's own tissues and cells *(autoimmunity)*.

This chapter is devoted to diseases caused by too little immunity or too much immunologic reactivity. We also consider amyloidosis, a disease in which an abnormal protein, derived in some cases from fragments of immunoglobulins, is deposited in tissues. First, we review some of the important features of normal immune responses, to provide a foundation for understanding the abnormalities that give rise to immunological diseases.

The Normal Immune Response

The normal immune response is best understood in the context of defense against infectious pathogens, the classical definition of immunity. The mechanisms of protection against infections fall into two broad categories. *Innate immunity* (also called natural, or native, immunity) refers to defense mechanisms that are present even before infection and that have evolved to specifically recognize microbes and protect individuals against infections. *Adaptive immunity* (also called acquired, or specific, immunity) consists of mechanisms that are stimulated by ("adapt to") microbes and are capable of recognizing microbial and nonmicrobial substances. Innate immunity is the first line of defense, because it is always ready to prevent and eradicate infections. Adaptive immunity develops later, after exposure to microbes, and is even more powerful than innate immunity in combating infections. By convention, the term "immune response" refers to adaptive immunity.

INNATE IMMUNITY

The major components of innate immunity are epithelial barriers that block entry of microbes, phagocytic cells (mainly neutrophils and macrophages), dendritic cells, natural killer (NK) cells, and several plasma proteins, including the proteins of the complement system. The two most important cellular reactions of innate immunity are: *inflammation*, the process in which phagocytic leukocytes are recruited and activated to kill microbes, and *anti-viral defense*, mediated by dendritic cells and NK cells. Leukocytes and epithelial cells that participate in innate immunity are capable of recognizing components of microbes that are shared among related microbes and are often essential for the infectivity of these pathogens (and thus cannot be mutated to allow the microbes to evade the defense

mechanisms). These microbial structures are called *pathogenassociated molecular patterns*. Leukocytes also recognize molecules released by injured and necrotic cells, which are sometimes called *danger-associated molecular patterns*. The cellular receptors that recognize these molecules are often called *pattern recognition receptors*. The best-defined pattern recognition receptors are a family of proteins called *Toll-like receptors (TLRs)*[1] that are homologous to the *Drosophila* protein Toll. Different TLRs are specific for components of different bacteria and viruses. TLRs are located on the cell surface and in endosomes, so they are able to recognize and initiate cellular responses to extracellular and ingested microbes. Other microbial sensors are located in the cytoplasm, where they recognize bacteria and viruses that may have colonized cells. Upon recognition of microbes, the TLRs and other sensors signal by a common pathway that leads to the activation of transcription factors, notably NF-κB (nuclear factor κB). NF-κB turns on the production of cytokines and proteins that stimulate the microbicidal activities of various cells, notably the phagocytes. Other cellular receptors bind microbes for phagocytosis; these include receptors for mannose residues, which are typical of microbial but not host glycoproteins, and receptors for opsonins such as antibodies and complement proteins that coat microbes.

Epithelia of the skin and gastrointestinal and respiratory tracts provide mechanical barriers to the entry of microbes from the external environment. Epithelial cells also produce anti-microbial molecules such as defensins, and lymphocytes located in the epithelia combat microbes at these sites. If microbes do breach epithelial boundaries, other defense mechanisms are called in.

Monocytes and *neutrophils* are phagocytes in the blood that can rapidly be recruited to any site of infection; monocytes that enter the tissues and mature are called *macrophages* (Chapter 2). *Dendritic cells* produce type I interferons, anti-viral cytokines that inhibit viral infection and replication; these cells are described below, in the context of antigen display to lymphocytes. *Natural killer cells* provide early protection against many viruses and intracellular bacteria; their properties and functions are also described below.

The proteins of the *complement system*, which were described in Chapter 2 , are some of the most important plasma proteins of the innate immune system. Recall that in innate immunity the complement system is activated by microbes using the alternative and lectin pathways; in adaptive immunity it is activated by antibodies using the classical pathway. Other circulating proteins of innate immunity are mannose-binding lectin and C-reactive protein, both of which coat microbes for phagocytosis. Lung surfactant is also a component of innate immunity, providing protection against inhaled microbes.

The early innate immune response not only provides the initial defense against infections but is also involved in triggering the subsequent, more powerful adaptive immune response.

ADAPTIVE IMMUNITY

The adaptive immune system consists of lymphocytes and their products, including antibodies. The receptors of lymphocytes are much more diverse than those of the innate immune system, but lymphocytes are not inherently specific for microbes, and they are capable of recognizing a vast array of foreign substances. In the remainder of this introductory section we focus on lymphocytes and the reactions of the adaptive immune system.

There are two types of adaptive immunity: humoral immunity, which protects against extracellular microbes and their toxins, and cell-mediated (or cellular) immunity, which is responsible for defense against intracellular microbes. Humoral immunity is mediated by B (bone marrow–derived) lymphocytes and their secreted products, antibodies (also called immunoglobulins, Ig), and cellular immunity is mediated by T (thymus-derived) lymphocytes. Both classes of lymphocytes express highly specific receptors for a wide variety of substances, called *antigens*.

COMPONENTS OF THE IMMUNE SYSTEM: CELLS, TISSUES, AND SELECTED MOLECULES

Before describing normal and pathologic immune responses, it is important to summarize the salient characteristics of some of the important participants in these responses.

Cells of the Immune System

Although lymphocytes appear morphologically unimpressive and similar to one another, they are actually remarkably heterogeneous and specialized in molecular properties and functions. The major classes of lymphocytes and their functions in adaptive immunity are illustrated in Figure 6-1 . Lymphocytes and other cells involved in immune responses are not fixed in particular tissues (as are cells in most of the organs of the body) but are capable of migrating among lymphoid and other tissues and the vascular and lymphatic circulations. This feature permits lymphocytes to home to any site of infection. In lymphoid organs, different classes of lymphocytes are anatomically segregated in such a way that they interact with one another only when stimulated to do so by encounter with antigens and other stimuli. Mature lymphocytes that have not encountered the antigen for which they are specific are said to be *naive* (immunologically inexperienced). After they are activated by recognition of antigens and other signals described later, lymphocytes differentiate into *effector cells*, which perform the function of eliminating microbes, and *memory cells*, which live in a state of heightened awareness and are better able to combat the microbe in case it returns. The process of lymphocyte differentiation into effector and memory cells is summarized below.

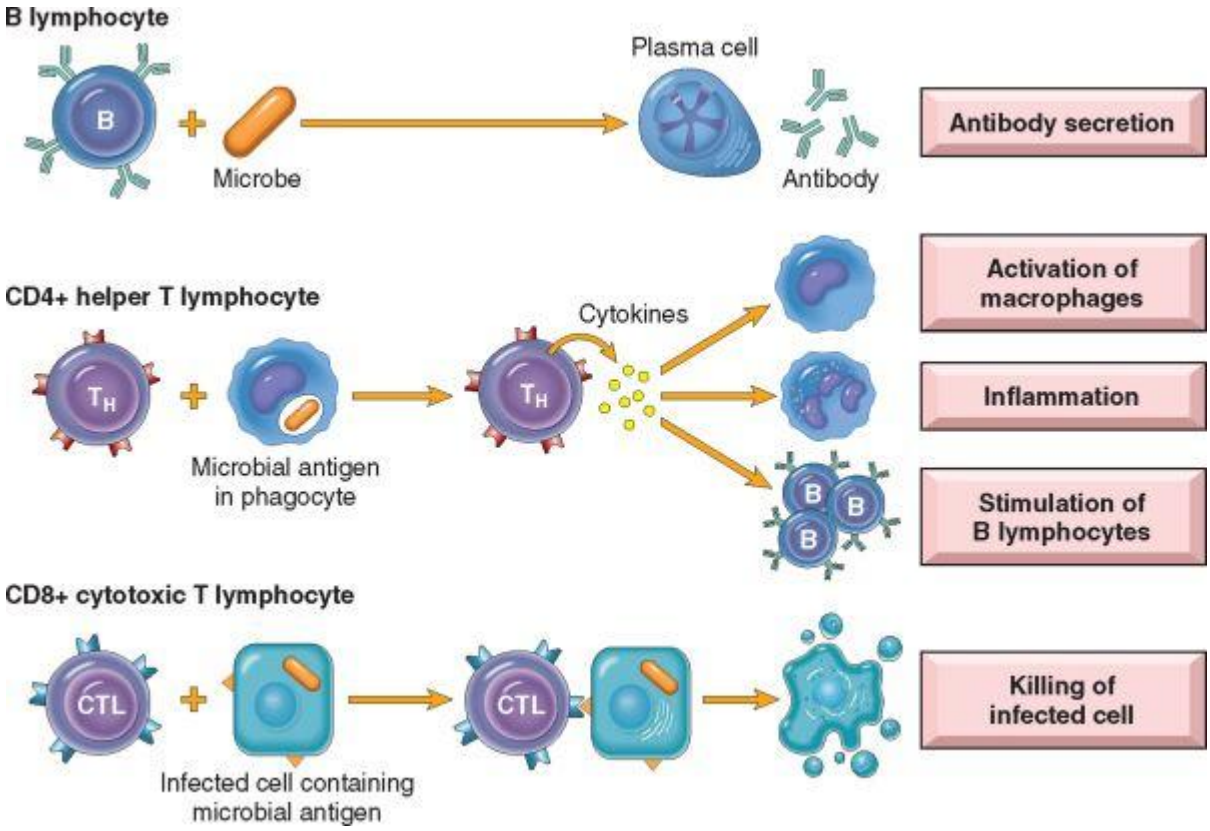

FIGURE 6-1 The principal classes of lymphocytes and their functions in adaptive immunity.

T Lymphocytes

T lymphocytes develop from precursors in the thymus. Mature T cells are found in the blood, where they constitute 60% to 70% of lymphocytes, and in T-cell zones of peripheral lymphoid organs (described below). Each T cell recognizes a specific cell-bound antigen by means of an antigen-specific T-cell receptor (TCR).[2] In approximately 95% of T cells the TCR consists of a disulfide-linked heterodimer made up of an α and a β polypeptide chain (Fig. 6-2), each having a variable (antigen-binding) region and a constant region. *The αβ TCR recognizes peptide antigens that are displayed by major histocompatibility complex (MHC) molecules on the surfaces of antigen-presenting cells (APCs).* (The function of MHC proteins is described later.) By limiting the specificity of T cells for peptides displayed by cell surface MHC molecules, called MHC *restriction*, the immune system ensures that T cells see only cell-associated antigens (e.g., those derived from microbes in cells).

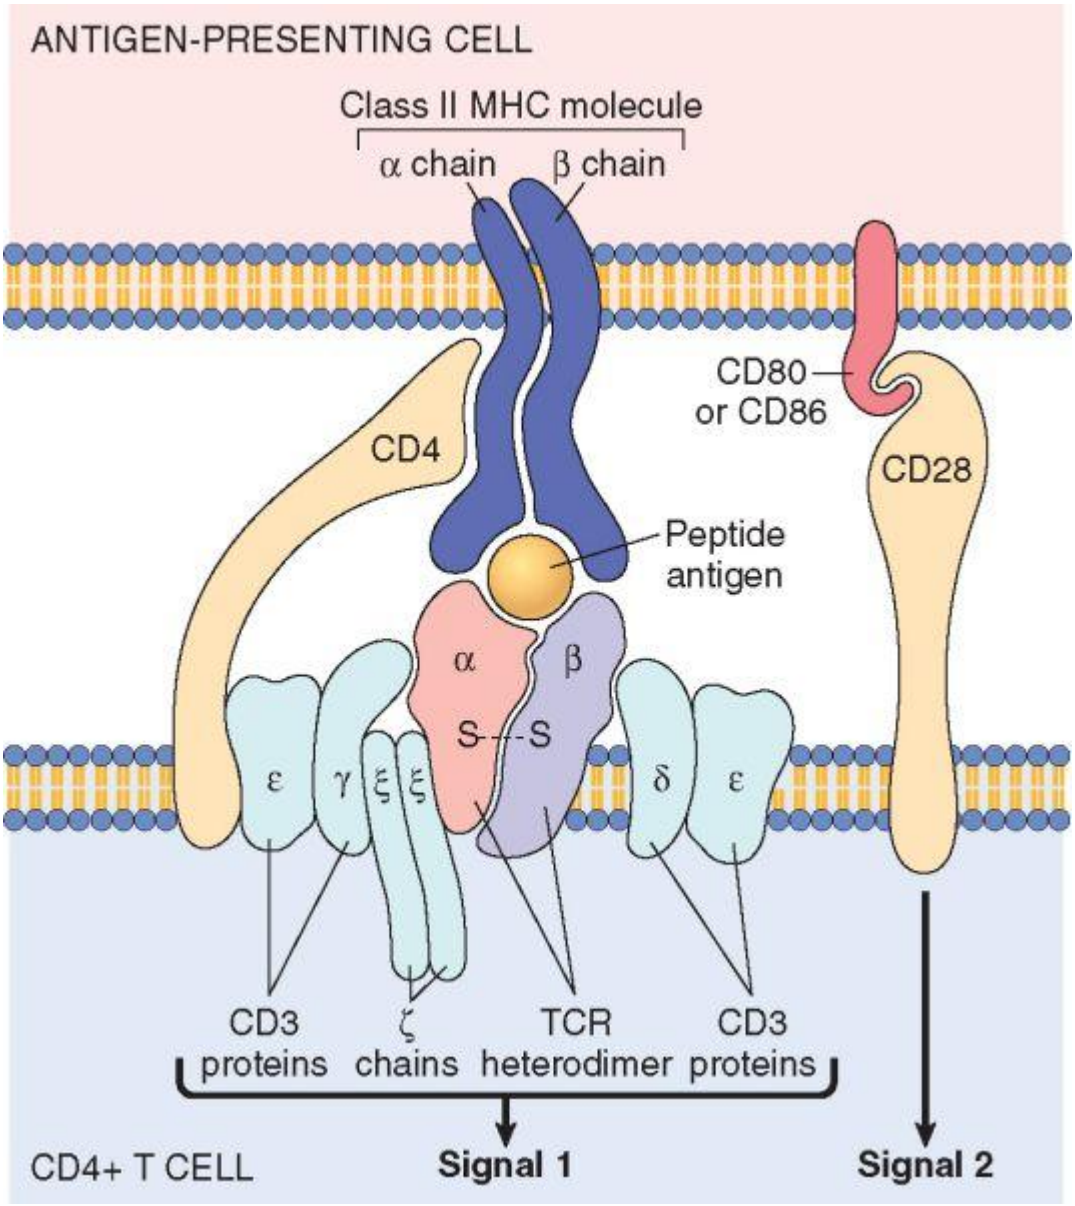

FIGURE 6-2 The T-cell receptor (TCR) complex and other molecules involved in T-cell activation. The TCR heterodimer, consisting of an α and a β chain, recognizes antigen (in the form of peptide-MHC complexes expressed on antigen-presenting cells, or APCs), and the linked CD3 complex and ζ chains initiate activating signals. CD4 and CD28 are also involved in T-cell activation. (Note that some T cells express CD8 and not CD4; these molecules serve analogous roles.) The sizes of the molecules are not drawn to scale. MHC, major histocompatibility complex.

TCR diversity is generated by somatic rearrangement of the genes that encode the TCR α and β chains.[3] All cells of the body, including lymphocyte progenitors, contain TCR genes in the germ-line configuration, which cannot be expressed as TCR proteins. During T cell development in the thymus, the TCR genes rearrange to form many different combinations that can be transcribed and translated into functional antigen receptors. The enzyme in developing lymphocytes that mediates rearrangement of antigen receptor genes is the product of *RAG-1* and *RAG-2* (recombination activating genes); inherited defects in RAG proteins result in a failure to generate mature lymphocytes. Whereas each T cell expresses TCR molecules of one specificity, collectively, the full complement of T cells in an individual is capable of recognizing a very large number of antigens. It is important to note that unrearranged (germ-line) TCR genes are present in all non-T cells in the body, but only T cells contain rearranged TCR genes. Hence, the *presence of rearranged TCR genes, which can be demonstrated by molecular analysis, is a marker of T-lineage cells*. Furthermore, because each T cell and its clonal progeny have a unique DNA rearrangement (and hence a unique TCR), it is possible to distinguish polyclonal (non-neoplastic) T-cell proliferations from monoclonal (neoplastic) T-cell proliferations. Thus, *analysis of antigen receptor gene rearrangements is a valuable assay for detecting lymphoid tumors* (Chapter 13).

Each TCR is noncovalently linked to five polypeptide chains, which form the CD3 complex and the ζ chain dimer (see Fig. 6-2).[4] The CD3 and ζ proteins are invariant (i.e., identical) in all T cells. They are involved in the transduction of signals into the T cell after the TCR has bound the antigen. Together with the TCR, these proteins form the "TCR complex."

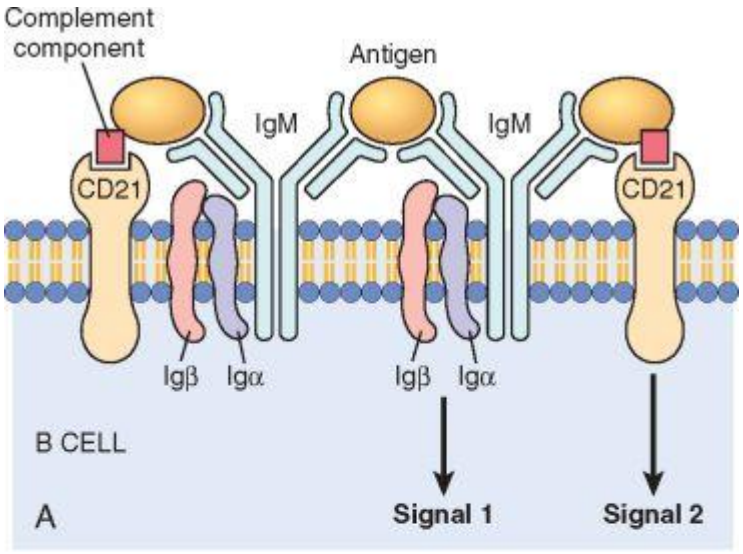
A small population of mature T cells expresses another type of TCR composed of γ and δ polypeptide chains.[5] The γδ TCR recognizes peptides, lipids, and small molecules, without a requirement for display by MHC proteins. γδ T cells tend to aggregate at epithelial surfaces, such as the skin and mucosa of the gastrointestinal and urogenital tracts, suggesting that these cells are sentinels that protect against microbes that try to enter through epithelia. However, the functions of γδ T cells are not known. Another small subset of T cells expresses markers that are found on NK cells; these cells are called NK-T cells.[6] NK-T cells express a very limited diversity of TCRs, and they recognize glycolipids that are displayed by the MHC-like molecule CD1. The functions of NK-T cells are also not well defined.

In addition to CD3 and ζ proteins, T cells express several other proteins that assist the TCR complex in functional responses. These include CD4, CD8, CD2, integrins, and CD28.[7] CD4 and CD8 are expressed on two mutually exclusive subsets of αβ T cells. CD4 is expressed on approximately 60% of mature CD3+ T cells, which function as cytokine-secreting helper cells that help macrophages and B lymphocytes to combat infections, whereas CD8 is expressed on about 30% of T cells, which function as cytotoxic (killer) T lymphocytes (CTLs) to destroy host cells harboring microbes. CD4 and CD8 serve as "coreceptors" in T-cell activation, so called because they work with the antigen receptor in responses to antigen. During antigen presentation, CD4 molecules bind to class II MHC molecules that are displaying antigen (see Fig. 6-2), and CD8 molecules bind to class I MHC molecules. When the antigen receptor of a T cell recognizes antigen, the CD4 or CD8 coreceptor initiates signals that are necessary for activation of the T cells. Because of this requirement for co-receptors, CD4+ helper T cells can recognize and respond to antigen displayed only by class II MHC molecules, whereas CD8+ cytotoxic T cells recognize cell-bound antigens only in association with class I MHC molecules; this segregation is described below.

To respond, T cells have to recognize not only antigen-MHC complexes but additional signals provided by APCs. We will describe these later, when we summarize the steps in cell-mediated immune responses.

B Lymphocytes

B lymphocytes develop from precursors in the bone marrow. Mature B cells constitute 10% to 20% of the circulating peripheral lymphocyte population and are also present in peripheral lymphoid tissues such as lymph nodes, spleen, and mucosa-associated lymphoid tissues. B cells recognize antigen via the B-cell antigen receptor complex. Membrane-bound antibodies called IgM and IgD, present on the surface of all mature, naive B cells, are the antigen-binding component of the B-cell receptor complex (Fig. 6-3). As with T cells, each B-cell receptor has a unique antigen specificity, derived from RAG-mediated rearrangements of Ig genes. Thus, as in T cells, *analysis of Ig gene rearrangements is useful for identifying monoclonal B-cell tumors*. After stimulation by antigen and other signals (described later), B cells develop into *plasma cells* that secrete antibodies, the mediators of humoral immunity. In addition to membrane Ig, the B-cell antigen receptor complex contains a heterodimer of two invariant proteins called Igα and Igβ. Similar to the CD3 and ζ proteins of the TCR complex, Igα and Igβ are essential for signal transduction through the antigen receptor. B cells also express several other molecules that are essential for their responses. These include complement receptors, Fc receptors, and CD40. The type 2 complement receptor (CR2, or CD21) is also the receptor for the Epstein-Barr virus (EBV), and hence EBV readily infects B cells.



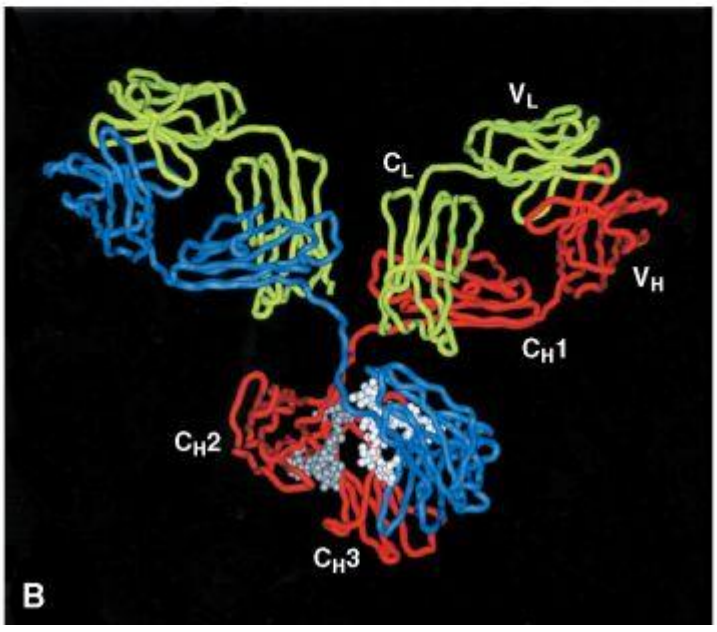


FIGURE 6-3 Structure of antibodies and the B-cell antigen receptor. **A**, The B-cell receptor complex is composed of membrane immunoglobulin M (IgM; or IgD, not shown), which recognize antigens, and the associated signaling proteins Igα and Igβ. CD21 is a receptor for a complement component that also promotes B-cell activation. **B**, Crystal structure of a secreted IgG molecule, showing the arrangement of the variable (V) and constant (C) regions of the heavy (H) and light (L) chains. *(Courtesy of Dr. Alex McPherson, University of California, Irvine, CA.)*

Dendritic Cells

There are two types of cells with dendritic morphology that are functionally quite different. Both have numerous fine cytoplasmic processes that resemble dendrites, from which they derive their name. One type is called *interdigitating dendritic cells*, or just *dendritic cells* (Fig. 6-4).[8] These cells are the most important *antigen-presenting cells (APCs) for initiating primary T-cell responses against protein antigens* (described later). Several features of dendritic cells account for their key role in antigen presentation. First, these cells are located at the right place to capture antigens—under epithelia, the common site of entry of microbes and foreign antigens, and in the interstitia of all tissues, where antigens may be produced. Immature dendritic cells within the epidermis are called *Langerhans cells*. Second, dendritic cells express many receptors for capturing and responding to microbes (and other antigens), including TLRs and mannose receptors. Third, in response to microbes, dendritic cells are recruited to the T-cell zones of lymphoid organs, where they are ideally located to present antigens to T cells. Fourth, dendritic cells express high levels of the molecules needed for presenting antigens to and activating CD4+ T cells.

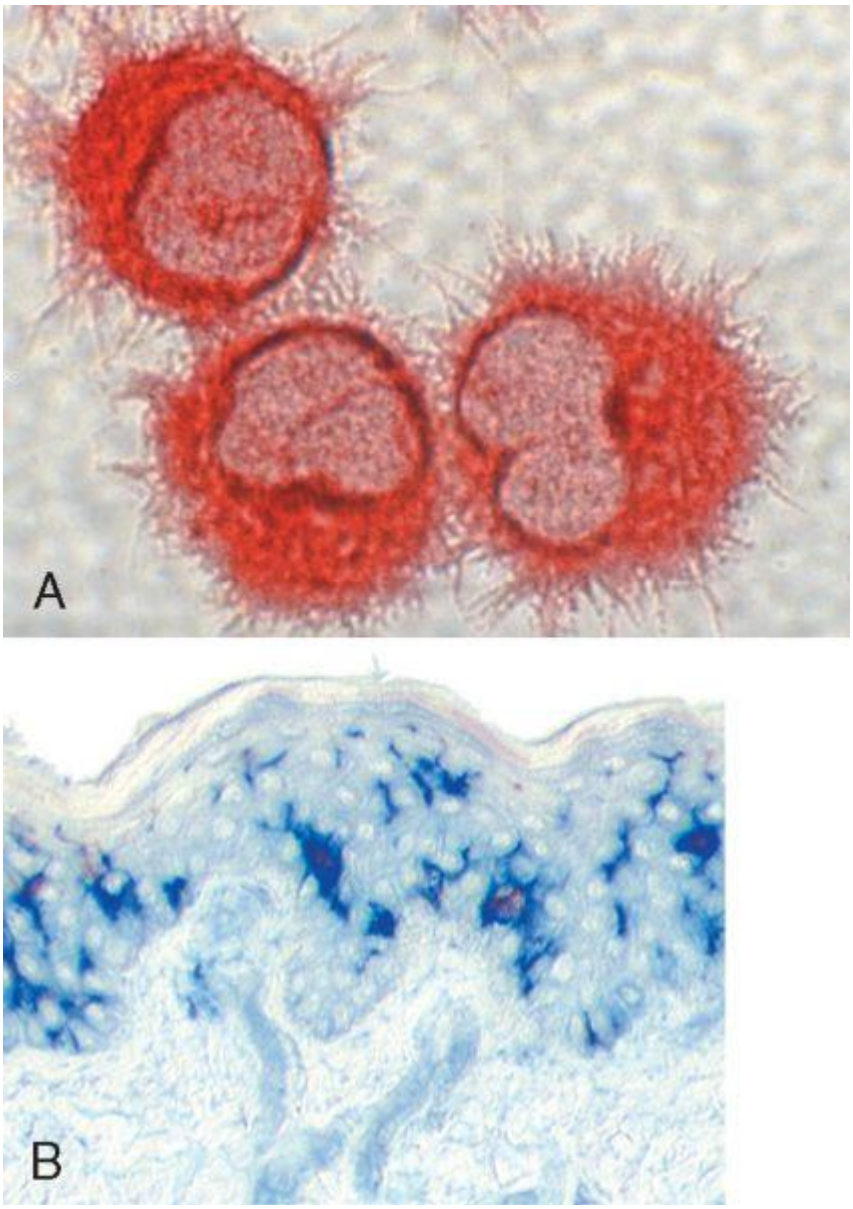

FIGURE 6-4 Dendritic cells. **A**, Cultured dendritic cells showing the prominent surface projections. **B**, The location of dendritic cells (Langerhans cells) in the epidermis (stained blue using an immunohistochemical method). *(Courtesy of Dr. Y-J. Liu, M.D. Anderson Cancer Center, Houston, TX.)*

The other type of cell with dendritic morphology is present in the germinal centers of lymphoid follicles in the spleen and lymph nodes and is hence called *follicular dendritic cell*.[9] These cells bear Fc receptors for IgG and receptors for C3b and can trap antigen bound to antibodies or complement proteins. Such cells play a role in humoral immune responses by presenting antigens to B cells and selecting the B cells that have the highest affinity for the antigen, thus improving the quality of the antibody produced.

Macrophages

Macrophages are a part of the mononuclear phagocyte system; their origin, differentiation, and role in inflammation are discussed in Chapter 2 . Here we need only to emphasize their important functions in the induction and effector phases of adaptive immune responses.

- Macrophages that have phagocytosed microbes and protein antigens process the antigens and present peptide fragments to T cells. Thus, macrophages function as APCs in T-cell activation.
- Macrophages are key effector cells in certain forms of cell-mediated immunity, the reaction that serves to eliminate intracellular microbes. In this type of response, T cells activate macrophages and enhance their ability to kill ingested microbes (discussed below).
- Macrophages also participate in the effector phase of humoral immunity. As discussed in Chapter 2 , macrophages efficiently phagocytose and destroy microbes that are opsonized (coated) by IgG or C3b.

Natural Killer Cells

NK cells make up approximately 10% to 15% of peripheral blood lymphocytes. They do not express TCRs or Ig. Morphologically, NK cells are somewhat larger than small lymphocytes, and they contain abundant azurophilic granules; because of these characteristics, they are also called *large granular lymphocytes*. NK cells are endowed with the ability to kill a variety of infected and tumor cells, without prior exposure to or activation by these microbes or tumors. This ability makes NK cells an early line of defense against viral infections and, perhaps, some tumors. Two cell surface molecules, CD16 and CD56, are commonly used to identify NK cells. CD16 is an Fc receptor for IgG, and it confers on NK cells the ability to lyse IgG-coated target cells. This phenomenon is known as *antibody-dependent cell-mediated cytotoxicity (ADCC)*.

The functional activity of NK cells is regulated by a balance between signals from activating and inhibitory receptors[10] (Fig. 6-5). There are many types of activating receptors, of which the NKG2D family is the best characterized. The NKG2D receptors recognize surface molecules that are induced by various kinds of stress, such as infection and DNA damage. NK cell inhibitory receptors recognize self–class I MHC molecules, which are expressed on all healthy cells. These receptors belong to two major families: killer cell Ig-like receptors and the CD94 family of lectins (carbohydrate-recognizing proteins). The inhibitory receptors prevent NK cells from killing normal cells. Virus infection or neoplastic transformation often induces expression of ligands for activating receptors and at the same time reduces the expression of class I MHC molecules. As a result the balance is tilted toward activation, and the infected or tumor cell is killed.

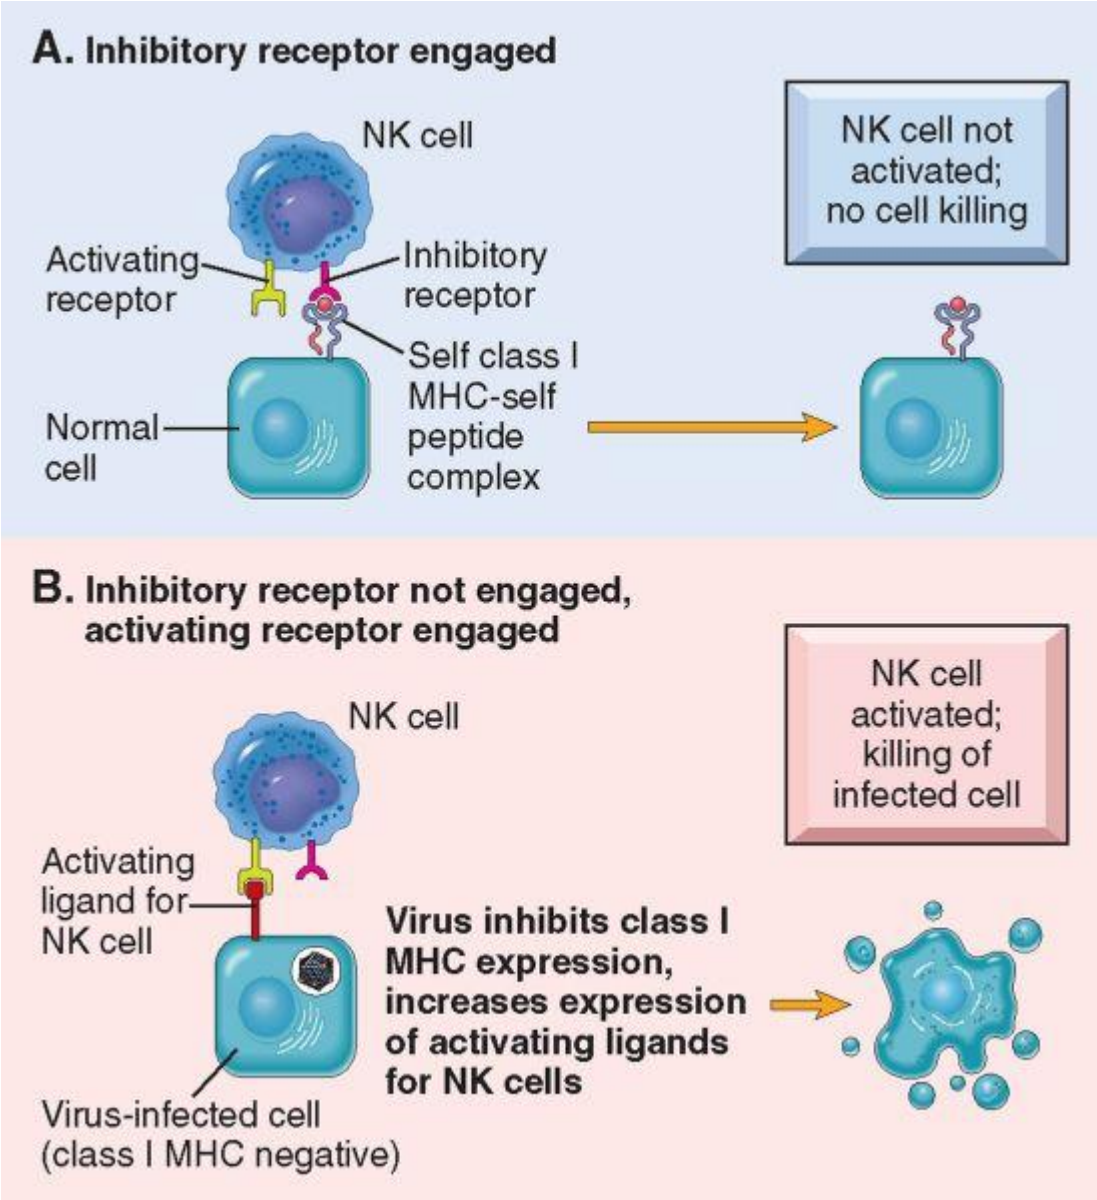

FIGURE 6-5 Activating and inhibitory receptors of natural killer (NK) cells. **A**, Healthy cells express self–class I MHC molecules, which are recognized by inhibitory receptors, thus ensuring that NK cells do not attack normal cells. Note that healthy cells may express ligands for activating receptors (not shown) or may not express such ligands (as shown), but they do not activate NK cells because they engage the inhibitory receptors. **B**, In infected and stressed cells, class I MHC expression is reduced so that the inhibitory receptors are not engaged, and ligands for activating receptors are expressed. The result is that NK cells are activated and the infected cells are killed.

NK cells also secrete cytokines, such as interferon-γ (IFN-γ), which activates macrophages to destroy ingested microbes, and thus NK cells provide early defense against intracellular microbial infections. The activity of NK cells is regulated by many cytokines, including the interleukins IL-2, IL-15, and IL-12. IL-2 and IL-15 stimulate proliferation of NK cells, whereas IL-12 activates killing and secretion of IFN-γ.

The tissues of the immune system consist of the generative (also called primary, or central) lymphoid organs, in which T and B lymphocytes mature and become competent to respond to antigens, and the peripheral (or secondary) lymphoid organs, in which adaptive immune responses to microbes are initiated.

Generative Lymphoid Organs

The principal generative lymphoid organs are the thymus, where T cells develop, and the bone marrow, the site of production of all blood cells and where B lymphocytes mature. These organs are described in Chapter 13 .

Peripheral Lymphoid Organs

The peripheral lymphoid organs consist of the lymph nodes, spleen, and the mucosal and cutaneous lymphoid tissues. These tissues are organized to concentrate antigens, APCs, and lymphocytes in a way that optimizes interactions among these cells and the development of adaptive immune responses.

Lymph nodes are nodular aggregates of lymphoid tissues located along lymphatic channels throughout the body (Fig. 6-6). As lymph passes through lymph nodes, APCs in the nodes are able to sample the antigens of microbes that may enter through epithelia into tissues and are carried in the lymph. In addition, dendritic cells pick up and transport antigens of microbes from epithelia via the lymphatic vessels to the lymph nodes. Thus, the antigens of microbes that enter through epithelia or colonize tissues become concentrated in draining lymph nodes.

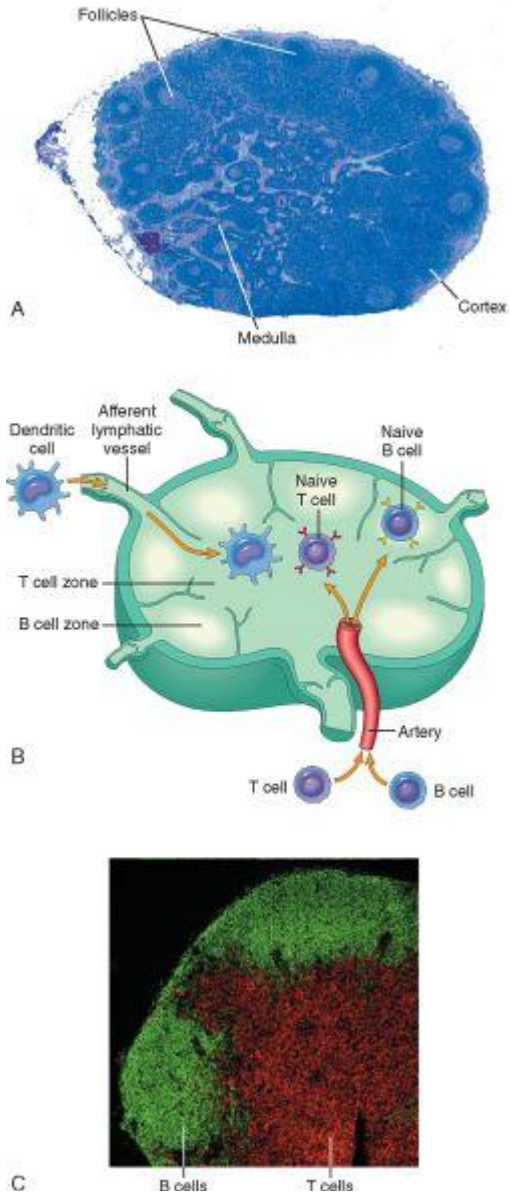

FIGURE 6-6 Morphology of a lymph node. **A**, The histology of a lymph node, with an outer cortex containing follicles and an inner medulla. **B**, The segregation of B cells and T cells in different regions of the lymph node, illustrated schematically. **C**, The location of B cells (stained green, using the immunofluorescence technique) and T cells (stained red) in a lymph node. *(Courtesy of Drs. Kathryn Pape and Jennifer Walter, University of Minnesota School of Medicine, Minneapolis, MN.)*

The *spleen* is an abdominal organ that serves the same role in immune responses to blood-borne antigen as that of lymph nodes in responses to lymph-borne antigens. Blood entering the spleen flows through a network of sinusoids. Blood-borne antigens are trapped by dendritic cells and macrophages in the spleen.

The cutaneous and mucosal lymphoid systems are located under the epithelia of the skin and the gastrointestinal and respiratory tracts, respectively. They respond to antigens that enter by breaches in the epithelium. Pharyngeal tonsils and Peyer's patches of the intestine are two anatomically defined

mucosal lymphoid tissues. At any time, more than half the body's lymphocytes are in the mucosal tissues (reflecting the large size of these tissues), and many of these are memory cells.

Within the peripheral lymphoid organs, T lymphocytes and B lymphocytes are segregated into different regions (see Fig. 6-6). In lymph nodes the B cells are concentrated in discrete structures, called *follicles*, located around the periphery, or cortex, of each node. If the B cells in a follicle have recently responded to an antigen, this follicle may contain a central region called a *germinal center*. The T lymphocytes are concentrated in the paracortex, adjacent to the follicles. The follicles contain the follicular dendritic cells that are involved in the activation of B cells, and the paracortex contains the dendritic cells that present antigens to T lymphocytes. In the spleen, T lymphocytes are concentrated in periarteriolar lymphoid sheaths surrounding small arterioles, and B cells reside in the follicles.

The anatomic organization of peripheral lymphoid organs is tightly regulated to allow immune responses to develop.[11][12][13] The location of B cells and T cells in the lymphoid follicles and paracortical areas, respectively, is dictated by chemokines produced in these anatomic locales. When the lymphocytes are activated by antigens they alter their expression of chemokine receptors. As a result, the B cells and T cells leave their homes, migrate toward each other and meet at the edge of follicles, where helper T cells interact with and help B cells to differentiate into antibody-producing cells.

Lymphocyte Recirculation

Lymphocytes constantly recirculate between tissues and home to particular sites; naive lymphocytes traverse the peripheral lymphoid organs where immune responses are initiated, and effector lymphocytes migrate to sites of infection and inflammation[14] (Fig. 6-7). This process of lymphocyte recirculation is most relevant for T cells, because effector T cells have to locate and eliminate microbes at any site of infection. By contrast, plasma cells remain in lymphoid organs and do not need to migrate to sites of infection because they secrete antibodies that are carried to distant tissues. Therefore, we will limit our discussion of lymphocyte recirculation to T lymphocytes.

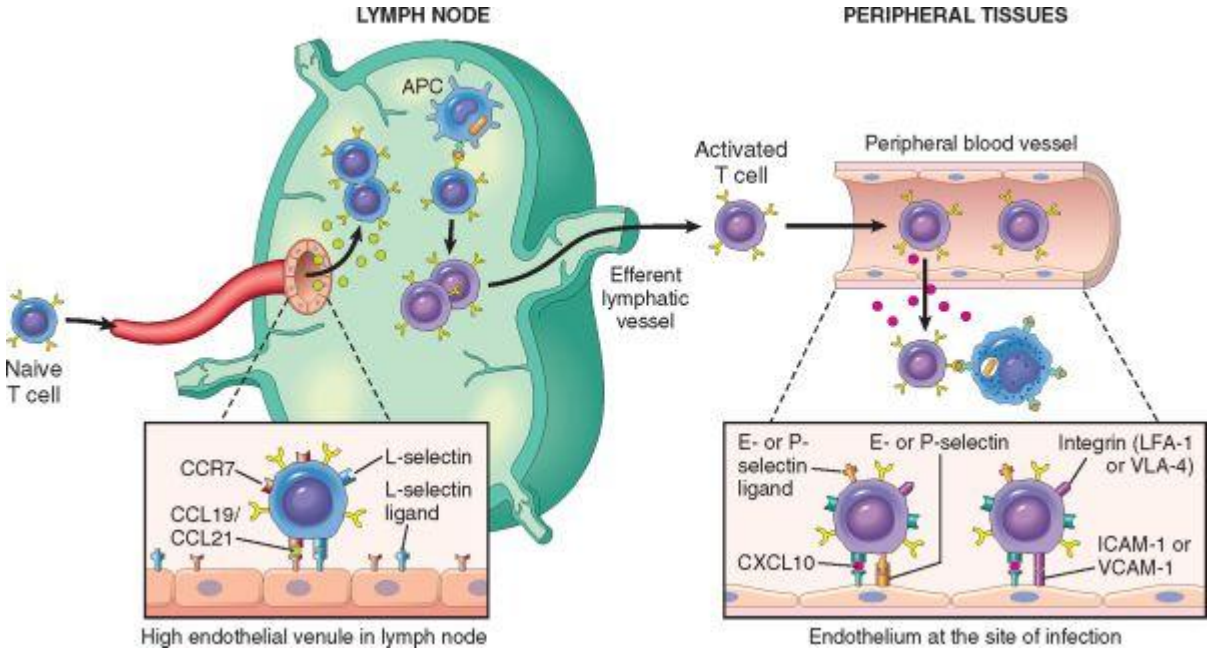

FIGURE 6-7 Migration of naive and effector T lymphocytes. Naive T lymphocytes home to lymph nodes as a result of L-selectin and integrin binding to their ligands on high endothelial venules (HEVs). Chemokines expressed in lymph nodes (called CCL19 and CCL21) bind to receptors (CCR7) on naive T cells, enhancing integrin-dependent adhesion and inducing migration of the cells through the HEV wall. Activated T lymphocytes, including effector and memory cells, home to sites of infection in peripheral tissues, and this migration is mediated

by E-selectin and P-selectin, integrins, and chemokines secreted at inflammatory sites (e.g., CXCL10) that are recognized by chemokine receptors (e.g., CXCR3) that are expressed on activated T cells. APC, antigen-presenting cell; ICAM-1, intercellular adhesion molecule 1; VCAM-1, vascular cell adhesion molecule 1.

Naive T lymphocytes that have exited the thymus migrate to lymph nodes and enter the T-cell zones through specialized postcapillary venules, called *high endothelial venules (HEVs)* (see Fig. 6-7). In the lymph node, a naive T cell may encounter the antigen that it specifically recognizes on the surface of an APC and is activated. During this process, the cells alter their expression of adhesion molecules and chemokine receptors. Differentiated effector T cells ultimately leave the lymph nodes, enter the circulation, and migrate into the tissues that harbor the microbes.

Major Histocompatibility Complex (MHC) Molecules: Peptide Display System of Adaptive Immunity

Because MHC molecules are fundamental to the recognition of antigens by T cells and are linked to many autoimmune diseases, it is important to briefly review the structure and function of these molecules.[15] MHC molecules were discovered as products of genes that evoke rejection of transplanted organs, and their name derives from the recognition that they are responsible for tissue compatibility between individuals. *The physiologic function of MHC molecules is to display peptide fragments of proteins for recognition by antigen-specific T cells*.[16] In humans the genes encoding the major histocompatibility molecules are clustered on a small segment of chromosome 6, the *major histocompatibility complex*, or the *human leukocyte antigen* (HLA) complex (Fig. 6-8), so named because in humans MHC-encoded proteins were initially detected on leukocytes by the binding of antibodies. The HLA system is highly polymorphic, meaning that there are many alleles of each MHC gene in the population and each individual inherits one set of these alleles that is different from the alleles in most other individuals. This, as we see subsequently, constitutes a formidable barrier in organ transplantation.

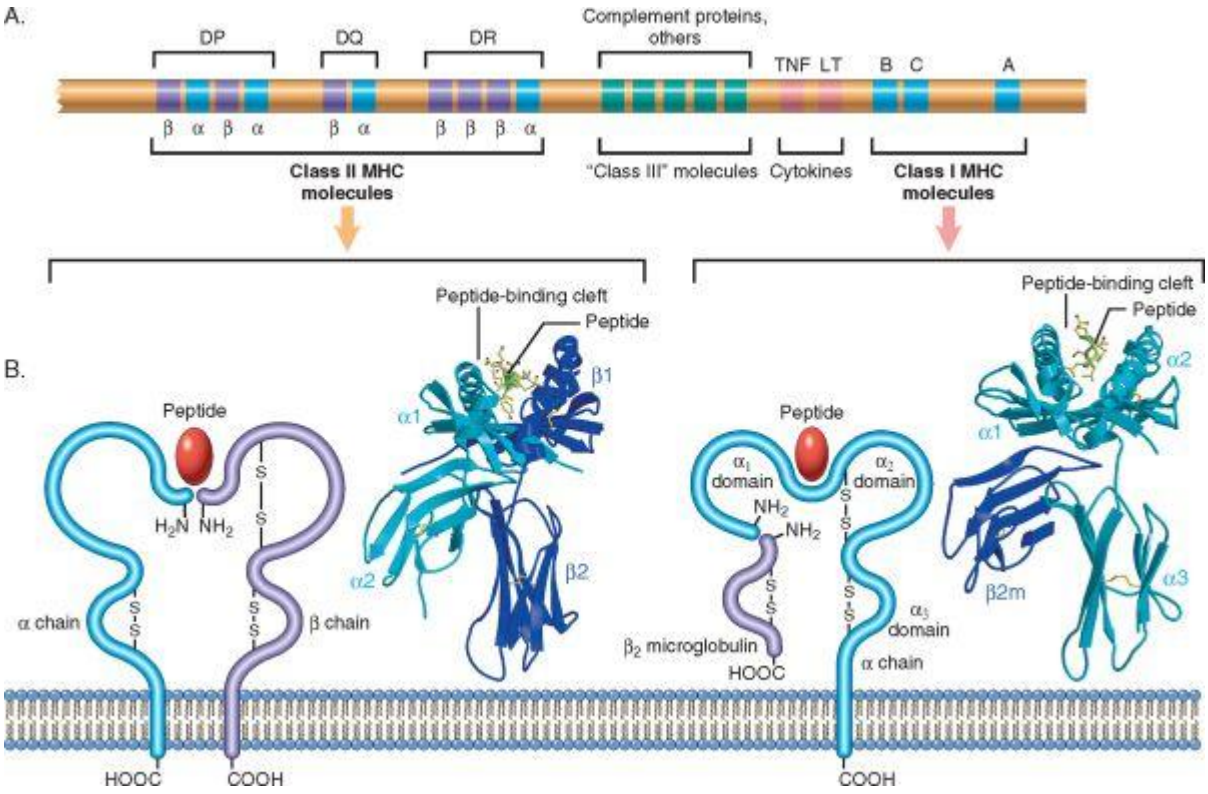

FIGURE 6-8 The human leukocyte antigen (HLA) complex and the structure of HLA molecules. **A**, The location of genes in the HLA complex. The relative locations, sizes, and distances between genes are not to scale. Genes that encode several proteins involved in antigen processing (the TAP transporter, components of the proteasome, and HLA-DM) are located in the class II region (not shown). **B**, Schematic diagrams and crystal structures of class I and class II HLA molecules. *(Courtesy of Drs. Kathryn Pape and Jennifer Walter, University of Minnesota School of Medicine, Minneapolis, MN.)*

On the basis of their structure, cellular distribution, and function, MHC gene products are classified into three groups.

- *Class I MHC molecules* are expressed on all nucleated cells and platelets. They are encoded by three closely linked loci, designated *HLA-A*, *HLA-B*, and *HLA-C* (see Fig. 6-9). Each class I MHC molecule is a heterodimer consisting of a polymorphic α, or heavy, chain (44-kD) linked noncovalently to a smaller (12-kD) nonpolymorphic peptide called β_2-microglobulin, which is not encoded within the MHC. The extracellular region of the α chain is divided into three domains: α1, α2, and α3. Crystal structure of class I molecules has revealed that the α1 and α2 domains form a cleft, or groove, where peptides bind.[16] The polymorphic residues line the sides and the base of the peptide-binding groove; the variation in this region explains why different class I alleles bind different peptides.

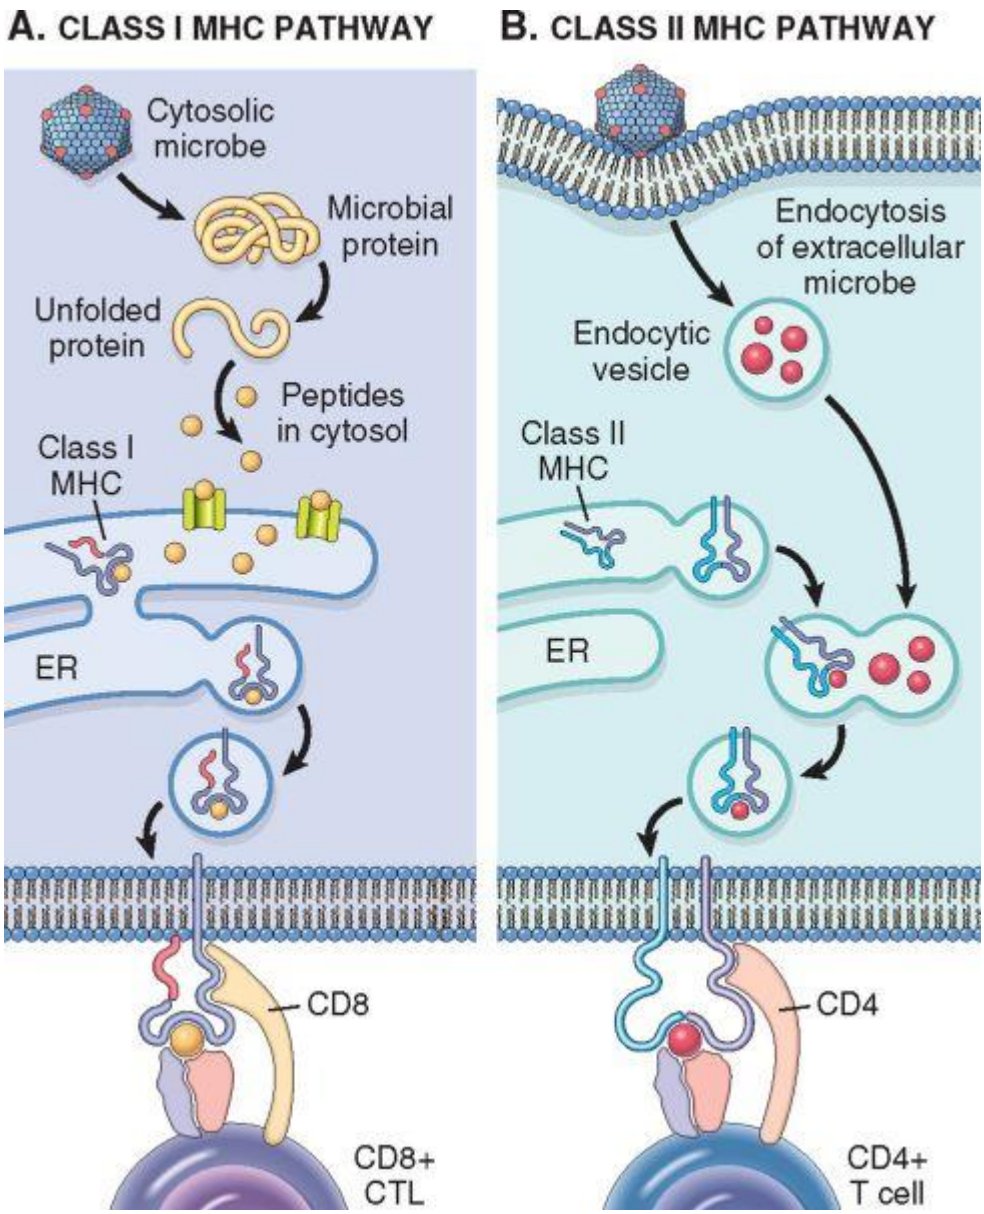

FIGURE 6-9 Antigen processing and display by major histocompatibility complex (MHC) molecules. **A**, In the class I MHC pathway, peptides are produced from proteins in the cytosol and transported to the endoplasmic reticulum (ER), where they bind to class I MHC molecules. The peptide-MHC complexes are transported to the cell surface and displayed for recognition by CD8+ T cells. **B**, In the class II MHC pathway, proteins are ingested into vesicles and degraded into peptides, which bind to class II MHC molecules being transported in the same vesicles. The class II–peptide complexes are expressed on the cell surface and recognized by CD4+ T cells.

Class I MHC molecules display peptides that are derived from proteins, such as viral antigens, that are located in the cytoplasm and usually produced in the cell, and class I–associated peptides are recognized by CD8+ *T lymphocytes* (Fig. 6-9A). Cytoplasmic proteins are degraded in proteasomes and peptides are transported into the endoplasmic reticulum (ER) where the peptides bind to newly synthesized class I molecules.[17] Peptide-loaded MHC molecules associate with β_2-microglobulin to form a stable trimer that is transported to the cell surface. The nonpolymorphic α3 domain of class I MHC molecules has a binding site for CD8, and therefore the peptide–class I complexes are recognized by CD8+ T cells, which function as CTLs. In this interaction, the TCR recognizes the MHC-peptide complex, and the CD8 molecule, acting as a coreceptor, binds to the class I heavy chain. Thus, CD8+ cytotoxic T cells

recognize peptides that are produced by cytoplasmic microbes (typically viruses) or in tumors and kill cells harboring these infections or the tumor cells. Since CD8+ T cells recognize peptides only if presented as a complex with self–class I MHC molecules, CD8+ T cells are said to be *class I MHC–restricted*. Because one of the important functions of CD8+ CTLs is to eliminate viruses, which may infect any nucleated cell, it makes good sense that all nucleated cells express class I HLA molecules and can be surveyed by CD8+ T cells.

- *Class II MHC molecules* are encoded in a region called *HLA-D*, which has three subregions: *HLA-DP*, *HLA-DQ*, and *HLA-DR*. Each class II molecule is a heterodimer consisting of a noncovalently associated α chain and β chain, both of which are polymorphic. The extracellular portions of the α and β chains have two domains each: α1, α2 and β1, β2. Crystal structure of class II molecules has revealed that, similar to class I molecules, they have peptide-binding clefts facing outward[16] (see Fig. 6-8). This cleft is formed by an interaction of the α1 and β1 domains, and it is in this portion that most class II alleles differ. Thus, as with class I molecules, polymorphism of class II molecules is associated with differential binding of antigenic peptides.

Class II MHC molecules present antigens that are internalized into vesicles, and are typically derived from extracellular microbes and soluble proteins (Fig. 6-9B). The internalized proteins are proteolytically digested in endosomes or lysosomes. Peptides resulting from proteolytic cleavage then associate with class II heterodimers in the vesicles, and the stable peptide-MHC complexes are transported to the cell surface. The class II β2 domain has a binding site for CD4, and therefore, the class II–peptide complex is recognized by CD4+ T cells, which function as helper cells. In this interaction, the CD4 molecule acts as the co-receptor. Because CD4+ T cells can recognize antigens only in the context of self–class II molecules, they are referred to as *class II MHC–restricted*. In contrast to class I molecules, class II MHC molecules are mainly expressed on cells that present ingested antigens and respond to T-cell help (macrophages, B lymphocytes, and dendritic cells).

- The MHC locus also contains genes that encode some complement components and the cytokines tumor necrosis factor (TNF) and lymphotoxin, as well as some proteins that have no apparent role in the immune system. The class II locus contains genes that encode many proteins involved in antigen processing and presentation, such as components of the proteasome, peptide transporter, and a class II–like molecule called DM that facilitates peptide binding to class II molecules.

The combination of HLA alleles in each individual is called the *HLA haplotype*. Any given individual inherits one set of HLA genes from each parent and thus typically expresses two different molecules for every locus. Because of the polymorphism of the HLA loci, virtually innumerable combinations of molecules exist in the population, and each individual expresses an MHC profile on his or her cell surface that is different from the haplotypes of most other individuals. It is believed that this polymorphism evolved to ensure that at least some individuals in a species would be able to display any microbial peptide and thus provide protection against any infection. The same polymorphism means that no two individuals (other than identical twins) are likely to express the same MHC molecules, and therefore grafts exchanged between these individuals are recognized as foreign and attacked by the immune system.

MHC molecules play key roles in regulating T cell–mediated immune responses in several ways. First, because different antigenic peptides bind to different MHC molecules, it follows that an individual mounts an immune response against a protein antigen only if he or she inherits the gene(s) for those MHC molecule(s) that can bind peptides derived from the antigen and present it to T cells. The consequences of inheriting a given MHC (e.g., class II) gene depend on the nature of the antigen bound by the class II molecule. For example, if the antigen is a peptide from ragweed pollen, the individual who expresses class II molecules capable of binding the antigen would be genetically prone to allergic reactions against pollen. In contrast, an inherited capacity to bind a bacterial peptide may provide

resistance to the infection by evoking a protective antibody response. Second, by segregating cytoplasmic and internalized antigens, MHC molecules ensure that the correct immune response is mounted against different microbes—CTLs against cytoplasmic microbes, and antibodies and macrophages (both of which are activated by helper T cells) against extracellular microbes.

HLA and Disease Association

A variety of diseases are associated with the inheritance of certain HLA alleles (Table 6-1).[18] The most striking of these is the association between ankylosing spondylitis and *HLA-B27*; individuals who inherit this class I HLA allele have a 90-fold greater chance (relative risk) of developing the disease as compared with those who do not carry *HLA-B27*. The diseases that show association with the HLA locus can be broadly grouped into the following categories:

1. *Inflammatory diseases*, including ankylosing spondylitis and several postinfectious arthropathies, all associated with *HLA-B27*
2. *Autoimmune diseases*, including autoimmune endocrinopathies, associated mainly with alleles at the *DR* locus
3. *Inherited errors of metabolism*, such as 21-hydroxylase deficiency (*HLA-BW47*) and hereditary hemochromatosis (*HLA-A*)

TABLE 6-1 -- Association of HLA Alleles and Inflammatory Diseases

Disease	HLA Allele	Relative Risk (%)
Ankylosing spondylitis	*B27*	90–100
Postgonococcal arthritis	*B27*	14
Acute anterior uveitis	*B27*	14
Rheumatoid arthritis	*DR4*	4
Chronic active hepatitis	*DR3*	13
Primary Sjögren syndrome	*DR3*	9
Type 1 diabetes	*DR3*	5
	DR4	6
	DR3/DR4	20

The mechanisms underlying these associations are not fully understood. In the immunological and inflammatory diseases, the inheritance of particular HLA alleles likely influences the T-cell response, but it has proved difficult to define precisely how. In some cases (e.g., 21-hydroxylase deficiency), the linkage results because the relevant disease-associated gene, in this case the gene for 21-hydroxylase, maps within the HLA complex. Similarly, in hereditary hemochromatosis, a gene that is mutated, called *HFE*, maps within the HLA locus. The HFE protein resembles MHC molecules structurally, but its function is in the regulation of iron transport (Chapter 18).

Cytokines: Messenger Molecules of the Immune System

The induction and regulation of immune responses involve multiple interactions among lymphocytes, dendritic cells, macrophages, other inflammatory cells (e.g., neutrophils), and endothelial cells. Some of these interactions depend on cell-to-cell contact; however, many interactions and effector functions of leukocytes are mediated by short-acting secreted mediators called *cytokines*. Molecularly defined cytokines are called *interleukins*, because they mediate communications between leukocytes. Most cytokines have a wide spectrum of effects, and some are produced by several different cell types.

It is convenient to classify cytokines into distinct functional classes, although many belong to multiple categories.

- *Cytokines of innate immunity* are produced rapidly in response to microbes and other stimuli, are made principally by macrophages, dendritic cells, and NK cells, and mediate inflammation and anti-viral defense; these include TNF, IL-1, IL-12, type I IFNs, IFN-γ, and chemokines (Chapter 2).
- *Cytokines of adaptive immune responses* are made principally by CD4+ T lymphocytes in response to antigen and other signals, and function to promote lymphocyte proliferation and differentiation and to activate effector cells. The main ones in this group are IL-2, IL-4, IL-5, IL-17, and IFN-γ; their roles in immune responses are described below.
- Some cytokines stimulate hematopoiesis and are called *colony-stimulating factors* because they are assayed by their ability to stimulate formation of blood cell colonies from bone marrow progenitors (Chapter 13). Their functions are to increase leukocyte numbers during immune and inflammatory responses, and to replace leukocytes that are consumed during such responses.

The knowledge gained about cytokines has numerous practical therapeutic applications. Inhibiting cytokine production or actions is an approach for controlling the harmful effects of inflammation and tissue-damaging immune reactions. Patients with rheumatoid arthritis often show dramatic responses to TNF antagonists, an elegant example of rationally designed and molecularly targeted therapy. Conversely, recombinant cytokines can be administered to enhance immunity against cancer or microbial infections (immunotherapy).

OVERVIEW OF LYMPHOCYTE ACTIVATION AND IMMUNE RESPONSES

All adaptive immune responses develop in steps, consisting of: antigen recognition, activation of specific lymphocytes to proliferate and differentiate into effector and memory cells, elimination of the antigen, and decline of the response, with memory cells being the long-lived survivors. The major events in each step are summarized below; these general principles apply to protective responses against microbes as well as pathologic responses that injure the host.

The Display and Recognition of Antigens

Lymphocytes specific for a large number of antigens exist before exposure to the antigen, and when an antigen enters, it selects the specific cells and activates them. This fundamental concept is called the *clonal selection hypothesis*. According to this hypothesis, antigen-specific clones of lymphocytes develop before and independent of exposure to antigen. The cells constituting each clone have identical antigen receptors, which are different from the receptors on the cells of all other clones. It is estimated that there are about 10^7 to 10^9 different specificities in the total pool of about 10^{12} lymphocytes in an adult, and therefore, at least this many antigens can be recognized by the adaptive immune system. It follows that the number of lymphocytes specific for any one antigen is very small, probably less than 1 in 100,000 to 1 in 1 million cells. To permit a small number of lymphocytes to find antigen anywhere in the body, the immune system has specialized mechanisms for capturing antigens and displaying them to lymphocytes. Microbes and their protein antigens are captured by dendritic cells that are resident in epithelia and tissues. These cells carry their antigenic cargo to draining lymph nodes (Fig. 6-10).[19] Here the antigens are processed and displayed complexed with MHC molecules on the cell surface (see Fig. 6-9).

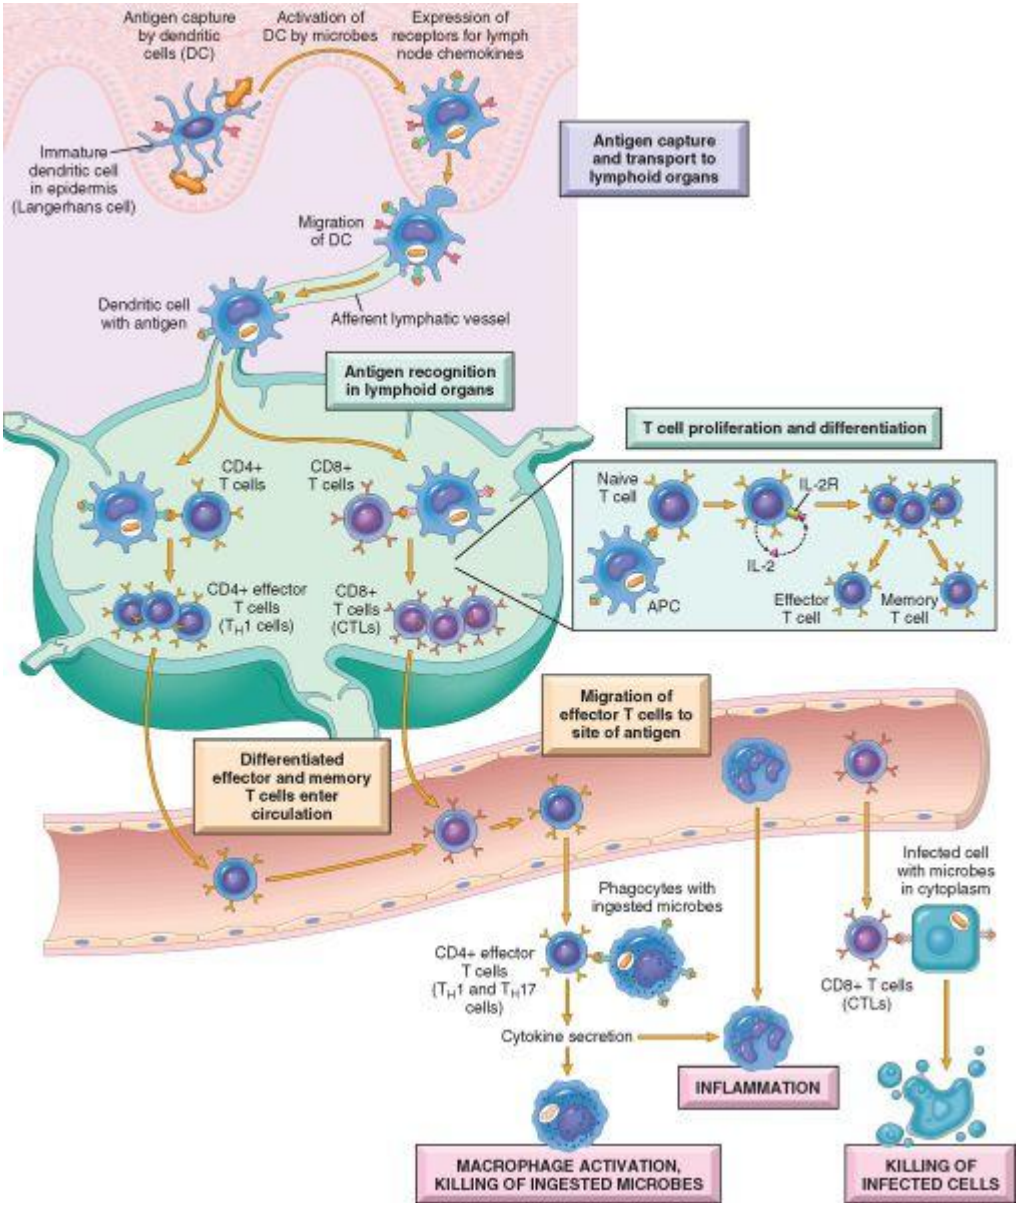

FIGURE 6-10 Cell-mediated immunity. Dendritic cells (DCs) capture microbial antigens from epithelia and tissues and transport the antigens to lymph nodes. During this process, the DCs mature, and express high levels of MHC molecules and costimulators. Naive T cells recognize MHC-associated peptide antigens displayed on DCs. The T cells are activated to proliferate and to differentiate into effector and memory cells, which migrate to sites of infection and serve various functions in cell-mediated immunity. CD4+ effector T cells of the T_H1 subset recognize the antigens of microbes ingested by phagocytes, and activate the phagocytes to kill the microbes. CD4+ T cells also induce inflammation. CD8+ cytotoxic T lymphocytes (CTLs) kill infected cells harboring microbes in the cytoplasm. Not shown are T_H2 cells, which are especially important in defense against helminthic infections. Some activated T cells differentiate into long-lived memory cells. APC, antigen-presenting cell.

B lymphocytes use their antigen receptors (membrane-bound antibody molecules) to recognize antigens of many different chemical types, including proteins, polysaccharides, and lipids.

At the same time as the antigens of a microbe are recognized by T and B lymphocytes, the microbe elicits an innate immune response; in the case of immunization with a protein antigen, the innate response is induced by the adjuvant given with the antigen. During this innate response the microbe activates APCs to express molecules called *costimulators* and to secrete cytokines that stimulate the

proliferation and differentiation of T lymphocytes. The principal costimulators for T cells are the B7 proteins (CD80 and CD86) that are expressed on APCs and are recognized by the CD28 receptor on naive T cells.[20] Thus, antigen ("signal 1") and costimulatory molecules produced during innate immune responses to microbes ("signal 2") function cooperatively to activate antigen-specific lymphocytes (see Fig. 6-3). The requirement for microbetriggered signal 2 ensures that the adaptive immune response is induced by microbes and not by harmless substances. In immune responses to tumors and transplants, "signal 2" may be provided by substances released from necrotic cells (the "danger-associated molecular patterns" mentioned earlier).

The reactions and functions of T and B lymphocytes differ in important ways and are best considered separately.

Cell-Mediated Immunity: Activation of T Lymphocytes and Elimination of Intracellular Microbes

Naive T lymphocytes are activated by antigen and costimulators in peripheral lymphoid organs, and proliferate and differentiate into effector cells that migrate to any site where the antigen (microbe) is present (see Fig. 6-10). One of the earliest responses of CD4+ helper T cells is secretion of the cytokine IL-2 and expression of high-affinity receptors for IL-2. IL-2 is a growth factor that acts on these T lymphocytes and stimulates their proliferation, leading to an increase in the number of antigen-specific lymphocytes. The functions of helper T cells are mediated by the combined actions of CD40-ligand (CD40L) and cytokines. When CD4+ helper T cells recognize antigens being displayed by macrophages or B lymphocytes, the T cells express CD40L, which engages CD40 on the macrophages or B cells and activates these cells.

Some of the progeny of the expanded T cells differentiate into effector cells that can secrete different sets of cytokines, and thus perform different functions (Fig. 6-11).[21] The best defined subsets of differentiated CD4+ helper cells are the T_H1 and T_H2 subsets. Cells of the T_H1 subset secrete the cytokine IFN-γ, which is a potent macrophage activator. The combination of CD40- and IFN-γ–mediated activation results in the induction of microbicidal substances in macrophages, leading to the destruction of ingested microbes. T_H2 cells produce IL-4, which stimulates B cells to differentiate into IgE-secreting plasma cells, and IL-5, which activates eosinophils. Eosinophils and mast cells bind to IgE-coated microbes such as helminthic parasites, and function to eliminate helminths. A third subset of CD4+ T cells that has been discovered recently is called the T_H17 subset because the signature cytokine of these cells is IL-17.[22,][23] T_H17 cells are powerful recruiters of neutrophils and monocytes, and thus play major roles in several inflammatory diseases. They may also be important for defense against some bacterial and fungal infections in which neutrophilic inflammation is a prominent feature. We will return to the generation and functions of these subsets when we discuss hypersensitivity reactions.

	T_H1	T_H2	T_H17
Cytokines produced	IFN-γ	IL-4, IL-5, IL-13	IL-17, IL-22, chemokines
Cytokines that induce this subset	IFN-γ, IL-12	IL-4	TGF-β, IL-6, IL-1, IL-23
Immunological reactions triggered	Macrophage activation, stimulation of IgG antibody production	Stimulation of IgE production, activation of mast cells and eosinophils	Recruitment of neutrophils, monocytes
Host defense against	Intracellular microbes	Helminthic parasites	Extracellular bacteria, fungi
Role in disease	Immune-mediated chronic inflammatory diseases (often autoimmune)	Allergies	Immune-mediated chronic inflammatory diseases (often autoimmune)

FIGURE 6-11 Subsets of helper T (T_H) cells. In response to stimuli (mainly cytokines) present at the time of antigen recognition, naive CD4+ T_H cells may differentiate into populations of effector cells that produce distinct sets of cytokines and perform different functions. The dominant immune reactions elicited by each subset, and its role in host defense and immunological diseases, are summarized.

Activated CD8+ lymphocytes differentiate into CTLs that kill cells harboring microbes in the cytoplasm. By destroying the infected cells, CTLs eliminate the reservoirs of infection.

Humoral Immunity: Activation of B Lymphocytes and Elimination of Extracellular Microbes

Upon activation, B lymphocytes proliferate and then differentiate into plasma cells that secrete different classes of antibodies with distinct functions (Fig. 6-12). Many polysaccharide and lipid antigens have multiple identical antigenic determinants (epitopes) that are able to engage many antigen receptor molecules on each B cell and initiate the process of B-cell activation. Typical globular protein antigens are not able to bind to many antigen receptors, and the full response of B cells to protein antigens requires help from CD4+ T cells.[24] B cells ingest protein antigens into vesicles, degrade them, and display peptides bound to MHC molecules for recognition by helper T cells. The helper T cells express CD40L and secrete cytokines, which work together to activate the B cells.

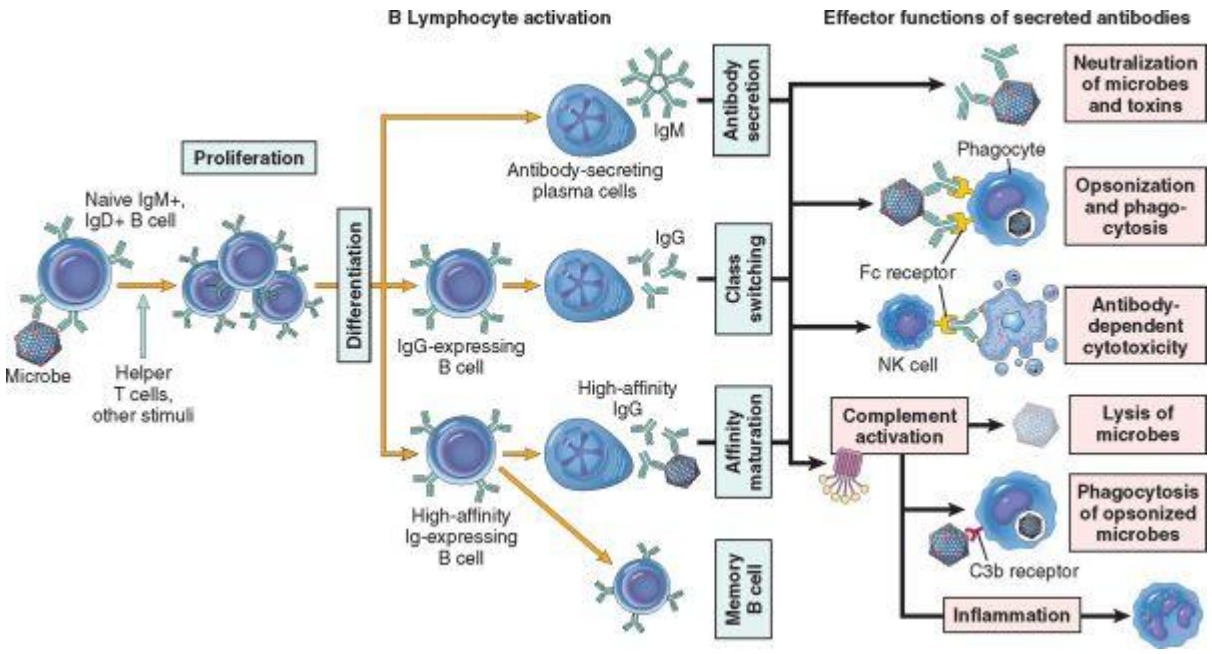

FIGURE 6-12 Humoral immunity. Naive B lymphocytes recognize antigens, and under the influence of T_H cells and other stimuli (not shown), the B cells are activated to proliferate and to differentiate into antibody-secreting plasma cells. Some of the activated B cells undergo heavy-chain class switching and affinity maturation, and some become long-lived memory cells. Antibodies of different heavy-chain classes (isotypes) perform different effector functions, shown on the right. See text for abbreviations.

Each plasma cell secretes antibodies that have the same antigen binding site as the cell surface antibodies (B-cell receptors) that first recognized the antigen. Polysaccharides and lipids stimulate secretion mainly of IgM antibody. Protein antigens, by virtue of CD40L- and cytokine-mediated helper T-cell actions, induce the production of antibodies of different classes, or isotypes (IgG, IgA, IgE). Cytokines that induce isotype switching include IFN-γ and IL-4. Helper T cells also stimulate the production of antibodies with high affinities for the antigen. This process, called *affinity maturation*, improves the quality of the humoral immune response. Isotype switching and affinity maturation occur mainly in germinal centers, which are formed by proliferating B cells, especially in helper T cell-dependent responses to protein antigens.

The humoral immune response combats microbes in many ways (see Fig. 6-12). Antibodies bind to microbes and prevent them from infecting cells, thus "neutralizing" the microbes. IgG antibodies coat ("opsonize") microbes and target them for phagocytosis, since phagocytes (neutrophils and macrophages) express receptors for the Fc tails of IgG. IgG and IgM activate the complement system by the classical pathway, and complement products promote phagocytosis and destruction of microbes. The production of most opsonizing and complement-fixing IgG antibodies is stimulated by T_H1 helper cells, which respond to many bacteria and viruses; thus, the protective response to most bacteria and viruses is driven by T_H1 cells. Some antibodies serve special roles at particular anatomic sites. IgA is secreted from mucosal epithelia and neutralizes microbes in the lumens of the respiratory and gastrointestinal tracts (and other mucosal tissues). IgG is actively transported across the placenta and protects the newborn until the immune system becomes mature. IgE and eosinophils cooperate to kill parasites, mainly by release of eosinophil granule contents that are toxic to the worms. As mentioned above, T_H2 cells secrete cytokines that stimulate the production of IgE and activate eosinophils, and thus the response to helminths is orchestrated by T_H2 cells.

Most circulating IgG antibodies have half-lives of about 3 weeks. Some antibody-secreting plasma cells migrate to the bone marrow and live for years, continuing to produce low levels of antibodies.

Decline of Immune Responses and Immunological Memory

The majority of effector lymphocytes induced by an infectious pathogen die by apoptosis after the microbe is eliminated, thus returning the immune system to its basal resting state, called homeostasis. The initial activation of lymphocytes also generates long-lived *memory cells*, which may survive for years after the infection. Memory cells are an expanded pool of antigen-specific lymphocytes (more numerous than the naive cells specific for any antigen that are present before encounter with that antigen), and that respond faster and more effectively when re-exposed to the antigen than do naive cells.[25] This is why the generation of memory cells is an important goal of vaccination.

The brief outline of basic immunology presented above provides a foundation for considering the diseases of the immune system. Our subsequent discussion will be divided into disorders caused by an abnormally active immune system, called *hypersensitivity disorders*, and the rejection of transplants, followed by diseases caused by a defective immune system, called *immunodeficiency diseases*. We close with a consideration of amyloidosis, a disorder that is often associated with immune and inflammatory diseases.

2.6.2 Hypersensitivity & Autoimmune Disorders

Before discussing specific immunological diseases, we start with a summary of the general mechanisms of hypersensitivity.

MECHANISMS OF HYPERSENSITIVITY REACTIONS

Individuals who have been previously exposed to an antigen are said to be sensitized. Sometimes, repeat exposures to the same antigen trigger a pathologic reaction; such reactions are described as *hypersensitivity*, implying an excessive response to antigen. There are several important general features of hypersensitivity disorders.

- *Both exogenous and endogenous antigens may elicit hypersensitivity reactions*. Humans live in an environment teeming with substances capable of eliciting immune responses. Exogenous antigens include those in dust, pollens, foods, drugs, microbes, chemicals, and some blood products that are used in clinical practice. The immune responses against such exogenous antigens may take a variety of forms, ranging from annoying but trivial discomforts, such as itching of the skin, to potentially fatal diseases, such as bronchial asthma and anaphylaxis. Injurious immune reactions may also be evoked by endogenous tissue antigens. Immune responses against self, or autologous, antigens, cause the important group of *autoimmune diseases*.
- *The development of hypersensitivity diseases (both allergic and autoimmune disorders) is often associated with the inheritance of particular susceptibility genes*. HLA genes and many non-HLA genes have been implicated in different diseases; specific examples will be described in the context of the diseases.
- A general principle that has emerged is that *hypersensitivity reflects an imbalance between the effector mechanisms of immune responses and the control mechanisms that serve to normally limit such responses*. We will return to this concept when we consider autoimmunity.

Hypersensitivity diseases can be classified on the basis of the immunologic mechanism that mediates the disease (Table 6-2). This classification is of value in distinguishing the manner in which the immune response causes tissue injury and disease, and the accompanying pathologic and clinical manifestations. However, it is now increasingly recognized that multiple mechanisms may be operative in any one hypersensitivity disease. The main types of hypersensitivity reactions are the following:

- In *immediate hypersensitivity (type I hypersensitivity)*, the immune response is mediated by T_H2 cells, IgE antibodies, and mast cells, and results in the release of mediators that act on vessels and smooth muscle and of pro-inflammatory cytokines that recruit inflammatory cells.
- In *antibody-mediated disorders (type II hypersensitivity)*, secreted IgG and IgM antibodies participate directly in injury to cells by promoting their phagocytosis or lysis and in injury to tissues by inducing inflammation. Antibodies may also interfere with cellular functions and cause disease without tissue injury.
- In *immune complex–mediated disorders (type III hypersensitivity)*, IgG and IgM antibodies bind antigens usually in the circulation, and the antigen-antibody complexes deposit in tissues and induce inflammation. The leukocytes that are recruited (neutrophils and monocytes) produce tissue damage by release of lysosomal enzymes and generation of toxic free radicals.
- In *cell-mediated immune disorders (type IV hypersensitivity)*, sensitized T lymphocytes (T_H1 and T_H17 cells and CTLs) are the cause of the cellular and tissue injury. T_H2 cells induce lesions that are part of immediate hypersensitivity reactions, and are not considered a form of type IV hypersensitivity.

TABLE 6-2 -- Mechanisms of Immunologically Mediated Hypersensitivity Reactions

Type of Reaction	Prototypic Disorder	Immune Mechanisms	Pathologic Lesions
Immediate (type I) hypersensitivity	Anaphylaxis; allergies; bronchial asthma (atopic forms)	Production of IgE antibody → immediate release of vasoactive amines and other mediators from mast cells; later recruitment of inflammatory cells	Vascular dilation, edema, smooth muscle contraction, mucus production, tissue injury, inflammation
Antibody-mediated (type II) hypersensitivity	Autoimmune hemolytic anemia; Goodpasture syndrome	Production of IgG, IgM → binds to antigen on target cell or tissue → phagocytosis or lysis of target cell by activated complement or Fc receptors; recruitment of leukocytes	Phagocytosis and lysis of cells; inflammation; in some diseases, functional derangements without cell or tissue injury
Immune complex–mediated (type III) hypersensitivity	Systemic lupus erythematosus; some forms of glomer-ulonephritis; serum sickness; Arthus reaction	Deposition of antigen-antibody complexes → complement activation → recruitment of leukocytes by complement products and Fc receptors → release of enzymes and other toxic molecules	Inflammation, necrotizing vasculitis (fibrinoid necrosis)
Cell-mediated (type IV) hypersensitivity	Contact dermatitis; multiple sclerosis; type I diabetes; rheumatoid arthritis; inflammatory bowel disease; tuberculosis	Activated T lymphocytes → **(i)** release of cytokines → inflammation and macrophage activation; **(ii)** T cell–mediated cytotoxicity	Perivascular cellular infiltrates; edema; granuloma formation; cell destruction

Immediate (Type I) Hypersensitivity

Immediate, or type I, hypersensitivity is a rapid immunologic reaction occurring within minutes after the combination of an antigen with antibody bound to mast cells in individuals previously sensitized to the antigen.[26] These reactions are often called *allergy*, and the antigens that elicit them are allergens. Immediate hypersensitivity may occur as a systemic disorder or as a local reaction. The systemic reaction usually follows injection of an antigen into a sensitized individual. Sometimes, within minutes the patient goes into a state of shock, which may be fatal. Local reactions are diverse and vary depending on the portal of entry of the allergen. They may take the form of localized cutaneous swellings (skin allergy, hives), nasal and conjunctival discharge (allergic rhinitis and conjunctivitis), hay fever, bronchial asthma, or allergic gastroenteritis (food allergy). Many local type I hypersensitivity reactions have two well-defined phases (Fig. 6-13). The *immediate* or *initial reaction* is characterized by vasodilation, vascular leakage, and depending on the location, smooth muscle spasm or glandular

secretions. These changes usually become evident within 5 to 30 minutes after exposure to an allergen and tend to subside in 60 minutes. In many instances (e.g., allergic rhinitis and bronchial asthma), a second, *late-phase reaction* sets in 2 to 24 hours later without additional exposure to antigen and may last for several days. This late-phase reaction is characterized by infiltration of tissues with eosinophils, neutrophils, basophils, monocytes, and CD4+ T cells as well as tissue destruction, typically in the form of mucosal epithelial cell damage.

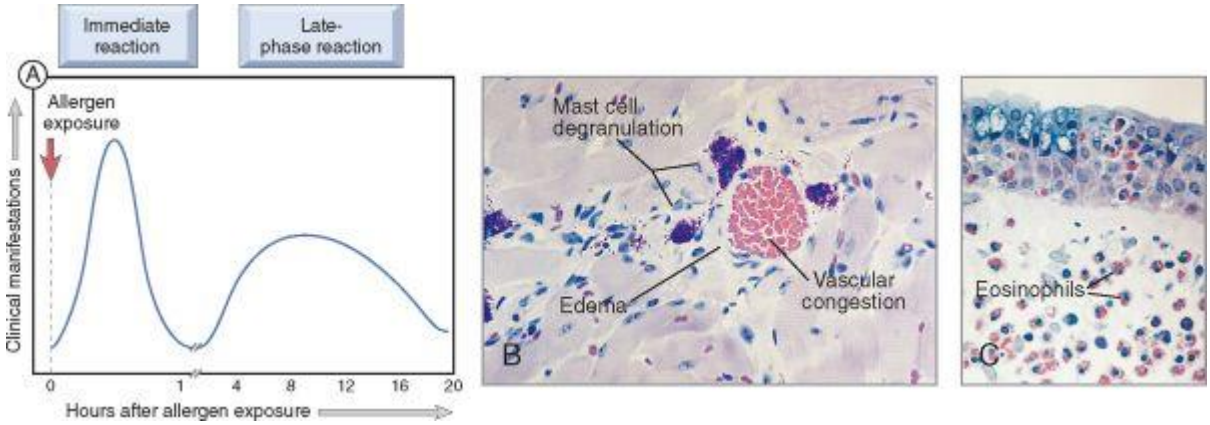

FIGURE 6-13 Immediate hypersensitivity. **A**, Kinetics of the immediate and late-phase reactions. The immediate vascular and smooth muscle reaction to allergen develops within minutes after challenge (allergen exposure in a previously sensitized individual), and the late-phase reaction develops 2 to 24 hours later. **B, C**, Morphology: The immediate reaction (**B**) is characterized by vasodilation, congestion, and edema, and the late-phase reaction (**C**) is characterized by an inflammatory infiltrate rich in eosinophils, neutrophils, and T cells. *(Courtesy of Dr. Daniel Friend, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

Most immediate hypersensitivity reactions are mediated by IgE antibody–dependent activation of mast cells and other leukocytes (Fig. 6-14). Because mast cells are central to the development of immediate hypersensitivity, we first review some of their salient characteristics.[27] *Mast cells* are bone marrow–derived cells that are widely distributed in the tissues. They are abundant near blood vessels and nerves and in subepithelial tissues, which explains why local immediate hypersensitivity reactions often occur at these sites. Mast cells have cytoplasmic membrane-bound granules that contain a variety of biologically active mediators. The granules also contain acidic proteoglycans that bind basic dyes such as toluidine blue. As is detailed next, mast cells (and basophils) are activated by the cross-linking of high-affinity IgE Fc receptors; in addition, mast cells may also be triggered by several other stimuli, such as complement components C5a and C3a (called *anaphylatoxins* because they elicit reactions that mimic anaphylaxis), both of which act by binding to receptors on the mast cell membrane. Other mast cell secretagogues include some chemokines (e.g., IL-8), drugs such as codeine and morphine, adenosine, mellitin (present in bee venom), and physical stimuli (e.g., heat, cold, sunlight). Basophils are similar to mast cells in many respects, including the presence of cell surface IgE Fc receptors as well as cytoplasmic granules. In contrast to mast cells, however, basophils are not normally present in tissues but rather circulate in the blood in extremely small numbers. (Most allergic reactions occur in tissues, and the role of basophils in these reactions is not as well established as that of mast cells.) Similar to other granulocytes, basophils can be recruited to inflammatory sites.

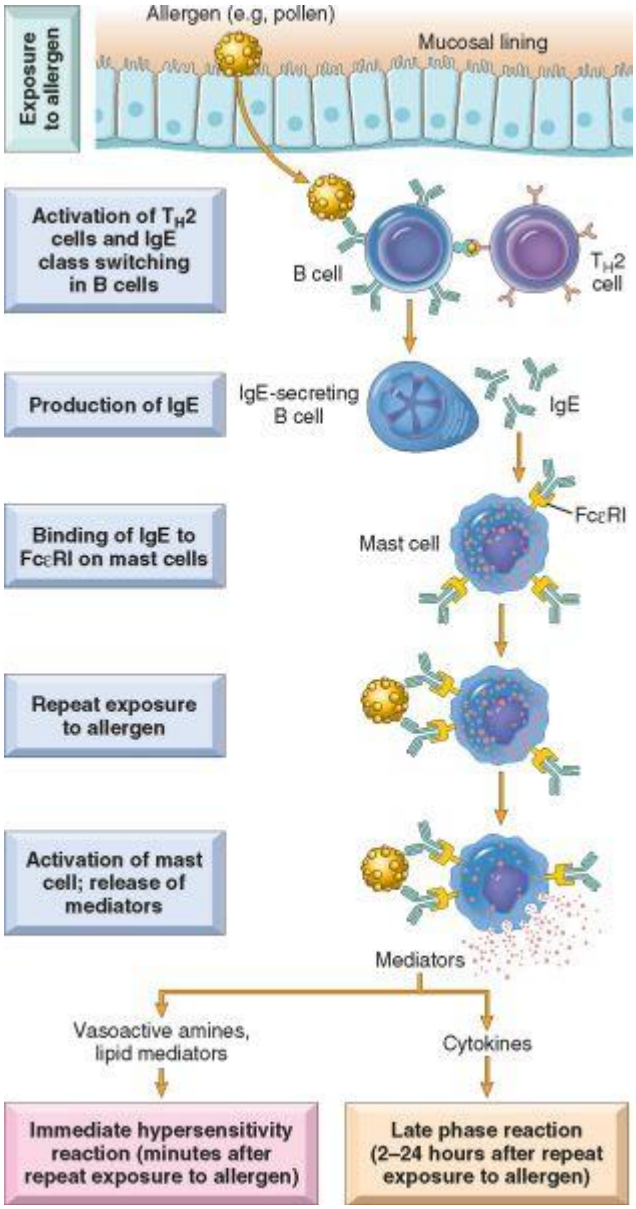

FIGURE 6-14 Sequence of events in immediate (type I) hypersensitivity. Immediate hypersensitivity reactions are initiated by the introduction of an allergen, which stimulates T_H2 responses and IgE production in genetically susceptible individuals. IgE binds to Fc receptors (FcεRI) on mast cells, and subsequent exposure to the allergen activates the mast cells to secrete the mediators that are responsible for the pathologic manifestations of immediate hypersensitivity. See text for abbreviations.

T_H2 cells play a central role in the initiation and propagation of immediate hypersensitivity reactions by stimulating IgE production and promoting inflammation.[28,][29] The first step in the generation of T_H2 cells is the presentation of the antigen to naive CD4+ helper T cells, probably by dendritic cells that capture the antigen from its site of entry. In response to antigen and other stimuli, including cytokines such as IL-4 produced at the local site, the T cells differentiate into T_H2 cells. The newly minted T_H2 cells produce a number of cytokines upon subsequent encounter with the antigen; as we mentioned earlier, the signature cytokines of this subset are IL-4, IL-5, and IL-13. IL-4 acts on B cells to stimulate class switching to IgE, and promotes the development of additional T_H2 cells. IL-5 is involved in the development and activation of eosinophils, which, as we discuss subsequently, are important effectors

of type I hypersensitivity. IL-13 enhances IgE production and acts on epithelial cells to stimulate mucus secretion. In addition, T_H2 cells (as well as mast cells and epithelial cells) produce chemokines that attract more T_H2 cells, as well as other leukocytes, to the reaction site.[28]

Mast cells and basophils express a high-affinity receptor, called FcεRI, that is specific for the Fc portion of IgE, and therefore avidly binds IgE antibodies. When a mast cell, armed with IgE antibodies, is exposed to the specific allergen, a series of reactions takes place, leading eventually to the release of an arsenal of powerful mediators responsible for the clinical expression of immediate hypersensitivity reactions. In the first step in this sequence, antigen (allergen) binds to the IgE antibodies previously attached to the mast cells. Multivalent antigens bind to and cross-link adjacent IgE antibodies and the underlying IgE Fc receptors. The bridging of the Fcε receptors activates signal transduction pathways from the cytoplasmic portion of the receptors. These signals lead to mast cell degranulation with the discharge of preformed (primary) mediators that are stored in the granules, and de novo synthesis and release of secondary mediators, including lipid products and cytokines (Fig. 6-15). These mediators are responsible for the initial, sometimes explosive, symptoms of immediate hypersensitivity, and they also set into motion the events that lead to the late-phase reaction.[26]

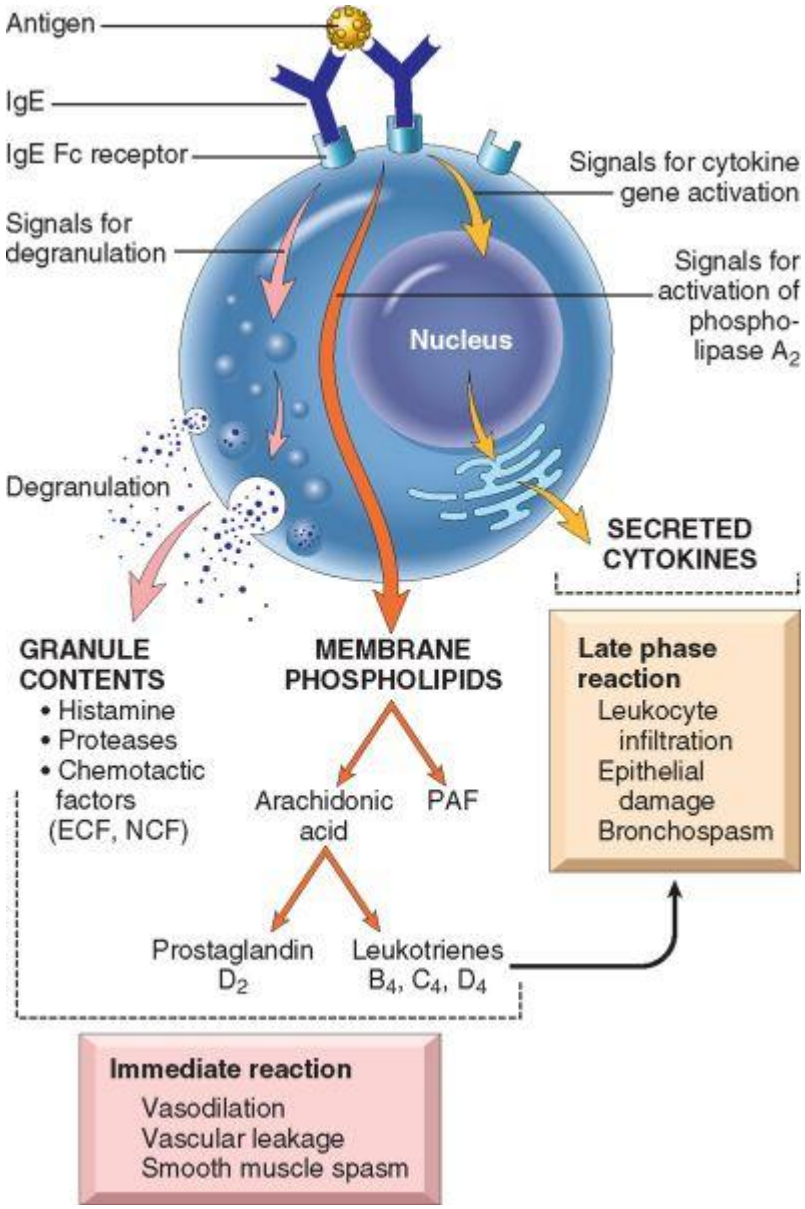

FIGURE 6-15 Mast cell mediators. Upon activation, mast cells release various classes of mediators that are responsible for the immediate and late-phase reactions. ECF, eosinophil chemotactic factor; NCF, neutrophil chemotactic factor (neither of these is biochemically defined); PAF, platelet-activating factor.

Preformed Mediators.

Mediators contained within mast cell granules are the first to be released, and can be divided into three categories:

- *Vasoactive amines*. The most important mast cell–derived amine is *histamine*. Histamine causes intense smooth muscle contraction, increased vascular permeability, and increased mucus secretion by nasal, bronchial, and gastric glands.
- *Enzymes*. These are contained in the granule matrix and include neutral proteases (chymase, tryptase) and several acid hydrolases. The enzymes cause tissue damage and lead to the generation of kinins and activated components of complement (e.g., C3a) by acting on their precursor proteins.
- *Proteoglycans*. These include heparin, a well-known anticoagulant, and chondroitin sulfate. The proteoglycans serve to package and store the amines in the granules.

Lipid Mediators.

The major *lipid mediators* are synthesized by sequential reactions in the mast cell membranes that lead to activation of phospholipase A_2, an enzyme that acts on membrane phospholipids to yield *arachidonic acid*. This is the parent compound from which leukotrienes and prostaglandins are derived by the 5-lipoxygenase and cyclooxygenase pathways (Chapter 2).

- *Leukotrienes*. Leukotrienes C_4 and D_4 are the most potent vasoactive and spasmogenic agents known. On a molar basis, they are several thousand times more active than histamine in increasing vascular permeability and causing bronchial smooth muscle contraction. Leukotriene B_4 is highly chemotactic for neutrophils, eosinophils, and monocytes.
- *Prostaglandin D_2*. This is the most abundant mediator produced in mast cells by the cyclooxygenase pathway. It causes intense bronchospasm as well as increased mucus secretion.
- *Platelet-activating factor (PAF)*. PAF (Chapter 2) is produced by some mast cell populations. It causes platelet aggregation, release of histamine, bronchospasm, increased vascular permeability, and vasodilation. In addition, it is chemotactic for neutrophils and eosinophils, and at high concentrations it activates the inflammatory cells, causing them to degranulate. Although the production of PAF is also triggered by the activation of phospholipase A_2, it is not a product of arachidonic acid metabolism.

Cytokines.

Mast cells are sources of many cytokines, which may play an important role at several stages of immediate hypersensitivity reactions. The cytokines include: TNF, IL-1, and chemokines, which promote leukocyte recruitment (typical of the late-phase reaction); IL-4, which amplifies the T_H2 response; and numerous others. The inflammatory cells that are recruited by mast cell–derived TNF and chemokines are additional sources of cytokines and of histamine-releasing factors that cause further mast cell degranulation.

The development of immediate hypersensitivity reactions is dependent on the coordinated actions of a variety of chemotactic, vasoactive, and spasmogenic compounds (Table 6-3). Some, such as histamine and leukotrienes, are released rapidly from sensitized mast cells and are responsible for the intense immediate reactions characterized by edema, mucus secretion, and smooth muscle spasm; others, exemplified by cytokines, set the stage for the late-phase response by recruiting additional leukocytes. Not only do these inflammatory cells release additional waves of mediators (including cytokines), but

they also cause epithelial cell damage. Epithelial cells themselves are not passive bystanders in this reaction; they can also produce soluble mediators, such as chemokines.

TABLE 6-3 -- Summary of the Action of Mast Cell Mediators in Immediate (Type I) Hypersensitivity

Action	Mediators
Vasodilation, increased vascular permeability	Histamine
	PAF
	Leukotrienes C_4, D_4, E_4
	Neutral proteases that activate complement and kinins
	Prostaglandin D_2
Smooth muscle spasm	Leukotrienes C_4, D_4, E_4
	Histamine
	Prostaglandins
	PAF
Cellular infiltration	Cytokines (e.g., chemokines, TNF)
	Leukotriene B_4
	Eosinophil and neutrophil chemotactic factors (not defined biochemically)

PAF, platelet-activating factor; TNF, tumor necrosis factor.

Among the cells that are recruited in the late-phase reaction, *eosinophils* are particularly important.[30] They are recruited to sites of immediate hypersensitivity reactions by chemokines, such as eotaxin and others, that may be produced by epithelial cells, T_H2 cells, and mast cells. The survival of eosinophils in tissues is favored by IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF), and IL-5 is the most potent eosinophil-activating cytokine known. Eosinophils liberate proteolytic enzymes as well as two unique proteins called major basic protein and eosinophil cationic protein, which are toxic to epithelial cells. Activated eosinophils and other leukocytes also produce leukotriene C_4 and PAF and directly activate mast cells to release mediators. Thus, *the recruited cells amplify and sustain the inflammatory response without additional exposure to the triggering antigen*. It is now believed that this late-phase reaction is a major cause of symptoms in some type I hypersensitivity disorders, such as allergic asthma. Therefore, treatment of these diseases requires the use of broad-spectrum anti-inflammatory drugs, such as steroids.

Susceptibility to immediate hypersensitivity reactions is genetically determined. The term *atopy* refers to a predisposition to develop localized immediate hypersensitivity reactions to a variety of inhaled and ingested allergens. Atopic individuals tend to have higher serum IgE levels, and more IL-4–producing T_H2 cells, compared with the general population. A positive family history of allergy is found in 50% of atopic individuals. The basis of familial predisposition is not clear, but studies in patients with asthma reveal linkage to several gene loci.[31] Candidate genes have been mapped to 5q31, where genes encoding the cytokines IL-3, IL-4, IL-5, IL-9, IL-13, and GM-CSF are located. This locus has attracted great attention because of the known roles of many of these cytokines in the reaction, but how the disease-associated polymorphisms influence the biology of the cytokines is not known. Linkage has also

been noted to 6p, close to the HLA complex, suggesting that the inheritance of certain HLA alleles permits reactivity to certain allergens.

A significant proportion of immediate hypersensitivity reactions are triggered by temperature extremes and exercise, and do not involve T_H2 cells or IgE; such reactions are sometimes called "non-atopic allergy." It is believed that in these cases mast cells are abnormally sensitive to activation by various non-immune stimuli.

A final point that should be mentioned in this general discussion of immediate hypersensitivity disorders is that the incidence of many of these diseases is increasing in developed countries, and seems to be related to a decrease in infections during early life. These observations have led to an idea, sometimes called the *hygiene hypothesis*, that reduced exposure to microbes resets the immune system in such a way that T_H2 responses develop more readily against common environmental antigens. This hypothesis, however, is controversial, and the underlying mechanisms are not defined.

To summarize, immediate (type I) hypersensitivity is a complex disorder resulting from an IgE-mediated triggering of mast cells and subsequent accumulation of inflammatory cells at sites of antigen deposition. These events are regulated mainly by the induction of T_H2 helper T cells that stimulate production of IgE (which promotes mast cell activation), cause accumulation of inflammatory cells (particularly eosinophils), and trigger secretion of mucus. The clinical features result from release of mast cell mediators as well as the eosinophil-rich inflammation.

With this consideration of the basic mechanisms of type I hypersensitivity, we turn to some conditions that are important examples of IgE-mediated disease.

Systemic Anaphylaxis

Systemic anaphylaxis is characterized by vascular shock, widespread edema, and difficulty in breathing. It may occur in sensitized individuals in hospital settings after administration of foreign proteins (e.g., antisera), hormones, enzymes, polysaccharides, and drugs (such as the antibiotic penicillin), or in the community setting following exposure to food allergens (e.g. peanuts, shellfish) or insect toxins (e.g. those in bee venom).[32] Extremely small doses of antigen may trigger anaphylaxis, for example, the tiny amounts used in skin testing for various forms of allergies. Because of the risk of severe allergic reactions to minute quantities of peanuts, the U.S. Congress is considering a bill to ban peanut snacks from the confined quarters of commercial airplanes. Within minutes after exposure, itching, hives, and skin erythema appear, followed shortly thereafter by a striking contraction of respiratory bronchioles and respiratory distress. Laryngeal edema results in hoarseness and further compromises breathing. Vomiting, abdominal cramps, diarrhea, and laryngeal obstruction follow, and the patient may go into shock and even die within the hour. The risk of anaphylaxis must be borne in mind when certain therapeutic agents are administered. Although patients at risk can generally be identified by a previous history of some form of allergy, the absence of such a history does not preclude the possibility of an anaphylactic reaction.

Local Immediate Hypersensitivity Reactions

About 10% to 20% of the population suffers from allergies involving localized reactions to common environmental allergens, such as pollen, animal dander, house dust, foods, and the like. Specific diseases include urticaria, angioedema, allergic rhinitis (hay fever), and bronchial asthma; these are discussed elsewhere in the book.

Antibody-Mediated (Type II) Hypersensitivity

This type of hypersensitivity is caused by antibodies that react with antigens present on cell surfaces or in the extracellular matrix. The antigenic determinants may be intrinsic to the cell membrane or matrix, or they may take the form of an exogenous antigen, such as a drug metabolite, that is adsorbed on a cell surface or matrix. In either case the hypersensitivity reaction results from the binding of antibodies to normal or altered cell surface antigens. The antibody-dependent mechanisms that cause tissue injury and disease are illustrated in Figure 6-16 and described next.

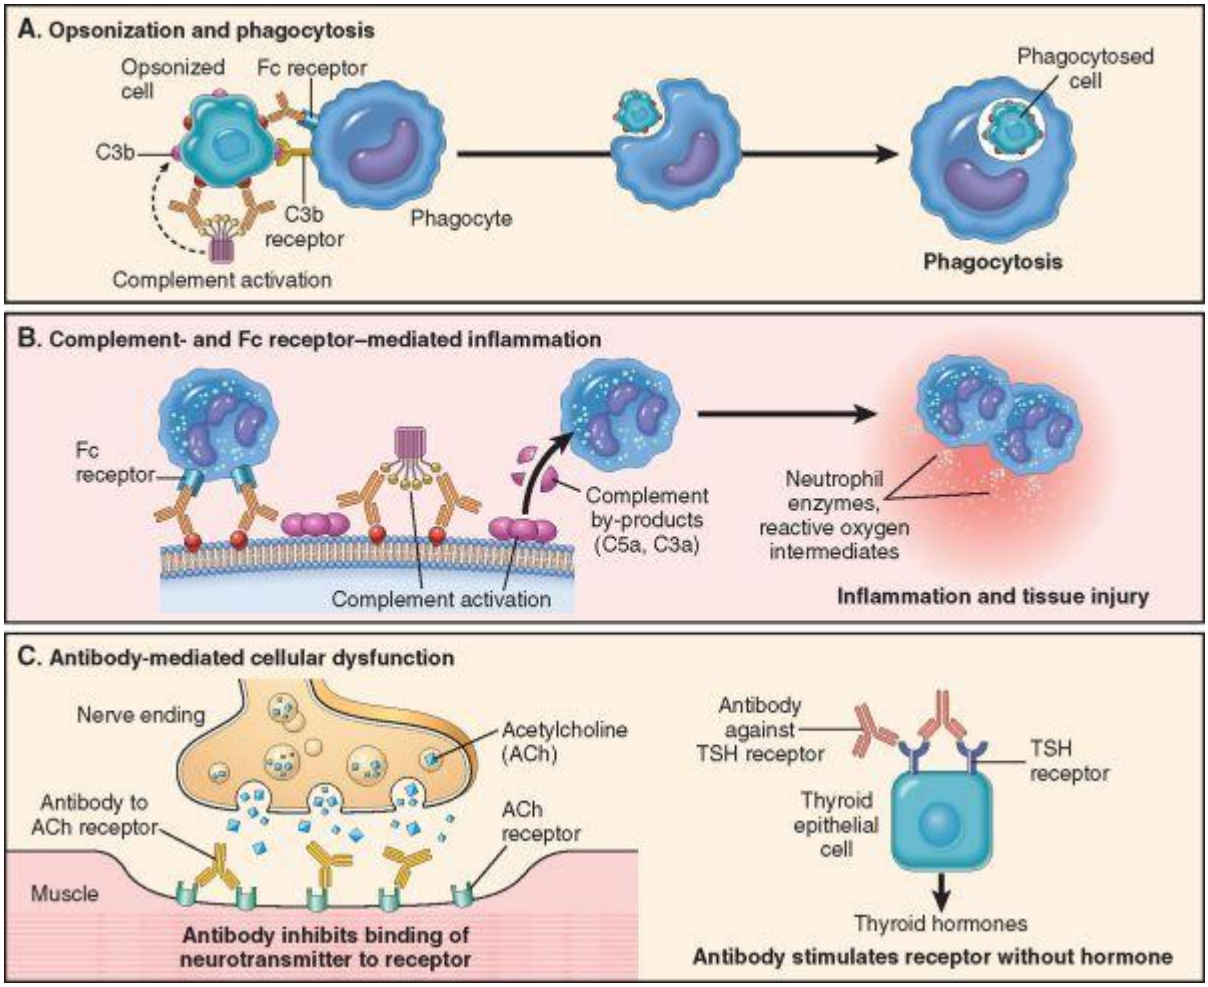

FIGURE 6-16 Mechanisms of antibody-mediated injury. **A**, Opsonization of cells by antibodies and complement components and ingestion by phagocytes. **B**, Inflammation induced by antibody binding to Fc receptors of leukocytes and by complement breakdown products. **C**, Anti-receptor antibodies disturb the normal function of receptors. In these examples, antibodies to the acetylcholine (ACh) receptor impair neuromuscular transmission in myasthenia gravis, and antibodies against the thyroid-stimulating hormone (TSH) receptor activate thyroid cells in Graves disease.

Opsonization and Phagocytosis

Phagocytosis is largely responsible for depletion of cells coated with antibodies. Cells opsonized by IgG antibodies are recognized by phagocyte Fc receptors, which are specific for the Fc portions of some IgG subclasses. In addition, when IgM or IgG antibodies are deposited on the surfaces of cells, they may activate the complement system by the classical pathway. Complement activation generates by-products, mainly C3b and C4b, which are deposited on the surfaces of the cells and recognized by phagocytes that express receptors for these proteins. The net result is phagocytosis of the opsonized cells and their destruction (Fig. 6-16A). Complement activation on cells also leads to the formation of the membrane

attack complex, which disrupts membrane integrity by "drilling holes" through the lipid bilayer, thereby causing osmotic lysis of the cells. This mechanism of depletion is probably effective only with cells that have thin cell walls, such as *Neisseria* bacteria.

Antibody-mediated destruction of cells may occur by another process called *antibody-dependent cellular cytotoxicity (ADCC)*. Cells that are coated with low concentrations of IgG antibody are killed by a variety of effector cells, which bind to the target by their receptors for the Fc fragment of IgG, and cell lysis proceeds without phagocytosis. ADCC may be mediated by monocytes, neutrophils, eosinophils, and NK cells. The role of ADCC in particular hypersensitivity diseases is uncertain.

Clinically, antibody-mediated cell destruction and phagocytosis occur in the following situations: (1) *transfusion reactions*, in which cells from an incompatible donor react with and are opsonized by preformed antibody in the host; (2) *hemolytic disease of the newborn (erythroblastosis fetalis)*, in which there is an antigenic difference between the mother and the fetus, and antibodies (of the IgG class) from the mother cross the placenta and cause destruction of fetal red cells; (3) *autoimmune hemolytic anemia*, *agranulocytosis*, and *thrombocytopenia*, in which individuals produce antibodies to their own blood cells, which are then destroyed; and (4) *certain drug reactions*, in which a drug acts as a "hapten" by attaching to surface molecules of red cells and antibodies are produced against the drug–membrane protein complex.

Inflammation

When antibodies deposit in fixed tissues, such as basement membranes and extracellular matrix, the resultant injury is due to inflammation. The deposited antibodies activate complement, generating by-products, including chemotactic agents (mainly C5a), which direct the migration of polymorphonuclear leukocytes and monocytes, and anaphylatoxins (C3a and C5a), which increase vascular permeability (Fig. 6-16B). The leukocytes are activated by engagement of their C3b and Fc receptors. This results in the release or generation of a variety of pro-inflammatory substances, including prostaglandins, vasodilator peptides, and chemotactic substances. Leukocyte activation leads to the production of other substances that damage tissues, such as lysosomal enzymes, including proteases capable of digesting basement membrane, collagen, elastin, and cartilage, and reactive oxygen species. It was once thought that complement was the major mediator of antibody-induced inflammation, but knockout mice lacking Fc receptors also show striking reduction in these reactions. It is now believed that inflammation in antibody-mediated (and immune complex–mediated) diseases is due to both complement- and Fc receptor–dependent reactions.[33]

Antibody-mediated inflammation is the mechanism responsible for tissue injury in some forms of *glomerulonephritis*, *vascular rejection* in organ grafts, and other disorders (Table 6-4).

TABLE 6-4 -- Examples of Antibody-Mediated Diseases (Type II Hypersensitivity)

Disease	Target Antigen	Mechanisms of Disease	Clinicopathologic Manifestations
Autoimmune hemolytic anemia	Red cell membrane proteins (Rh blood group antigens, I antigen)	Opsonization and phagocytosis of red cells	Hemolysis, anemia
Autoimmune thrombocytopenic purpura	Platelet membrane proteins (GpIIb: IIIa integrin)	Opsonization and phagocytosis of platelets	Bleeding
Pemphigus vulgaris	Proteins in intercellular junctions of epidermal cells (epidermal cadherin)	Antibody-mediated activation of proteases, disruption of intercellular adhesions	Skin vesicles (bullae)
Vasculitis caused by	Neutrophil granule proteins,	Neutrophil degranulation and	Vasculitis

Disease	Target Antigen	Mechanisms of Disease	Clinicopathologic Manifestations
ANCA	presumably released from activated neutrophils	inflammation	
Goodpasture syndrome	Noncollagenous protein in basement membranes of kidney glomeruli and lung alveoli	Complement- and Fc receptor–mediated inflammation	Nephritis, lung hemorrhage
Acute rheumatic fever	Streptococcal cell wall antigen; antibody cross-reacts with myocardial antigen	Inflammation, macrophage activation	Myocarditis, arthritis
Myasthenia gravis	Acetylcholine receptor	Antibody inhibits acetylcholine binding, down-modulates receptors	Muscle weakness, paralysis
Graves disease (hyperthyroidism)	TSH receptor	Antibody-mediated stimulation of TSH receptors	Hyperthyroidism
Insulin-resistant diabetes	Insulin receptor	Antibody inhibits binding of insulin	Hyperglycemia, ketoacidosis
Pernicious anemia	Intrinsic factor of gastric parietal cells	Neutralization of intrinsic factor, decreased absorption of vitamin B_{12}	Abnormal erythropoiesis, anemia

ANCA, antineutrophil cytoplasmic antibodies; TSH, thyroid-stimulating hormone.

Cellular Dysfunction

In some cases, antibodies directed against cell surface receptors impair or dysregulate function without causing cell injury or inflammation (Fig. 6-16C). For example, in *myasthenia gravis*, antibodies reactive with acetylcholine receptors in the motor end plates of skeletal muscles block neuromuscular transmission and therefore cause muscle weakness. The converse (i.e., antibody-mediated stimulation of cell function) is the basis of *Graves disease*. In this disorder, antibodies against the thyroid-stimulating hormone receptor on thyroid epithelial cells stimulate the cells, resulting in hyperthyroidism.

Immune Complex–Mediated (Type III) Hypersensitivity

Antigen-antibody complexes produce tissue damage mainly by eliciting inflammation at the sites of deposition. The pathologic reaction is initiated when antigen combines with antibody within the circulation (circulating immune complexes), and these are deposited typically in vessel walls.[34] Sometimes the complexes are formed at extravascular sites where antigen may have been "planted" previously (called in situ immune complexes). The antigens that form immune complexes may be *exogenous*, such as a foreign protein that is injected or produced by an infectious microbe, or *endogenous*, if the individual produces antibody against self-components (autoimmunity). Examples of immune complex disorders and the antigens involved are listed in Table 6-5 . Immune complex–mediated diseases can be *systemic*, if immune complexes are formed in the circulation and are deposited in many organs, or *localized* to particular organs, such as the kidney (glomerulonephritis), joints (arthritis), or the small blood vessels of the skin if the complexes are deposited or formed in these tissues.

TABLE 6-5 -- Examples of Immune Complex–Mediated Diseases

Disease	Antigen Involved	Clinicopathologic Manifestations
Systemic lupus erythematosus	Nuclear antigens	Nephritis, skin lesions, arthritis, others
Poststreptococcal glomerulonephritis	Streptococcal cell wall antigen(s); may be “planted” in glomerular basement membrane	Nephritis
Polyarteritis nodosa	Hepatitis B virus antigens in some cases	Systemic vasculitis
Reactive arthritis	Bacterial antigens (e.g., *Yersinia*)	Acute arthritis
Serum sickness	Various proteins, e.g., foreign serum protein (horse anti-thymocyte globulin)	Arthritis, vasculitis, nephritis
Arthus reaction (experimental)	Various foreign proteins	Cutaneous vasculitis

Systemic Immune Complex Disease

Acute serum sickness is the prototype of a systemic immune complex disease; it was once a frequent sequela to the administration of large amounts of foreign serum (e.g., serum from immunized horses used for protection against diphtheria). In modern times the disease is infrequent, but it is an informative model that has taught us a great deal about systemic immune complex disorders.

The pathogenesis of systemic immune complex disease can be divided into three phases: (1) formation of antigen-antibody complexes in the circulation; (2) deposition of the immune complexes in various tissues, thus initiating (3) an inflammatory reaction at the sites of immune complex deposition (Fig. 6-17).

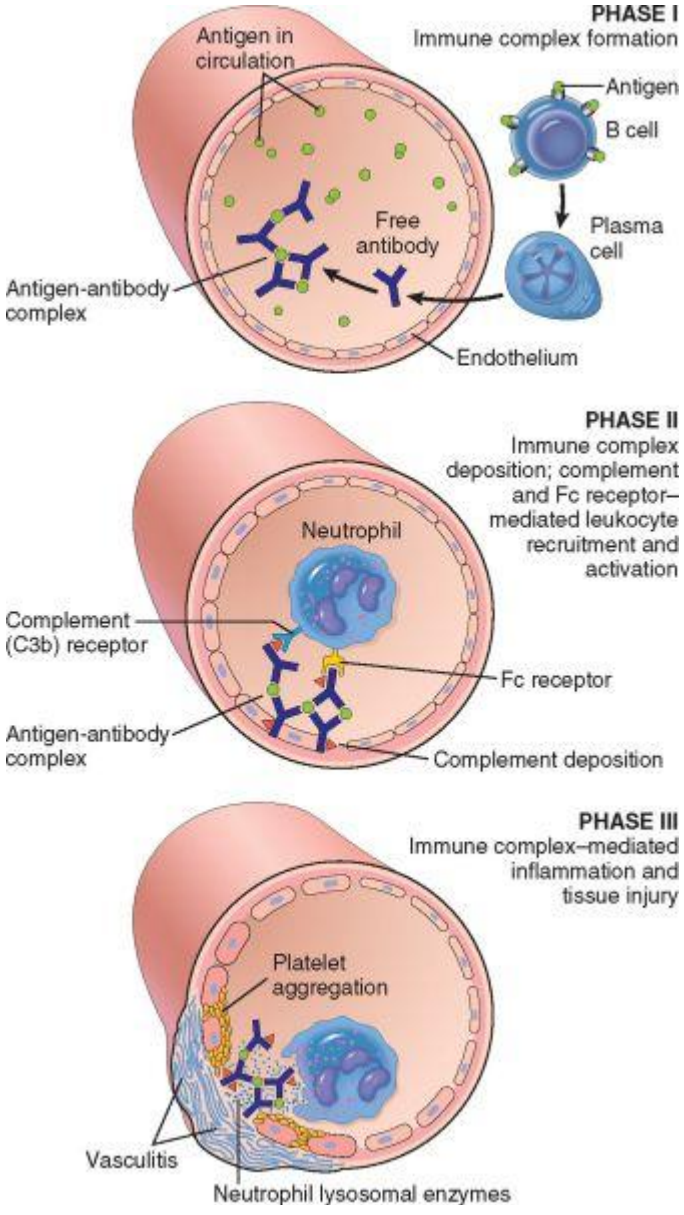

FIGURE 6-17 Pathogenesis of systemic immune complex–mediated disease (type III hypersensitivity). The three sequential phases in the development of immune complex diseases are shown.

Formation of Immune Complexes.

The introduction of a protein antigen triggers an immune response that results in the formation of antibodies, typically about a week after the injection of the protein. These antibodies are secreted into the blood, where they react with the antigen still present in the circulation and form antigen-antibody complexes.

Deposition of Immune Complexes.

In the next phase the circulating antigen-antibody complexes are deposited in various tissues. The factors that determine whether immune complex formation will lead to tissue deposition and disease are

not fully understood, but the major influences seem to be the characteristics of the complexes and local vascular alterations.

In general, complexes that are of medium size, formed in slight antigen excess, are the most pathogenic. Organs where blood is filtered at high pressure to form other fluids, like urine and synovial fluid, are favored; hence, immune complexes frequently deposit in glomeruli and joints.[35]

Tissue Injury Caused by Immune Complexes.

Once complexes are deposited in the tissues, they initiate an acute inflammatory reaction (the third phase). During this phase (approximately 10 days after antigen administration), clinical features such as fever, urticaria, joint pains (arthralgias), lymph node enlargement, and proteinuria appear. Wherever complexes deposit the tissue damage is similar. The mechanisms of inflammation and injury were discussed above, in the discussion of antibody-mediated injury. The resultant inflammatory lesion is termed *vasculitis* if it occurs in blood vessels, *glomerulonephritis* if it occurs in renal glomeruli, *arthritis* if it occurs in the joints, and so on.

It is clear that complement-fixing antibodies (i.e., IgG and IgM) and antibodies that bind to leukocyte Fc receptors (some subclasses of IgG) induce the pathologic lesions of immune complex disorders. The important role of complement in the pathogenesis of the tissue injury is supported by the observations that during the active phase of the disease, consumption of complement leads to a decrease in serum levels of C3. In fact, serum C3 levels can, in some cases, be used to monitor disease activity.

Morphology. The principal morphologic manifestation of immune complex injury is acute necrotizing vasculitis, with necrosis of the vessel wall and intense neutrophilic infiltration. The necrotic tissue and deposits of immune complexes, complement, and plasma protein produce a smudgy eosinophilic deposit that obscures the underlying cellular detail, an appearance termed **fibrinoid necrosis** (Fig. 6-18). When deposited in the kidney, the **complexes can be seen on immunofluorescence microscopy as granular lumpy deposits of immunoglobulin and complement** and on electron microscopy as electron-dense deposits along the glomerular basement membrane (see Figs. 6-30 and 6-31).

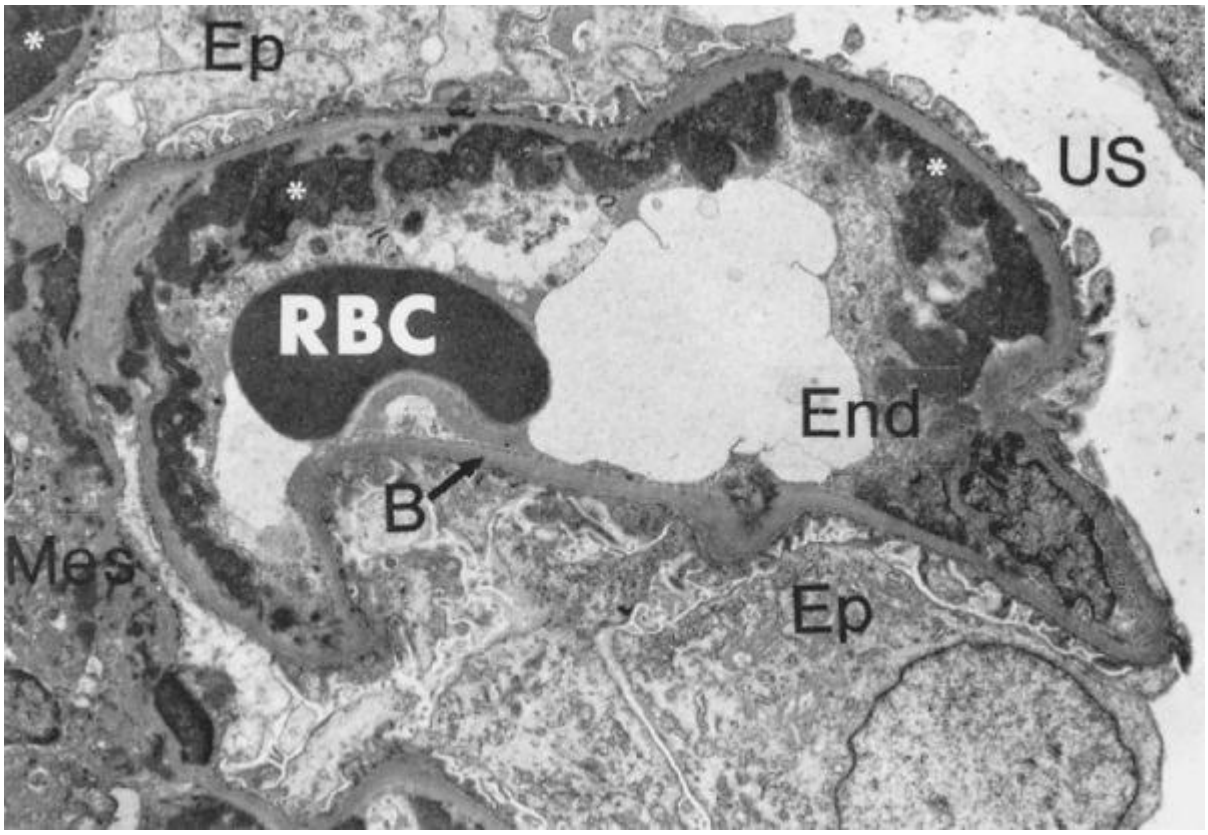

FIGURE 6-31 Immune complex deposition in systemic lupus erythematosus (SLE). Electron micrograph of a renal glomerular capillary loop from a patient with SLE nephritis shows subendothelial dense deposits corresponding to "wire loops" seen by light microscopy. Deposits are also present in the mesangium. B, basement membrane; End, endothelium; Ep, epithelium; RBC, red blood cell; US, urinary space *(Courtesy of Dr. Edwin Eigenbrodt, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

If the disease results from a single large exposure to antigen (e.g., acute serum sickness and perhaps acute poststreptococcal glomerulonephritis), the lesions tend to resolve, as a result of catabolism of the immune complexes. A *chronic form of serum sickness* results from repeated or prolonged exposure to an antigen. This occurs in several human diseases, such as systemic lupus erythematosus (SLE), which is associated with persistent antibody responses to autoantigens. In many diseases, however, the morphologic changes and other findings suggest immune complex deposition but the inciting antigens are unknown. Included in this category are membranous glomerulonephritis, many cases of polyarteritis nodosa, and several other vasculitides.

Local Immune Complex Disease (Arthus Reaction)

The *Arthus reaction* is a localized area of tissue necrosis resulting from acute immune complex vasculitis, usually elicited in the skin. The reaction can be produced experimentally by intracutaneous injection of antigen in a previously immunized animal that contains circulating antibodies against the antigen. As the antigen diffuses into the vascular wall, it binds the preformed antibody, and large immune complexes are formed locally. These complexes precipitate in the vessel walls and cause fibrinoid necrosis, and superimposed thrombosis worsens the ischemic injury.

T Cell–Mediated (Type IV) Hypersensitivity

The cell-mediated type of hypersensitivity is initiated by antigen-activated (sensitized) T lymphocytes, including CD4+ and CD8+ T cells (Fig. 6-19). CD4+ T cell–mediated hypersensitivity induced by environmental and self-antigens can be a cause of chronic inflammatory disease. Many autoimmune diseases are now known to be caused by inflammatory reactions driven by CD4+ T cells (Table 6-6). In some of these T cell–mediated autoimmune diseases, CD8+ cells may also be involved. In fact, in certain forms of T cell–mediated reactions, especially those that follow viral infections, CD8+ cells may be the dominant effector cells.

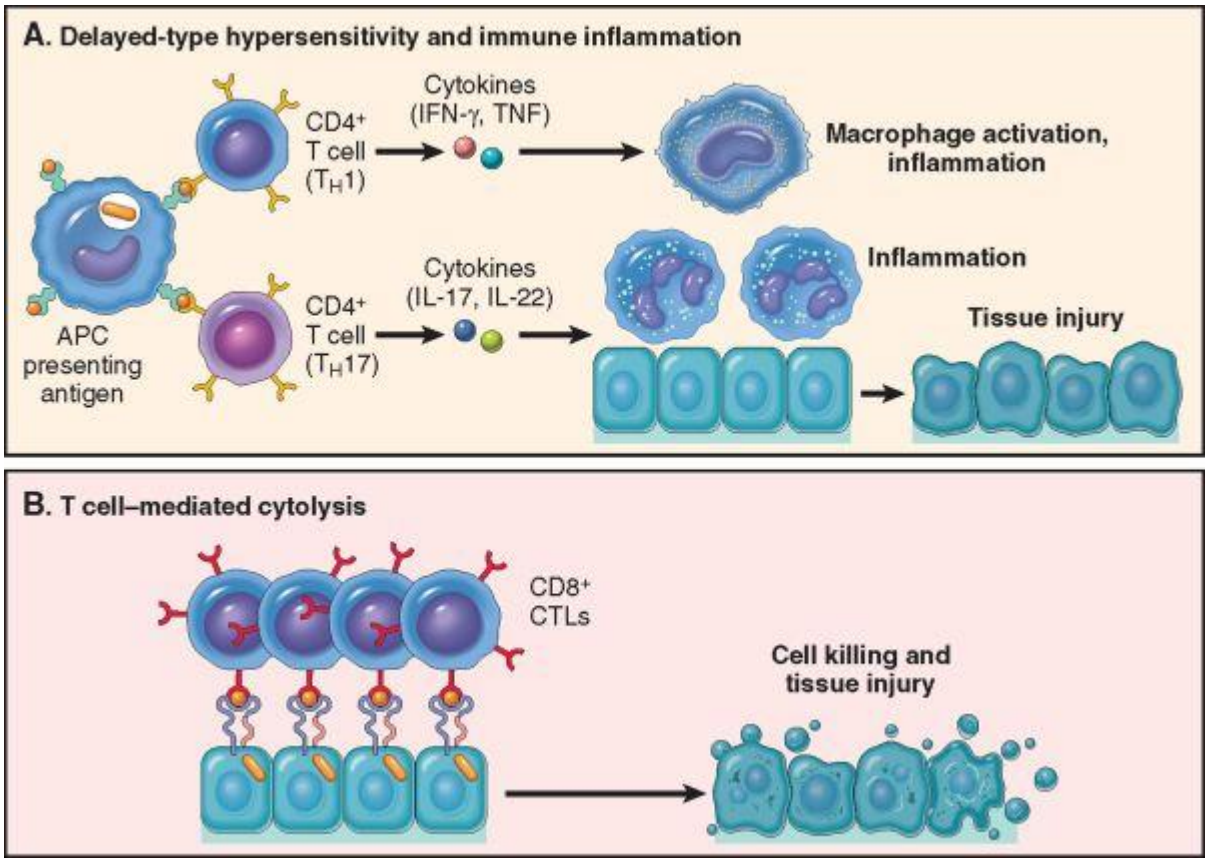

FIGURE 6-19 Mechanisms of T cell–mediated (type IV) hypersensitivity reactions. **A**, In delayed-type hypersensitivity reactions, CD4+ T_H1 cells (and sometimes CD8+ T cells, not shown) respond to tissue antigens by secreting cytokines that stimulate inflammation and activate phagocytes, leading to tissue injury. CD4+ T_H17 cells contribute to inflammation by recruiting neutrophils (and, to a lesser extent, monocytes). **B**, In some diseases, CD8+ cytotoxic T lymphocytes (CTLs) directly kill tissue cells. APC, antigen-presenting cell. See text for other abbreviations.

TABLE 6-6 -- Examples of T Cell–Mediated (Type IV) Hypersensitivity

Disease	Specificity of Pathogenic T Cells	Clinicopathologic Manifestations
Type 1 diabetes mellitus	Antigens of pancreatic islet β cells (insulin, glutamic acid decarboxylase, others)	Insulitis (chronic inflammation in islets), destruction of β cells; diabetes
Multiple sclerosis	Protein antigens in CNS myelin (myelin basic protein, proteolipid protein)	Demyelination in CNS with perivascular inflammation; paralysis, ocular lesions
Rheumatoid arthritis	Unknown antigen in joint synovium (type II collagen?); role of antibodies?	Chronic arthritis with inflammation, destruction of articular cartilage and bone
Crohn disease	Unknown antigen; role for commensal bacteria	Chronic intestinal inflammation, obstruction

Disease	Specificity of Pathogenic T Cells	Clinicopathologic Manifestations
Peripheral neuropathy; Guillain-Barré syndrome?	Protein antigens of peripheral nerve myelin	Neuritis, paralysis
Contact sensitivity (dermatitis)	Various environmental antigens (e.g., poison ivy)	Skin inflammation with blisters

CNS, central nervous system.

Reactions of CD4+ T Cells: Delayed-Type Hypersensitivity and Immune Inflammation

Inflammatory reactions caused by CD4+ T cells were initially characterized on the basis of *delayed-type hypersensitivity (DTH)* to exogenously administered antigens. The same immunological events are responsible for chronic inflammatory reactions against self-tissues. Because of the central role of the adaptive immune system in such inflammation, it is sometimes referred to as *immune inflammation*. Both T_H1 and T_H17 cells contribute to organ-specific diseases in which inflammation is a prominent aspect of the pathology.[36] The inflammatory reaction associated with T_H1 cells is dominated by activated macrophages, and that triggered by T_H17 cells has a greater neutrophil component.

The cellular events in T cell–mediated hypersensitivity consist of a series of reactions in which cytokines play important roles. The reactions can be divided into the following stages.

Proliferation and Differentiation of CD4+ T Cells.

Naive CD4+ T cells recognize peptides displayed by dendritic cells and secrete IL-2, which functions as an autocrine growth factor to stimulate proliferation of the antigen-responsive T cells. The subsequent differentiation of antigen-stimulated T cells to T_H1 or T_H17 cells is driven by the cytokines produced by APCs at the time of T-cell activation (see Fig. 6-13).[36] In some situations the APCs (dendritic cells and macrophages) produce IL-12, which induces differentiation of CD4+ T cells to the T_H1 subset. IFN-γ produced by these effector cells promotes further T_H1 development, thus amplifying the reaction. If the APCs produce inflammatory cytokines such as IL-1, IL-6, and a close relative of IL-12 called IL-23, these work in collaboration with transforming growth factor-β (TGF-β) (made by many cell types) to stimulate differentiation of T cells to the T_H17 subset. Some of the differentiated effector cells enter the circulation and may remain in the memory pool of T cells for long periods, sometimes years.

Responses of Differentiated Effector T Cells.

Upon repeat exposure to an antigen, previously activated T cells recognize the antigen displayed by APCs and respond. T_H1 cells secrete cytokines, mainly IFN-γ, which are responsible for many of the manifestations of delayed-type hypersensitivity. IFN-γ–activated macrophages are altered in several ways: their ability to phagocytose and kill microorganisms is markedly augmented; they express more class II MHC molecules on the surface, thus facilitating further antigen presentation; they secrete TNF, IL-1, and chemokines, which promote inflammation (Chapter 2); and they produce more IL-12, thereby amplifying the T_H1 response. Thus, activated macrophages serve to eliminate the offending antigen; if the activation is sustained, continued inflammation and tissue injury result.

T_H17 cells are activated by some microbial antigens and by self-antigens in autoimmune diseases. Activated T_H17 cells secrete IL-17, IL-22, chemokines, and several other cytokines. Collectively, these cytokines recruit neutrophils and monocytes to the reaction, thus promoting inflammation. T_H17 cells also produce IL-21, which amplifies the T_H17 response.

The classic example of DTH is the *tuberculin reaction*, which is produced by the intracutaneous injection of purified protein derivative (PPD, also called tuberculin), a protein-containing antigen of the tubercle bacillus. In a previously sensitized individual, reddening and induration of the site appear in 8 to 12 hours, reach a peak in 24 to 72 hours, and thereafter slowly subside. Morphologically, delayed-type hypersensitivity is characterized by the accumulation of mononuclear cells, mainly CD4+ T cells and macrophages, around venules, producing perivascular "cuffing" (Fig. 6-20). In fully developed lesions, the venules show marked endothelial hypertrophy, reflecting cytokine-mediated endothelial activation.

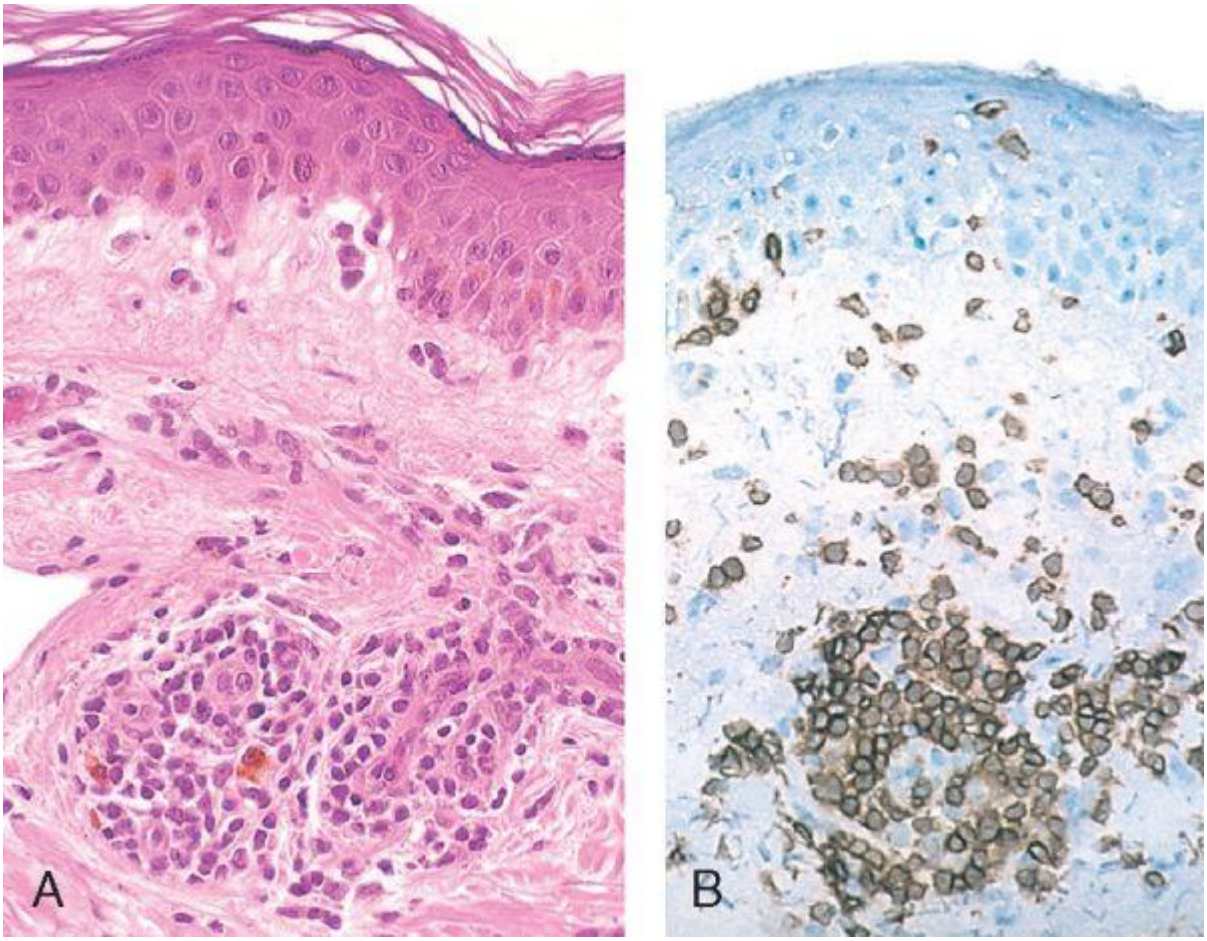

FIGURE 6-20 Delayed hypersensitivity reaction in the skin. **A**, Perivascular infiltration by T cells and mononuclear phagocytes. **B**, Immunoperoxidase staining reveals a predominantly perivascular cellular infiltrate that marks positively with antibodies specific to CD4. *(Courtesy of Dr. Louis Picker, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

With certain persistent or nondegradable antigens, such as tubercle bacilli colonizing the lungs or other tissues, the perivascular infiltrate is dominated by macrophages over a period of 2 or 3 weeks. The activated macrophages often undergo a morphologic transformation into epithelium-like cells and are then referred to as *epithelioid cells*. A microscopic aggregation of epithelioid cells, usually surrounded by a collar of lymphocytes, is referred to as a *granuloma* (Fig. 6-21). This pattern of inflammation, called *granulomatous inflammation* (Chapter 2), is typically associated with strong T-cell activation with cytokine production (Fig. 6-22). It can also be caused by foreign bodies that activate macrophages without eliciting an adaptive immune response.

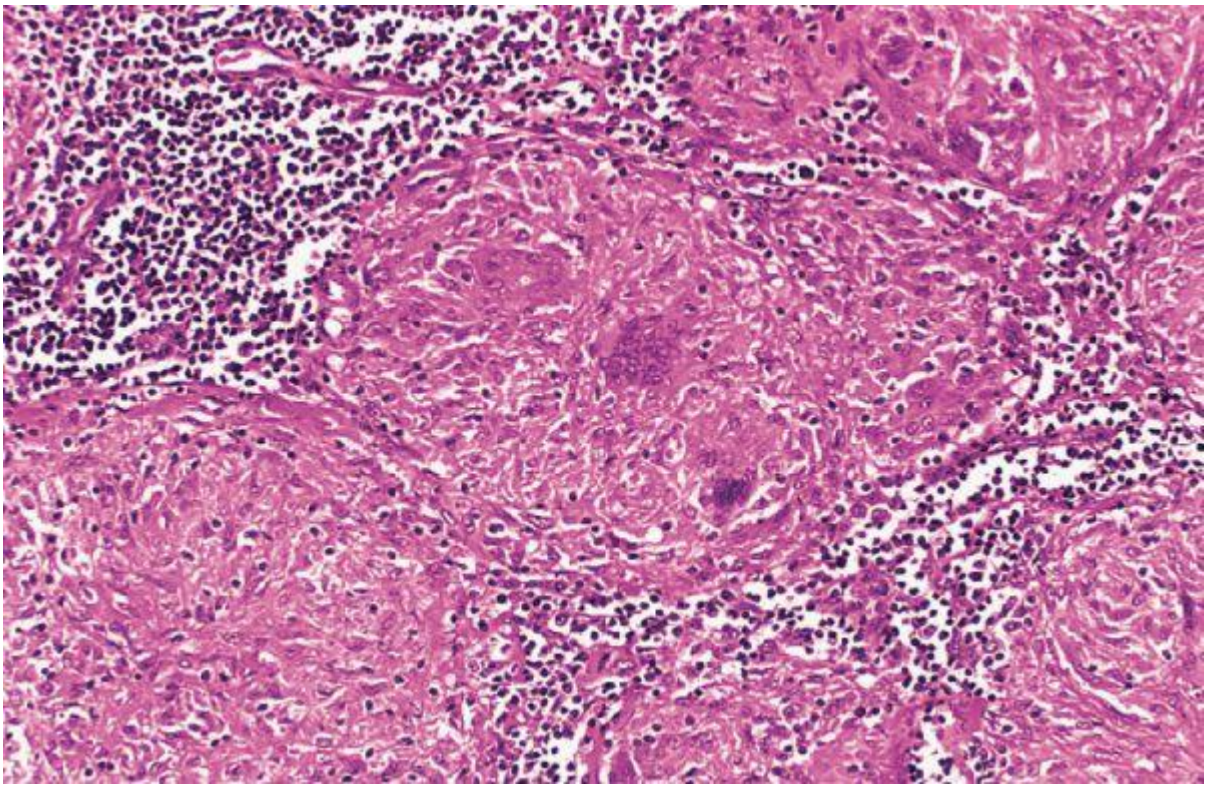

FIGURE 6-21 Granulomatous inflammation. A section of a lymph node shows several granulomas, each made up of an aggregate of epithelioid cells and surrounded by lymphocytes. The granuloma in the center shows several multinucleate giant cells. *(Courtesy of Dr. Trace Worrell, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

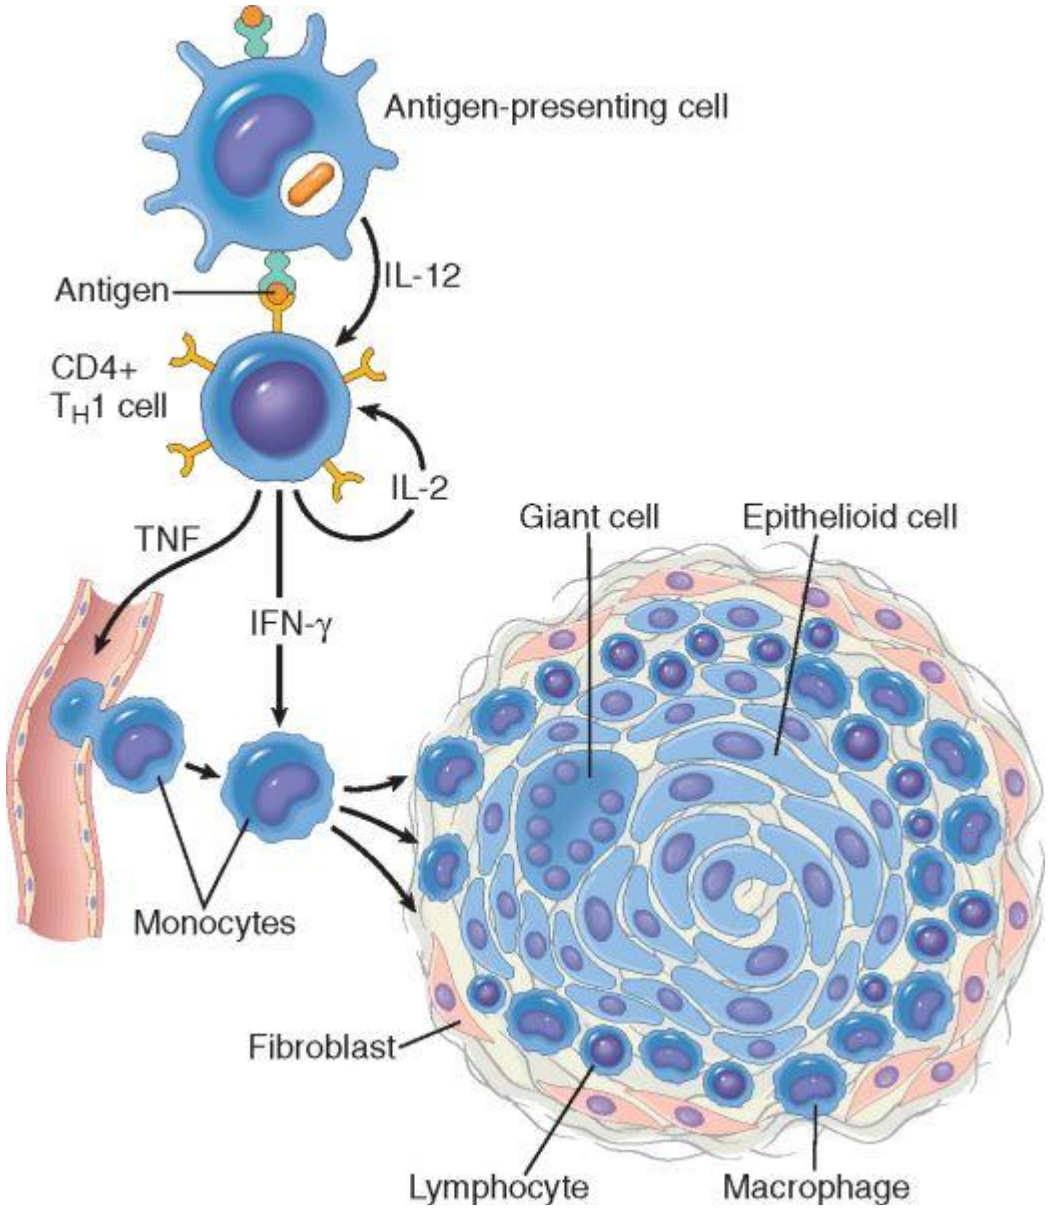

FIGURE 6-22 Mechanisms of granuloma formation. Schematic illustration of the events that give rise to the formation of granulomas in cell-mediated (type IV) hypersensitivity reactions. Note the role played by cytokines. See text for abbreviations.

Contact dermatitis is a common example of tissue injury resulting from DTH reactions. It may be evoked by contact with urushiol, the antigenic component of poison ivy or poison oak, and presents as a vesicular dermatitis (Fig. 6-23).

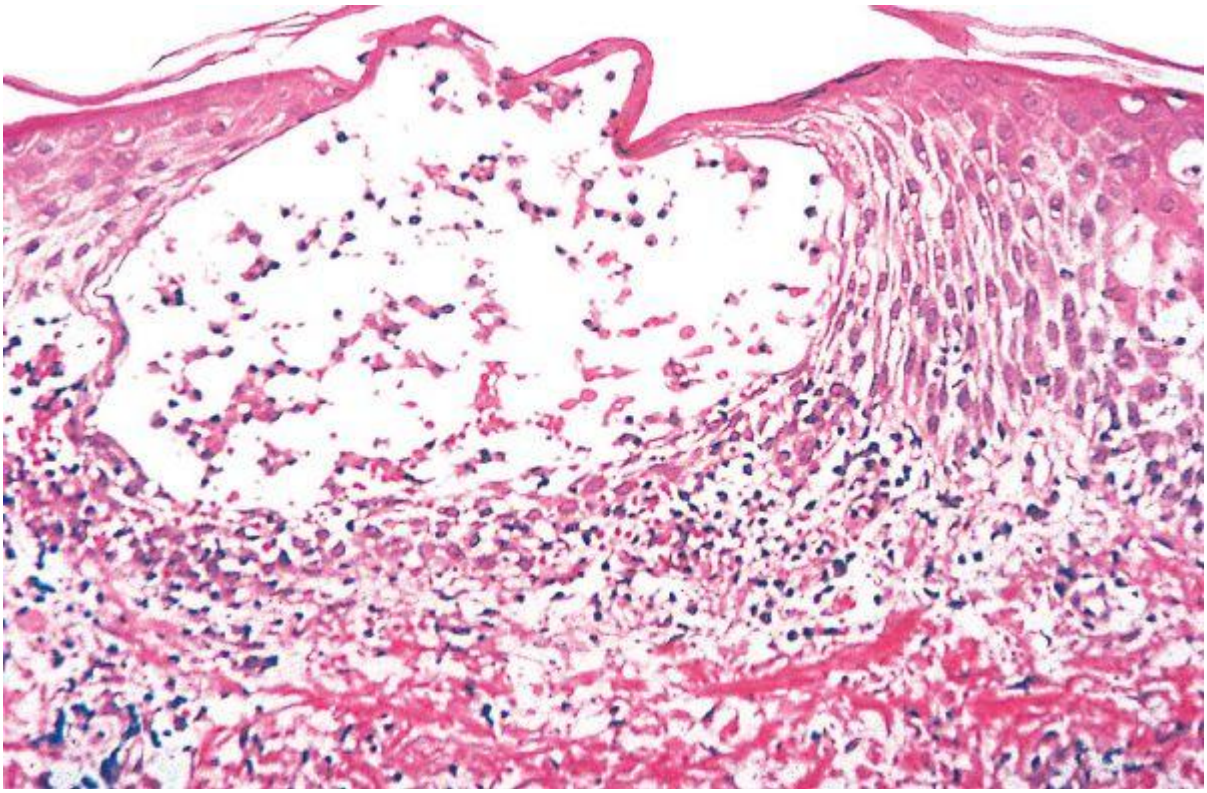

FIGURE 6-23 Contact dermatitis. The lesion shows an epidermal blister (vesicle) with dermal and epidermal mononuclear infiltrates. *(Courtesy of Dr. Louis Picker, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Reactions of CD8+ T Cells: Cell-Mediated Cytotoxicity

In this type of T cell–mediated reaction, CD8+ CTLs kill antigen-bearing target cells. Tissue destruction by CTLs may be an important component of many T cell–mediated diseases, such as type 1 diabetes. CTLs directed against cell surface histocompatibility antigens play an important role in graft rejection, to be discussed later. They also play a role in reactions against viruses. In a virus-infected cell, viral peptides are displayed by class I MHC molecules and the complex is recognized by the TCR of CD8+ T lymphocytes. The killing of infected cells leads to the elimination of the infection, and is responsible for cell damage that accompanies the infection (e.g., in viral hepatitis). Tumor-associated antigens are also presented on the cell surface, and CTLs are involved in tumor rejection (Chapter 7).

The principal mechanism of T cell–mediated killing of targets involves *perforins* and *granzymes*, preformed mediators contained in the lysosome-like granules of CTLs.[37] CTLs that recognize the target cells secrete a complex consisting of perforin, granzymes, and a protein called serglycin, which enters target cells by endocytosis. In the target cell cytoplasm, perforin facilitates the release of the granzymes from the complex. Granzymes are proteases that cleave and activate caspases, which induce apoptosis of the target cells (Chapter 1). Activated CTLs also express Fas ligand, a molecule with homology to TNF, which can bind to Fas expressed on target cells and trigger apoptosis.

CD8+ T cells also produce cytokines, notably IFN-γ, and are involved in inflammatory reactions resembling DTH, especially following virus infections and exposure to some contact sensitizing agents.

AUTOIMMUNE DISEASES

Immune reactions against self-antigens—*autoimmunity*—are an important cause of certain diseases in humans, estimated to affect at least 1% to 2% of the US population. A growing number of diseases have been attributed to autoimmunity (Table 6-7). Autoantibodies can be found in the serum of apparently normal individuals, particularly in older age groups. Furthermore, innocuous autoantibodies are also formed after damage to tissue and may serve a physiologic role in the removal of tissue breakdown products. How, then, does one define *pathologic autoimmunity*? Ideally, at least three requirements should be met before a disorder is categorized as truly due to autoimmunity: (1) the presence of an immune reaction specific for some self-antigen or self-tissue; (2) evidence that such a reaction is not secondary to tissue damage but is of primary pathogenic significance; and (3) the absence of another well-defined cause of the disease. Similarity with experimental models of proven autoimmunity is also often used to support this mechanism in human diseases. Because of the uncertainty about the target antigens and the contribution of "true" autoimmunity, these disorders are often grouped under *immune-mediated inflammatory diseases*. This term also emphasizes the important contribution of chronic inflammation to the pathogenesis of these diseases.

TABLE 6-7 -- Immune-Mediated Inflammatory Diseases

DISEASES MEDIATED BY ANTIBODIES AND IMMUNE COMPLEXES
Organ-specific autoimmune diseases
Autoimmune hemolytic anemia
Autoimmune thrombocytopenia
Myasthenia gravis
Graves disease
Goodpasture syndrome
Systemic autoimmune diseases
Systemic lupus erythematosus (SLE)
Diseases caused by autoimmunity or by reactions to microbial antigens
Polyarteritis nodosa
DISEASES MEDIATED BY T CELLS
Organ-specific autoimmune diseases
Type 1 diabetes mellitus
Multiple sclerosis
Systemic autoimmune diseases
Rheumatoid arthritis[*]
Systemic sclerosis[*]
Sjogren syndrome[*]
Diseases caused by autoimmunity or by reactions to microbial antigens
Inflammatory bowel disease (Crohn disease, ulcerative colitis)
Inflammatory myopathies

[*] Antibodies may also play a role in these diseases.

The clinical manifestations of autoimmune disorders are extremely varied. On one end are conditions in which the immune responses are directed against a single organ or tissue, resulting in *organ-specific disease*, and on the other end are diseases in which the autoimmune reactions are against widespread antigens, resulting in *systemic* or *generalized disease*. Examples of organ-specific autoimmunity are type 1 diabetes mellitus, in which the autoreactive T cells and antibodies are specific for β cells of the pancreatic islets, and multiple sclerosis, in which autoreactive T cells react against central nervous system myelin. The best example of systemic autoimmune disease is SLE, in which a diversity of antibodies directed against DNA, platelets, red cells, and protein-phospholipid complexes result in widespread lesions throughout the body. In the middle of the spectrum falls Goodpasture's syndrome, in which antibodies to basement membranes of lung and kidney induce lesions in these organs.

It is obvious that autoimmunity results from the loss of self-tolerance, and the question arises as to how this happens. Before we look for answers to this question, we review the mechanisms of immunological tolerance to self-antigens.

Immunological Tolerance

Immunological tolerance is the phenomenon of unresponsiveness to an antigen as a result of exposure of lymphocytes to that antigen. Self-tolerance refers to lack of responsiveness to an individual's own antigens, and it underlies our ability to live in harmony with our cells and tissues. Lymphocytes with receptors capable of recognizing self-antigens are being generated constantly, and these cells have to be eliminated or inactivated as soon as they recognize the antigens, to prevent them from causing harm. The mechanisms of self-tolerance can be broadly classified into two groups: central tolerance and peripheral tolerance (Fig. 6-24). [38] [39] [40] Each of these is considered briefly.

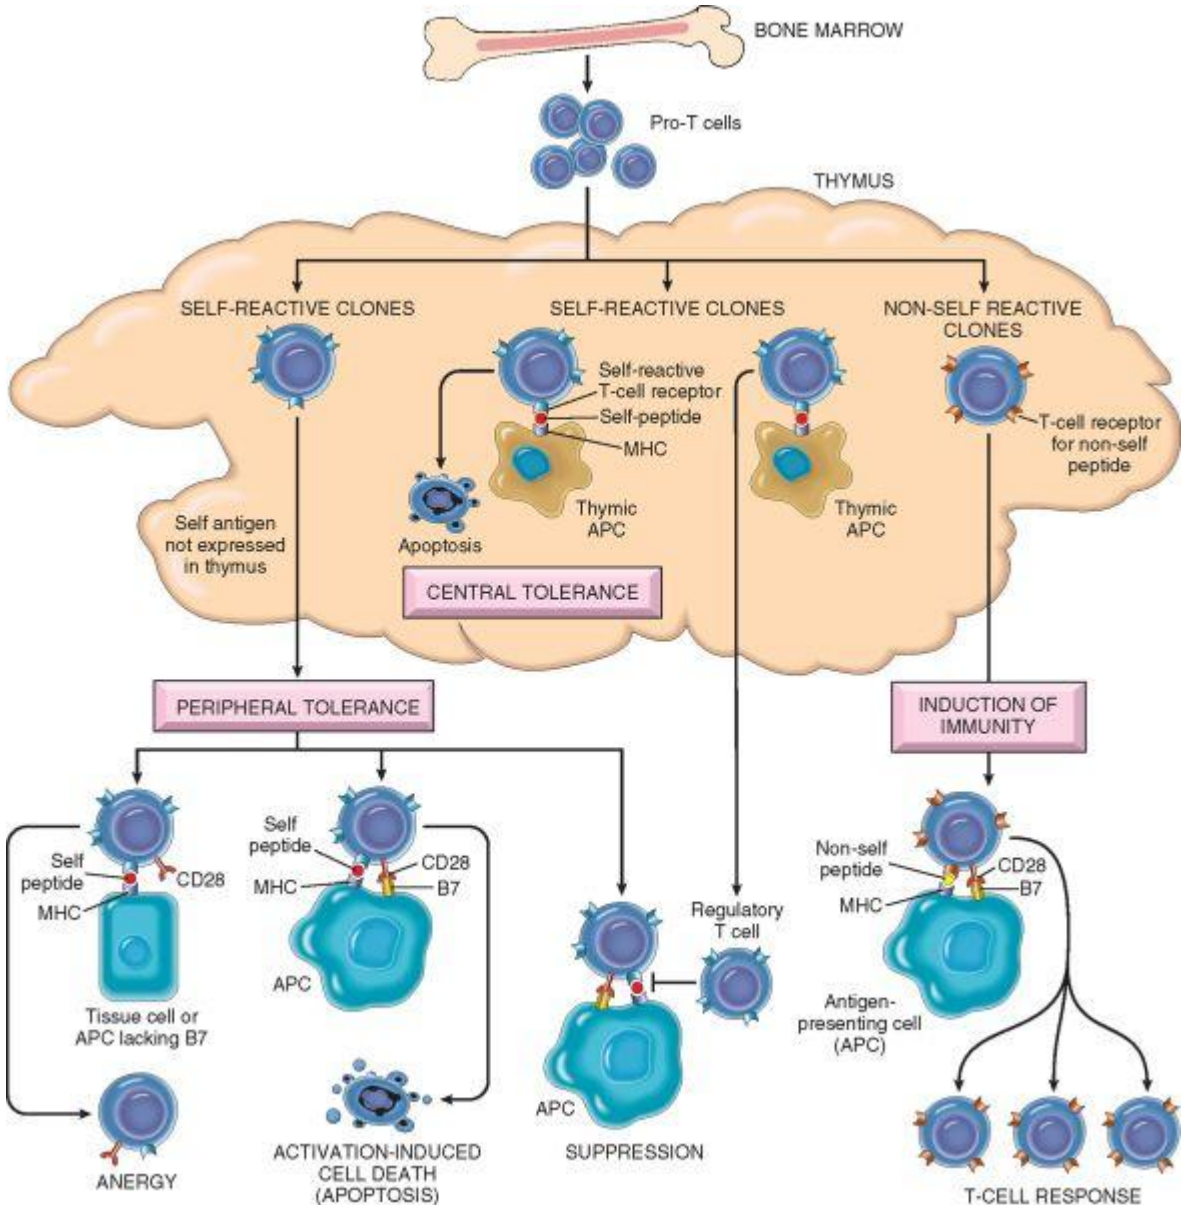

FIGURE 6-24 Mechanisms of immunological tolerance. Schematic illustration of the mechanisms of central and peripheral tolerance to self-antigens, shown for CD4+ T cells. APC, antigen-presenting cell. See text for other abbreviations.

Central Tolerance.

In this process, immature self-reactive T- and B-lymphocyte clones that recognize self-antigens during their maturation in the central (or generative) lymphoid organs (the thymus for T cells and the bone marrow for B cells) are killed or rendered harmless.[41] The mechanisms of central tolerance in T and B cells show some similarities and differences.

- In developing T cells, random somatic gene rearrangements generate diverse TCRs. Such antigen-independent TCR generation produces many lymphocytes that express high-affinity receptors for self-antigens. When immature lymphocytes encounter the antigens in the thymus, the cells die by apoptosis. This process, called *negative selection* or *deletion*, is responsible for eliminating many self-reactive lymphocytes from the T-cell pool. A wide variety of autologous protein antigens, including antigens thought to be restricted to peripheral tissues, are processed and presented by thymic antigen-presenting cells in

association with self-MHC molecules and can, therefore, be recognized by potentially self-reactive T cells. A protein called AIRE (autoimmune regulator) stimulates expression of some "peripheral tissue-restricted" self-antigens in the thymus and is thus critical for deletion of immature T cells specific for these antigens.[42] Mutations in the *AIRE* gene are the cause of an autoimmune polyendocrinopathy (Chapter 24). In the CD4+ T-cell lineage, some of the cells that see self antigens in the thymus do not die but develop into regulatory T cells (described later).

- When developing B cells strongly recognize self-antigens in the bone marrow, many of them reactivate the machinery of antigen receptor gene rearrangement and begin to express new antigen receptors, not specific for self-antigens. This process is called *receptor editing*; it is estimated that a quarter to half of all B cells in the body may have undergone receptor editing during their maturation.[43] If receptor editing does not occur, the self-reactive cells undergo apoptosis, thus purging potentially dangerous lymphocytes from the mature pool.

Central tolerance, however, is far from perfect. Not all self-antigens may be present in the thymus, and hence T cells bearing receptors for such autoantigens escape into the periphery. There is similar "slippage" in the B-cell system. Self-reactive lymphocytes that escape negative selection can inflict tissue injury unless they are deleted or muzzled in the peripheral tissues.

Peripheral Tolerance.

Several mechanisms silence potentially autoreactive T and B cells in peripheral tissues; these are best defined for T cells.[40] These mechanisms include the following:

- *Anergy:* This refers to prolonged or irreversible functional inactivation of lymphocytes, induced by encounter with antigens under certain conditions.[44] We discussed earlier that activation of antigen-specific T cells requires two signals: recognition of peptide antigen in association with self-MHC molecules on the surface of APCs and a set of costimulatory signals ("second signals") from APCs. These second signals are provided by certain T cell–associated molecules, such as CD28, that bind to their ligands (the costimulators B7-1 and B7-2) on APCs. If the antigen is presented by cells that do not bear the costimulators a negative signal is delivered, and the cell becomes anergic (see Fig. 6-24). Because costimulatory molecules are not expressed or are weakly expressed on resting dendritic cells in normal tissues, the encounter between autoreactive T cells and their specific self-antigens displayed by these dendritic cells may lead to anergy. Two mechanisms of T-cell anergy have been demonstrated in various experimental systems. First, the cells lose their ability to trigger biochemical signals from the TCR complex, in part because of activation of ubiquitin ligases and proteolytic degradation of receptor-associated signaling proteins.[45] Second, T cells that recognize self-antigens receive an inhibitory signal from receptors that are structurally homologous to CD28 but serve the opposite functions. Two of these inhibitory receptors are CTLA-4, which (like CD28) also binds to B7 molecules, and PD-1, which binds to two ligands that are expressed on a wide variety of cells.[46] How T cells choose to use CD28 to recognize B7 molecules and be activated, or CTLA-4 to recognize the same B7 molecules and become anergic, is an intriguing question to which there are no clear answers. Nevertheless, the importance of these inhibitory mechanisms has been established by the finding that mice in which the gene encoding CTLA-4 or PD-1 is knocked out develop autoimmune diseases. Furthermore, polymorphisms in the *CTLA4* gene are associated with some autoimmune endocrine diseases in humans. Interestingly, some tumors and viruses may have evolved to use the same pathways of immune regulation to evade immune attack.

Anergy also affects mature B cells in peripheral tissues. It is believed that if B cells encounter self-antigen in peripheral tissues, especially in the absence of specific helper T cells, the B cells become unable to respond to subsequent antigenic stimulation and may be excluded from lymphoid follicles, resulting in their death.

- *Suppression by regulatory T cells:* A population of T cells called *regulatory T cells* plays a major role in preventing immune reactions against self-antigens.[47] Regulatory T cells develop mainly in the thymus, as a result of recognition of self-antigens (see Fig. 6-24), but they may also be induced in peripheral lymphoid tissues. The best-defined regulatory T cells are CD4+ cells that constitutively express CD25, the α chain of the IL-2 receptor, and a transcription factor of the forkhead family, called Foxp3. Both IL-2 and Foxp3 are

required for the development and maintenance of functional CD4+ regulatory T cells.[48] Mutations in *Foxp3* result in severe autoimmunity in humans and mice; in humans these mutations are the cause of a systemic autoimmune disease called IPEX (for immune dysregulation, polyendocrinopathy, enteropathy, X-linked). In mice knockout of the gene encoding IL-2 or the IL-2 receptor α or β chain also results in severe multi-organ autoimmunity, because IL-2 is essential for the maintenance of regulatory T cells. Recent genome-wide association studies have revealed that polymorphisms in the *CD25* gene are associated with multiple sclerosis and other autoimmune diseases, raising the possibility of a regulatory T-cell defect contributing to these diseases. The mechanisms by which regulatory T cells suppress immune responses are not fully defined. The inhibitory activity of these cells may be mediated by the secretion of immunosuppressive cytokines such as IL-10 and TGF-β, which inhibit lymphocyte activation and effector functions.

- *Deletion by activation-induced cell death:* CD4+ T cells that recognize self-antigens may receive signals that promote their death by apoptosis. This process has been called activation-induced cell death, because it is a consequence of T-cell activation. Two mechanisms of activation-induced cell death have been proposed, based on studies in mice.[49] It is postulated that if T cells recognize self-antigens, they may express a pro-apoptotic member of the Bcl family, called Bim, without anti-apoptotic members of the family like Bcl-2 and Bcl-x (whose induction requires the full set of signals for lymphocyte activation). Unopposed Bim triggers apoptosis by the mitochondrial pathway (Chapter 1). A second mechanism of activation-induced death of CD4+ T cells and B cells involves the Fas-Fas ligand system. Lymphocytes as well as many other cells express Fas (CD95), a member of the TNF-receptor family. FasL, a membrane protein that is structurally homologous to the cytokine TNF, is expressed mainly on activated T lymphocytes. The engagement of Fas by FasL induces apoptosis of activated T cells by the death receptor pathway (Chapter 1). It is postulated that if self-antigens engage antigen receptors of self-antigen–specific T cells, Fas and FasL are co-expressed, leading to elimination of the cells via Fas-mediated apoptosis (see Fig. 6-24). Self-reactive B cells may also be deleted by FasL on T cells engaging Fas on the B cells. The importance of this mechanism in the peripheral deletion of autoreactive lymphocytes is highlighted by two strains of mice that are natural mutants of Fas or FasL. Both these strains of mice develop an autoimmune disease resembling human SLE, associated with generalized lymphoproliferation. In humans a similar disease is caused by mutations in the *FAS* gene; it is called the autoimmune lymphoproliferative syndrome.[50]

Some antigens are hidden (sequestered) from the immune system, because the tissues in which these antigens are located do not communicate with the blood and lymph. Thus, self-antigens in these tissues do not induce tolerance but fail to elicit immune responses and are essentially ignored by the immune system. This is believed to be the case for the testis, eye, and brain, all of which are called *immune-privileged sites* because it is difficult to induce immune responses to antigens introduced into these sites. If the antigens of these tissues are released, for example, as a consequence of trauma or infection, the result may be an immune response that leads to prolonged tissue inflammation and injury. This is the postulated mechanism for post-traumatic orchitis and uveitis.

Mechanisms of Autoimmunity: General Principles

Autoimmunity arises from a combination of the inheritance of susceptibility genes, which may contribute to the breakdown of self-tolerance, and environmental triggers, such as infections and tissue damage, which promote the activation of self-reactive lymphocytes (Fig. 6-25).[51,][52] In general, these genetic and environmental influences conspire to create an imbalance between control mechanisms that normally function to prevent self-reactivity and pathways that lead to the generation and activation of pathogenic effector lymphocytes. In the following section we discuss how genetic and other factors contribute to the development of autoimmunity.

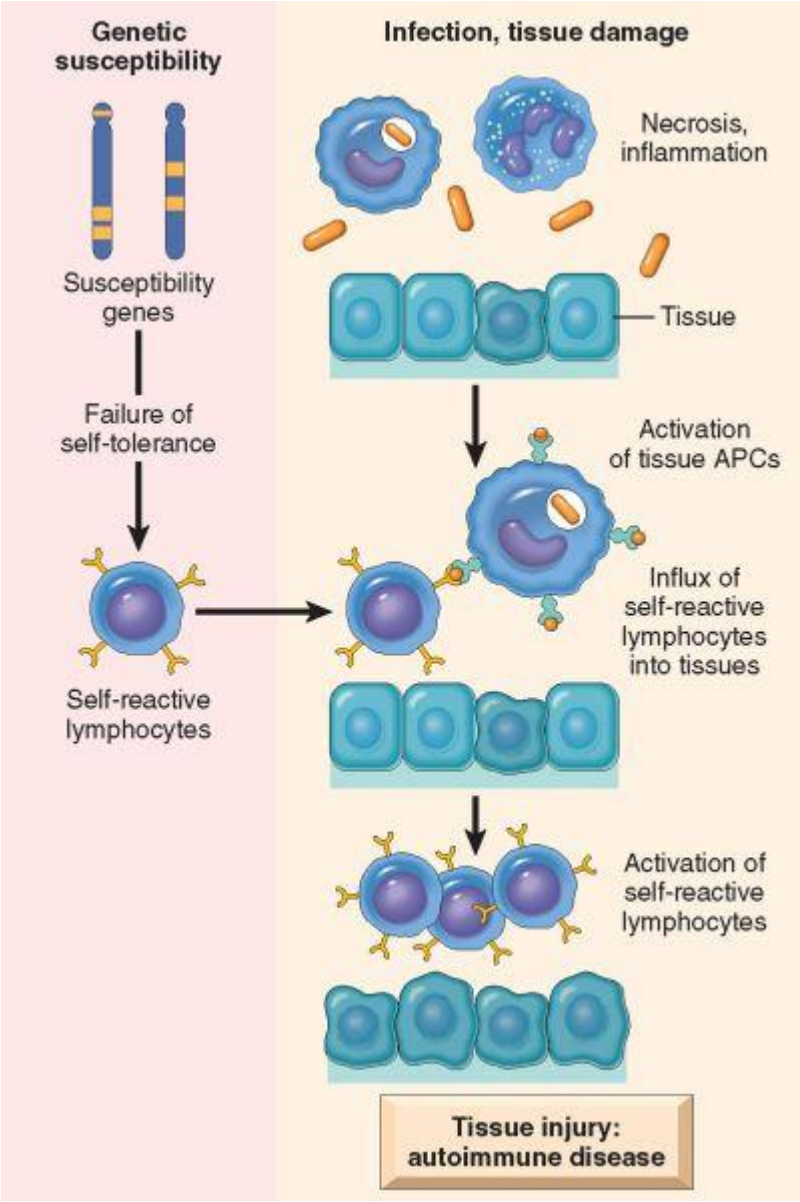

FIGURE 6-25 Pathogenesis of autoimmunity. Autoimmunity results from multiple factors, including susceptibility genes that may interfere with self-tolerance and environmental triggers (tissue injury, inflammation) that promote lymphocyte entry into tissues, activation of self-reactive lymphocytes, and tissue damage.

Role of Susceptibility Genes.

It has been known for decades that autoimmunity has a genetic component. The incidence of the disease is greater in twins of affected individuals than in the general population, and greater in monozygotic than in dizygotic twins. *Most autoimmune diseases are complex multigenic disorders*.[53] [54] [55] Among the genes known to be associated with autoimmunity, the greatest contribution is that of HLA genes. The concept of HLA association with diseases was mentioned earlier (see Table 6-1). Although this association has been well established for many years, the underlying mechanisms remain obscure. It is postulated that the presence of particular MHC alleles affects the negative selection of T cells in the thymus or the development of regulatory T cells, but there is little proof for either possibility. It should be pointed out that many normal individuals inherit the MHC alleles that are disease-associated in

patient populations, and normal MHC molecules are capable of presenting self-antigens. Therefore, the presence of particular MHC alleles is not, by itself, the cause of autoimmunity.

Genome-wide association studies (Chapter 5) have shown that multiple non-MHC genes are associated with various autoimmune diseases. Some of these genes are disease-specific, but many of the associations are seen in multiple disorders, suggesting that the products of these genes affect general mechanisms of immune regulation and self-tolerance. Three recently described genetic associations are especially interesting. Polymorphisms in a gene called *PTPN-22*, which encodes a protein tyrosine phosphatase, are associated with rheumatoid arthritis, type 1 diabetes, and several other autoimmune diseases.[56] Because these disorders have a fairly high prevalence (especially rheumatoid arthritis), *PTPN-22 is said to be the gene that is most frequently implicated in autoimmunity*. It is postulated that the disease-associated variants encode a phosphatase that is functionally defective and is thus unable to fully control the activity of tyrosine kinases, which are involved in many lymphocyte responses. The net result is excessive lymphocyte activation. Polymorphisms in the gene for *NOD-2* are associated with Crohn disease, a form of inflammatory bowel disease, especially in certain ethnic populations.[57] NOD-2 is a cytoplasmic sensor of microbes, expressed in epithelial and many other cells. According to one hypothesis, the disease-associated variant is ineffective at sensing intestinal microbes, resulting in entry of and chronic inflammatory responses against normally well-tolerated commensal bacteria. The genes encoding the *IL-2 receptor (CD25)* and *IL-7 receptor* α chains are associated with multiple sclerosis and other autoimmune diseases. These cytokines may control the maintenance of regulatory T cells. Although these genetic associations are beginning to reveal interesting clues about pathogenesis, the links between the genes, functions of their encoded proteins, and the diseases remain to be established.

We have already mentioned that in mice and humans, knockouts and natural mutations affecting several individual genes result in autoimmunity. These genes include *AIRE*, *CTLA4*, *PD1*, *Fas*, *FasL*, and *IL2* and its receptor *CD25*. In addition, B cells express an Fc receptor that recognizes IgG antibodies bound to antigens and switches off further antibody production (a normal negative-feedback mechanism). Knockout of this receptor results in autoimmunity, pre-sumably because the B cells can no longer be controlled. These examples are very informative about pathways of self-tolerance and immune regulation, but the diseases caused by these single gene mutations are rare and not representative of the common autoimmune disorders.

Role of Infections.

Many autoimmune diseases are associated with infections, and clinical flare-ups are often preceded by infectious prodromes. Two mechanisms have been postulated to explain the link between infections and autoimmunity (Fig. 6-26). First, infections may up-regulate the expression of costimulators on APCs. If these cells are presenting self-antigens, the result may be a breakdown of anergy and activation of T cells specific for the self-antigens. Second, some microbes may express antigens that have the same amino acid sequences as self-antigens. Immune responses against the microbial antigens may result in the activation of self-reactive lymphocytes. This phenomenon is called *molecular mimicry*. A clear example of such mimicry is rheumatic heart disease, in which antibodies against streptococcal proteins cross-react with myocardial proteins and cause myocarditis (Chapter 12). But more subtle molecular mimicry may be involved in classical autoimmune diseases as well.

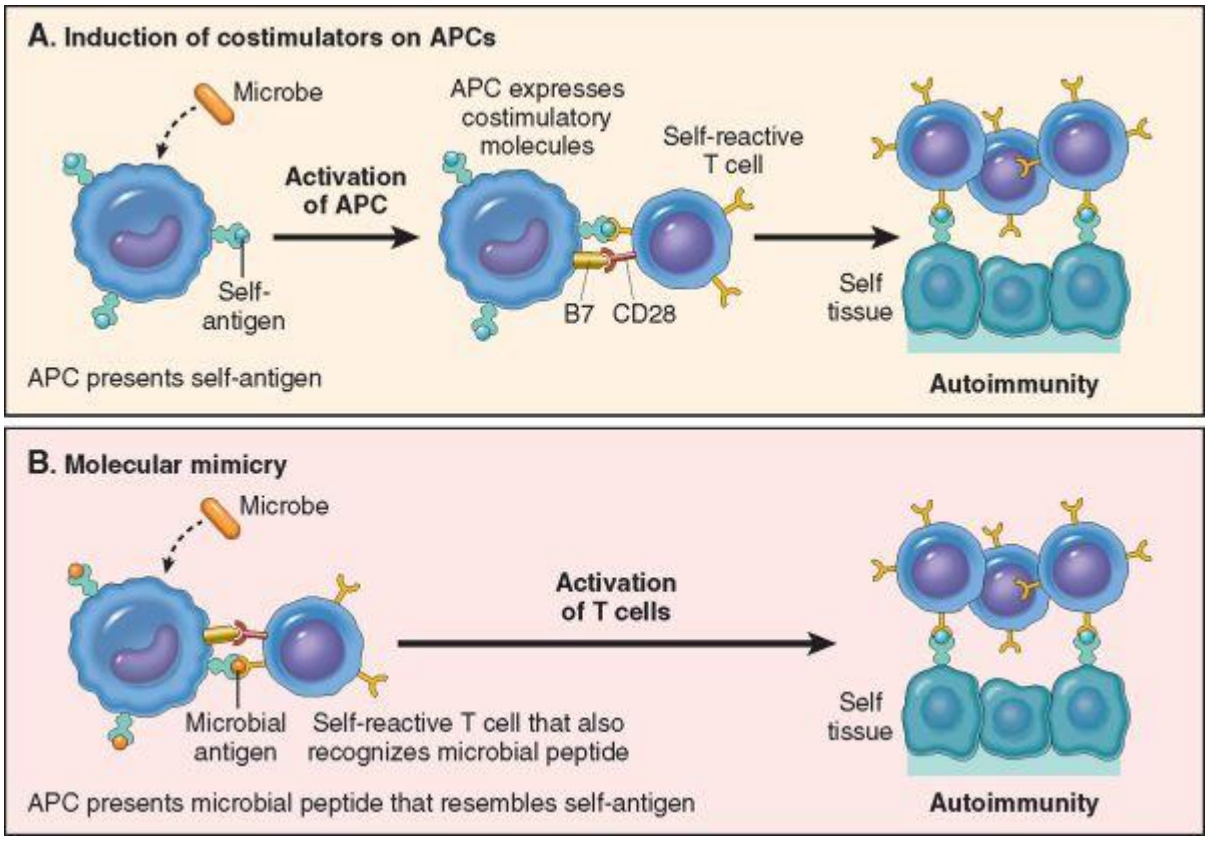

FIGURE 6-26 Postulated role of infections in autoimmunity. Infections may promote activation of self-reactive lymphocytes by inducing the expression of costimulators (**A**), or microbial antigens may mimic self-antigens and activate self-reactive lymphocytes as a cross-reaction (**B**).

Microbes may induce other abnormalities that promote autoimmune reactions. Some viruses, such as Epstein-Barr virus (EBV) and HIV, cause polyclonal B-cell activation, which may result in production of autoantibodies. The tissue injury that is common in infections may release self-antigens and structurally alter self-antigens so that they are able to activate T cells that are not tolerant to these new, modified antigens. Infections may induce the production of cytokines that recruit lymphocytes, including potentially self-reactive lymphocytes, to sites of self-antigens.

Although the role of infections in triggering autoimmunity has received a great deal of attention, recent epidemiologic studies suggest that the incidence of autoimmune diseases is increasing in developed countries as infections are better controlled. In some animal models (e.g., of type 1 diabetes) infections greatly reduce the incidence of disease. Thus, *paradoxically, infections may protect against some autoimmune diseases*.[58] The underlying mechanisms are unclear; an intriguing possibility is that infections promote low-level IL-2 production, and this is essential for maintaining regulatory T cells.

General Features of Autoimmune Diseases

Diseases caused by autoimmunity have some important general features.

- Once an autoimmune disease has been induced it tends to be progressive, sometimes with sporadic relapses and remissions, and the damage becomes inexorable. One reason for this is that the immune system contains many intrinsic amplification loops that allow small numbers of antigen-specific lymphocytes to accomplish their task of eradicating complex infections. When the response is inappropriately directed

against self-tissues, the very same amplification mechanisms exacerbate injury. Another reason for the persistence and progression of autoimmune disease is the phenomenon of *epitope spreading*. Infections, and even the initial autoimmune response, may damage tissues, release self-antigens and expose epitopes of the antigens that are normally concealed from the immune system. The result is continuing activation of lymphocytes that recognize these previously hidden epitopes; since these epitopes were not expressed normally, the lymphocytes did not become tolerant to them. The activation of such autoreactive T cells is referred to as epitope spreading because the immune response "spreads" to epitopes that were initially not recognized.[59]

- The clinical and pathologic manifestations of an autoimmune disease are determined by the nature of the underlying immune response. T_H1 responses are associated with destructive macrophage-rich inflammation and the production of antibodies that cause tissue damage by activating complement and binding to Fc receptors. T_H17 responses are believed to underlie inflammatory lesions dominated by neutrophils as well as monocytes.
- Different autoimmune diseases show substantial clinical, pathologic, and serologic overlaps. For this reason, precise phenotypic classification of these disorders is often a challenge.

With this background we can proceed to a discussion of specific autoimmune diseases. Table 6-7 lists both systemic and organ-specific autoimmune disorders. The systemic diseases tend to involve blood vessels and connective tissues, and therefore, they are often classified as *collagen vascular diseases*. Our focus here is on prototypic systemic autoimmune diseases; organ-specific disorders are covered elsewhere in the book.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)

SLE is the prototype of a multisystem disease of autoimmune origin, characterized by a vast array of autoantibodies, particularly antinuclear antibodies (ANAs). *Acute or insidious in its onset, it is a chronic, remitting and relapsing, often febrile illness characterized principally by injury to the skin, joints, kidney, and serosal membranes*. Virtually every other organ in the body, however, may also be affected. The clinical presentation of SLE is so variable that the American College of Rheumatology has established a complex set of criteria for this disorder (Table 6-8). SLE is a fairly common disease, with a prevalence that may be as high as 1 in 2500 in certain populations.[60] Similar to many autoimmune diseases, SLE predominantly affects women, with a frequency of 1 in 700 among women of childbearing age and a female-to-male ratio of 9 : 1. By comparison, the female-to-male ratio is only 2 : 1 for disease developing during childhood or after the age of 65. The prevalence of the disease is 2–3 fold higher in blacks and Hispanics than in whites. Although SLE usually arises in the 20s and 30s, it may manifest at any age, even in early childhood.

TABLE 6-8 -- 1997 Revised Criteria for Classification of Systemic Lupus Erythematosus[*]

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion, or

Criterion	Definition
	Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder	Persistent proteinuria >0.5 gm/dL or >3 if quantitation not performed or
	Cellular casts—may be red blood cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance), or
	Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder	Hemolytic anemia—with reticulocytosis, or
	Leukopenia—<4.0 × 10^9 cells/L (4000 cells/mm^3) total on two or more occasions, or
	Lymphopenia—<1.5 × 10^9 cells/L (1500 cells/mm^3) on two or more occasions, or
	Thrombocytopenia—<100 × 10^9 cells/L (100 × 10^3 cells/mm^3) in the absence of offending drugs
10. Immunological disorder	Anti-DNA antibody to native DNA in abnormal titer, or
	Anti-Sm—presence of antibody to Sm nuclear antigen, or
	Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard test, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by negative *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome

From Tan EM et al: The revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 25:1271, 1982; and Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 40:1725, 1997.

* This classification, based on 11 criteria, was proposed for the purpose of identifying patients in clinical studies. A person is said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any period of observation.

Spectrum of Autoantibodies in SLE

The hallmark of the disease is the production of autoantibodies. Some antibodies recognize diverse nuclear and cytoplasmic components of the cell that are neither organ- nor species-specific, and others are directed against cell surface antigens of blood cells. Apart from their value in the diagnosis and management of patients with SLE, these antibodies are of major pathogenetic significance, as, for example, in the immune complex–mediated glomerulonephritis so typical of this disease.[61,][62]

Antinuclear antibodies (ANAs) are directed against nuclear antigens and can be grouped into four categories[63]: (1) antibodies to DNA, (2) antibodies to histones, (3) antibodies to nonhistone proteins bound to RNA, and (4) antibodies to nucleolar antigens. Table 6-9 lists several ANAs and their association with SLE as well as with other autoimmune diseases to be discussed later. The most widely used method for detecting ANAs is indirect immunofluorescence, which can identify antibodies that bind to a variety of nuclear antigens, including DNA, RNA, and proteins (collectively called *generic*

ANAs). The pattern of nuclear fluorescence suggests the type of antibody present in the patient's serum. Four basic patterns are recognized:

- *Homogeneous or diffuse nuclear staining* usually reflects antibodies to chromatin, histones, and, occasionally, double-stranded DNA.
- *Rim or peripheral staining* patterns are most often indicative of antibodies to double-stranded DNA.
- *Speckled pattern* refers to the presence of uniform or variable-sized speckles. This is one of the most commonly observed patterns of fluorescence and therefore the least specific. It reflects the presence of antibodies to non-DNA nuclear constituents. Examples include Sm antigen, ribonucleoprotein, and SS-A and SS-B reactive antigens (see Table 6-9).
- *Nucleolar pattern* refers to the presence of a few discrete spots of fluorescence within the nucleus and represents antibodies to RNA. This pattern is reported most often in patients with systemic sclerosis.

TABLE 6-9 -- Antinuclear Antibodies in Various Autoimmune Diseases

Nature of Antigen	Antibody System	Disease, % Positive					
		SLE	Drug-Induced LE	Systemic Sclerosis—Diffuse	Limited Scleroderma—CREST	Sjögren Syndrome	Inflammatory Myopathies
Many nuclear antigens (DNA, RNA, proteins)	Generic ANA (indirect IF)	>95	>95	70–90	70–90	50–80	40–60
Native DNA	Anti–double-stranded DNA	40–60	<5	<5	<5	<5	<5
Histones	Antihistone	50–70	>95	<5	<5	<5	<5
Core proteins of small nuclear RNP particles (Smith antigen)	Anti-Sm	20–30	<5	<5	<5	<5	<5
RNP (U1RNP)	Nuclear RNP	30–40	<5	15	10	<5	<5
RNP	SS-A(Ro)	30–50	<5	<5	<5	70–95	10
RNP	SS-B(La)	10–15	<5	<5	<5	60–90	<5
DNA topoisomerase I	Scl-70	<5	<5	28–70	10–18	<5	<5
Centromeric proteins	Anticentromere	<5	<5	22–36	90	<5	<5
Histidyl-tRNA synthetase	Jo-1	<5	<5	<5	<5	<5	25

ANA, antinuclear antibodies; IF, immunofluorescence; LE, lupus erythematosus; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus.

The fluorescence patterns are not absolutely specific for the type of antibody, and because many autoantibodies may be present, combinations of patterns are frequent. *The immunofluorescence test for*

ANAs is sensitive because it is positive in virtually every patient with SLE, but it is not specific because patients with other autoimmune diseases also frequently score positive (see Table 6-9). Furthermore, approximately 5% to 15% of normal individuals have low titers of these antibodies, and the incidence increases with age. *Antibodies to double -stranded DNA and the so-called Smith (Sm) antigen are virtually diagnostic of SLE*.[64]

In addition to ANAs, lupus patients have a host of other autoantibodies. Some are directed against blood cells, such as red cells, platelets, and lymphocytes; others react with proteins in complex with phospholipids. In recent years there has been much interest in these so-called *antiphospholipid antibodies*. They are present in 40% to 50% of lupus patients. They are actually directed against epitopes of plasma proteins that are revealed when the proteins are in complex with phospholipids. Included among these proteins are prothrombin, annexin V, β_2-glycoprotein I, protein S, and protein C.[65] *Antibodies against the phospholipid–β_2-glycoprotein complex also bind to cardiolipin antigen, used in syphilis serology, and therefore lupus patients may have a false-positive test result for syphilis*. Some of these antibodies interfere with in vitro clotting tests, such as partial thromboplastin time. Therefore, these antibodies are sometimes referred to as *lupus anticoagulant*. Despite having a circulating anticoagulant that delays clotting in vitro, these patients have complications associated with a *hypercoagulable state*.[66] They have venous and arterial thromboses, which may be associated with recurrent spontaneous miscarriages and focal cerebral or ocular ischemia. This constellation of clinical features, in association with lupus, is referred to as the *secondary antiphospholipid antibody syndrome*. The pathogenesis of thrombosis in these patients is unknown; possible mechanisms are discussed in Chapter 4 . Some patients develop these autoantibodies and the clinical syndrome without associated SLE. They are said to have the primary antiphospholipid syndrome (Chapter 4).

Etiology and Pathogenesis of SLE

The cause of SLE remains unknown, but the existence in these patients of a seemingly limitless number of antibodies against self-constituents indicates that the *fundamental defect in SLE is a failure of the mechanisms that maintain self-tolerance*. As is true of most autoimmune diseases, both genetic and environmental factors play a role in the pathogenesis of SLE.[67]

Genetic Factors

SLE is a genetically complex disease with contributions from MHC and multiple non-MHC genes. Many lines of evidence support a genetic predisposition.[68,][69]

- Family members of patients have an increased risk of developing SLE. As many as 20% of clinically unaffected first-degree relatives of SLE patients reveal autoantibodies and other immunoregulatory abnormalities.
- There is a higher rate of concordance (>20%) in monozygotic twins when compared with dizygotic twins (1% to 3%).
- Studies of HLA associations support the concept that MHC genes regulate production of particular autoantibodies. Specific alleles of the *HLA-DQ* locus have been linked to the production of anti–double-stranded DNA, anti-Sm, and antiphospholipid antibodies, although the relative risk is small.
- Some lupus patients (-6%) have inherited deficiencies of early complement components, such as C2, C4, or C1q. Lack of complement may impair removal of circulating immune complexes by the mononuclear phagocyte system, thus favoring tissue deposition. Knockout mice lacking C4 or certain complement receptors are also prone to develop lupus-like autoimmunity. Various mechanisms have been invoked, including failure to clear immune complexes and loss of B-cell self-tolerance. It has also been proposed that deficiency of C1q results in defective phagocytic clearance of apoptotic cells.[70] Many cells normally undergo apoptosis, and if they are not cleared their nuclear components may elicit immune responses.
- In animal models of SLE, several non-MHC susceptibility loci have been identified. The best-known animal

model is the (NZB × NZW)F_1 mouse strain. In different versions of this strain, as many as 20 loci are believed to be associated with the disease.[71]

Immunological Factors

Recent studies in animal models and patients are revealing several immunological aberrations that collectively may result in the persistence and uncontrolled activation of self-reactive lymphocytes.

- Defective elimination of self-reactive B cells in the bone marrow or defects in peripheral tolerance mechanisms may lead to *failure of self-tolerance in B cells*.[72]
- In models of SLE and in some patients there is evidence that *CD4+ helper T cells* specific for nucleosomal antigens also *escape tolerance* and contribute to the production of high-affinity pathogenic autoantibodies.[73]
- Nuclear DNA and RNA contained in immune complexes may activate B lymphocytes by engaging *TLRs*, which function normally to sense microbial products, including nucleic acids. Thus, B cells specific for nuclear antigens may get second signals from TLRs and may be activated, resulting in increased production of antinuclear autoantibodies.[74]
- Recent analyses of patients have revealed a striking molecular signature in peripheral blood lymphocytes that suggests exposure to *type I interferons*.[75] These cytokines are antiviral cytokines that are normally produced during innate immune responses to viruses. It may be that nucleic acids engage TLRs on dendritic cells and stimulate the production of interferons. In other words, self–nucleic acids mimic their microbial counterparts. The role of interferons in SLE is also unclear; these cytokines may activate dendritic cells and B cells and promote T_H1 responses, all of which may contribute to the production of pathogenic autoantibodies.
- Other cytokines that may play a role in unregulated B-cell activation include the TNF family member, BAFF, which promotes survival of B cells. In some patients and animal models, increased production of BAFF has been reported, prompting attempts to block the cytokine or its receptor as therapy for autoimmune diseases.[76]

Environmental Factors.

There are many indications that *environmental* or nongenetic factors must also be involved in the pathogenesis of SLE. Exposure to *ultraviolet (UV) light* exacerbates the disease in many individuals. UV irradiation may induce apoptosis in cells and may alter the DNA in such a way that it becomes immunogenic, perhaps because of enhanced recognition by TLRs.[77] In addition, UV light may modulate the immune response, for example, by stimulating keratinocytes to produce IL-1, a cytokine known to promote inflammation. *Sex hormones* seem to exert an important influence on the occurrence and manifestations of SLE. During the reproductive years the frequency of SLE is 10 times greater in women than in men in the age group of 17 through 55 years, and exacerbation has been noted during normal menses and pregnancy. *Drugs* such as hydralazine, procainamide, and D-penicillamine can induce an SLE-like response in humans.[78]

A Model for the Pathogenesis of SLE.

It is clear from this discussion that the immunological abnormalities in SLE—both documented and postulated—are as varied and complex as is the clinical presentation (discussed later). Nevertheless, an attempt can be made to synthesize the new results into a hypothetical model of the pathogenesis of SLE (Fig. 6-27). UV irradiation and other environmental insults lead to the apoptosis of cells. Inadequate clearance of the nuclei of these cells results in a large burden of nuclear antigens.[79] An underlying abnormality in B and T lymphocytes is responsible for defective tolerance, because of which self-reactive lymphocytes survive and remain functional. These lymphocytes are stimulated by self nuclear antigens, and antibodies are produced against the antigens. Complexes of the antigens and antibodies bind to Fc receptors on B cells and dendritic cells, and may be internalized. The nucleic acid components engage TLRs and stimulate B cells to produce autoantibodies and activate dendritic cells to produce interferons and other cytokines, which further enhance the immune response and cause more

apoptosis. The net result is a cycle of antigen release and immune activation resulting in the production of high-affinity autoantibodies.

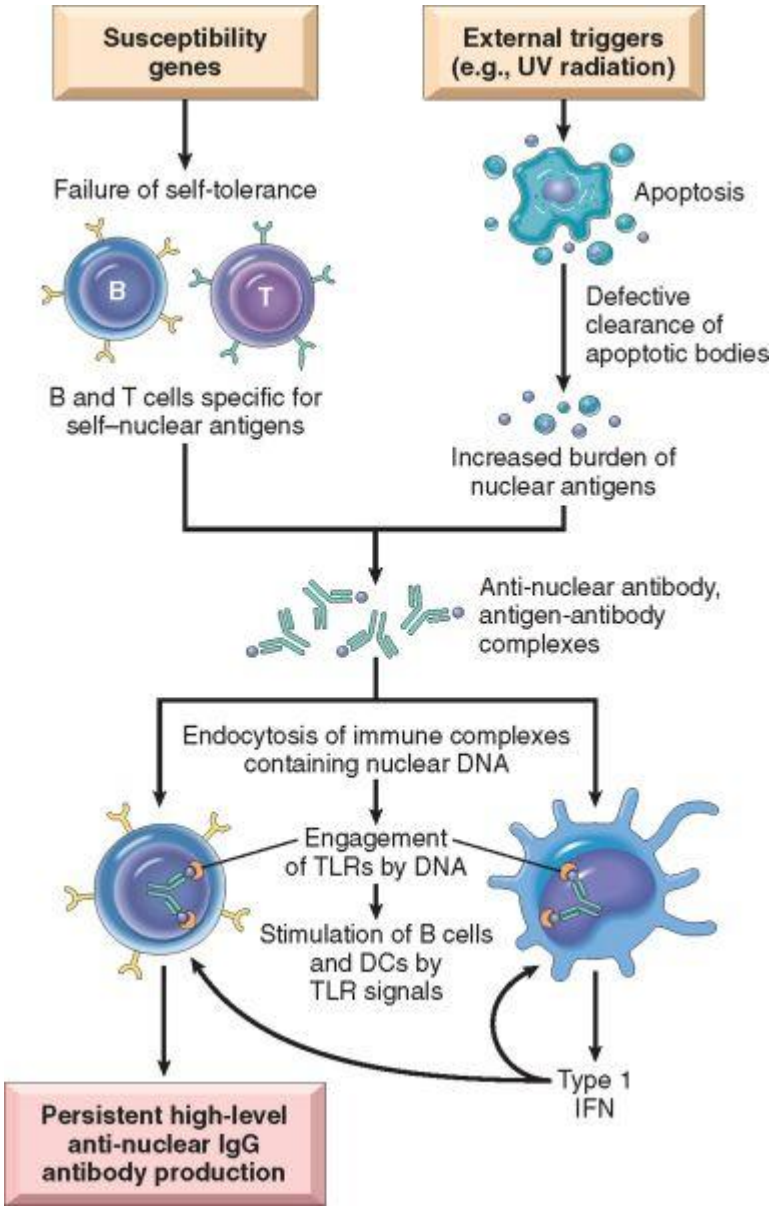

FIGURE 6-27 Model for the pathogenesis of systemic lupus erythematosus. In this hypothetical model, susceptibility genes interfere with the maintenance of self-tolerance and external triggers lead to persistence of nuclear antigens. The result is an antibody response against self–nuclear antigens, which is amplified by the action of nucleic acids on dendritic cells (DCs) and B cells, and the production of type 1 interferons. TLRs, Toll-like receptors.

Mechanisms of Tissue Injury.

Regardless of the exact mechanisms by which autoantibodies are formed, they are clearly the mediators of tissue injury. *Most of the visceral lesions are caused by immune complexes (type III hypersensitivity).* DNA–anti-DNA complexes can be detected in the glomeruli and small blood vessels. Low levels of serum complement (secondary to consumption of complement proteins) and granular deposits of complement and immunoglobulins in the glomeruli further support the immune complex nature of the disease. *Autoantibodies specific for red cells, white cells, and platelets opsonize these cells and promote*

their phagocytosis and lysis. There is no evidence that ANAs, which are involved in immune complex formation, can penetrate intact cells. If cell nuclei are exposed, however, the ANAs can bind to them. In tissues, nuclei of damaged cells react with ANAs, lose their chromatin pattern, and become homogeneous, to produce so-called LE bodies or hematoxylin bodies. Related to this phenomenon is the LE cell, which is readily seen when blood is agitated in vitro. The LE cell is any phagocytic leukocyte (blood neutrophil or macrophage) that has engulfed the denatured nucleus of an injured cell. The demonstration of LE cells in vitro was used in the past as a test for SLE. With new techniques for detection of ANAs, however, this test is now largely of historical interest. Sometimes, LE cells are found in pericardial or pleural effusions in patients.

To summarize, SLE is a complex disorder of multifactorial origin resulting from interactions among genetic, immunological, and environmental factors that act in concert to cause activation of helper T cells and B cells and result in the production of several species of pathogenic autoantibodies.

Morphology. The morphologic changes in SLE are extremely variable, as are the clinical manifestations and course of disease. The constellation of clinical, serologic, and morphologic changes is essential for diagnosis (see Table 6-8). The frequency of individual organ involvement is shown in Table 6-10 . The most characteristic lesions result from immune complexes depositing in blood vessels, kidneys, connective tissue, and skin.

An acute necrotizing vasculitis involving capillaries, small arteries and arterioles may be present in any tissue.[80] The arteritis is characterized by fibrinoid deposits in the vessel walls. In chronic stages, vessels undergo fibrous thickening with luminal narrowing.

***Kidney*.** Lupus nephritis affects up to 50% of SLE patients. The principal mechanism of injury is immune complex deposition in the glomeruli, tubular or peritubular capillary basement membranes, or larger blood vessels. Other injuries may include thrombi in glomerular capillaries, arterioles, or arteries, often associated with antiphospholipid antibodies.

All of the glomerular lesions described below are the result of deposition of immune complexes that are regularly present in the mesangium or along the entire basement membrane and sometimes throughout the glomerulus. The immune complexes consist of DNA and anti-DNA antibodies, but other antigens such as histones have also been implicated. Both in situ formation and deposition of preformed circulating immune complexes may contribute to the injury, but the reason for the wide spectrum of histopathologic lesions (and clinical manifestations) in lupus nephritis patients remains uncertain.

A morphologic classification of lupus nephritis has proven to be clinically useful.[81] Five patterns are recognized: minimal mesangial (class I); mesangial proliferative (class II); focal proliferative (class III); diffuse proliferative (class IV); and membranous (class V). None of these patterns is specific for lupus.

Mesangial lupus glomerulonephritis is seen in 10% to 25% of patients and is characterized by mesangial cell proliferation and immune complex deposition without involvement of glomerular capillaries. There is no or slight (class I) to moderate (class II) increase in both mesangial matrix and number of mesangial cells. **Granular mesangial deposits of immunoglobulin and complement are always present**. Classes III to V nephritis, described below, are usually superimposed on some degree of mesangial changes.

Focal proliferative glomerulonephritis (class III) is seen in 20% to 35% of patients, and is defined

by fewer than 50% involvement of all glomeruli. The lesions may be segmental (affecting only a portion of the glomerulus) or global (involving the entire glomerulus). Affected glomeruli may exhibit crescent formation, fibrinoid necrosis, proliferation of endothelial and mesangial cells, infiltrating leukocytes, and eosinophilic deposits or intracapillary thrombi (Fig. 6-28), which often correlate with hematuria and proteinuria. Some patients may progress to diffuse proliferative glomerulonephritis. The active (or proliferative) inflammatory lesions can heal completely or lead to chronic global or segmental glomerular scarring.

Diffuse proliferative glomerulonephritis (class IV) is the most severe form of lupus nephritis, occurring in 35% to 60% of patients. Pathologic glomerular changes may be identical to focal (class III) lupus nephritis, including proliferation of endothelial, mesangial and, sometimes, epithelial cells (Fig. 6-29), with the latter producing cellular crescents that fill Bowman's space (Chapter 20). The entire glomerulus is frequently affected but segmental lesions also may occur. Both acutely injured and chronically scarred glomeruli in focal or diffuse lupus nephritis are qualitatively indistinguishable from one another; the distinction is based solely on the percentage of glomerular involvement (<50% for class III vs >50% for class IV). Patients with diffuse glomerulonephritis are usually symptomatic, showing hematuria as well as proteinuria. Hypertension and mild to severe renal insufficiency are also common.

Membranous glomerulonephritis (class V) is characterized by diffuse thickening of the capillary walls, which is similar to idiopathic membranous glomerulonephritis, described in Chapter 20 . This lesion is seen in 10% to 15% of lupus nephritis patients, is usually accompanied by severe proteinuria or nephrotic syndrome, and may occur concurrently with focal or diffuse lupus nephritis.

Granular deposits of antibody and complement can be detected by immunofluorescence (Fig. 6-30). Electron microscopy demonstrates electron-dense deposits that represent immune complexes in mesangial, intramembranous, subepithelial, or subendothelial locations. All classes show variable amounts of mesangial deposits. In membranous lupus nephritis, the deposits are predominantly subepithelial (between the basement membrane and visceral epithelial cells). Subendothelial deposits (between the endothelium and the basement membrane) are seen in the proliferative types (classes III and IV) but may be encountered rarely in class I, II, and V lupus nephritis (Fig. 6-31). When prominent, subendothelial deposits create a homogeneous thickening of the capillary wall, which are seen by light microscopy as a "**wire-loop**" lesion (Fig. 6-32). Such wire loops are often found in both focal and diffuse proliferative (class III or IV) lupus nephritis, which reflects active disease.

Changes in the **interstitium and tubules are frequently present** in lupus nephritis patients. Rarely, tubulointerstitial lesions may be the dominant abnormality. Discrete immune complexes similar to those in glomeruli are present in the tubular or peritubular capillary basement membranes in many lupus nephritis patients.

***Skin*.** Characteristic erythema affects the facial butterfly (malar) area (bridge of the nose and cheeks) in approximately 50% of patients, but a similar rash may also be seen on the extremities and trunk. Urticaria, bullae, maculopapular lesions, and ulcerations also occur. **Exposure to sunlight incites or accentuates the erythema**. Histologically the involved areas show vacuolar degeneration of the basal layer of the epidermis (Fig. 6-33A). In the dermis, there is variable edema and perivascular inflammation. Vasculitis with fibrinoid necrosis may be prominent. Immunofluorescence microscopy shows deposition of immunoglobulin and complement along the dermoepidermal junction (Fig. 6-33B), which may also be present in uninvolved skin. This finding is not diagnostic of SLE and is sometimes seen in scleroderma or dermatomyositis.

***Joints*.** Joint involvement is typically a nonerosive synovitis with little deformity, which contrasts

with rheumatoid arthritis.

***Central Nervous System*.** The pathologic basis of central nervous system symptoms is not entirely clear, but antibodies against a synaptic membrane protein have been implicated.[82,][83] Neuropsychiatric symptoms of SLE have often been ascribed to acute vasculitis, but in histologic studies of the nervous system in such patients significant vasculitis is rarely present. Instead, noninflammatory occlusion of small vessels by intimal proliferation is sometimes noted, which may be due to endothelial damage by antiphospholipid antibodies.

***Pericarditis and Other Serosal Cavity Involvement*.** Inflammation of the serosal lining membranes may be acute, subacute, or chronic. During the acute phases, the mesothelial surfaces are sometimes covered with fibrinous exudate. Later they become thickened, opaque, and coated with a shaggy fibrous tissue that may lead to partial or total obliteration of the serosal cavity.

Cardiovascular system involvement may manifest as damage to any layer of the heart.[84] Symptomatic or asymptomatic pericardial involvement is present in up to 50% of patients. Myocarditis, or mononuclear cell infiltration, is less common and may cause resting tachycardia and electrocardiographic abnormalities. Valvular abnormalities primarily of the mitral and aortic valves manifest as diffuse leaflet thickening that may be associated with dysfunction (stenosis and/or regurgitation). Valvular (or so-called Libman-Sacks) endocarditis was more common prior to the widespread use of steroids. This **nonbacterial verrucous endocarditis** takes the form of single or multiple 1- to 3-mm warty deposits on any heart valve, distinctively on either surface of the leaflets (Fig. 6-34). By comparison, the vegetations in infective endocarditis are considerably larger, and those in rheumatic heart disease (Chapter 12) are smaller and confined to the lines of closure of the valve leaflets.

An increasing number of patients have clinical evidence of coronary artery disease (angina, myocardial infarction) owing to coronary atherosclerosis. This complication is noted particularly in young patients with long-standing disease and especially in those who have been treated with corticosteroids. The pathogenesis of accelerated coronary atherosclerosis is unclear but is probably multifactorial. The traditional risk factors, including hypertension, obesity, and hyperlipidemia, are more common in SLE patients than in control populations. In addition, immune complexes and antiphospholipid antibodies may cause endothelial damage and promote atherosclerosis.

***Spleen*.** Splenomegaly, capsular thickening, and follicular hyperplasia are common features. Central penicilliary arteries may show concentric intimal and smooth muscle cell hyperplasia, producing so-called onion-skin lesions.

***Lungs*.** Pleuritis and pleural effusions are the most common pulmonary manifestations, affecting almost 50% of patients. Alveolar injury with edema and hemorrhage is less common. In some cases, there is chronic interstitial fibrosis and secondary pulmonary hypertension. None of these changes is specific for SLE.

***Other Organs and Tissues*.** LE, or hematoxylin, bodies in the bone marrow or other organs are strongly indicative of SLE. Lymph nodes may be enlarged with hyperplastic follicles or even demonstrate necrotizing lymphadenitis.

TABLE 6-10 -- Clinical and Pathologic Manifestations of Systemic Lupus Erythematosus

Clinical Manifestation	Prevalence in Patients (%)[*]
Hematologic	100

Arthritis	80–90
Skin	85
Fever	55–85
Fatigue	80–100
Weight loss	60
Renal	50–70
Neuropsychiatric	25–35
Pleuritis	45
Myalgia	35
Pericarditis	25
Gastrointestinal	20
Raynaud phenomenon	15–40
Ocular	15
Peripheral neuropathy	15

* The percentages are approximate and may vary with age, ethnicity, and other factors.

Clinical Features.

SLE is a multisystem disease that is highly variable in its clinical presentation. Typically, the patient is a young woman with some, but not necessarily all, of the following features: a butterfly rash over the face, fever, pain but no deformity in one or more peripheral joints (feet, ankles, knees, hips, fingers, wrists, elbows, shoulders), pleuritic chest pain, and photosensitivity. In many patients, however, the presentation of SLE is subtle and puzzling, taking forms such as a febrile illness of unknown origin, abnormal urinary findings, or joint disease masquerading as rheumatoid arthritis or rheumatic fever. ANAs are found in virtually 100% of patients, but it must be remembered that ANAs are not specific (see Table 6-9). A variety of clinical findings may point toward renal involvement, including hematuria,

red cell casts, proteinuria, and in some cases the classic nephrotic syndrome (Chapter 20). Laboratory evidence of some hematologic derangement is seen in virtually every case, but in some patients anemia or thrombocytopenia may be the presenting manifestation as well as the dominant clinical problem. In still others, mental aberrations, including psychosis or convulsions, or coronary artery disease may be prominent clinical problems. Patients with SLE are also prone to infections, presumably because of their underlying immune dysfunction and treatment with immunosuppressive drugs.

The course of the disease is variable and unpredictable. Rare acute cases result in death within weeks to months. More often, with appropriate therapy, the disease is characterized by flare-ups and remissions spanning a period of years or even decades. During acute flare-ups, increased formation of immune complexes and the accompanying complement activation often result in hypocomplementemia. Disease exacerbations are usually treated by corticosteroids or other immunosuppressive drugs. Even without therapy, in some patients the disease may run a benign course with skin manifestations and mild hematuria for years. The outcome has improved significantly, and an approximately 90% 5-year and 80% 10-year survival can be expected. *The most common causes of death are renal failure and intercurrent infections*. Coronary artery disease is also becoming an important cause of death. Patients treated with steroids and immunosuppressive drugs incur the usual risks associated with such therapy.

As mentioned earlier, involvement of skin along with multisystem disease is fairly common in SLE. The following sections describe two syndromes in which the cutaneous involvement is the exclusive or most prominent feature.

Chronic Discoid Lupus Erythematosus.

Chronic discoid lupus erythematosus is a disease in which the skin manifestations may mimic SLE, but systemic manifestations are rare.[85] It is characterized by the presence of skin plaques showing varying degrees of edema, erythema, scaliness, follicular plugging, and skin atrophy surrounded by an elevated erythematous border. The face and scalp are usually affected, but widely disseminated lesions occasionally occur. The disease is usually confined to the skin, but 5% to 10% of patients with discoid lupus erythematosus develop multisystem manifestations after many years. Conversely, some patients with SLE may have prominent discoid lesions in the skin. Approximately 35% of patients show a positive ANA test, but *antibodies to double-stranded DNA are rarely present*. Immunofluorescence studies of skin biopsy specimens show deposition of immunoglobulin and C3 at the dermoepidermal junction similar to that in SLE.

Subacute Cutaneous Lupus Erythematosus.

This condition also presents with predominant skin involvement and can be distinguished from chronic discoid lupus erythematosus by several criteria. The skin rash in this disease tends to be widespread, superficial, and nonscarring, although scarring lesions may occur in some patients. Most patients have mild systemic symptoms consistent with SLE. Furthermore, there is a strong association with antibodies to the SS-A antigen and with the *HLA-DR3* genotype. Thus, the term *subacute cutaneous lupus erythematosus* seems to define a group intermediate between SLE and lupus erythematosus localized only to skin.[85]

Drug-Induced Lupus Erythematosus

A lupus erythematosus–like syndrome may develop in patients receiving a variety of drugs, including hydralazine, procainamide, isoniazid, and D-penicillamine, to name only a few.[78] Many of these drugs are associated with the development of ANAs, but most patients do not have symptoms of lupus erythematosus. For example, 80% of patients receiving procainamide test positive for ANAs, but only one third of these manifest clinical symptoms, such as arthralgias, fever, and serositis. *Although multiple*

organs are affected, renal and central nervous system involvement is distinctly uncommon. There are serologic and genetic differences from classical SLE, as well. Antibodies specific for double-stranded DNA are rare, but there is an *extremely high frequency of antibodies specific for histone*. Persons with the *HLA-DR4* allele are at a greater risk of developing lupus erythematosus after administration of hydralazine. The disease remits after withdrawal of the offending drug.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic inflammatory disease that affects primarily the joints but may involve extra-articular tissues such as the skin, blood vessels, lungs, and heart. Abundant evidence supports the autoimmune nature of the disease. Because the principal manifestations of the disease are in the joints, it is discussed in Chapter 26 .

SJÖGREN SYNDROME

Sjögren syndrome is a chronic disease characterized by dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia) resulting from immunologically mediated destruction of the lacrimal and salivary glands. It occurs as an isolated disorder (primary form), also known as the sicca syndrome, or more often in association with another autoimmune disease (secondary form). Among the associated disorders, rheumatoid arthritis is the most common, but some patients have SLE, polymyositis, scleroderma, vasculitis, mixed connective tissue disease, or thyroiditis.

Etiology and Pathogenesis

The characteristic decrease in tears and saliva (sicca syndrome) is the result of *lymphocytic infiltration* and fibrosis of the lacrimal and salivary glands.[86,][87] The infiltrate contains predominantly activated CD4+ helper T cells and some B cells, including plasma cells. About 75% of patients have rheumatoid factor (an antibody reactive with self-IgG) whether or not coexisting rheumatoid arthritis is present. ANAs are detected in 50% to 80% of patients. A host of other organ-specific and non–organ-specific antibodies have also been identified. Most important, however, are antibodies directed against two ribonucleoprotein antigens, SS-A (Ro) and SS-B (La) (see Table 6-9), which can be detected in as many as 90% of patients by sensitive techniques. These antibodies are thus considered serologic markers of the disease. Patients with high titers of antibodies to SS-A are more likely to have early disease onset, longer disease duration, and extraglandular manifestations, such as cutaneous vasculitis and nephritis.[62] These autoantibodies are also present in a smaller percentage of patients with SLE and hence are not diagnostic of Sjögren syndrome.

As with other autoimmune diseases, Sjögren syndrome shows some association, albeit weak, with certain HLA alleles. Studies of whites and blacks suggest linkage of the primary form with *HLA-B8*, *HLA-DR3*, and *DRW52* as well as *HLA-DQA1* and *HLA-DQB1* loci; in patients with anti-SS-A or anti-SS-B antibodies, specific alleles of *HLA-DQA1* and *HLA-DQB1* are frequent. This suggests that, as in SLE, inheritance of certain class II molecules predisposes to the development of particular autoantibodies.

Although the pathogenesis of Sjögren syndrome remains obscure, aberrant T-cell and B-cell activation are both implicated. The initiating trigger may be a viral infection of the salivary glands, which causes local cell death and release of tissue self-antigens. In genetically susceptible individuals, CD4+ T cells and B cells specific for these self-antigens may have escaped tolerance and are able to react. The result is inflammation, tissue damage, and, eventually, fibrosis. The nature of the autoantigen(s) recognized by these lymphocytes is still mysterious. A cytoskeletal protein called α-fodrin is a candidate autoantigen, but its role in disease development has not been established yet.[88] The viruses that may serve as the initiating stimuli are also unknown but may include the perennial culprit in chronic inflammatory

diseases, Epstein-Barr virus, and hepatitis C virus.[89] In addition, a small proportion of individuals infected with the human retrovirus human T-cell lymphotropic virus type 1 develop a clinical picture and pathologic changes virtually identical to those seen in Sjögren syndrome.

Morphology. As mentioned earlier, lacrimal and salivary glands are the major targets of the disease, although other exocrine glands, including those lining the respiratory and gastrointestinal tracts and the vagina, may also be involved. The earliest histologic finding in both the major and the minor salivary glands is **periductal and perivascular lymphocytic infiltration**. Eventually the lymphocytic infiltrate becomes extensive (Fig. 6-35), and in the larger salivary glands lymphoid follicles with germinal centers may be seen. The ductal lining epithelial cells may show hyperplasia, thus obstructing the ducts. Later there is atrophy of the acini, fibrosis, and hyalinization; still later in the course atrophy and replacement of parenchyma with fat are seen. In some cases the lymphoid infiltrate may be so intense as to give the appearance of a lymphoma. Indeed, these patients are at high risk for development of B-cell lymphomas, and molecular assessments of clonality may be necessary to distinguish intense reactive chronic inflammation from early involvement by lymphoma.

The lack of tears leads to drying of the corneal epithelium, which becomes inflamed, eroded, and ulcerated; the oral mucosa may atrophy, with inflammatory fissuring and ulceration; and dryness and crusting of the nose may lead to ulcerations and even perforation of the nasal septum.

Clinical Features.

Sjögren syndrome occurs most commonly in women between the ages of 50 and 60. As might be expected, symptoms result from inflammatory destruction of the exocrine glands. The keratoconjunctivitis produces blurring of vision, burning, and itching, and thick secretions accumulate in the conjunctival sac. The xerostomia results in difficulty in swallowing solid foods, a decrease in the ability to taste, cracks and fissures in the mouth, and dryness of the buccal mucosa. Parotid gland enlargement is present in half the patients; dryness of the nasal mucosa, epistaxis, recurrent bronchitis,

and pneumonitis are other symptoms. Manifestations of extraglandular disease are seen in one third of patients and include synovitis, diffuse pulmonary fibrosis, and peripheral neuropathy. These are more common in patients with high titers of antibodies specific for SS-A. In contrast to SLE, glomerular lesions are extremely rare in Sjögren syndrome. Defects of tubular function, however, including renal tubular acidosis, uricosuria, and phosphaturia, are often seen and are associated histologically with tubulointerstitial nephritis (Chapter 20). About 60% of patients have another accompanying autoimmune disorder, such as rheumatoid arthritis, and these patients also have the symptoms and signs of that disorder.

The combination of lacrimal and salivary gland inflammatory involvement was once called *Mikulicz disease*. The name has now been replaced, however, by *Mikulicz syndrome*, broadened to include lacrimal and salivary gland enlargement from any cause, including sarcoidosis, leukemia, lymphoma, and other tumors. *Biopsy of the lip (to examine minor salivary glands) is essential for the diagnosis of Sjögren syndrome.*

The lymph nodes of patients with Sjögren syndrome are often hyperplastic, but the most intense lymphocytic response is seen in the tissues that are the focal point of the autoimmune response, particularly the salivary and lacrimal glands. In early stages of the disease, this immune infiltrate consists of a mixture of polyclonal T and B cells. However, if the reaction continues unabated there is a strong tendency over time for individual clones within the population of B cells to gain a growth advantage, presumably because of the acquisition of somatic mutations. Emergence of a dominant B cell clone is usually indicative of the development of a marginal zone lymphoma, a specific type of B cell malignancy that often arises in the setting of chronic lymphocytic inflammation. About 5% of Sjögren patients develop lymphoma, an incidence that is 40-fold greater than normal. Certain other autoimmune disorders (e.g., Hashimoto thyroiditis) are also associated with a high risk of marginal zone lymphoma (Chapter 13).

SYSTEMIC SCLEROSIS (SCLERODERMA)

Systemic sclerosis is a chronic disease characterized by: (1) chronic inflammation thought to be the result of autoimmunity, (2) widespread damage to small blood vessels, and (3) progressive interstitial and perivascular fibrosis in the skin and multiple organs.[90] Although the term *scleroderma* is ingrained in clinical medicine, this disease is better named systemic sclerosis because it is characterized by excessive fibrosis throughout the body. The skin is most commonly affected, but the gastrointestinal tract, kidneys, heart, muscles, and lungs also are frequently involved. In some patients the disease seems to remain confined to the skin for many years, but in the majority it progresses to visceral involvement with death from renal failure, cardiac failure, pulmonary insufficiency, or intestinal malabsorption. The clinical heterogeneity of systemic sclerosis has been recognized by classifying the disease into two major categories: *diffuse scleroderma*, characterized by widespread skin involvement at onset, with rapid progression and early visceral involvement; and *limited scleroderma*, in which the skin involvement is often confined to fingers, forearms, and face. Visceral involvement occurs late; hence, the clinical course is relatively benign. Some patents with the limited disease also develop a combination of calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia, called the *CREST syndrome*. Several other variants and related conditions, such as eosinophilic fasciitis, occur far less frequently and are not described here.

Etiology and Pathogenesis

The cause of systemic sclerosis is not known. *Autoimmune responses, vascular damage, and collagen deposition all contribute to the ultimate tissue injury* (Fig. 6-36).[90,][91]

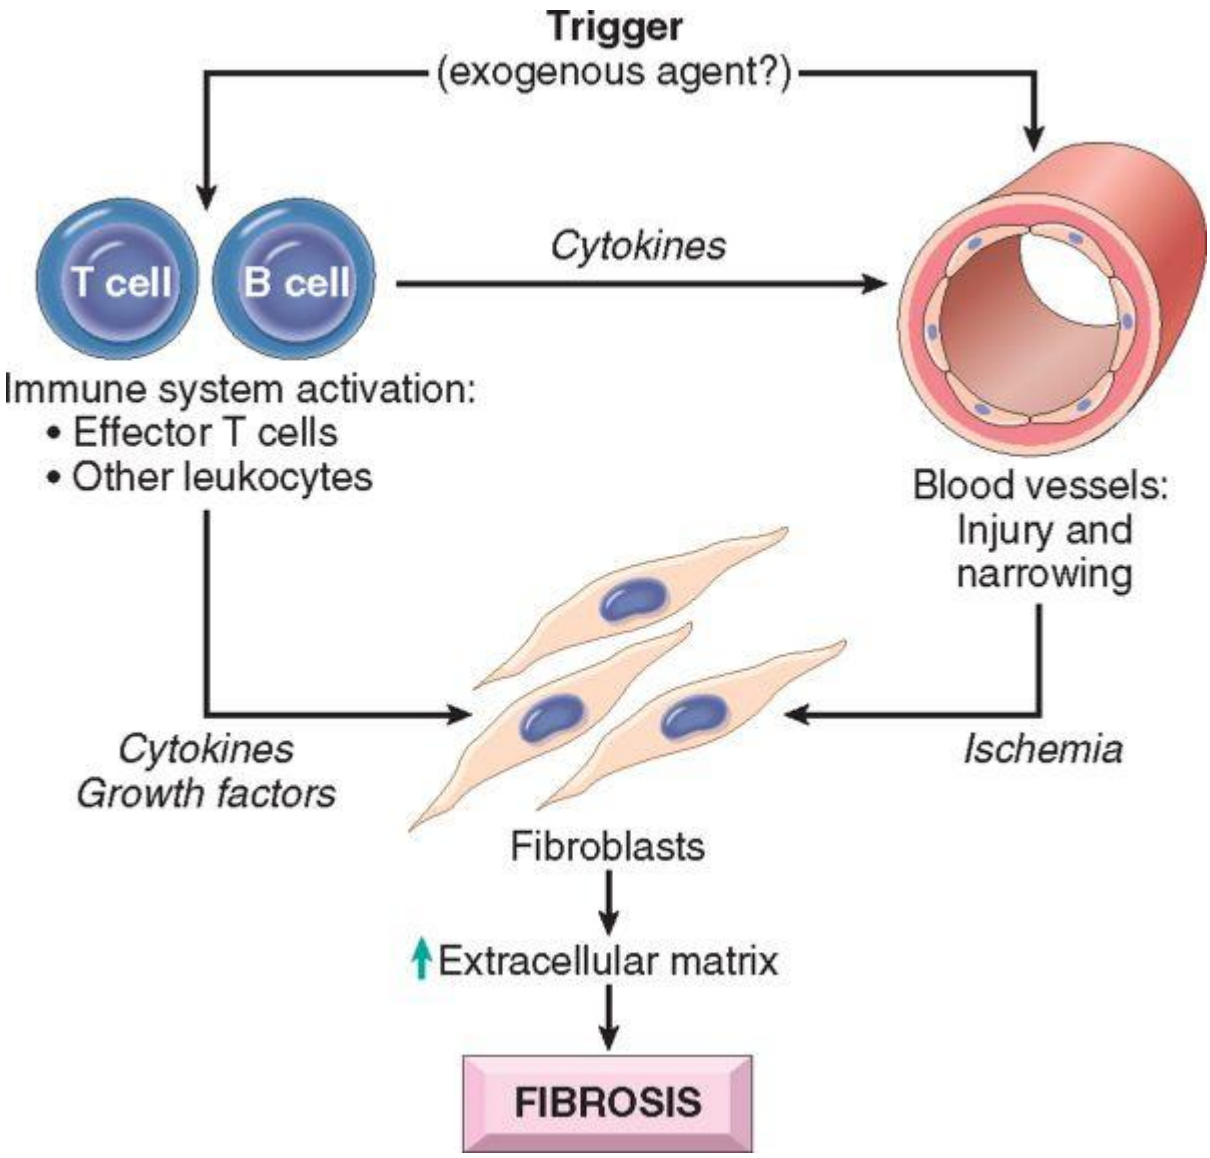

FIGURE 6-36 Possible mechanisms leading to systemic sclerosis.

Abnormal Immune Responses

It is proposed that *CD4+ T cells responding to an as yet unidentified antigen accumulate in the skin and release cytokines that activate inflammatory cells and fibroblasts*.[92] Although inflammatory infiltrates are typically sparse in the skin of patients with systemic sclerosis, activated CD4+ T cells can be found in many patients, and T_H2 cells have been isolated from the skin. Several cytokines produced by these T cells, including TGF-β and IL-13, can stimulate transcription of genes that encode collagen and other extracellular matrix proteins (e.g., fibronectin) in fibroblasts. Other cytokines recruit leukocytes and propagate the chronic inflammation.

There is also evidence for inappropriate activation of humoral immunity, and the presence of various autoantibodies provides diagnostic and prognostic information.[93] Virtually all patients have ANAs that react with a variety of nuclear antigens. Two ANAs strongly associated with systemic sclerosis have been described. One of these, directed against *DNA topoisomerase* I (anti-Scl 70), is highly specific.

Depending on the ethnic group and the assay, it is present in 10% to 20% of patients with diffuse systemic sclerosis. Patients who have this antibody are more likely to have pulmonary fibrosis and peripheral vascular disease. The other, an *anticentromere antibody*, is found in 20% to 30% of patients, who tend to have the CREST syndrome or limited cutaneous systemic sclerosis. Only rarely does the same patient have both antibodies. The role of these ANAs in the pathogenesis of the disease is unclear; it has been postulated that some of these antibodies may stimulate fibrosis, but the evidence in support of this idea is not convincing.

Vascular Damage

Microvascular disease is consistently present early in the course of systemic sclerosis and may be the initial lesion. Intimal proliferation is evident in 100% of digital arteries of patients with systemic sclerosis. Capillary dilation with leaking, as well as destruction, is also common. Nailfold capillary loops are distorted early in the course of disease, and later they disappear. Thus, there is unmistakable morphologic evidence of microvascular injury. Telltale signs of endothelial activation and injury (e.g., increased levels of von Willebrand factor) and increased platelet activation (increased percentage of circulating platelet aggregates) have also been noted. However, what causes the vascular injury is not known; it could be the initiating event or the result of chronic inflammation, with mediators released by inflammatory cells inflicting damage on microvascular endothelium. Repeated cycles of endothelial injury followed by platelet aggregation lead to release of platelet and endothelial factors (e.g., PDGF, TGF-β) that trigger perivascular fibrosis. Activated or injured endothelial cells themselves may release PDGF and factors chemotactic for fibroblasts. Vascular smooth muscle cells also show abnormalities, such as increased expression of adrenergic receptors. Eventually, widespread narrowing of the microvasculature leads to ischemic injury and scarring. Whether endothelial injury can also be initiated by toxic effects of environmental triggers remains uncertain but cannot be definitively excluded.

Fibrosis

The progressive fibrosis characteristic of the disease may be the culmination of multiple abnormalities, including the actions of fibrogenic cytokines produced by infiltrating leukocytes, hyperresponsiveness of fibroblasts to these cytokines, and scarring following upon ischemic damage caused by the vascular lesions. There is also evidence for a primary abnormality in collagen production. Consistent with this notion is the finding that a polymorphism in the gene encoding connective tissue growth factor is associated with systemic sclerosis.[94] In mouse models of Marfan syndrome caused by mutations in the fibrillin-1 gene, some features of systemic sclerosis are also seen,[95] suggesting again that connective tissue abnormalities may contribute to this disease.

Morphology. Virtually all organs can be involved in systemic sclerosis. Prominent changes occur in the skin, alimentary tract, musculoskeletal system, and kidney, but lesions also are often present in the blood vessels, heart, lungs, and peripheral nerves.

Skin. A great majority of patients have diffuse, sclerotic atrophy of the skin, which usually begins in the fingers and distal regions of the upper extremities and extends proximally to involve the upper arms, shoulders, neck, and face. Histologically, there are edema and perivascular infiltrates containing CD4+ T cells, together with swelling and degeneration of collagen fibers, which become eosinophilic. Capillaries and small arteries (150 to 500 μm in diameter) may show thickening of the basal lamina, endothelial cell damage, and partial occlusion. With progression of the disease, there is increasing fibrosis of the dermis, which becomes tightly bound to the subcutaneous structures. There is marked increase of compact collagen in the dermis, usually with thinning of the epidermis, loss of rete pegs, atrophy of the dermal appendages, and hyaline thickening of the walls of dermal arterioles and capillaries (Fig. 6-37). Focal and sometimes diffuse subcutaneous calcifications may develop,

especially in patients with the CREST syndrome. In advanced stages the fingers take on a tapered, clawlike appearance with limitation of motion in the joints, and the face becomes a drawn mask. Loss of blood supply may lead to cutaneous ulcerations and to atrophic changes in the terminal phalanges (Fig. 6-38). Sometimes the tips of the fingers undergo autoamputation.

Alimentary Tract. The alimentary tract is affected in approximately 90% of patients. Progressive atrophy and collagenous fibrous replacement of the muscularis may develop at any level of the gut but are most severe in the esophagus. The lower two thirds of the esophagus often develops a rubber-hose inflexibility. The associated dysfunction of the lower esophageal sphincter gives rise to gastroesophageal reflux and its complications, including Barrett metaplasia (Chapter 17) and strictures. The mucosa is thinned and may be ulcerated, and there is excessive collagenization of the lamina propria and submucosa. Loss of villi and microvilli in the small bowel is the anatomic basis for the malabsorption syndrome sometimes encountered.

Musculoskeletal System. Inflammation of the synovium, associated with hypertrophy and hyperplasia of the synovial soft tissues, is common in the early stages; fibrosis later ensues. These changes are reminiscent of rheumatoid arthritis, but joint destruction is not common in systemic sclerosis. In a small subset of patients (approximately 10%), inflammatory myositis indistinguishable from polymyositis may develop.

Kidneys. Renal abnormalities occur in two thirds of patients with systemic sclerosis. The most prominent are the vascular lesions. Interlobular arteries show intimal thickening as a result of deposition of mucinous or finely collagenous material, which stains histochemically for glycoprotein and acid mucopolysaccharides. There is also concentric proliferation of intimal cells. These changes may resemble those seen in malignant hypertension, but in scleroderma the alterations are restricted to vessels 150 to 500 μm in diameter and are not always associated with hypertension. Hypertension, however, does occur in 30% of patients with scleroderma, and in 20% it takes an ominously rapid, downhill course (malignant hypertension). In hypertensive patients, vascular alterations are more pronounced and are often associated with fibrinoid necrosis involving the arterioles together with thrombosis and infarction. Such patients often die of renal failure, which accounts for about 50% of deaths in persons with this disease. There are no specific glomerular changes.

Lungs. The lungs are involved in more than 50% of individuals with systemic sclerosis. This involvement may manifest as pulmonary hypertension and interstitial fibrosis. Pulmonary vasospasm, secondary to pulmonary vascular endothelial dysfunction, is considered important in the pathogenesis of pulmonary hypertension. Pulmonary fibrosis, when present, is indistinguishable from that seen in idiopathic pulmonary fibrosis (Chapter 15).

Heart. Pericarditis with effusion and myocardial fibrosis, along with thickening of intramyocardial arterioles, occurs in one third of the patients. Clinical myocardial involvement, however, is less common.

Dermatology, University of Texas Southwestern Medical School, Dallas, TX.)

Clinical Features.

Systemic sclerosis has a female-to-male ratio of 3 : 1, with a peak incidence in the 50- to 60-year age group. Although systemic sclerosis shares many features with SLE, rheumatoid arthritis (Chapter 26), and polymyositis (Chapter 27), *its distinctive features are the striking cutaneous changes*, notably skin thickening. *Raynaud's phenomenon*, manifested as episodic vasoconstriction of the arteries and arterioles of the extremities, is seen in virtually all patients and precedes other symptoms in 70% of cases. *Dysphagia* attributable to esophageal fibrosis and its resultant hypomotility are present in more than 50% of patients. Eventually, destruction of the esophageal wall leads to atony and dilation, especially at its lower end. Abdominal pain, intestinal obstruction, or malabsorption syndrome with weight loss and anemia reflect involvement of the small intestine. Respiratory difficulties caused by the pulmonary fibrosis may result in right-sided cardiac dysfunction, and myocardial fibrosis may cause either arrhythmias or cardiac failure. Mild proteinuria occurs in as many as 30% of patients, but rarely is the proteinuria severe enough to cause a nephrotic syndrome. The most ominous manifestation is malignant hypertension, with the subsequent development of fatal renal failure, but in its absence progression of the disease may be slow. The disease tends to be more severe in blacks, especially black women. As treatment of the renal crises has improved, pulmonary disease has become the major cause of death in systemic sclerosis.

As mentioned earlier, the CREST syndrome is seen in some patients with limited systemic sclerosis. It is characterized by calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, telangiectasia, and the presence of anticentromere antibodies. Patients with the CREST syndrome have relatively limited involvement of skin, often confined to fingers, forearms, and face, and calcification of the subcutaneous tissues. Involvement of the viscera, including esophageal lesions, pulmonary hypertension, and biliary cirrhosis, may not occur at all or occur late. In general the patients live longer than those with systemic sclerosis with diffuse visceral involvement at the outset.

INFLAMMATORY MYOPATHIES

Inflammatory myopathies comprise an uncommon, heterogeneous group of disorders characterized by injury and inflammation of mainly the skeletal muscles, which are probably immunologically mediated. Three distinct disorders, *dermatomyositis*, *polymyositis*, and *inclusion-body myositis*, are included in this category. These may occur alone or with other immune-mediated diseases, particularly systemic sclerosis. These diseases are described in Chapter 27 .

MIXED CONNECTIVE TISSUE DISEASE

The term *mixed connective tissue disease* is used to describe a disease with clinical features that are a mixture of the features of SLE, systemic sclerosis, and polymyositis.[96] The disease is characterized *serologically by high titers of antibodies to ribonucleoprotein particle–containing U1 ribonucleoprotein*. Typically, mixed connective tissue disease shows modest renal involvement and a good response to corticosteroids, at least in the short term. Because the clinical features overlap with other diseases, it has been suggested that mixed connective tissue disease is not a distinct entity but that different patients represent subsets of SLE, systemic sclerosis, and polymyositis. The disease can also, over time, evolve into classical SLE or systemic sclerosis. Two of the more serious complications of mixed connective tissue disease are pulmonary hypertension and renal disease resembling that associated with systemic sclerosis.

POLYARTERITIS NODOSA AND OTHER VASCULITIDES

Polyarteritis nodosa belongs to a group of diseases characterized by necrotizing inflammation of the walls of blood vessels and showing strong evidence of an immunological pathogenetic mechanism.[97,][98] The general term *noninfectious vasculitis* differentiates these conditions from those due to direct infection of the blood vessel wall (such as occurs in the wall of an abscess) and serves to emphasize that any type of vessel may be involved—arteries, arterioles, veins, or capillaries.

Noninfectious vasculitis is encountered in many clinical settings. A detailed classification and description of vasculitides is presented in Chapter 11 on blood vessels, where the immunological mechanisms are also discussed.

2.6.3 Rejection of Tissue Transplants

Transplant rejection is discussed here because it involves several of the immunological reactions that underlie immune-mediated inflammatory diseases. A major barrier to transplantation is the process of *rejection*, in which the recipient's immune system recognizes the graft as being foreign and attacks it.

Mechanisms of Recognition and Rejection of Allografts

Rejection is a complex process in which both cell-mediated immunity and circulating antibodies play a role[99]; moreover, the contributions of these two mechanisms are often reflected in the histologic features of the rejected organs.

T Cell–Mediated Reactions

The critical role of T cells in transplant rejection has been documented both in humans and in experimental animals. T cell–mediated graft rejection is called *cellular rejection*, and it involves destruction of graft cells by CD8+ CTLs and delayed hypersensitivity reactions triggered by activated CD4+ helper cells. The major antigenic differences between a donor and recipient that result in rejection of transplants are differences in highly polymorphic HLA alleles. The recipient's T cells recognize donor antigens from the graft (the allogeneic antigens, or alloantigens) by two pathways, called *direct* and *indirect* (Fig. 6-39).[100]

- In the *direct pathway*, T cells of the transplant recipient recognize allogeneic (donor) MHC molecules on the surface of APCs in the graft. It is believed that dendritic cells carried in the donor organs are the most important APCs for initiating the antigraft response, because they not only express high levels of class I and II MHC molecules but also are endowed with costimulatory molecules (e.g., B7-1 and B7-2). The T cells of the host encounter the donor dendritic cells either within the grafted organ or after the dendritic cells migrate to the draining lymph nodes. CD8+ T cells recognize class I MHC mdecules and differentiate into active CTLs, which can kill the graft cells by mechanisms already discussed. CD4+ helper T cells recognize allogeneic class II molecules and proliferate and differentiate into T_H1 (and possibly T_H17) effector cells. Cytokines secreted by the activated CD4+ T cells trigger a delayed hypersensitivity reaction in the graft, resulting in increased vascular permeability and local accumulation of mononuclear cells (lymphocytes and macrophages), and graft injury caused by the activated macrophages. The direct recognition of allogeneic MHC molecules seems paradoxical to the rules of self-MHC restriction: If T cells normally are restricted to recognizing foreign peptides displayed by self-MHC molecules, why should these T cells recognize foreign MHC? The probable explanation is that allogeneic MHC molecules, with their bound peptides, resemble, or mimic, the self-MHC–foreign peptide complexes that are recognized by self-MHC–restricted T cells. Thus, recognition of allogeneic MHC molecules is a cross-reaction of T cells selected to recognize self-MHC plus foreign peptides.
- In the *indirect pathway* of allorecognition, recipient T lymphocytes recognize MHC antigens of the graft donor after they are presented by the recipient's own APCs. This process involves the uptake and processing of MHC and other foreign molecules from the grafted organ by host APCs. The peptides derived from the donor tissue are presented by the host's own MHC molecules, like any other foreign peptide. Thus,

the indirect pathway is similar to the physiologic processing and presentation of other foreign (e.g., microbial) antigens. The indirect pathway generates CD4+ T cells that enter the graft and recognize graft antigens being displayed by host APCs that have also entered the graft, and the result is a delayed hypersensitivity type of reaction. However, CD8+ CTLs that may be generated by the indirect pathway cannot directly recognize or kill graft cells, because these CTLs recognize graft antigens presented by the host's APCs. Therefore, when T cells react to a graft by the indirect pathway, the principal mechanism of cellular rejection may be T-cell cytokine production and delayed hypersensitivity. It is postulated that the direct pathway is the major pathway in acute cellular rejection, whereas the indirect pathway is more important in chronic rejection. However, this separation is by no means absolute.

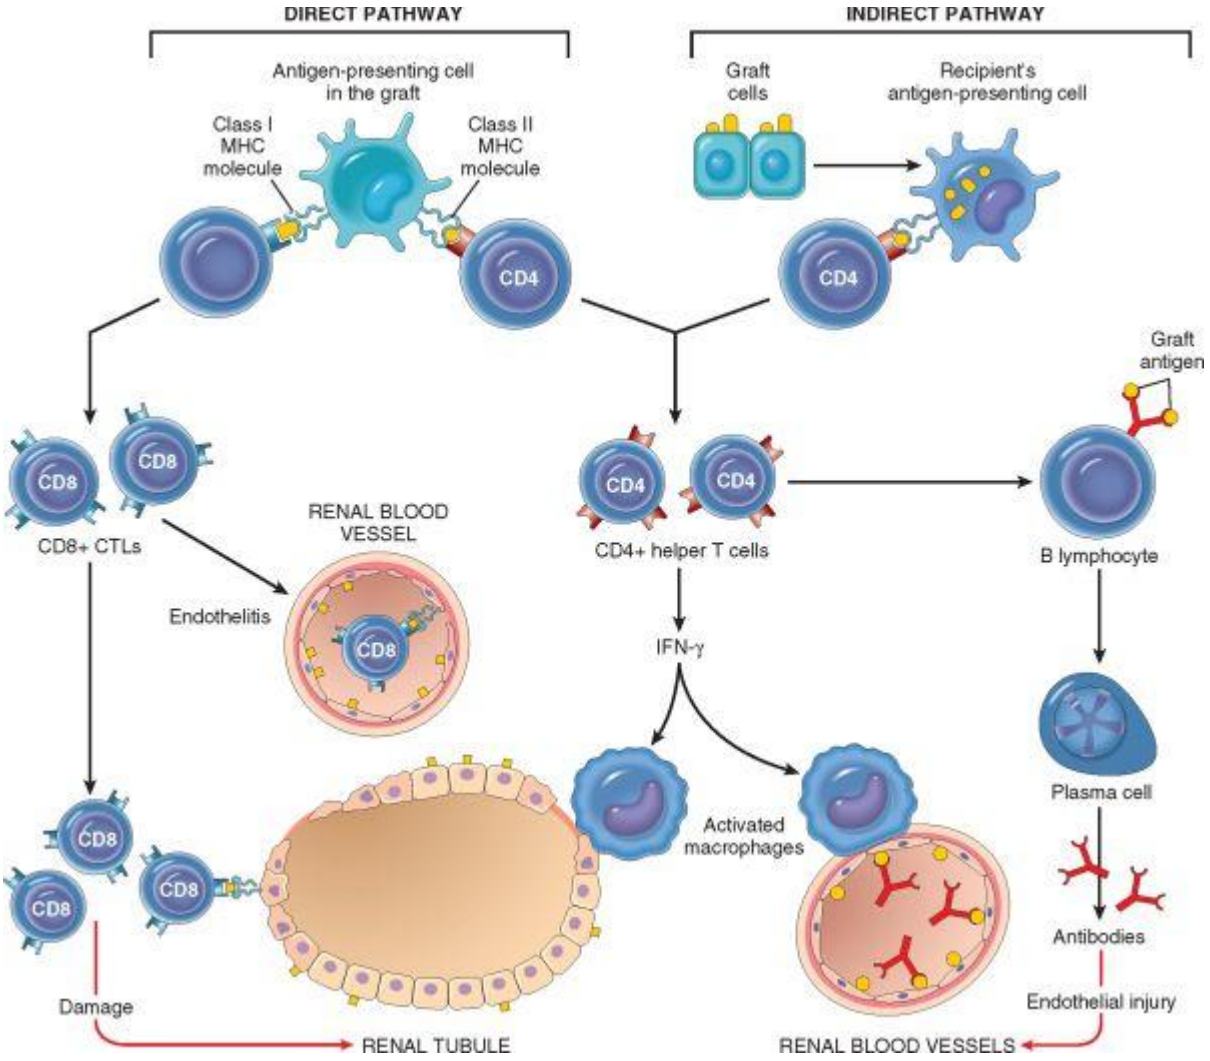

FIGURE 6-39 Recognition and rejection of organ allografts. In the direct pathway, donor class I and class II MHC antigens on antigen-presenting cells in the graft (along with costimulators, not shown) are recognized by host CD8+ cytotoxic T cells and CD4+ helper T cells, respectively. CD4+ cells proliferate and produce cytokines (e.g., IFN-γ), which induce tissue damage by a local delayed hypersensitivity reaction. CD8+ T cells responding to graft antigens differentiate into CTLs that kill graft cells. In the indirect pathway graft antigens are picked up, processed, and displayed by host APCs and activate CD4+ T cells, which damage the graft by a local delayed hypersensitivity reaction and stimulate B lymphocytes to produce antibodies.

Antibody-Mediated Reactions

Although T cells are pivotal in the rejection of organ transplants, antibodies produced against alloantigens in the graft are also important mediators of rejection.[101] This process is called *humoral rejection*, and it can take two forms. *Hyperacute rejection occurs when preformed antidonor antibodies*

are present in the circulation of the recipient. Such antibodies may be present in a recipient who has previously rejected a kidney transplant. Multiparous women who develop anti-HLA antibodies against paternal antigens shed from the fetus may have preformed antibodies to grafts taken from their husbands or children, or even from unrelated individuals who share HLA alleles with the husbands. Prior blood transfusions can also lead to presensitization, because platelets and white blood cells are rich in HLA antigens and donors and recipients are usually not HLA-identical. With the current practice of cross-matching, that is, testing recipient's serum for antibodies against donor's cells, hyperacute rejection is no longer a significant clinical problem.

In recipients not previously sensitized to transplantation antigens, exposure to the class I and class II HLA antigens of the donor graft may evoke antibodies. The antibodies formed by the recipient may cause injury by several mechanisms, including complement-dependent cytotoxicity, inflammation, and antibody-dependent cell-mediated cytotoxicity. *The initial target of these antibodies in rejection seems to be the graft vasculature*. Thus, antibody-dependent *acute humoral rejection* is usually manifested by a vasculitis, sometimes referred to as *rejection vasculitis*.

Rejection of Kidney Grafts

Because kidneys were the first solid organs to be transplanted and more kidneys have been transplanted than any other organ, much of our understanding of the clinical and pathologic aspects of solid-organ transplantation is based on studies of renal allografts.

Morphology. On the basis of the morphology and the underlying mechanism, **rejection reactions are classified as hyperacute, acute, and chronic**. The morphologic changes in these patterns are described below as they relate to renal transplants. Similar changes may occur in any other vascularized organ transplant and are discussed in relevant chapters.

Hyperacute Rejection. This form of rejection occurs within minutes or hours after transplantation. A hyperacutely rejecting kidney rapidly becomes cyanotic, mottled, and flaccid, and may excrete a mere few drops of bloody urine. Immunoglobulin and complement are deposited in the vessel wall, causing endothelial injury and fibrin-platelet thrombi (Fig. 6-40A). Neutrophils rapidly accumulate within arterioles, glomeruli, and peritubular capillaries. As these changes become diffuse and intense, the glomeruli undergo thrombotic occlusion of the capillaries, and fibrinoid necrosis occurs in arterial walls. The kidney cortex then undergoes outright necrosis (infarction), and such nonfunctioning kidneys have to be removed.

Acute Rejection. This may occur within days of transplantation in the untreated recipient or may appear suddenly months or even years later, after immunosuppression has been used and terminated. In any one patient, cellular or humoral immune mechanisms may predominate. Histologically, humoral rejection is associated with vasculitis, whereas cellular rejection is marked by an interstitial mononuclear cell infiltrate.

Acute cellular rejection is most commonly seen within the initial months after transplantation and is heralded by clinical and biochemical signs of renal failure (Chapter 20). Histologically, there may be extensive interstitial mononuclear cell infiltration and edema as well as mild interstitial hemorrhage (Fig. 6-40B). As might be expected, immunohistochemical staining reveals both CD4+ and CD8+ T lymphocytes, which express markers of activated T cells, such as the α chain of the IL-2 receptor. Glomerular and peritubular capillaries contain large numbers of mononuclear cells that may also invade the tubules, causing focal tubular necrosis. In addition to causing tubular damage, CD8+ T cells may injure vascular endothelial cells, causing a so-called **endothelitis**. The affected vessels have

swollen endothelial cells, and at places the lymphocytes can be seen between the endothelium and the vessel wall. The recognition of cellular rejection is important because, in the absence of an accompanying humoral rejection, patients respond well to immunosuppressive therapy. Cyclosporine, a widely used immunosuppressive drug, is also nephrotoxic, and hence the histologic changes resulting from cyclosporine may be superimposed.

Acute humoral rejection (rejection vasculitis) is mediated by antidonor antibodies, and hence it is manifested mainly by damage to the blood vessels. This may take the form of necrotizing vasculitis with endothelial cell necrosis, neutrophilic infiltration, deposition of immunoglobulins, complement, and fibrin, and thrombosis. Such lesions are associated with extensive necrosis of the renal parenchyma. In many cases, the vasculitis is less acute and is characterized by marked thickening of the intima with proliferating fibroblasts, myocytes, and foamy macrophages (Fig. 6-40C). The resultant narrowing of the arterioles may cause infarction or renal cortical atrophy. The proliferative vascular lesions mimic arteriosclerotic thickening and are believed to be caused by cytokines that cause proliferation of vascular smooth muscle cells. Deposition of the complement breakdown product C4d in allografts is a strong indicator of humoral rejection, because C4d is produced during activation of the complement system by the antibody-dependent classical pathway.[101,][102] The importance of making this diagnosis is that it provides a rationale for treating affected patients with B cell–depleting agents.

Chronic Rejection. In recent years acute rejection has been significantly controlled by immunosuppressive therapy, and chronic rejection has emerged as an important cause of graft failure.[103] Patients with chronic rejection present clinically with a progressive renal failure manifested by a rise in serum creatinine over a period of 4 to 6 months. Chronic rejection is dominated by vascular changes, interstitial fibrosis, and tubular atrophy with loss of renal parenchyma (Fig. 6-41). The **vascular changes** consist of dense, obliterative intimal fibrosis, principally in the cortical arteries. These vascular lesions result in renal ischemia, manifested by glomerular loss, interstitial fibrosis and tubular atrophy, and shrinkage of the renal parenchyma. The glomeruli may show scarring, with duplication of basement membranes; this appearance is sometimes called chronic transplant glomerulopathy. Chronically rejecting kidneys usually have interstitial mononuclear cell infiltrates of plasma cells and numerous eosinophils.

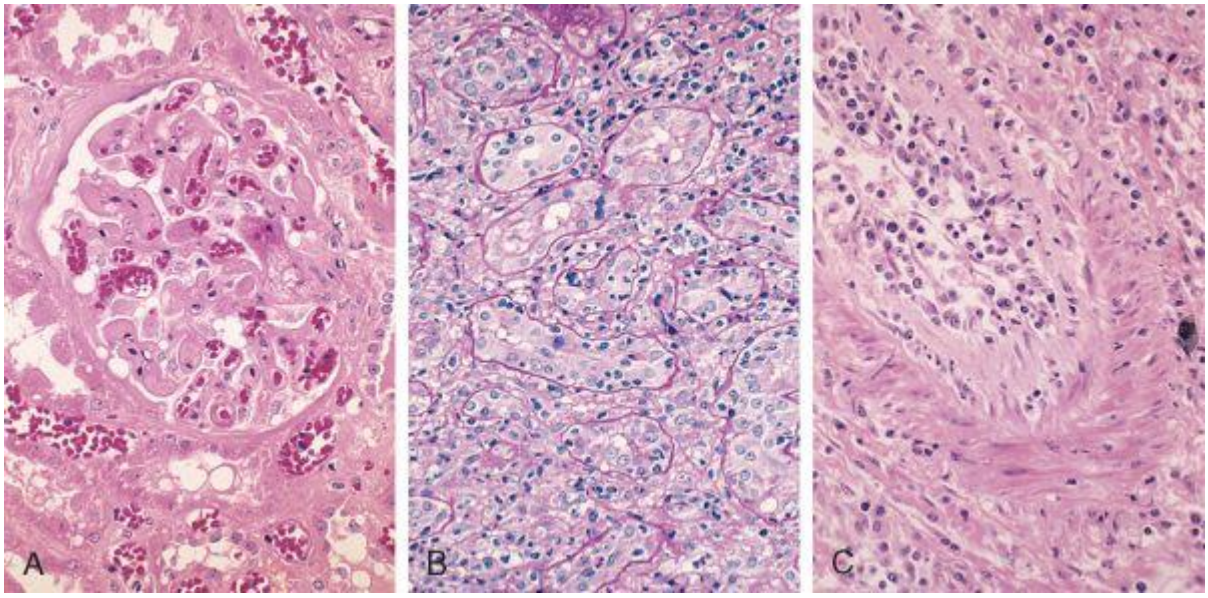

FIGURE 6-40 Morphology of hyperacute and acute graft rejection. **A**, Hyperacute rejection of a kidney allograft showing endothelial damage, platelet and thrombin thrombi, and early neutrophil infiltration in a glomerulus. **B**, Acute cellular rejection of a kidney allograft with inflammatory cells in the interstitium and between epithelial cells of the tubules. **C**, Acute humoral rejection of a kidney allograft (rejection vasculitis) with inflammatory cells and proliferating smooth muscle cells in the intima. *(Courtesy of Dr. Helmut Rennke, Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.)*

Methods of Increasing Graft Survival

The value of HLA matching between donor and recipient varies in different solid-organ transplants. In kidney transplants, there is substantial benefit if all the polymorphic HLA alleles are matched (both inherited alleles of *HLA-A*, *-B* and *DR*). However, HLA matching is usually not even done for transplants of liver, heart, and lungs, because other considerations, such as anatomic compatibility, severity of the underlying illness, and the need to minimize the time of organ storage, override the potential benefits of HLA matching.

Except in the case of identical twins, who obviously express the same histocompatibility antigens, *immunosuppressive therapy* is a practical necessity in all other donor-recipient combinations.[104] The mainstay of immunosuppression is the drug *cyclosporine*. Cyclosporine works by blocking activation of a transcription factor called nuclear factor of activated T cells (NFAT), which is required for transcription of cytokine genes, in particular, the gene that encodes IL-2. Additional drugs that are used to treat rejection include azathioprine (which inhibits leukocyte development from bone marrow precursors), steroids (which block inflammation), rapamycin and mycophenolate mofetil (both of which inhibit lymphocyte proliferation), and monoclonal anti–T-cell antibodies (e.g., monoclonal anti-CD3 and antibodies against the IL-2 receptor α chain [CD25], which opsonize and eliminate the cells and may also block T-cell activation). Another, more recent, strategy for reducing antigraft immune responses is to prevent host T cells from receiving costimulatory signals from dendritic cells during the initial phase of sensitization. This can be accomplished by interrupting the interaction between the B7

molecules on the dendritic cells of the graft donor with the CD28 receptors on host T cells, for example, by administration of proteins that bind to B7 costimulators.

Although immunosuppression prolongs graft survival, it carries its own risks. The price paid in the form of increased susceptibility to opportunistic infections is not small. These patients are also at increased risk for developing EBV-induced lymphomas, human papillomavirus–induced squamous cell carcinomas, and Kaposi sarcoma (Chapter 11), all probably the result of reactivation of latent viral infections because of diminished host defenses. To circumvent the untoward effects of immunosuppression, much effort is being devoted to induce donor-specific tolerance in graft recipients.[105] For instance, giving donor cells to graft recipients may prevent reactions to the graft, perhaps because the donor inoculum contains cells, such as immature dendritic cells, that induce tolerance to the donor alloantigens. This approach may result in long-term *mixed chimerism*, in which the recipient lives with the injected donor cells. Other strategies being tested include injecting regulatory T cells at the time of transplantation, and promoting the death of alloreactive T cells in the recipient.

Transplantation of Other Solid Organs

In addition to the kidney, a variety of organs, such as the liver (Chapter 18), heart (Chapter 12), lungs, and pancreas, are also transplanted. The rejection reaction against liver transplants is not as vigorous as might be expected from the degree of HLA disparity. The molecular basis of this “privilege” is not understood.

Transplantation of Hematopoietic Cells

Use of hematopoietic stem cell transplants for hematologic malignancies, certain nonhematologic cancers, aplastic anemias, thalassemias, and certain immunodeficiency states is increasing. Transplantation of genetically engineered hematopoietic stem cells may also be useful for somatic cell gene therapy, and is being evaluated in some immunodeficiencies. Hematopoietic stem cells are usually obtained from the bone marrow but may also be harvested from peripheral blood after they are mobilized from the bone marrow by administration of hematopoietic growth factors. In most of the conditions in which bone marrow transplantation is indicated, the recipient is irradiated to destroy the immune system (and sometimes, cancer cells) and to create a graft bed. Several features distinguish bone marrow transplants from solid-organ transplants. Two problems that are unique to bone marrow transplantation are graft-versus-host (GVH) disease and immunodeficiency.

GVH disease occurs in any situation in which immunologically competent cells or their precursors are transplanted into immunologically crippled recipients, and the transferred cells recognize alloantigens in the host.[106] It is seen most commonly in the setting of bone marrow transplantation but, rarely, may occur following transplantation of solid organs rich in lymphoid cells (e.g., the liver) or transfusion of unirradiated blood. When immune-compromised recipients receive normal bone marrow cells from allogeneic donors, the immunocompetent T cells present in the donor marrow recognize the recipient's HLA antigens as foreign and react against them. To try to minimize GVH disease, bone marrow transplants are done between donor and recipient that are HLA-matched using sensitive DNA sequencing methods for molecular typing of HLA alleles.

Acute GVH disease occurs within days to weeks after allogeneic bone marrow transplantation. Although any organ may be affected, the major clinical manifestations result from involvement of the *immune system and epithelia of the skin, liver, and intestines*. Involvement of skin in GVH disease is manifested by a generalized rash that may lead to desquamation in severe cases. Destruction of small bile ducts gives rise to jaundice, and mucosal ulceration of the gut results in bloody diarrhea. Although tissue injury may be severe, the affected tissues are usually not heavily infiltrated by lymphocytes. It is

believed that in addition to direct cytotoxicity by CD8+ T cells, considerable damage is inflicted by cytokines released by the sensitized donor T cells.

Chronic GVH disease may follow the acute syndrome or may occur insidiously. These patients have extensive cutaneous injury, with destruction of skin appendages and fibrosis of the dermis. The changes may resemble systemic sclerosis (discussed earlier). Chronic liver disease manifested by cholestatic jaundice is also frequent. Damage to the gastrointestinal tract may cause esophageal strictures. The immune system is devastated, with involution of the thymus and depletion of lymphocytes in the lymph nodes. Not surprisingly, the patients experience recurrent and life-threatening infections. Some patients develop manifestations of autoimmunity, postulated to result from the grafted CD4+ helper T cells reacting with host B cells and stimulating these cells, some of which may be capable of producing autoantibodies.

Because GVH disease is mediated by T lymphocytes contained in the donor bone marrow, depletion of donor T cells before transfusion virtually eliminates the disease. This protocol, however, has proved to be a mixed blessing: GVH disease is ameliorated, but the incidence of graft failures and EBV-related B-cell lymphoma and the recurrence of disease in leukemic patients increase. It seems that the multifaceted T cells not only mediate GVH disease but also are required for engraftment of the transplanted marrow stem cells, suppression of EBV-infected B-cell clones, and control of leukemic cells. The latter, called *graft-versus-leukemia* effect, can be quite dramatic. Deliberate induction of graft-versus-leukemia effect by infusion of allogeneic T cells is being used in the treatment of chronic myelogenous leukemia when patients relapse after bone marrow transplantation.

Immunodeficiency is a frequent complication of bone marrow transplantation. The immunodeficiency may be a result of prior treatment, myeloablative preparation for the graft, a delay in repopulation of the recipient's immune system, and attack on the host's immune cells by grafted lymphocytes. Affected individuals are profoundly immunosuppressed and are easy prey to infections. Although many different types of organisms may infect patients, infection with cytomegalovirus is particularly important. This usually results from activation of previously silent infection. Cytomegalovirus-induced pneumonitis can be a fatal complication.

2.6.4 Immunodeficiency Syndromes

Immunodeficiencies can be divided into the *primary immunodeficiency* disorders, which are almost always genetically determined, and *secondary immunodeficiency* states, which may arise as complications of cancers, infections, malnutrition, or side effects of immunosuppression, irradiation, or chemotherapy for cancer and other diseases. The primary immunodeficiency syndromes are accidents of nature that provide valuable insights into some of the critical molecules of the human immune system. Here we briefly discuss the more important primary immunodeficiencies, to be followed by a more detailed description of acquired immunodeficiency syndrome (AIDS), the most devastating example of secondary immunodeficiency.

PRIMARY IMMUNODEFICIENCIES

Most primary immunodeficiency diseases are genetically determined and affect the humoral and/or cellular arms of adaptive immunity (mediated by B and T lymphocytes, respectively) or the defense mechanisms of innate immunity (NK cells, phagocytes, or complement). Defects in adaptive immunity are often subclassified on the basis of the primary component involved (i.e., B cells or T cells or both). However, these distinctions are not clear-cut; for instance, T-cell defects almost always lead to impaired antibody synthesis, and hence isolated deficiencies of T cells are often indistinguishable clinically from combined deficiencies of T and B cells. Although these disorders were once thought to be quite rare, some form of mild genetic immune deficiency is, in fact, present in many individuals.[107] Most primary

immunodeficiencies manifest themselves in infancy, between 6 months and 2 years of life, and they are detected because the affected infants are susceptible to recurrent infections. The nature of infecting organisms depends to some extent on the nature of the underlying defect, as summarized in Table 6-11 . Defects of phagocytes were discussed in Chapter 2 . Here we present selected examples of other immunodeficiencies. We begin with isolated defects in B cells, followed by a discussion of combined immunodeficiencies and defects in complement proteins. Finally, Wiskott-Aldrich syndrome, a complex disorder affecting lymphocytes as well as platelets, is presented. With advances in genetic analyses, the mutations responsible for many of the common primary immunodeficiencies have now been identified (Fig. 6-42).[108,][109]

TABLE 6-11 -- Examples of Infections in Immunodeficiencies

Pathogen Type	T-Cell Defect	B-Cell Defect	Granulocyte Defect	Complement Defect
Bacteria	Bacterial sepsis	Streptococci, staphylococci, *Haemophilus*	Staphylococci, *Pseudomonas*	Neisserial infections, other pyogenic infections
Viruses	Cytomegalovirus, Epstein-Barr virus, severe varicella, chronic infections with respiratory and intestinal viruses	Enteroviral encephalitis		
Fungi and parasites	*Candida, Pneumocystis jiroveci*	Severe intestinal giardiasis	*Candida, Nocardia, Aspergillus*	
Special features	Aggressive disease with opportunistic pathogens, failure to clear infections	Recurrent sinopulmonary infections, sepsis, chronic meningitis		

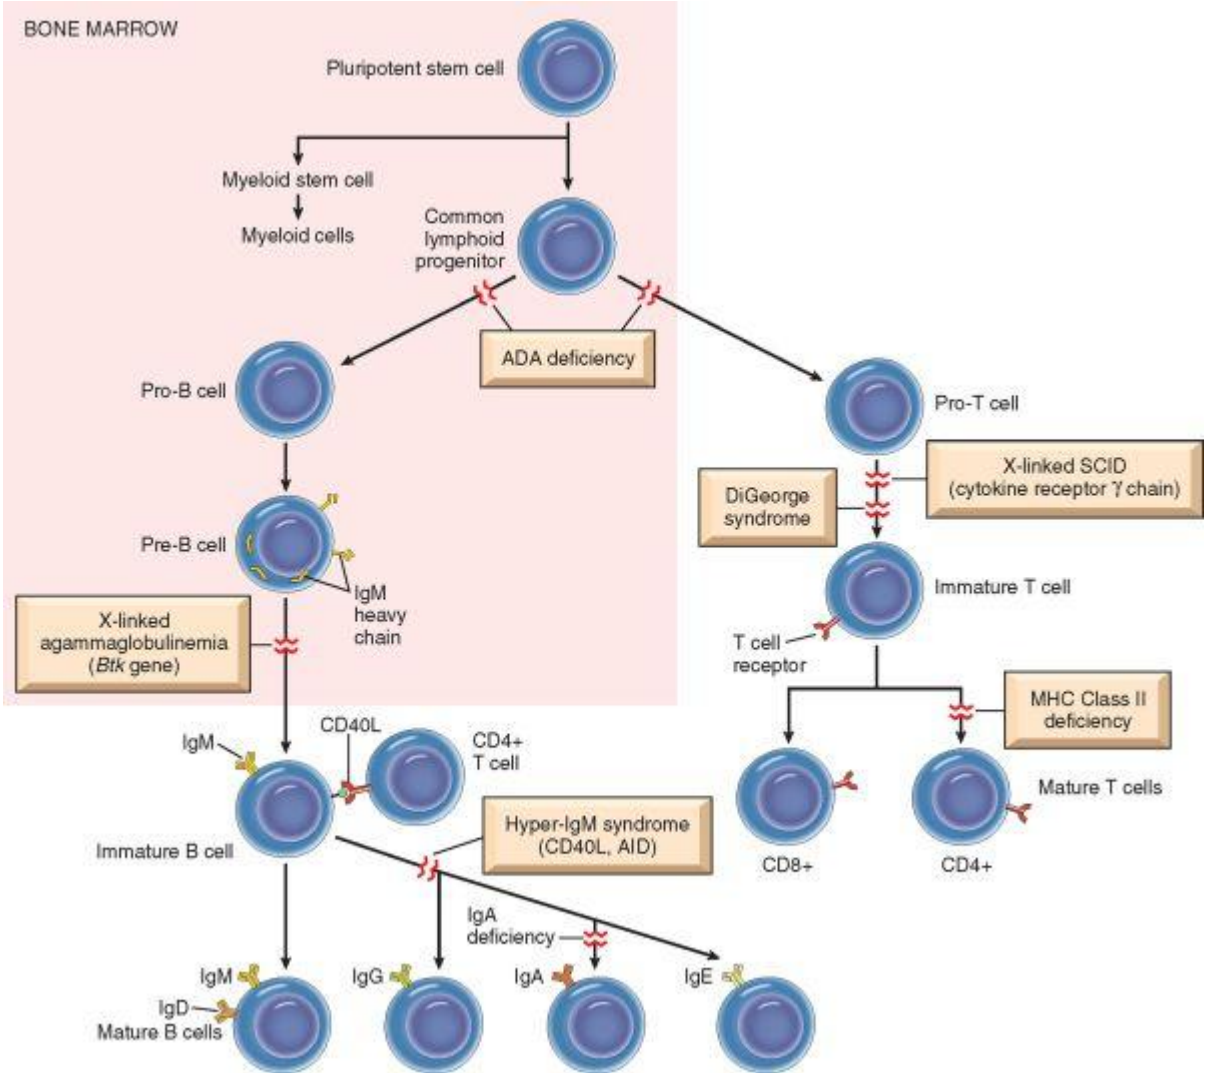

FIGURE 6-42 Simplified scheme of lymphocyte development and sites of block in some primary immunodeficiency diseases are shown. The affected genes are indicated in parentheses for some of the disorders. ADA, adenosine deaminase; AID, activation-induced deaminase; CD40L, CD40 ligand (also known as CD154); SCID, severe combined immune deficiency.

X-Linked Agammaglobulinemia (Bruton's Agammaglobulinemia)

X-linked agammaglobulinemia is one of the more common forms of primary immunodeficiency.[110] *It is characterized by the failure of B-cell precursors (pro-B cells and pre-B cells) to develop into mature B cells*. During normal B-cell maturation in the bone marrow, the Ig heavy-chain genes are rearranged first, in pre-B cells, and these are expressed on the cell surface in association with a "surrogate" light chain, where they deliver signals that induce rearrangement of the Ig light-chain genes and further maturation. This need for Ig-initiated signals is a quality control mechanism that ensures that maturation will proceed only if functional Ig proteins are expressed. X-linked agammaglobulinemia is caused by mutations in a cytoplasmic tyrosine kinase, called *Bruton tyrosine kinase (Btk)*; the gene that encodes it is located on the long arm of the X chromosome at Xq21.22.[95] Btk is a protein tyrosine kinase that is associated with the Ig receptor complex of pre-B and mature B cells and is needed to transduce signals from the receptor. When it is mutated, the pre-B cell receptor cannot deliver signals, and maturation stops at this stage. Because light chains are not produced, the complete antigen receptor molecule (which contains Ig heavy and light chains) cannot be assembled and transported to the cell membrane.

As an X-linked disease, this disorder is seen almost entirely in males, but sporadic cases have been described in females, possibly caused by mutations in some other gene that functions in the same pathway. *The disease usually does not become apparent until about 6 months of age, as maternal immunoglobulins are depleted*. In most cases, recurrent bacterial infections of the respiratory tract, such as acute and chronic pharyngitis, sinusitis, otitis media, bronchitis, and pneumonia, call attention to the underlying immune defect. Almost always the causative organisms are *Haemophilus influenzae*, *Streptococcus pneumoniae*, or *Staphylococcus aureus*. These organisms are normally opsonized by antibodies and cleared by phagocytosis. Because antibodies are important for neutralizing infectious viruses that are present in the bloodstream or mucosal secretions or being passed from cell to cell, individuals with this disease are also susceptible to certain viral infections, especially those caused by enteroviruses, such as echovirus, poliovirus, and coxsackievirus. These viruses infect the gastrointestinal tract, and from here they can disseminate to the nervous system via the blood. Thus, immunization with live poliovirus carries the risk of paralytic poliomyelitis, and echovirus can cause fatal encephalitis. For similar reasons, *Giardia lamblia*, an intestinal protozoan that is normally resisted by secreted IgA, causes persistent infections in persons with this disorder. In general, however, most intracellular viral, fungal, and protozoal infections are handled quite well by the intact T cell–mediated immunity.

The classic form of this disease has the following characteristics:

- B cells are absent or markedly decreased in the circulation, and the serum levels of all classes of immunoglobulins are depressed. Pre-B cells, which express the B-lineage marker CD19 but not membrane Ig, are found in normal numbers in the bone marrow.
- Germinal centers of lymph nodes, Peyer's patches, the appendix, and tonsils are underdeveloped.
- Plasma cells are absent throughout the body.
- T cell–mediated reactions are normal.

Autoimmune diseases, such as arthritis and dermatomyositis, occur with increased frequency, in as many as 35% of individuals with this disease, which is paradoxical in the presence of an immune deficiency. It is likely that these autoimmune disorders are caused by a breakdown of self-tolerance resulting in autoimmunity, but chronic infections associated with the immune deficiency may play a role in inducing the inflammatory reactions. The treatment of X-linked agammaglobulinemia is replacement therapy with immunoglobulins. In the past, most patients succumbed to infection in infancy or early childhood. Prophylactic intravenous Ig therapy allows most individuals to reach adulthood.

Common Variable Immunodeficiency

This relatively common but poorly defined entity represents a heterogeneous group of disorders.[111,][112] The feature common to all patients is hypogammaglobulinemia, generally affecting all the antibody classes but sometimes only IgG. The diagnosis of common variable immunodeficiency is based on exclusion of other well-defined causes of decreased antibody production.

As might be expected in a heterogeneous group of disorders, both sporadic and inherited forms of the disease occur. In familial forms there is no single pattern of inheritance. Relatives of such patients have a high incidence of selective IgA deficiency (see later). These studies suggest that at least in some cases, selective IgA deficiency and common variable immunodeficiency may represent different expressions of a common genetic defect in antibody synthesis. In contrast to X-linked agammaglobulinemia, most individuals with common variable immunodeficiency have normal or near-normal numbers of B cells in the blood and lymphoid tissues. These B cells, however, are not able to differentiate into plasma cells.

Both intrinsic B-cell defects and abnormalities in T helper cell–mediated activation of B cells may account for the antibody deficiency in this disease. Families have been reported in which the underlying abnormality is in a receptor for a cytokine called BAFF that promotes the survival and differentiation of B cells, or in a molecule called ICOS (inducible costimulator) that is homologous to CD28 and is involved in T-cell activation and in interactions between T and B cells.[111] However, the known mutations account for a minority of cases.

The clinical manifestations of common variable immunodeficiency are caused by antibody deficiency, and hence they resemble those of X-linked agammaglobulinemia. The patients typically present with recurrent sinopulmonary pyogenic infections. In addition, about 20% of patients present with recurrent herpesvirus infections. Serious enterovirus infections causing meningoencephalitis may also occur. Individuals with this disorder are also prone to the development of persistent diarrhea caused by *G. lamblia*. In contrast to X-linked agammaglobulinemia, common variable immunodeficiency affects both sexes equally, and the onset of symptoms is later—in childhood or adolescence. Histologically the B-cell areas of the lymphoid tissues (i.e., lymphoid follicles in nodes, spleen, and gut) are hyperplastic. The enlargement of B-cell areas probably reflects defective regulation, that is, B cells can proliferate in response to antigen but do not produce antibodies, and therefore the normal feedback inhibition by IgG is absent.

As in X-linked agammaglobulinemia, these patients have a high frequency of autoimmune diseases (approximately 20%), including rheumatoid arthritis. The risk of lymphoid malignancy is also increased, and an increase in gastric cancer has been reported.

Isolated IgA Deficiency

Isolated IgA deficiency is a common immunodeficiency. In the United States it occurs in about 1 in 600 individuals of European descent.[113] It is far less common in blacks and Asians. Affected individuals have extremely *low levels of both serum and secretory IgA*. It may be familial, or acquired in association with toxoplasmosis, measles, or some other viral infection. The association of IgA deficiency with common variable immunodeficiency was mentioned earlier. Most individuals with this disease are asymptomatic. Because IgA is the major Ig in external secretions, mucosal defenses are weakened, and infections occur in the respiratory, gastrointestinal, and urogenital tracts. Symptomatic patients commonly present with recurrent sinopulmonary infections and diarrhea. Some individuals with IgA deficiency are also deficient in the IgG2 and IgG4 subclasses of IgG. This group of patients is particularly prone to developing infections. In addition, IgA-deficient patients have a high frequency of respiratory tract allergy and a variety of autoimmune diseases, particularly SLE and rheumatoid arthritis. The basis of the increased frequency of autoimmune and allergic diseases is not known. When transfused with blood containing normal IgA, some of these patients develop severe, even fatal, anaphylactic reactions, because the IgA behaves like a foreign antigen (since the patients do not produce it and are not tolerant to it).

The basic defect in IgA deficiency is impaired differentiation of naive B lymphocytes to IgA-producing cells. The molecular basis of this defect in most patients is still unknown. Defects in a receptor for the B cell–activating cytokine, BAFF, have been described in some patients.

Hyper-IgM Syndrome

In hyper-IgM syndrome the *affected patients make IgM antibodies but are deficient in their ability to produce IgG, IgA, and IgE antibodies*. It is now known that the defect in this disease affects the ability of helper T cells to deliver activating signals to B cells and macrophages. As discussed earlier in the chapter, many of the functions of CD4+ helper T cells require the engagement of CD40 on B cells, macrophages and dendritic cells by CD40L (also called CD154) expressed on antigen-activated T cells.

This interaction triggers Ig class switching and affinity maturation in B cells, and stimulates the microbicidal functions of macrophages. Approximately 70% of individuals with hyper-IgM syndrome have the X-linked form of the disease, caused by mutations in the gene encoding CD40L located on Xq26.[114] In the remaining persons the disease is inherited in an autosomal recessive pattern. Most of these patients have mutations in the gene encoding CD40 or the enzyme called activation-induced deaminase, a DNA-editing cytosine deaminase that is required for class switching and affinity maturation.

The serum of persons with this syndrome contains normal or elevated levels of IgM but no IgA or IgE and extremely low levels of IgG. The number of B and T cells is normal. Many of the IgM antibodies react with elements of blood, giving rise to autoimmune hemolytic anemia, thrombocytopenia, and neutropenia. In older patients there may be uncontrolled proliferation of IgM-producing plasma cells with infiltrations of the gastrointestinal tract. Although the proliferating B cells are polyclonal, extensive infiltration may lead to death.

Clinically, individuals with the hyper-IgM syndrome present with recurrent pyogenic infections, because the level of opsonizing IgG antibodies is low. In addition, those with CD40L mutations are also susceptible to pneumonia caused by the intracellular organism *Pneumocystis jiroveci*, because of the defect in cell-mediated immunity.

DiGeorge Syndrome (Thymic Hypoplasia)

DiGeorge syndrome is a T-cell deficiency that results from failure of development of the third and fourth pharyngeal pouches. The latter give rise to the thymus, the parathyroids, some of the clear cells of the thyroid, and the ultimobranchial body. Thus, individuals with this syndrome have a variable loss of T cell–mediated immunity (resulting from hypoplasia or lack of the thymus), tetany (resulting from lack of the parathyroids), and congenital defects of the heart and great vessels. In addition, the appearance of the mouth, ears, and facies may be abnormal. Absence of cell-mediated immunity is caused by low numbers of T lymphocytes in the blood and lymphoid tissues and poor defense against certain fungal and viral infections. The T-cell zones of lymphoid organs—paracortical areas of the lymph nodes and the periarteriolar sheaths of the spleen—are depleted. Ig levels may be normal or reduced, depending on the severity of the T-cell deficiency.

DiGeorge syndrome is not a familial disorder. It results from the deletion of a gene that maps to chromosome 22q11.[115] This deletion is seen in 90% of patients, and DiGeorge syndrome is now considered a component of the *22q11 deletion syndrome*, discussed in Chapter 5 . One mutation that has been associated with the DiGeorge syndrome affects a member of the T-box family of transcription factors, which may be involved in development of the branchial arch and the great vessels.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) represents a constellation of genetically distinct syndromes, all having in common *defects in both humoral and cell-mediated immune responses*.[116] Affected infants present with prominent thrush (oral candidiasis), extensive diaper rash, and failure to thrive. Some patients develop a morbilliform rash shortly after birth because maternal T cells are transferred across the placenta and attack the fetus, causing GVH disease. Persons with SCID are extremely susceptible to recurrent, severe infections by a wide range of pathogens, including *Candida albicans*, *P. jiroveci*, *Pseudomonas*, cytomegalovirus, varicella, and a whole host of bacteria. Without bone marrow transplantation, death occurs within the first year of life. Despite the common clinical manifestations, the underlying defects are quite different in different forms of SCID, and in many cases the genetic lesion is not known. Often, the SCID defect resides in the T-cell compartment, with a secondary impairment of humoral immunity.

The most common form, accounting for 50% to 60% of cases, is X-linked, and hence SCID is more common in boys than in girls. The genetic defect in the X-linked form is a *mutation in the common γ-chain (γc) subunit of cytokine receptors*. This transmembrane protein is part of the signal-transducing components of the receptors for IL-2, IL-4, IL-7, IL-9, IL-11, IL-15, and IL-21. IL-7 is required for the survival and proliferation of lymphoid progenitors, particularly T-cell precursors. As a result of defective IL-7 receptor signaling, there is a profound defect in the earliest stages of lymphocyte development, especially T-cell development.[117] T-cell numbers are greatly reduced, and although B cells are normal in number, antibody synthesis is severely impaired because of lack of T-cell help. IL-15 is important for the maturation and proliferation of NK cells, and because the common γ chain is a component of the receptor for IL-15, these individuals often have a deficiency of NK cells as well.

The remaining cases of SCID are inherited as autosomal recessive. The most common cause of autosomal recessive SCID is a *deficiency of the enzyme adenosine deaminase (ADA)*. Although the mechanisms by which ADA deficiency causes SCID are not entirely clear, it has been proposed that deficiency of ADA leads to accumulation of deoxyadenosine and its derivatives (e.g., deoxy-ATP), which are toxic to rapidly dividing immature lymphocytes, especially those of the T-cell lineage.[118] Hence there may be a greater reduction in the number of T lymphocytes than of B lymphocytes.

Several other less common causes of autosomal recessive SCID have been discovered:

- Mutations in recombinase-activating genes prevent the somatic gene rearrangements essential for the assembly of T-cell receptor and Ig genes.[119] This blocks the development of T and B cells.
- An intracellular kinase called Jak3 is essential for signal transduction through the common cytokine receptor γ chain (which is mutated in X-linked SCID, as discussed above). Mutations of Jak3 therefore have the same effects as mutations in the γc chain.[120]
- Several mutations have been described in signaling molecules, including kinases associated with the T-cell antigen receptor and components of calcium channels that are required for entry of calcium and activation of many signaling pathways.
- Mutations that impair the expression of class II MHC molecules prevent the development of CD4+ T cells.[121] CD4+ T cells are involved in cellular immunity and provide help to B cells, and hence class II MHC deficiency results in combined immunodeficiency. This disease, called the *bare lymphocyte syndrome*, is usually caused by mutations in transcription factors that are required for class II MHC gene expression.

The histologic findings in SCID depend on the underlying defect. In the two most common forms (ADA deficiency and γc mutation), the thymus is small and devoid of lymphoid cells. In SCID caused by ADA deficiency, remnants of Hassall's corpuscles can be found, whereas in X-linked SCID the thymus contains lobules of undifferentiated epithelial cells resembling fetal thymus. In either case other lymphoid tissues are hypoplastic as well, with marked depletion of T-cell areas and in some cases both T-cell and B-cell zones.

Currently, bone marrow transplantation is the mainstay of treatment, but X-linked SCID is the first human disease in which gene therapy has been successful.[122] For gene therapy a normal γc gene is expressed in bone marrow stem cells of patients using a retroviral vector, and the cells are transplanted back into the patients. The clinical experience is small, but some patients have shown reconstitution of their immune systems for over a year after therapy. Unfortunately, however, 20% of these patients have developed acute T-cell leukemias, which appear to have been triggered by the activation of oncogenes by the integrated retrovirus,[123] highlighting the dangers of this particular approach to gene therapy. Patients with ADA deficiency have also been treated with bone marrow transplantation and, more recently, with gene therapy to introduce a normal ADA gene into T-cell precursors.

Immunodeficiency with Thrombocytopenia and Eczema (Wiskott-Aldrich Syndrome)

Wiskott-Aldrich syndrome is an X-linked recessive disease characterized by thrombocytopenia, eczema, and a marked vulnerability to recurrent infection, ending in early death.[124] The thymus is morphologically normal, at least early in the course of the disease, but there is progressive secondary depletion of T lymphocytes in the peripheral blood and in the T-cell zones (paracortical areas) of the lymph nodes, with variable loss of cellular immunity. Patients do not make antibodies to polysaccharide antigens, and the response to protein antigens is poor. IgM levels in the serum are low, but levels of IgG are usually normal. Paradoxically the levels of IgA and IgE are often elevated. Patients are also prone to developing non-Hodgkin B-cell lymphomas. The Wiskott-Aldrich syndrome is caused by mutations in the gene encoding *Wiskott-Aldrich syndrome protein (WASP)*, which is located at Xp11.23. This protein belongs to a family of proteins that are believed to link membrane receptors, such as antigen receptors, to cytoskeletal elements. The WASP protein may be involved in cytoskeleton-dependent responses, including cell migration and signal transduction, but the essential functions of this protein in lymphocytes and platelets are unclear. The only treatment is bone marrow transplantation.

Genetic Deficiencies of the Complement System

The complement system plays critical roles in host defense and inflammation. Hereditary deficiencies have been described for virtually all components of the complement system and several of the regulators.[125] A deficiency of C2 is the most common of all. With a deficiency of C2 or the other early components of the classical pathway (i.e., C1 [C1q, r, or s] or C4), there is little or no increase in susceptibility to infections, but the dominant manifestation is an increased incidence of an SLE-like autoimmune disease, as discussed earlier. Presumably, the alternative complement pathway is adequate for the control of most infections. Deficiency of components of the alternative pathway (properdin and factor D) is rare. It is associated with recurrent pyogenic infections. The C3 component of complement is required for both the classical and alternative pathways, and hence a deficiency of this protein results in susceptibility to serious and recurrent pyogenic infections. There is also increased incidence of immune complex–mediated glomerulonephritis; in the absence of complement, immune complex–mediated inflammation is presumably caused by Fc receptor–dependent leukocyte activation. The terminal components of complement C5, 6, 7, 8, and 9 are required for the assembly of the membrane attack complex involved in the lysis of organisms. With a deficiency of these late-acting components, there is increased susceptibility to recurrent neisserial (gonococcal and meningococcal) infections; *Neisseria* bacteria have thin cell walls and are especially susceptible to the lytic actions of complement. Some patients inherit a form of mannose-binding lectin, the plasma protein that initiates the lectin pathway of complement, that does not polymerize normally and is functionally defective. These individuals also show increased susceptibility to infections.

A deficiency of C1 inhibitor gives rise to *hereditary angioedema*.[126] This autosomal dominant disorder is more common than complement deficiency states. The C1 inhibitor is a protease inhibitor whose target enzymes are C1r and C1s of the complement cascade, factor XII of the coagulation pathway, and the kallikrein system. As discussed in Chapter 2 , these pathways are closely linked, and their unregulated activation can give rise to vasoactive peptides such as bradykinin. Although the exact nature of the bioactive compound produced in hereditary angioedema is uncertain, these patients have episodes of edema affecting skin and mucosal surfaces such as the larynx and the gastrointestinal tract. This may result in life-threatening asphyxia or nausea, vomiting, and diarrhea after minor trauma or emotional stress. Acute attacks of hereditary angioedema can be treated with C1 inhibitor concentrates prepared from human plasma.

Deficiency of other complement-regulatory proteins is the cause of paroxysmal nocturnal hemoglobinuria. In this disease there are mutations in enzymes required for glycophosphatidyl inositol linkages, which are essential for the assembly of decay-accelerating factor and CD59, both of which regulate complement.[127] Uncontrolled complement activation on the surface of red cells is believed to

be the basis of hemolysis (Chapter 14). Mutations in the complementregulatory protein factor H underlie about 10% of cases of a renal disease called hemolytic uremic syndrome, which is characterized by microvascular thrombosis in the kidneys (Chapter 20).

SECONDARY IMMUNODEFICIENCIES

Secondary immune deficiencies may be encountered in individuals with cancer, diabetes and other metabolic diseases, malnutrition, chronic infection, and renal disease. They also occur in persons receiving chemotherapy or radiation therapy for cancer, or immunosuppressive drugs to prevent graft rejection or to treat autoimmune diseases. Some of these secondary immunodeficiency states can be caused by defective lymphocyte maturation (when the bone marrow is damaged by radiation or chemotherapy or involved by tumors, such as leukemias and metastatic cancers), loss of immunoglobulins (as in proteinuric renal diseases), inadequate Ig synthesis (as in malnutrition), or lymphocyte depletion (from drugs or severe infections). *As a group, the secondary immune deficiencies are more common than the disorders of primary genetic origin*. The most common secondary immunodeficiency is AIDS, and we will describe this in the next section.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

AIDS is a disease caused by the retrovirus human immunodeficiency virus (HIV) and characterized by profound immunosuppression that leads to opportunistic infections, secondary neoplasms, and neurologic manifestations. The magnitude of this modern plague is truly staggering. By the end of 2006, more than a million cases of AIDS had been reported in the United States, where AIDS is the second leading cause of death in men between ages 25 and 44, and the third leading cause of death in women in this age group. Though initially recognized in the United States, AIDS is a global problem. It has now been reported from more than 190 countries around the world, and the pool of HIV-infected persons in Africa and Asia is large and expanding. By the year 2006, HIV had infected 60 million people worldwide, and nearly 20 million adults and children have died of the disease. There are about 33 million people living with HIV, of whom 65% are in Africa and over 20% in Asia; the prevalence rate in adults in sub-Saharan Africa is over 8%. It is estimated that 2.5 million people were newly infected with HIV during 2006, and 2.1 million deaths were caused by AIDS in that year alone. In this dismal scenario, there may be some good news. Because of public health measures, the infection rate seems to be decreasing, and some authorities believe it may have peaked in the late 1990s. Furthermore, improved antiviral therapies have resulted in fewer people dying of the disease. This, however, raises its own tragic concern; because more people are living with HIV, the risk of spreading the infection will increase if vigilance is relaxed.

The enormous medical and social burden of the AIDS problem has led to an explosion of research aimed at understanding HIV and its remarkable ability to cripple host defenses. The literature on AIDS is vast and expanding. Here we summarize the currently available data on the epidemiology, pathogenesis, and clinical features of HIV infection.

Epidemiology

Epidemiologic studies in the United States have identified five groups of adults at risk for developing AIDS. The case distribution in these groups is as follows:

- *Homosexual or bisexual men* constitute the largest group, accounting for over 50% of the reported cases. This includes about 5% who were intravenous drug abusers as well. Transmission of AIDS in this category appears to be on the decline: in 2005 about 48% of new cases were attributed to male homosexual contacts.
- *Intravenous drug abusers* with no previous history of homosexuality are the next largest group, representing

about 20% of infected individuals.

- *Hemophiliacs*, especially those who received large amounts of factor VIII or factor IX concentrates before 1985, make up about 0.5% of all cases.
- *Recipients of blood and blood components* who are not hemophiliacs but who received transfusions of HIV-infected whole blood or components (e.g., platelets, plasma) account for about 1% of patients. (Organs obtained from HIV-infected donors can also transmit AIDS.)
- *Heterosexual contacts* of members of other high-risk groups (chiefly intravenous drug abusers) constitute about 10% of the patient population. About 30% of new cases in 2005 were attributable to heterosexual contact. This is the most rapidly growing group of infected individuals, particularly women; in sub-Saharan Africa, where the infection rate is estimated to be about 10,000 new cases every day, more than half the infected individuals are women.
- In approximately 5% of cases the risk factors cannot be determined.

The epidemiology of AIDS is quite different in children under age 13. Close to 2% of all AIDS cases occur in this pediatric population, and worldwide over 500,000 new cases and almost 400,000 deaths were reported in children in the year 2006. In this group the vast majority acquired the infection by transmission of the virus from mother to child (discussed later).

It should be apparent from the preceding discussion that transmission of HIV occurs under conditions that facilitate exchange of blood or body fluids containing the virus or virus-infected cells. The three major routes of transmission are *sexual contact, parenteral inoculation,* and *passage of the virus from infected mothers to their newborns*.

- *Sexual transmission* is clearly the predominant mode of infection worldwide, accounting for over 75% of all cases of HIV transmission. Because the majority of infected people in the United States are men who have sex with men, most sexual transmission has occurred among homosexual men. The virus is carried in the semen, and it enters the recipient's body through abrasions in rectal or oral mucosa or by direct contact with mucosal lining cells. Viral transmission occurs in two ways: (1) direct inoculation into the blood vessels breached by trauma, and (2) infection of dendritic cells or CD4+ cells within the mucosa. Heterosexual transmission, though initially of less numerical importance in the United States, is globally the most common mode by which HIV is spread. In the past few years, even in the United States, *the rate of increase of heterosexual transmission has outpaced transmission by other means*. Such spread is occurring most rapidly in female sex partners of male intravenous drug abusers. As such, the number of women with AIDS is rising rapidly. In contrast to the U.S. experience, heterosexual transmission has always been the dominant mode of HIV infection in Asia and Africa.

In addition to male-to-male and male-to-female transmission, there is evidence supporting female-to-male transmission. HIV is present in vaginal secretions and cervical cells of infected women. In the United States this form of heterosexual spread is approximately 20-fold less common than male-to-female transmission. By contrast, in Africa and parts of Asia, the risk of female-to-male transmission is much higher. This observation is believed to be attributable to the presence of concurrent sexually transmitted disease. All forms of sexual transmission of HIV are enhanced by coexisting sexually transmitted diseases, especially those associated with genital ulceration. In this regard, syphilis, chancroid, and herpes are particularly important. Other sexually transmitted diseases, including gonorrhea and chlamydia, are also cofactors for HIV transmission, perhaps because in these genital inflammatory states there is greater concentration of the virus and virus-containing cells in genital fluids, as a result of increased numbers of inflammatory cells in the semen.

- *Parenteral transmission* of HIV has occurred in three groups of individuals: intravenous drug abusers, hemophiliacs who received factor VIII and factor IX concentrates, and random recipients of blood transfusion. Of these three, intravenous drug users constitute by far the largest group. Transmission occurs by sharing of needles, syringes, and other paraphernalia contaminated with HIV-containing blood.

Transmission of HIV by transfusion of blood or blood products, such as lyophilized factor VIII and factor IX concentrates, has been virtually eliminated. This fortunate outcome resulted from increasing use of recombinant clotting factors and from three public health measures: screening of donated blood and plasma for antibody to HIV, stringent purity criteria for factor VIII and factor IX preparations, and screening of donors on the basis of history. However, an extremely small risk of acquiring AIDS through transfusion of seronegative blood persists, because a recently infected individual may be antibody-negative. Currently, this risk is estimated to be 1 in more than 2 million units of blood transfused. Because it is now possible to detect HIV-associated p24 antigens in the blood before the development of humoral antibodies, this small risk is likely to decrease even further.

- As alluded to earlier, *mother-to-infant transmission* is the major cause of pediatric AIDS. Infected mothers can transmit the infection to their offspring by three routes: (1) in utero by transplacental spread, (2) during delivery through an infected birth canal, and (3) after birth by ingestion of breast milk. Of these, transmission during birth (intrapartum) and in the immediate period thereafter (peripartum) is considered to be the most common mode in the United States. The reported transmission rates vary from 7% to 49% in different parts of the world. Higher risk of transmission is associated with high maternal viral load and low CD4+ T-cell counts as well as chorioamnionitis. Currently, with antiretroviral therapy given to infected pregnant women in the United States, the mother-to-child transmission has been virtually eliminated.

Much concern has arisen in the lay public and among health care workers about spread of HIV infection outside the high-risk groups. Extensive studies indicate that *HIV infection cannot be transmitted by casual personal contact in the household, workplace, or school*. Spread by insect bites is virtually impossible. Regarding transmission of HIV infection to health care workers, an extremely small but definite risk seems to be present. Seroconversion has been documented after accidental needle-stick injury or exposure of nonintact skin to infected blood in laboratory accidents. After needle-stick accidents, the risk of seroconversion is believed to be about 0.3%, and antiretroviral therapy given within 24 to 48 hours of a needle stick can reduce the risk of infection eightfold. By comparison, approximately 30% of those accidentally exposed to hepatitis B–infected blood become seropositive.

Etiology: The Properties of HIV

AIDS is caused by HIV, a nontransforming human retrovirus belonging to the lentivirus family. Included in this group are feline immunodeficiency virus, simian immunodeficiency virus, visna virus of sheep, bovine immunodeficiency virus, and the equine infectious anemia virus.

Two genetically different but related forms of HIV, called *HIV-1 and HIV-2*, have been isolated from patients with AIDS. HIV-1 is the most common type associated with AIDS in the United States, Europe, and Central Africa, whereas HIV-2 causes a similar disease principally in West Africa and India. Specific tests for HIV-2 are available, and blood collected for transfusion is routinely screened for both HIV-1 and HIV-2 seropositivity. The ensuing discussion relates primarily to HIV-1 and diseases caused by it, but the information is generally applicable to HIV-2 as well.

Structure of HIV

Similar to most retroviruses, the HIV-1 virion is spherical and contains an electron-dense, cone-shaped core surrounded by a lipid envelope derived from the host cell membrane (Fig. 6-43). The virus core contains (1) the major capsid protein p24; (2) nucleocapsid protein p7/p9; (3) two copies of genomic RNA; and (4) the three viral enzymes (protease, reverse transcriptase, and integrase). p24 is the most readily detected viral antigen and is the target for the antibodies that are used for the diagnosis of HIV infection in the widely used enzyme-linked immunosorbent assay. The viral core is surrounded by a matrix protein called p17, which lies underneath the virion envelope. Studding the viral envelope are two viral glycoproteins, gp120 and gp41, which are critical for HIV infection of cells.

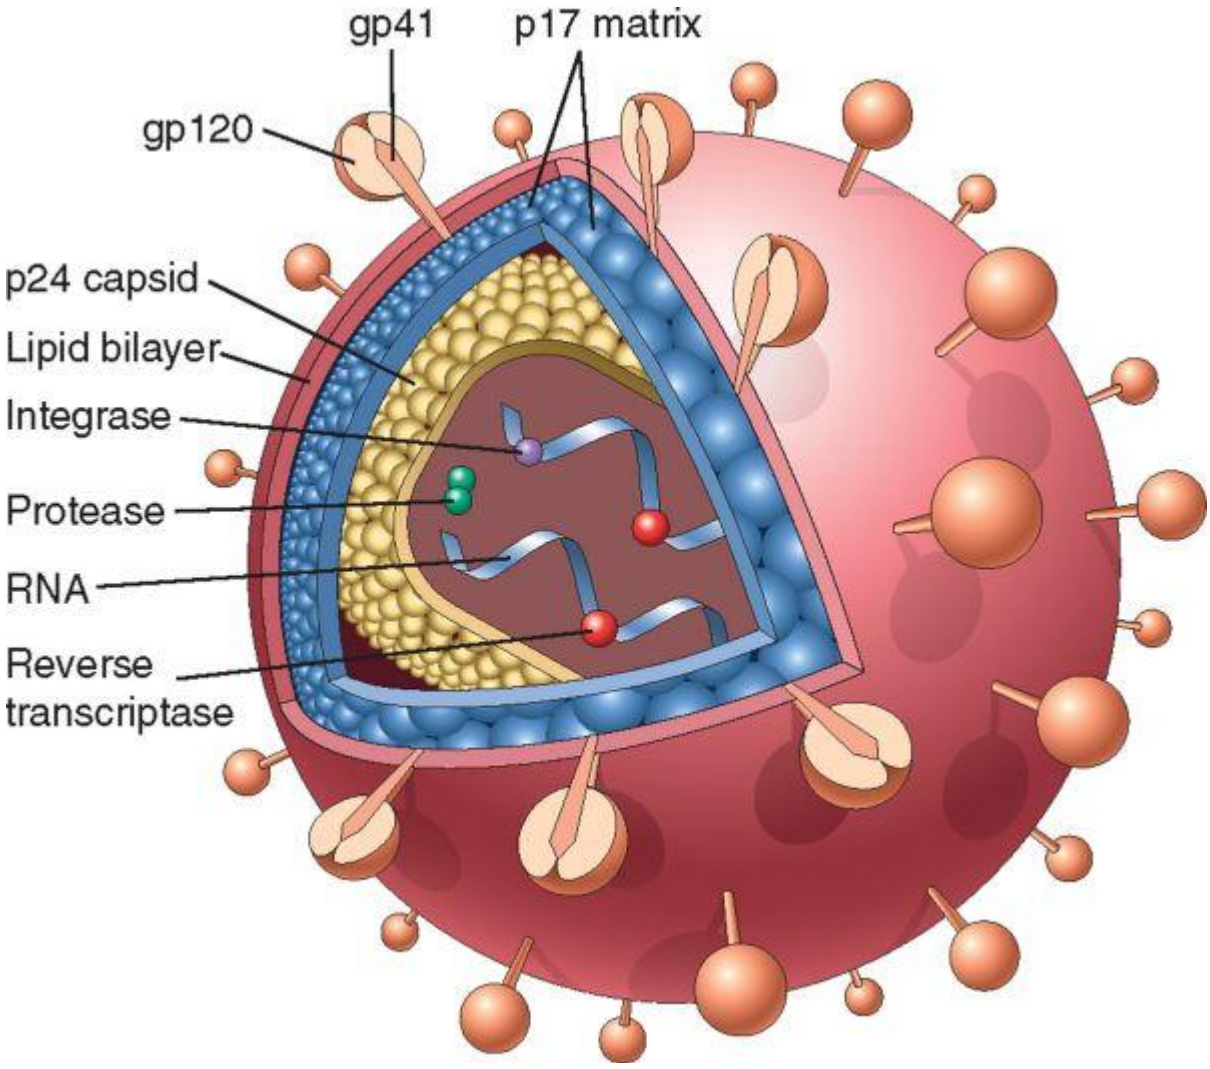

FIGURE 6-43 The structure of the human immune deficiency virus (HIV)–1 virion. The viral particle is covered by a lipid bilayer derived from the host cell and studded with viral glycoproteins gp41 and gp120.

The HIV-1 RNA genome contains the *gag*, *pol*, and *env* genes, which are typical of retroviruses (Fig. 6-44). The products of the *gag* and *pol* genes are translated initially into large precursor proteins that are cleaved by the viral protease to yield the mature proteins. The highly effective anti-HIV-1 protease inhibitor drugs prevent viral assembly by inhibiting the formation of mature viral proteins. In addition to these three standard retroviral genes, HIV contains several other accessory genes, including *tat*, *rev*, *vif*, *nef*, *vpr*, and *vpu*, that regulate the synthesis and assembly of infectious viral particles and the pathogenicity of the virus. [128] [129] [130] For example, the product of the *tat* (transactivator) gene causes a 1000-fold increase in the transcription of viral genes and is therefore critical for virus replication. The functions of other accessory proteins are indicated in Figure 6-44 .

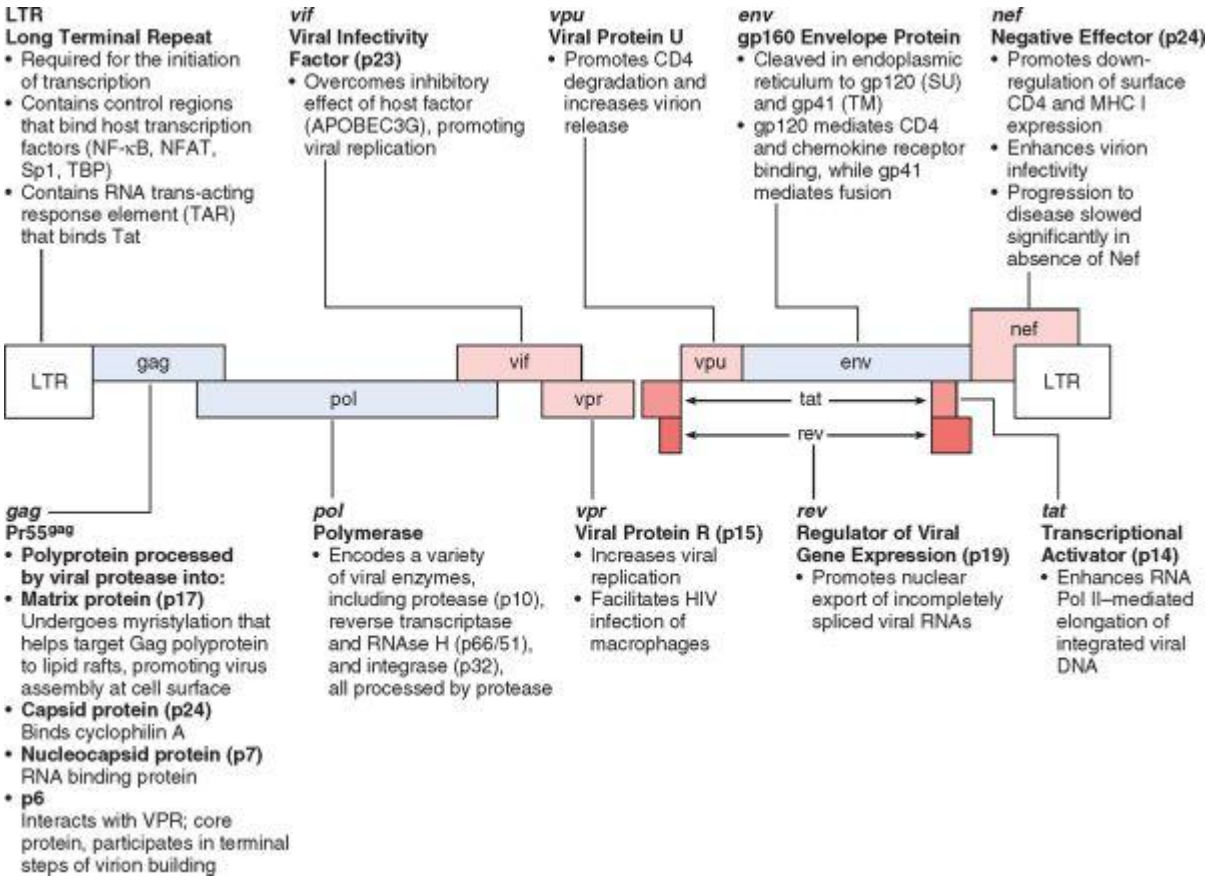

FIGURE 6-44 The HIV genome. Several viral genes and the functions of the encoded proteins are illustrated. The genes outlined in red are unique to HIV; others are shared by all retroviruses.

Molecular analysis of different HIV-1 isolates has revealed considerable variability in certain parts of their genome. Most variations are clustered in particular regions of the envelope glycoproteins. Because the humoral immune response against HIV-1 is targeted against its envelope, such variability poses problems for the development of a single antigen vaccine. On the basis of genetic analysis, HIV-1 can be divided into three subgroups, designated *M* (major), *O* (outlier), and *N* (neither *M* nor *O*). Group M viruses are the most common form worldwide, and they are further divided into several subtypes, or clades, designated A through K. Various subtypes differ in their geographic distribution; for example, subtype B is the most common form in western Europe and the United States, whereas subtype E is the most common clade in Thailand. Currently, clade C is the fastest-spreading clade worldwide, being present in India, Ethiopia, and Southern Africa.

Pathogenesis of HIV Infection and AIDS

While HIV can infect many tissues, *there are two major targets of HIV infection: the immune system and the central nervous system*. The effects of HIV infection on each of these two systems are discussed separately.

Profound immune deficiency, primarily affecting cell-mediated immunity, is the hallmark of AIDS. This results chiefly from infection of and a severe loss of CD4+ T cells as well as impairment in the function of surviving helper T cells.[131,][132] As discussed later, macrophages and dendritic cells are also

targets of HIV infection. HIV enters the body through mucosal tissues and blood and first infects T cells as well as dendritic cells and macrophages. The infection becomes established in lymphoid tissues, where the virus may remain latent for long periods. Active viral replication is associated with more infection of cells and progression to AIDS. We first describe the mechanisms involved in viral entry into T cells and macrophages and the replicative cycle of the virus within cells. This is followed by a more detailed review of the interaction between HIV and its cellular targets.

Life Cycle of HIV

The life cycle of HIV consists of infection of cells, integration of the provirus into the host cell genome, activation of viral replication, and production and release of infectious virus (Fig. 6-45).[133] The molecules and mechanisms of each of these steps are understood in considerable detail.

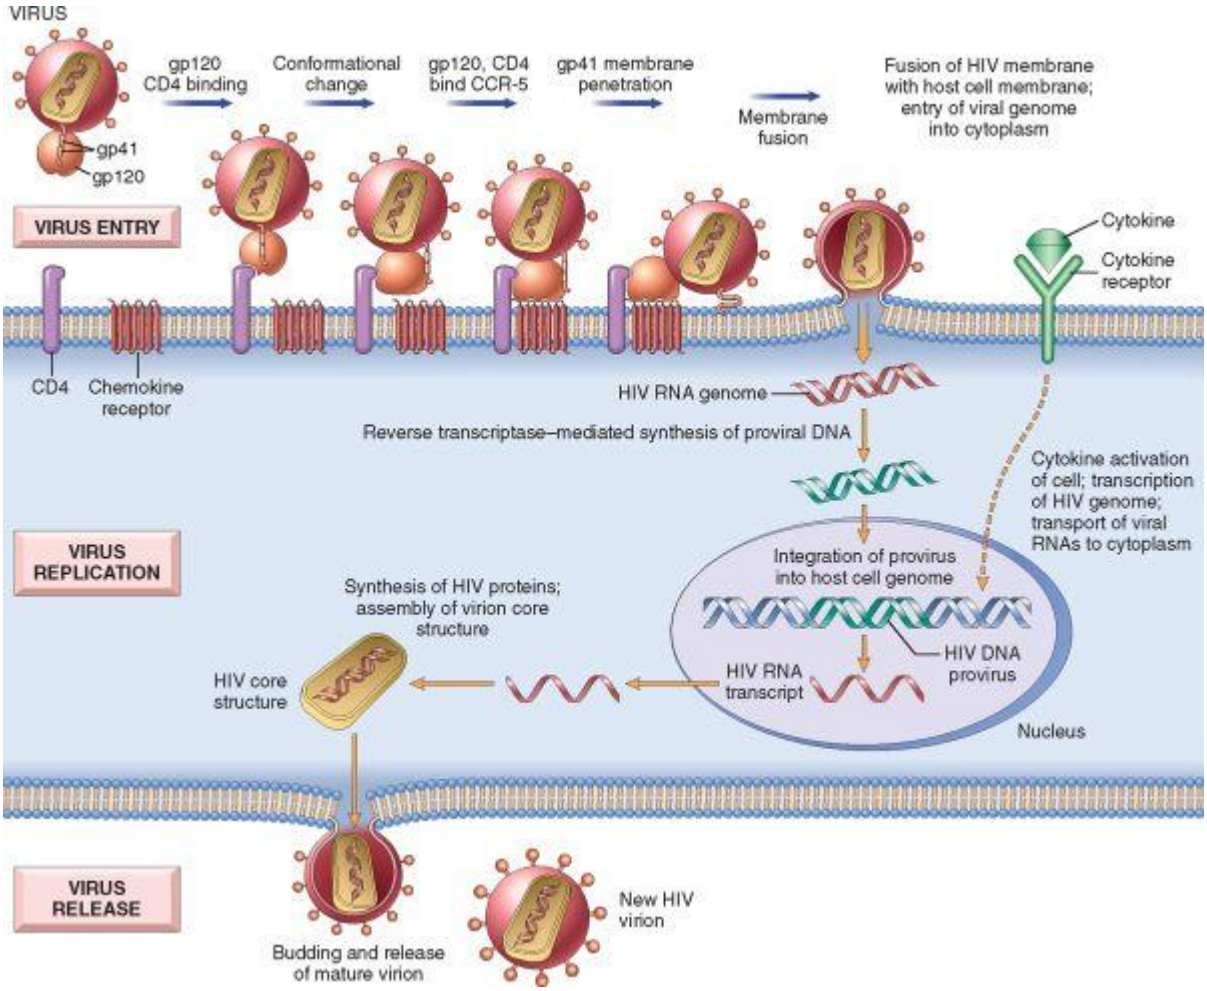

FIGURE 6-45 The life cycle of HIV, showing the steps from viral entry to production of infectious virions. *(Adapted with permission from Wain-Hobson S: HIV. One on one meets two. Nature 384:117, 1996. Copyright 1996, Macmillan Magazines Limited.)*

Infection of Cells by HIV

HIV infects cells by using the CD4 molecule as receptor and various chemokine receptors as coreceptors (Fig. 6-45). The requirement for CD4 binding explains the selective tropism of the virus for CD4+ T cells and other CD4+ cells, particularly monocytes/macrophages and dendritic cells.

Binding to CD4 is not sufficient for infection, however. HIV gp120 must also bind to other cell surface molecules (coreceptors) for entry into the cell. Chemokine receptors, particularly CCR5 and CXCR4, serve this role.[134] HIV isolates can be distinguished by their use of these receptors: R5 strains use CCR5, X4 strains use CXCR4, and some strains (R5×4) are dual-tropic. In approximately 90% of cases, the R5 (M-tropic) type of HIV is the dominant virus found in the blood of acutely infected individuals and early in the course of infection. Over the course of infection, however, T-tropic viruses gradually accumulate; these are especially virulent because T-tropic viruses are capable of infecting many T cells and even thymic T-cell precursors and cause greater T-cell depletion and impairment.

Molecular details of the deadly handshake between HIV glycoproteins and their cell surface receptors have been uncovered by elegant studies and are important to understand because they may provide the basis of anti-HIV therapy. The HIV envelope contains two glycoproteins, surface gp120 noncovalently attached to a transmembrane protein, gp41. *The initial step in infection is the binding of the gp120 envelope glycoprotein to CD4 molecules*. This binding leads to a conformational change that results in the formation of a new recognition site on gp120 for the coreceptors CCR5 or CXCR4. Binding to the coreceptors induces conformational changes in gp41 that result in the exposure of a hydrophobic region called the fusion peptide at the tip of gp41. This peptide inserts into the cell membrane of the target cells (e.g., T cells or macrophages), leading to fusion of the virus with the host cell.[135] After fusion the virus core containing the HIV genome enters the cytoplasm of the cell. The requirement for HIV binding to coreceptors may have important implications for the pathogenesis of AIDS. Chemokines sterically hinder HIV infection of cells in culture by occupying their receptors, and therefore, the level of chemokines in the tissues may influence the efficiency of viral infection in vivo. Also, polymorphisms in the gene encoding CCR5 are associated with different susceptibility to HIV infection. About 1% of white Americans inherit two defective copies of the CCR5 gene and are resistant to infection and the development of AIDS associated with R5 HIV isolates.[125] About 20% of individuals are heterozygous for this protective CCR5 allele; these persons are not protected from AIDS, but the onset of their disease after infection is somewhat delayed. Only rare homozygotes for the mutation have been found in African or East Asian populations.

Viral Replication

Once internalized, the RNA genome of the virus undergoes reverse transcription, leading to the synthesis of double-stranded complementary DNA (cDNA; proviral DNA) (see Fig. 6-45). In quiescent T cells, HIV cDNA may remain in the cytoplasm in a linear episomal form. In dividing T cells, the cDNA circularizes, enters the nucleus, and is then integrated into the host genome. After this integration, the provirus may be silent for months or years, a form of latent infection. Alternatively, proviral DNA may be transcribed, with the formation of complete viral particles that bud from the cell membrane. Such productive infection, when associated with extensive viral budding, leads to death of infected cells.

In vivo, HIV infects memory and activated T cells but is inefficient at productively infecting naive (unactivated) T cells. Naive T cells contain an active form of an enzyme that introduces mutations in the HIV genome. This enzyme has been given the rather cumbersome name APOBEC3G (for "apolipoprotein B mRNA-editing enzyme catalytic polypeptide-like editing complex 3").[136] It is a cytidine deaminase that introduces cytosine-to-uracil mutations in the viral DNA that is produced by reverse transcription. These mutations inhibit further DNA replication by mechanisms that are not fully defined. Activation of T cells converts cellular APOBEC3G into an inactive, high-molecular-mass complex, which explains why the virus can replicate in previously activated (e.g., memory) T cells and T-cell lines. HIV has also evolved to counteract this cellular defense mechanism; the viral protein Vif binds to APOBEC3G and promotes its degradation by cellular proteases.

Completion of the viral life cycle in latently infected cells occurs only after cell activation, and in the case of most CD4+ T cells virus activation results in cell lysis. Activation of T cells by antigens or

cytokines upregulates several transcription factors, including NF-κB, which stimulate transcription of genes encoding cytokines such as IL-2 and its receptor. In resting T cells, NF-κB is sequestered in the cytoplasm in a complex with members of the IκB (inhibitor of κB) protein. Cellular activation by antigen or cytokines induces cytoplasmic kinases that phosphorylate IκB and target it for enzymatic degradation, thus releasing NF-κB and allowing it to translocate to the nucleus. In the nucleus, NF-κB binds to sequences within the promoter regions of several genes, including those of cytokines that are expressed in activated T cells. The long-terminal-repeat sequences that flank the HIV genome also contain NF-κB–binding sites that can be triggered by the same transcription factors.[137] Imagine now a latently infected CD4+ cell that encounters an environmental antigen. Induction of NF-κB in such a cell (a physiologic response) activates the transcription of HIV proviral DNA (a pathologic outcome) and leads ultimately to the production of virions and to cell lysis. Furthermore, TNF and other cytokines produced by activated macrophages also stimulate NF-κB activity and thus lead to production of HIV RNA. Thus, it seems that HIV thrives when the host T cells and macrophages are physiologically activated, an act that can be best described as "subversion from within." Such activation in vivo may result from antigenic stimulation by HIV itself or by other infecting microorganisms. HIV-infected people are at increased risk for recurrent exposure to other infections, which lead to increased lymphocyte activation and production of pro-inflammatory cytokines. These, in turn, stimulate more HIV production, loss of additional CD4+ T cells, and more infection. Thus, it is easy to visualize how in individuals with AIDS a vicious cycle may be set up that culminates in inexorable destruction of the immune system.

Mechanism of T-Cell Immunodeficiency in HIV Infection

Loss of CD4+ T cells is mainly because of infection of the cells and the direct cytopathic effects of the replicating virus (Fig. 6-46).[138] Approximately 100 billion new viral particles are produced every day, and 1 to 2 billion CD4+ T cells die each day.[139] Because the frequency of infected cells in the circulation is very low, for many years it was suspected that the immunodeficiency is out of proportion to the level of infection and cannot be attributed to death of infected cells. In fact, many infected cells may be in mucosal and other peripheral lymphoid organs, and death of these cells is a major cause of the relentless, and eventually profound, cell loss. Also, to a point the immune system can replace the dying T cells, and hence the rate of T cell loss may appear deceptively low, but as the disease progresses, renewal of CD4+ T cells cannot keep up with the loss of these cells. Possible mechanisms by which the virus directly kills infected cells include increased plasma membrane permeability associated with budding of virus particles from the infected cells, and virus replication interfering with protein synthesis.

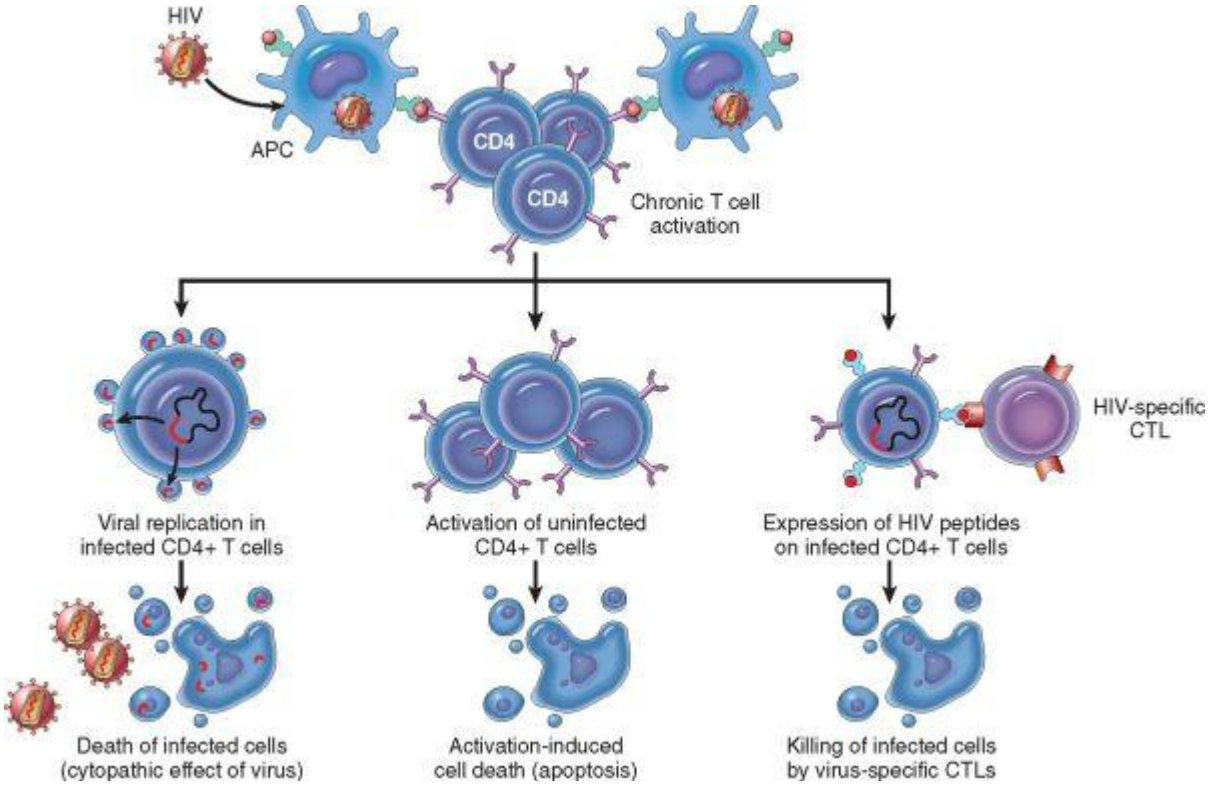

FIGURE 6-46 Mechanisms of CD4+ T-cell loss in HIV infection, showing some of the known and postulated mechanisms of T-cell depletion after HIV infection. APC, antigen-presenting cell; CTL, cytotoxic T lymphocyte.

In addition to direct killing of cells by the virus, other mechanisms may contribute to the loss of T cells (see Fig. 6-46).[140] These include:

- HIV colonizes the lymphoid organs (spleen, lymph nodes, tonsils) and may cause progressive destruction of the architecture and cellular composition of lymphoid tissues.
- Chronic activation of uninfected cells, responding to HIV itself or to infections that are common in individuals with AIDS, leads to apoptosis of these cells by the process of *activation-induced cell death*.[140,][141] Thus, the numbers of CD4+ T cells that die are far greater than the numbers of infected cells. The molecular mechanism of this type of cell death is not known.
- Loss of immature precursors of CD4+ T cells can also occur, either by direct infection of thymic progenitor cells or by infection of accessory cells that secrete cytokines essential for CD4+ T-cell maturation.
- Fusion of infected and uninfected cells with formation of syncytia (giant cells) can occur. In tissue culture the gp120 expressed on productively infected cells binds to CD4 molecules on uninfected T cells, followed by cell fusion. Fused cells develop ballooning and usually die within a few hours. This property of syncytia formation is generally confined to the T-tropic X4 type of HIV-1. For this reason, this type is often referred to as syncytia-inducing (SI) virus, in contrast to the R5 virus.
- Apoptosis of uninfected CD4+ T cells by binding of soluble gp120 to the CD4 molecule, followed by activation through the T-cell receptor by antigens. It has been suggested that such cross-linking of CD4 molecules and T-cell activation lead to aberrant signaling and activation of death pathways. CD8+ CTLs may kill uninfected CD4+ T cells that are coated with gp120 released from infected cells.

Although marked reduction in CD4+ T cells, a hallmark of AIDS, can account for most of the immunodeficiency late in the course of HIV infection, there is compelling evidence for *qualitative*

defects in T cells that can be detected even in asymptomatic HIV-infected persons. Reported defects include a reduction in antigen-induced T-cell proliferation, a decrease in T_H1-type responses relative to the T_H2 type, defects in intracellular signaling, and many more. The loss of T_H1 responses results in profound deficiency in cell-mediated immunity, leading to increased susceptibility to infections by viruses and other intracellular microbes. There is also a selective loss of the memory subset of CD4+ helper T cells early in the course of disease, which explains poor recall responses to previously encountered antigens.

Low-level chronic or latent infection of T cells (and macrophages, discussed below) is an important feature of HIV infection. It is widely believed that integrated provirus, without virus expression (latent infection), can remain in the cells for months to years. Even with potent antiviral therapy, which practically sterilizes the peripheral blood, latent virus lurks within the CD4+ cells (both T cells and macrophages) in the lymph nodes. According to some estimates, 0.05% of resting CD4+ T cells in the lymph nodes are latently infected. Because these CD4+ T cells are memory T cells, they are long-lived, with a life span of months to years, and thus provide a persistent reservoir of virus.

CD4+ T cells play a pivotal role in regulating both cellular and humoral immune responses. Therefore, loss of this "master regulator" has ripple effects on virtually every other component of the immune system, as summarized in Table 6-12 .

TABLE 6-12 -- Major Abnormalities of Immune Function in AIDS

LYMPHOPENIA
Predominantly caused by selective loss of the CD4+ helper T-cell subset
DECREASED T-CELL FUNCTION IN VIVO
Preferential loss of activated and memory T cells
Decreased delayed-type hypersensitivity
Susceptibility to opportunistic infections
Susceptibility to neoplasms
ALTERED T-CELL FUNCTION IN VITRO
Decreased proliferative response to mitogens, alloantigens, and soluble antigens
Decreased cytotoxicity
Decreased helper function for B-cell antibody production
Decreased IL-2 and IFN-γ production
POLYCLONAL B-CELL ACTIVATION
Hypergammaglobulinemia and circulating immune complexes
Inability to mount de novo antibody response to new antigens
Poor responses to normal B-cell activation signals in vitro
ALTERED MONOCYTE OR MACROPHAGE FUNCTIONS
Decreased chemotaxis and phagocytosis
Decreased class II HLA expression
Diminished capacity to present antigen to T cells

HLA, human leukocyte antigen; IFN-γ, interferon-γ; IL-1, etc., interleukin-1; TNF, tumor necrosis factor.

HIV Infection of Non-T Cells

In addition to infection and loss of CD4+ T cells, infection of macrophages[142] and dendritic cells[143] is also important in the pathogenesis of HIV infection. Similar to T cells, the majority of the *macrophages* that are infected by HIV are found in the tissues and the number of blood monocytes infected by the virus may be low. In certain tissues, such as the lungs and brain, as many as 10% to 50% of macrophages are infected. Several aspects of HIV infection of macrophages should be emphasized:

- Although cell division is required for replication of most retroviruses, HIV-1 can infect and multiply in terminally differentiated nondividing macrophages. This property of HIV-1 is dependent on the HIV-1 *vpr* gene. The Vpr protein allows nuclear targeting of the HIV preintegration complex through the nuclear pore.
- Infected macrophages bud relatively small amounts of virus from the cell surface, but these cells contain large numbers of virus particles often located in intracellular vacuoles. Even though macrophages allow viral replication, they are quite resistant to the cytopathic effects of HIV, in contrast to CD4+ T cells. Thus, macrophages may be reservoirs of infection, whose output remains largely protected from host defenses. In late stages of HIV infection, when CD4+ T-cell numbers decline greatly, macrophages may be an important site of continued viral replication.[144]
- Macrophages, in all likelihood, act as gatekeepers of infection. Recall that in more than 90% of cases acute HIV infection is characterized by predominantly circulating M-tropic strains. This finding suggests that the initial infection of macrophages or dendritic cells may be important in the pathogenesis of HIV disease.

Even uninfected monocytes are reported to have unexplained functional defects that may have important consequences for host defense. These defects include impaired microbicidal activity, decreased chemotaxis, decreased secretion of IL-1, inappropriate secretion of TNF, and poor capacity to present antigens to T cells. Also, even the low number of infected blood monocytes may be vehicles for HIV to be transported to various parts of the body, including the nervous system.

Studies have documented that, in addition to macrophages, two types of *dendritic cells* are also important targets for the initiation and maintenance of HIV infection: mucosal and follicular dendritic cells. It is thought that *mucosal dendritic cells are infected by the virus and transport it to regional lymph nodes*, where the virus is transmitted to CD4+ T cells.[143] Dendritic cells also express a lectin-like receptor that specifically binds HIV and displays it in an intact, infectious form to T cells, thus promoting infection of the T cells.[145] *Follicular dendritic cells in the germinal centers of lymph nodes, similar to macrophages, are potential reservoirs of HIV*. Although some follicular dendritic cells may be susceptible to HIV infection, most virus particles are found on the surface of their dendritic processes. Follicular dendritic cells have receptors for the Fc portion of immunoglobulins, and hence they trap HIV virions coated with anti-HIV antibodies. The antibody-coated virions localized to follicular dendritic cells retain the ability to infect CD4+ T cells as they traverse the intricate meshwork formed by the dendritic processes of the follicular dendritic cells.

Although much attention has been focused on T cells, macrophages, and dendritic cells because they can be infected by HIV, individuals with AIDS also display profound abnormalities of B-cell function. Paradoxically, there is polyclonal activation of B cells, resulting in germinal center B-cell hyperplasia (particularly early in the disease course), bone marrow plasmacytosis, hypergammaglobulinemia, and formation of circulating immune complexes. This activation may result from multiple interacting factors: reactivation of or reinfection with cytomegalovirus and EBV, both of which are polyclonal B-cell

activators, can occur; gp41 itself can promote B-cell growth and differentiation; and HIV-infected macrophages produce increased amounts of IL-6, which stimulates proliferation of B cells. *Despite the presence of spontaneously activated B cells, patients with AIDS are unable to mount antibody responses to newly encountered antigens*. This could be due, in part, to lack of T-cell help, but antibody responses against T-independent antigens are also suppressed, and hence there may be other intrinsic defects in B cells as well. Impaired humoral immunity renders these patients prey to disseminated infections caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae*, both of which require antibodies for effective opsonization and clearance.

Pathogenesis of Central Nervous System Involvement

The pathogenesis of neurologic manifestations deserves special mention because, in addition to the lymphoid system, the nervous system is a major target of HIV infection. Macrophages and microglia, cells in the central nervous system that belong to the macrophage lineage, are the predominant cell types in the brain that are infected with HIV.[146] It is believed that HIV is carried into the brain by infected monocytes. In keeping with this, the HIV isolates from the brain are almost exclusively M-tropic. The mechanism of HIV-induced damage of the brain, however, remains obscure. Because neurons are not infected by HIV, and the extent of neuropathologic changes is often less than might be expected from the severity of neurologic symptoms, most workers believe that the neurologic deficit is caused indirectly by viral products and by soluble factors produced by infected microglia. Included among the soluble factors are the usual culprits, such as IL-1, TNF, and IL-6. In addition, nitric oxide induced in neuronal cells by gp41 has been implicated. Direct damage of neurons by soluble HIV gp120 has also been postulated.

Natural History of HIV Infection

HIV disease begins with acute infection, which is only partly controlled by the adaptive immune response, and advances to chronic progressive infection of peripheral lymphoid tissues (Fig. 6-47). Virus typically enters through mucosal epithelia. The subsequent pathogenetic events and clinical manifestations of the infection can be divided into several phases: (1) an acute retroviral syndrome; (2) a middle, chronic phase, in which most individuals are asymptomatic; and (3) clinical AIDS (Figs. 6-47 and 6-48).[131,][132]

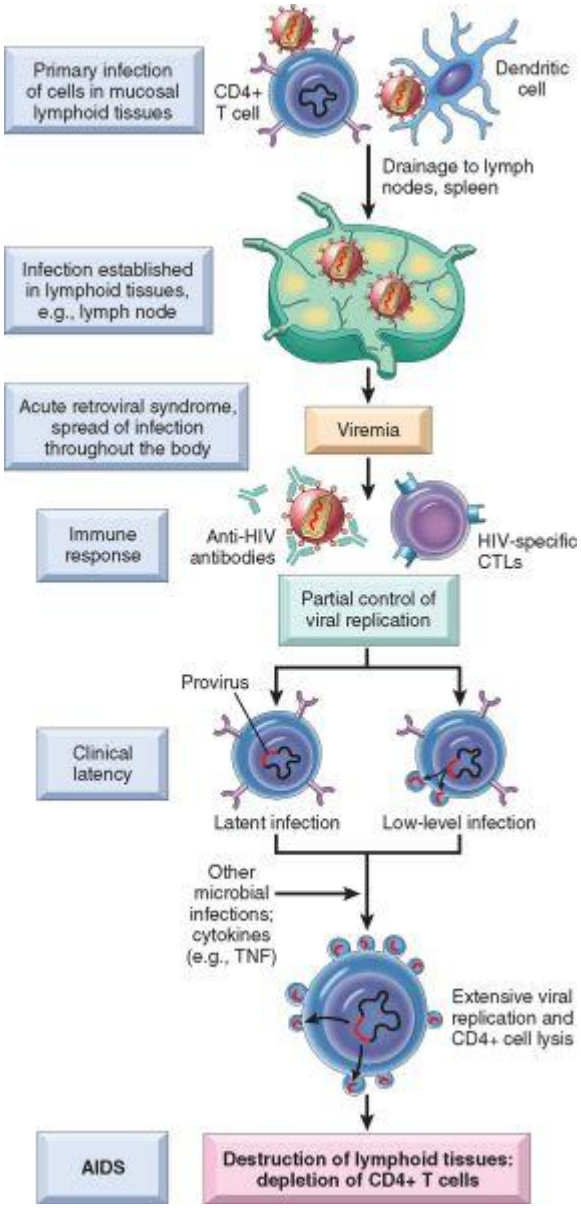

FIGURE 6-47 Pathogenesis of HIV-1 infection. The initial infection starts in mucosal tissues, involving mainly memory CD4+ T cells and dendritic cells, and spreads to lymph nodes. Viral replication leads to viremia and widespread seeding of lymphoid tissue. The viremia is controlled by the host immune response (not shown), and the patient then enters a phase of clinical latency. During this phase, viral replication in both T cells and macrophages continues unabated, but there is some immune containment of virus (not illustrated). There continues a gradual erosion of CD4+ cells and ultimately, CD4+ T-cell numbers decline, and the patient develops clinical symptoms of full-blown AIDS. CTL, cytotoxic T lymphocyte.

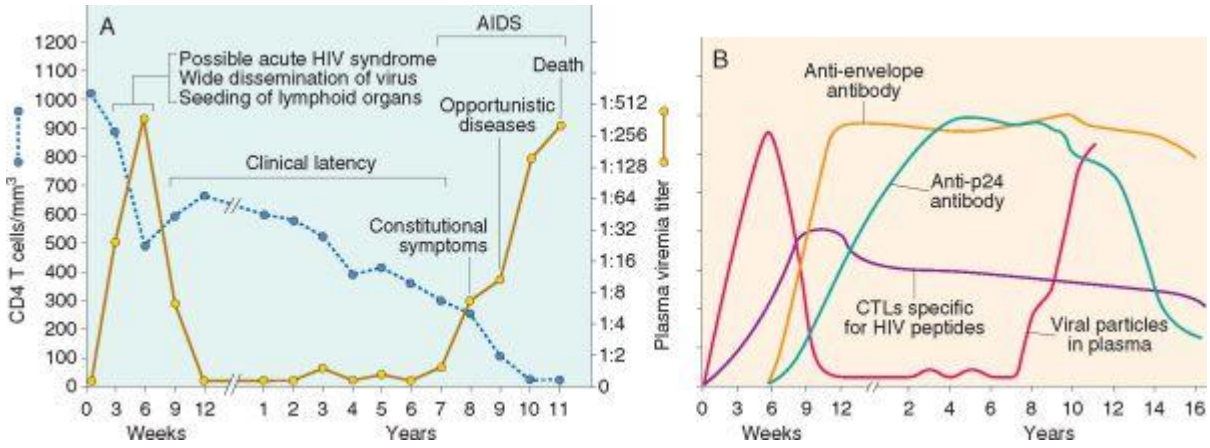

FIGURE 6-48 Clinical course of HIV infection. **A**, During the early period after primary infection there is dissemination of virus, development of an immune response to HIV, and often an acute viral syndrome. During the period of clinical latency, viral replication continues and the CD4+ T-cell count gradually decreases, until it reaches a critical level below which there is a substantial risk of AIDS-associated diseases. **B**, Immune response to HIV infection. A cytotoxic T lymphocyte (CTL) response to HIV is detectable by 2 to 3 weeks after the initial infection, and it peaks by 9 to 12 weeks. Marked expansion of virus-specific CD8+ T-cell clones occurs during this time, and up to 10% of a patient's CTLs may be HIV specific at 12 weeks. The humoral immune response to HIV peaks at about 12 weeks. *(Redrawn from Fauci AS, Lane HC: Human immunodeficiency virus disease: AIDS and related conditions. In Fauci AS, et al (eds): Harrison's Principles of Internal Medicine, 14th ed. New York, McGraw-Hill, 1997, p 1791.)*

Primary Infection, Virus Dissemination, and the Acute Retroviral Syndrome

Acute (early) infection is characterized by infection of memory CD4+ T cells (which express CCR5) in mu-cosal lymphoid tissues, and death of many infected cells. Because the mucosal tissues are the largest reservoir of T cells in the body, and a major site of residence of memory T cells, this local loss results in considerable depletion of lymphocytes.[147,][148] Few infected cells are detectable in the blood and other tissues.

Mucosal infection is followed by dissemination of the virus and the development of host immune responses. Dendritic cells in epithelia at sites of virus entry capture the virus and then migrate into the lymph nodes. Once in lymphoid tissues, dendritic cells may pass HIV on to CD4+ T cells through direct cell-cell contact. Within days after the first exposure to HIV, viral replication can be detected in the lymph nodes. This replication leads to viremia, during which high numbers of HIV particles are present in the patient's blood. The virus disseminates throughout the body and infects helper T cells, macrophages, and dendritic cells in peripheral lymphoid tissues.

As the HIV infection spreads, the individual mounts anti-viral humoral and cell-mediated immune responses.[149] These responses are evidenced by seroconversion (usually within 3 to 7 weeks of presumed exposure) and by the development of virus-specific CD8+ cytotoxic T cells. *HIV-specific CD8+ T cells are detected in the blood at about the time viral titers begin to fall and are most likely responsible for the initial containment of HIV infection*. These immune responses partially control the infection and viral production, and such control is reflected by a drop in viremia to low but detectable levels by about 12 weeks after the primary exposure.

The *acute retroviral syndrome* is the clinical presentation of the initial spread of the virus and the host response.[150] It is estimated that 40% to 90% of individuals who acquire a primary infection develop the viral syndrome. This typically occurs 3 to 6 weeks after infection, and resolves spontaneously in 2 to 4 weeks. Clinically, this phase is associated with a self-limited acute illness with nonspecific symptoms,

including sore throat, myalgias, fever, weight loss, and fatigue, resembling a flulike syndrome. Other clinical features, such as rash, cervical adenopathy, diarrhea, and vomiting, may also occur.

The viral load at the end of the acute phase reflects the equilibrium reached between the virus and the host response, and in a given patient it may remain fairly stable for several years. This level of steady-state viremia, or the viral "set point," is a predictor of the rate of decline of CD4+ T cells, and, therefore, progression of HIV disease. In one study, only 8% of patients with a viral load of less than 4350 copies of viral mRNA per microliter of blood progressed to clinical AIDS in 5 years, whereas 62% of those with a viral load of greater than 36,270 copies had developed AIDS in the same period.[151] From a practical standpoint, therefore, *the extent of viremia, measured as HIV-1 RNA levels, is a useful surrogate marker of HIV disease progression and is of clinical value in the management of people with HIV infection*.

Because the loss of immune containment is associated with declining CD4+ T-cell counts, the Centers for Disease Control (CDC) classification of HIV infection stratifies patients into three categories on the basis of CD4+ cell counts: CD4+ cells greater than or equal to 500 cells/µL, 200 to 499 cells/µL, and fewer than 200 cells/µL (Table 6-13). For clinical management, blood CD4+ T-cell counts are perhaps the most reliable short-term indicator of disease progression. For this reason, CD4+ cell counts and not viral load are the primary clinical measurements used to determine when to start combination antiretroviral therapy.

TABLE 6-13 -- CDC Classification Categories of HIV Infection

Clinical Categories		CD4+ T-Cell Categories		
		1	2	3
		≥ 500 cells/µL	200–499 cells/µL	<200 cells/µL
A.	Asymptomatic, acute (primary) HIV, or persistent generalized lymphadenopathy	A1	A2	A3
B.	Symptomatic, not A or C conditions	B1	B2	B3
C.	AIDS indicator conditions: including constitutional disease, neurologic disease, or neoplasm			

Data from CDC. Centers for Disease Control and Prevention: 1993 revised classifi cation system and expanded surveillance definition for AIDS among adolescents and adults. MMWR 41(RR-17):1, 1992.

Chronic Infection: Phase of Clinical Latency.

In the next, chronic phase of the disease, lymph nodes and the spleen are sites of continuous HIV replication and cell destruction (see Fig. 6-47). During this period of the disease, few or no clinical manifestations of the HIV infection are present. Therefore, this phase of HIV disease is called the clinical latency period. Although the majority of peripheral blood T cells do not harbor the virus, destruction of CD4+ T cells within lymphoid tissues continues during this phase, and the number of circulating blood CD4+ T cells steadily declines. More than 90% of the body's approximately 10^{12} T cells are normally found in lymphoid tissues, and it is estimated that HIV destroys up to 1×10^9 to 2×10^9 CD4+ T cells every day. Early in the course of the disease, the body may continue to make new CD4+ T cells, and therefore CD4+ T cells can be replaced almost as quickly as they are destroyed. At this stage, up to 10% of CD4+ T cells in lymphoid organs may be infected, but the frequency of circulating CD4+ T cells that are infected at any one time may be less than 0.1% of the total CD4+ T

cells. Eventually, over a period of years, the continuous cycle of virus infection, T-cell death, and new infection leads to a steady decline in the number of CD4+ T cells in the lymphoid tissues and the circulation.

Concomitant with this loss of CD4+ T cells, host defenses begin to wane, and the proportion of the surviving CD4+ cells infected with HIV increases, as does the viral burden per CD4+ cell. Not unexpectedly, HIV RNA levels may begin to increase as the host begins to lose the battle with the virus. How HIV escapes immune control is not entirely clear, but several mechanisms have been proposed.[152,][153] These include destruction of the CD4+ T cells that are critical for effective immunity, antigenic variation, and down-modulation of class I MHC molecules on infected cells so that viral antigens are not recognized by CD8+ CTLs. During this period the virus may evolve and switch from relying solely on CCR5 to enter its target cells to relying on either CXCR4 or both CCR5 and CXCR4. This coreceptor switch is associated with more rapid decline in CD4+ T-cell counts, presumably because of greater infection of T cells.

In this chronic phase of infection, patients are either asymptomatic or develop minor opportunistic infections, such as oral candidiasis (thrush), vaginal candidiasis, herpes zoster, and perhaps mycobacterial tuberculosis (the latter being particularly common in resource-poor regions such as sub-Saharan Africa). Autoimmune thrombocytopenia may also be noted (Chapter 14).

AIDS

The final phase is *progression to AIDS*, characterized by a breakdown of host defense, a dramatic increase in plasma virus, and severe, life-threatening clinical disease. Typically the patient presents with long-lasting fever (>1 month), fatigue, weight loss, and diarrhea. After a variable period, serious opportunistic infections, secondary neoplasms, or clinical neurologic disease (grouped under the rubric *AIDS indicator diseases*, discussed below) emerge, and the patient is said to have developed AIDS.

In the absence of treatment, most but not all patients with HIV infection progress to AIDS after a chronic phase lasting from 7 to 10 years. Exceptions to this typical course are exemplified by rapid progressors and long-term nonprogressors. In *rapid progressors* the middle, chronic phase is telescoped to 2 to 3 years after primary infection. About 5% to 15% of infected individuals are *long-term nonprogressors*, defined as untreated HIV-1–infected individuals who remain asymptomatic for 10 years or more, with stable CD4+ T-cell counts and low levels of plasma viremia (usually less than 500 viral RNA copies per milliliter).[154] Remarkably, about 1% of infected individuals have undetectable plasma virus (50–75 RNA copies/mL); these have been called *elite controllers*. Individuals with such an uncommon clinical course have attracted great attention in the hope that studying them may shed light on host and viral factors that influence disease progression. Studies thus far indicate that this group is heterogeneous with respect to the variables that influence the course of the disease. In most cases, the viral isolates do not show qualitative abnormalities, suggesting that the course of the disease cannot be attributed to a “wimpy” virus. In all cases there is evidence of a vigorous anti-HIV immune response, but the immune correlates of protection are still unknown. Some of these individuals have high levels of HIV-specific CD4+ and CD8+ T-cell responses, and these levels are maintained over the course of infection. Further studies, it is hoped, will provide the answers to this and other questions critical to understanding disease progression.

Clinical Features of AIDS

The clinical manifestations of HIV infection can be readily surmised from the foregoing discussion. They range from a mild acute illness to severe disease. Because the salient clinical features of the acute early and chronic middle phases of HIV infection were described earlier, here we summarize the clinical manifestations of the terminal phase, AIDS. At the outset it should be pointed out that the clinical

manifestations and opportunistic infections associated with HIV infection may differ in different parts of the world. Also, the course of the disease has been greatly modified by new antiretroviral therapies, and many complications that were once devastating are now infrequent.

In the United States, the typical adult patient with AIDS presents with fever, weight loss, diarrhea, generalized lymphadenopathy, multiple opportunistic infections, neurologic disease, and, in many cases, secondary neoplasms. The infections and neoplasms listed in Table 6-14 are included in the surveillance definition of AIDS.

TABLE 6-14 -- AIDS-Defining Opportunistic Infections and Neoplasms Found in Patients with HIV Infection

PROTOZOAL AND HELMINTHIC INFECTIONS
Cryptosporidiosis or isosporidiosis (enteritis)
Toxoplasmosis (pneumonia or CNS infection)
FUNGAL INFECTIONS
Pneumocystosis (pneumonia or disseminated infection)
Candidiasis (esophageal, tracheal, or pulmonary)
Cryptococcosis (CNS infection)
Coccidioidomycosis (disseminated)
Histoplasmosis (disseminated)
BACTERIAL INFECTIONS
Mycobacteriosis (“atypical,” e.g., *Mycobacterium avium-intracellulare*, disseminated or extrapulmonary; *M. tuberculosis*, pulmonary or extrapulmonary)
Nocardiosis (pneumonia, meningitis, disseminated)
Salmonella infections, disseminated
VIRAL INFECTIONS
Cytomegalovirus (pulmonary, intestinal, retinitis, or CNS infections)
Herpes simplex virus (localized or disseminated)
Varicella-zoster virus (localized or disseminated)
Progressive multifocal leukoencephalopathy

CNS, central nervous system.

Opportunistic Infections

Opportunistic infections account for the majority of deaths in untreated patients with AIDS. Many of these infections represent reactivation of latent infections, which are normally kept in check by a robust immune system but are not completely eradicated because the infectious agents have evolved to coexist with their hosts. The actual frequency of infections varies in different regions of the world, and has been markedly reduced by the advent of highly active antiretroviral therapy (HAART).[155] A brief summary of selected opportunistic infections is provided here.

Approximately 15% to 30% of untreated HIV-infected people develop pneumonia at some time during the course of the disease, caused by the fungus *Pneumocystis jiroveci* (reactivation of a prior latent infection). Before the advent of HAART, this infection was the presenting feature in about 20% of cases, but the incidence is much less in patients who respond to HAART.

Many patients present with an opportunistic infection other than *P. jiroveci* pneumonia. Among the most common pathogens are *Candida*, cytomegalovirus, atypical and typical mycobacteria, *Cryptococcus neoformans*, *Toxoplasma gondii*, *Cryptosporidium*, herpes simplex virus, papovaviruses, and *Histoplasma capsulatum*.

Candidiasis is the most common fungal infection in patients with AIDS, and infection of the oral cavity, vagina, and esophagus are its most common clinical manifestations. In asymptomatic HIV-infected individuals oral candidiasis is a sign of immunological decompensation, and it often heralds the transition to AIDS. Invasive candidiasis is infrequent in patients with AIDS, and it usually occurs when there is drug-induced neutropenia or use of indwelling catheters.

Cytomegalovirus may cause disseminated disease, although, more commonly, it affects the eye and gastrointestinal tract. Chorioretinitis was seen in approximately 25% of patients before the advent of HAART, but this has decreased dramatically after the initiation of HAART. Cytomegalovirus retinitis occurs almost exclusively in patients with CD4+ T cell counts below 50 per microliter. Gastrointestinal disease, seen in 5% to 10% of cases, manifests as esophagitis and colitis, the latter associated with multiple mucosal ulcerations.

Disseminated bacterial infection with *atypical mycobacteria* (mainly *M. avium-intracellulare*) also occurs late, in the setting of severe immunosuppression. Coincident with the AIDS epidemic, the incidence of tuberculosis has risen dramatically. Worldwide, almost a third of all deaths in AIDS patients are attributable to tuberculosis, but this complication remains uncommon in the United States. Patients with AIDS have reactivation of latent pulmonary disease as well as outbreaks of primary infection. In contrast to infection with atypical mycobacteria, *M. tuberculosis* manifests itself early in the course of AIDS. As with tuberculosis in other settings, the infection may be confined to lungs or may involve multiple organs. The pattern of expression depends on the degree of immunosuppression; dissemination is more common in patients with very low CD4+ T-cell counts. Most worrisome are reports indicating that a growing number of isolates are resistant to multiple anti-mycobacterial drugs.

Cryptococcosis occurs in about 10% of AIDS patients. As in other settings with immunosuppression, meningitis is the major clinical manifestation of cryptococcosis. *Toxoplasma gondii*, another frequent invader of the central nervous system in AIDS, causes encephalitis and is responsible for 50% of all mass lesions in the central nervous system.

JC virus, a human papovavirus, is another important cause of central nervous system infections in HIV-infected patients. It causes progressive multifocal leukoencephalopathy (Chapter 28). *Herpes simplex virus infection* is manifested by mucocutaneous ulcerations involving the mouth, esophagus, external genitalia, and perianal region. *Persistent diarrhea*, which is common in untreated patients with advanced AIDS, is often caused by infections with protozoans such as *Cryptosporidium*, *Isospora belli*, or microsporidia. These patients have chronic, profuse, watery diarrhea with massive fluid loss. Diarrhea may also result from infection with enteric bacteria, such as *Salmonella* and *Shigella*, as well as *M. avium-intracellulare*.

Tumors

Patients with AIDS have a high incidence of certain tumors, especially *Kaposi sarcoma (KS)*, non-Hodgkin B-cell lymphoma, cervical cancer in women, and anal cancer in men.[156] It is estimated that 25%

to 40% of untreated HIV-infected individuals will eventually develop a malignancy. A common feature of these tumors is that they are all believed to be caused by oncogenic DNA viruses, that is, kaposi sarcoma herpesvirus (Kaposi sarcoma), EBV (B-cell lymphoma), and human papillomavirus (cervical and anal carcinoma). Even in healthy people, any of these viruses may establish latent infections that are kept in check by a competent immune system. The increased risk of malignancy in AIDS patients exists mainly because of failure to contain the infections and reactivation of the viruses, as well as decreased immunity against the tumors.

Kaposi Sarcoma

Kaposi sarcoma, a vascular tumor that is otherwise rare in the United States, is the most common neoplasm in patients with AIDS. The morphology of KS and its occurrence in patients not infected with HIV are discussed in Chapter 11 . At the onset of the AIDS epidemic, up to 30% of infected homosexual or bisexual men had KS, but in recent years, with use of HAART there has been a marked decline in its incidence, from 15 cases per 1000 person years to less than 5 cases.[157]

The lesions of KS are characterized by the proliferation of spindle-shaped cells that express markers of both endothelial cells (vascular or lymphatic) and smooth muscle cells (Chapter 11). There is also a profusion of slitlike vascular spaces, suggesting that the lesions may arise from primitive mesenchymal precursors of vascular channels. In addition, KS lesions display chronic inflammatory cell infiltrates. Many of the features of KS suggest that it is not a malignant tumor (despite its ominous name).[158] For instance, spindle cells in many KS lesions are polyclonal or oligoclonal, although more advanced lesions occasionally show monoclonality. The spindle cells in many KS lesions are diploid and are dependent on growth factors for their proliferation. When these cells are implanted subcutaneously in immunodeficient mice they do not form tumors but transiently induce slitlike new blood vessels and inflammatory infiltrates in the surrounding tissue. These elements recall features of human KS but surprisingly are of murine origin, and when the human KS cells involute, these elements also regress. Based on these observations, the current model of KS pathogenesis is that the spindle cells produce pro-inflammatory and angiogenic factors, which recruit the inflammatory and neovascular components of the lesion, and the latter components supply signals that aid in spindle cell survival or growth (Fig. 6-49).

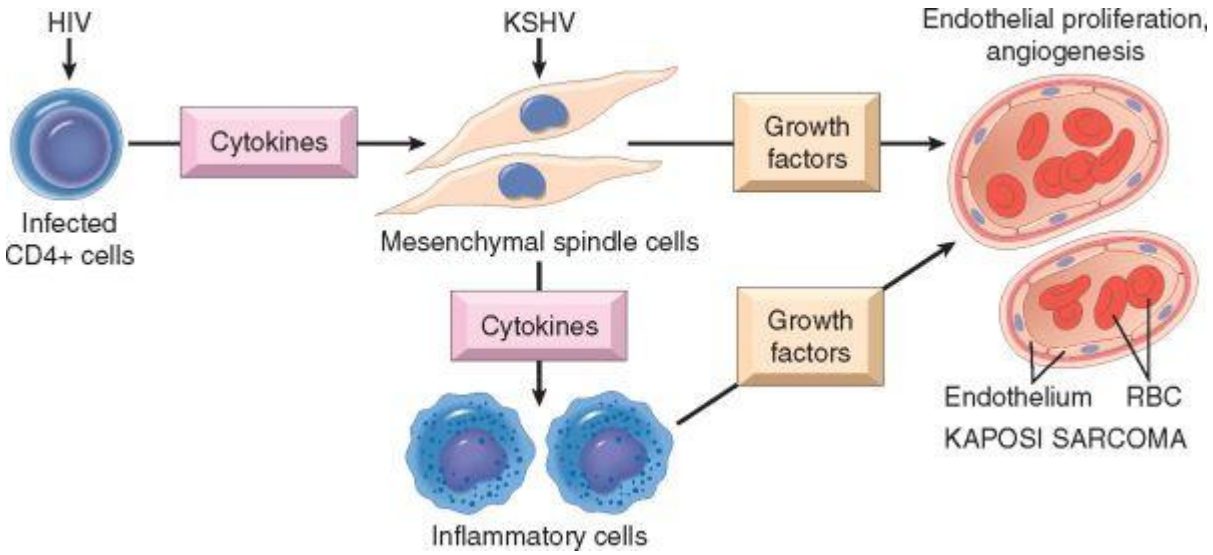

FIGURE 6-49 Postulated pathogenesis of Kaposi sarcoma (KS). Proposed roles of HIV, KS herpesvirus (KSHV; HHV8), and cytokines in the development of KS. Cytokines are produced by the mesenchymal cells infected by KSHV, or by HIV-infected CD4+ cells. B cells may also be

infected by KSHV; they are the probable cells in body cavity lymphomas, also associated with KSHV infection, but their role in KS is unclear.

But what initiates this cycle of events? There is compelling evidence that HIV itself is not the culprit, and that KS is caused by the *KS herpesvirus* (KSHV), also called *human herpesvirus 8* (HHV8).[159] Epidemiologic and molecular studies have established the link between KSHV and KS development. KSHV DNA is found in virtually all KS lesions, including those that occur in HIV-negative populations, and in the lesions, KSHV is strikingly localized to the spindle cells, which display predominantly latent infection. However, KSHV infection, while necessary for KS development, is not sufficient, and additional cofactors are needed. In the AIDS-related form, that cofactor is clearly HIV. (The relevant cofactors for HIV-negative KS remain unknown.) Debate continues over exactly how HIV contributes to KS development. The simplest model is that HIV-mediated immune suppression allows widespread dissemination of KSHV in the host, allowing it to access more spindle cells and set them on the path to uncontrolled growth. Another idea is that HIV-infected T cells produce cytokines or other proteins that promote spindle cell proliferation and survival. Clearly, these possibilities are not mutually exclusive.

Exactly how KSHV infection leads to KS is also still unclear.[158] Like other herpesviruses, KSHV establishes latent infection, during which several proteins are produced with potential roles in stimulating spindle cell proliferation and preventing apoptosis. These include a viral homologue of cyclin D and several inhibitors of p53. Such proteins could give latently infected cells a survival and growth advantage in vivo that would allow them to begin proliferating. But in addition to latent infection, a small subpopulation of cells in KS is undergoing lytic viral replication, with cell death and the release of viral progeny. The KSHV lytic cycle is remarkable for its production of numerous paracrine signaling molecules, including a viral homologue of the cytokine IL-6 and several chemokines. The latter probably play prominent roles in eliciting the inflammatory infiltrates that are an important feature of KS. The contribution of viral IL-6 is not yet clear. Another viral protein produced during lytic infection is a constitutively active G protein–coupled receptor. This protein has attracted attention because its expression activates the release of vascular endothelial growth factor (VEGF), which can promote angiogenesis in the surrounding tissue. Interestingly, expression of the viral G protein–coupled receptor in transgenic mice leads to the development of neovascular spaces vaguely reminiscent of those in KS. Thus, there is ample reason to believe that both latent and lytic KSHV infection contributes to KS pathogenesis.

KSHV infection is not restricted to endothelial cells. The virus is related phylogenetically to the lymphotropic sub-family of herpesviruses (γ-herpesvirus); in keeping with this, its genome is found in B cells of infected subjects. In fact, KSHV infection is also linked to rare B-cell lymphomas in AIDS patients (called *body cavity-based primary effusion lymphoma*) and to multicentric Castleman disease, a B-cell lymphoproliferative disorder.

Clinically, AIDS-associated KS is quite different from the sporadic form (Chapter 11). In HIV-infected individuals the tumor is usually widespread, affecting the skin, mucous membranes, gastrointestinal tract, lymph nodes, and lungs. These tumors also tend to be more aggressive than classic KS.

Lymphomas

AIDS-related lymphomas can be divided into three groups on the basis of their location: systemic, primary central nervous system, and body cavity–based lymphomas.[160] Systemic lymphomas involve lymph nodes as well as extranodal, visceral sites; they constitute 80% of all AIDS-related lymphomas. The central nervous system is the most common extranodal site affected, followed by the

gastrointestinal tract and, less commonly, virtually any other location, including the orbit, salivary glands, and lungs. The vast majority of these lymphomas are aggressive B-cell tumors that present in an advanced stage (Chapter 13). In addition to being commonly involved by systemic non-Hodgkin lymphomas, the central nervous system is also the primary site of lymphomatous involvement in 20% of HIV-infected patients who develop lymphomas. Primary central nervous system lymphoma is 1000 times more common in patients with AIDS than in the general population. Body cavity lymphomas are rare, but they attract attention because of their unusual presentation as pleural, peritoneal, or pericardial effusions.

The pathogenesis of AIDS-associated B-cell lymphomas probably involves sustained polyclonal B-cell activation, followed by the emergence of monoclonal or oligoclonal B-cell populations. It is believed that during the frenzy of proliferation, some clones undergo mutations or chromosomal translocations involving oncogenes or tumor suppressor genes, and subsequent neoplastic transformation (Chapter 7). There is morphologic evidence of B-cell activation in lymph nodes, and it is believed that such triggering of B cells is multifactorial. Patients with AIDS have high levels of several cytokines, some of which, including IL-6, are growth factors for B cells. In addition, there seems to be a role for EBV, known to be a polyclonal mitogen for B cells. Half of the systemic B-cell lymphomas and virtually all lymphomas primary in the central nervous system are latently infected with EBV. Other evidence of EBV infection includes oral hairy leukoplakia (white projections on the tongue), resulting from EBV-driven squamous cell proliferation of the oral mucosa (Chapter 16). In cases in which molecular footprints of EBV infection cannot be detected, other viruses and microbes may initiate polyclonal B-cell proliferation. There is no evidence that HIV by itself is capable of causing neoplastic transformation. The rare body cavity–based primary effusion lymphomas are uniformly latently infected with KSHV, discussed earlier.

With prolonged survival, the number of AIDS patients who develop non-Hodgkin lymphoma has increased steadily. It is currently believed that approximately 6% of all patients with AIDS develop lymphoma during their lifetime. Thus, the risk of developing non-Hodgkin lymphoma is approximately 120-fold greater than in the general population. In contrast to KS, immunodeficiency is firmly implicated as the central predisposing factor. It seems that patients with CD4+ T-cell counts below 50 per microliter incur an extremely high risk.

Other Tumors

In addition to KS and lymphomas, patients with AIDS also have an increased occurrence of carcinoma of the uterine cervix and of anal cancer. This is most likely due to reactivation of latent human papillomavirus (HPV) infection as a result of immunosuppression.[161] This virus is believed to be intimately associated with squamous cell carcinoma of the cervix and its precursor lesions, cervical dysplasia and carcinoma in situ (Chapters 7 and 22 . HPV-associated cervical dysplasia is 10 times more common in HIV-infected women as compared with uninfected women attending family planning clinics. Hence it is recommended that gynecologic examination be part of a routine work-up of HIV-infected women.

Central Nervous System Disease

Involvement of the central nervous system is a common and important manifestation of AIDS. Ninety percent of patients demonstrate some form of neurologic involvement at autopsy, and 40% to 60% have clinically manifest neurologic dysfunction. Importantly, in some patients, neurologic manifestations may be the sole or earliest presenting feature of HIV infection. In addition to opportunistic infections and neoplasms, several virally determined neuropathologic changes occur. These include a self-limited meningoencephalitis occurring at the time of seroconversion, aseptic meningitis, vacuolar myelopathy,

peripheral neuropathies, and, most commonly, a progressive encephalopathy designated clinically as the AIDS-dementia complex (Chapter 28).

Effect of Antiretroviral Drug Therapy on the Clinical Course of HIV Infection

The advent of new antiretroviral drugs that target the viral reverse transcriptase, protease, and integrase has changed the clinical face of AIDS. These drugs are given in combination to reduce the emergence of mutants that develop resistance to any one; treatment regimens are commonly called *highly active antiretroviral therapy (HAART)* or *combination antiretroviral therapy*. Over 25 antiretroviral drugs from six distinct drug classes have been developed for the management of HIV infection. When a combination of at least three effective drugs is used in a motivated, adherent patient, HIV replication is invariably reduced to below the level of quantification (<50 copies RNA per milliliter) and remains there indefinitely (as long as the patient adheres to therapy). Even when a drug-resistant virus breaks through, there are several second- and third-line options to again suppress the virus. Once the virus is suppressed, the progressive loss of CD4+ T cells is halted. Over a period of several years the peripheral CD4+ T-cell count slowly increases and often returns to a normal level (although for unclear reasons, a significant proportion of patients with suppressed viremia fail to fully reconstitute a normal CD4+ T-cell count). With the use of these drugs, in the United States the annual death rate from AIDS has decreased from its peak of 16 to 18 per 100,000 people in 1995–1996 to about 4 per 100,000 in 2005. Many AIDS-associated disorders, such as opportunistic infections with *P. jiroveci* and KS, are very uncommon now. Because of the greatly reduced mortality, an increased number of people are living with HIV, but since they are not virus-free, there is increased risk of spreading the infection.

Despite these dramatic improvements, several complications associated with HIV infection and its treatment have emerged. Some patients with advanced disease who are given antiretroviral therapy develop a paradoxical clinical deterioration during the period of recovery of the immune system. This occurs despite increasing CD4+ T-cell counts and decreasing viral load. This disorder has been called the *immune reconstitution inflammatory syndrome*.[162] Its basis is not understood but is postulated to be a poorly regulated host response to the high antigenic burden of persistent microbes. Perhaps a more important complication of long-term HAART pertains to an evolving series of long-term toxicities. These include but are not limited to lipoatrophy (loss of facial fat), lipoaccumulation (excess fat deposition centrally), elevated lipids, insulin resistance, peripheral neuropathy, premature cardiovascular disease, kidney disease, and hepatic dysfunction. The mechanisms underlying these toxicities remain undefined. Finally, it is now well recognized that non-AIDS morbidity is far more common than classic AIDS-related morbidity in long-term HAART-treated patients. Major causes of morbidity are cancer (including those not believed to be HIV related), accelerated cardiovascular disease, kidney disease, and liver disease. Many of these complications are occurring at a younger age in HIV-infected persons than in persons not infected with HIV. The mechanism for these non-AIDS related complications is not known, but persistent inflammation and/or T-cell dysfunction may be playing a role.

Morphology. The anatomic changes in the tissues (with the exception of lesions in the brain) are neither specific nor diagnostic. In general, the pathologic features of AIDS include those of widespread opportunistic infections, KS, and lymphoid tumors. Most of these lesions are discussed elsewhere, because they also occur in individuals who do not have HIV infection. Lesions in the central nervous system are described in Chapter 28 .

Biopsy specimens from enlarged lymph nodes in the early stages of HIV infection reveal a **marked follicular hyperplasia**. The mantle zones that surround the follicles are attenuated, and hence the germinal centers seem to merge with the interfollicular area. These changes, affecting primarily the

B-cell areas of the node, are the morphologic reflections of the polyclonal B-cell activation and hypergammaglobulinemia seen in patients with AIDS. Under the electron microscope and by in situ hybridization, HIV particles can be detected within the germinal centers. Here they seem to be concentrated on the processes of follicular dendritic cells, presumably trapped in the form of immune complexes. During the early phase of HIV infection, viral DNA can be found within the nuclei of CD4+ T cells located predominantly in the parafollicular regions. The B cell hyperplasia is also reflected in the bone marrow, which typically contains increased numbers of plasma cells, and in peripheral blood smears, which often demonstrate rouleaux, the abnormal stacking of red cells that results from hypergammaglobulinemia.

With disease progression, the frenzy of B-cell proliferation subsides and gives way to a pattern of severe follicular involution. The follicles are depleted of cells, and the **organized network of follicular dendritic cells is disrupted**. The germinal centers may even become hyalinized. During this advanced stage viral burden in the nodes is reduced, in part because of the disruption of the follicular dendritic cells. These "burnt-out" lymph nodes are atrophic and small and may harbor numerous opportunistic pathogens. Because of profound immunosuppression, the inflammatory response to infections both in the lymph nodes and at extranodal sites may be sparse or atypical. For example, mycobacteria may not evoke granuloma formation because CD4+ cells are deficient. In the empty-looking lymph nodes and in other organs, the presence of infectious agents may not be readily apparent without special stains. As might be expected, lymphoid depletion is not confined to the nodes; in later stages of AIDS, the spleen and thymus also appear to be "wastelands."

Despite spectacular advances in our understanding of HIV infection, the prognosis of patients with AIDS remains dismal. Although with effective drug therapy the mortality rate has declined in the United States, the treated patients still carry viral DNA in their lymphoid tissues. In fact, there is compelling evidence that even treated patients who remain asymptomatic, with virtually undetectable plasma virus, for years, develop active infection if they stop the treatment. Can there be a cure with persistent virus? Although a considerable effort has been mounted to develop a vaccine, many hurdles remain to be crossed before vaccine-based prophylaxis becomes a reality.[163,][164] Molecular analyses have revealed an alarming degree of polymorphism in viral isolates from different patients; this renders the task of producing a vaccine extremely difficult. This task is further complicated by the fact that the correlates of immune protection are not yet fully understood. At present, therefore, prevention, effective public health measures, and antiretroviral drugs remain the mainstays in the fight against AIDS.

2.6.5 Amyloidosis

Immunological mechanisms are suspected of contributing to a large number of diseases in addition to those already described in this chapter. Some of the entities are discussed in the chapters dealing with individual organs and systems. Amyloidosis is described here because it is a systemic disease that may involve components of the immune system, although the pathogenesis of the disease is probably related to abnormal protein folding and immunological abnormalities are associated with only some forms of amyloidosis.

Amyloid is a pathologic proteinaceous substance, deposited in the extracellular space in various tissues and organs of the body in a wide variety of clinical settings. Because amyloid deposition appears insidiously and sometimes mysteriously, its clinical recognition ultimately depends on morphologic identification of this distinctive substance in appropriate biopsy specimens. With the light microscope and hematoxylin and eosin stains, amyloid appears as an amorphous, eosinophilic, hyaline, extracellular substance that, with progressive accumulation, encroaches on and produces pressure atrophy of adjacent cells. To differentiate amyloid from other hyaline deposits (e.g., collagen, fibrin), a variety of

histochemical techniques, described later, are used. Perhaps most widely used is the Congo red stain, which under ordinary light imparts a pink or red color to tissue deposits, but far more striking and specific is the green birefringence of the stained amyloid when observed by polarizing microscopy (Fig. 6-50).

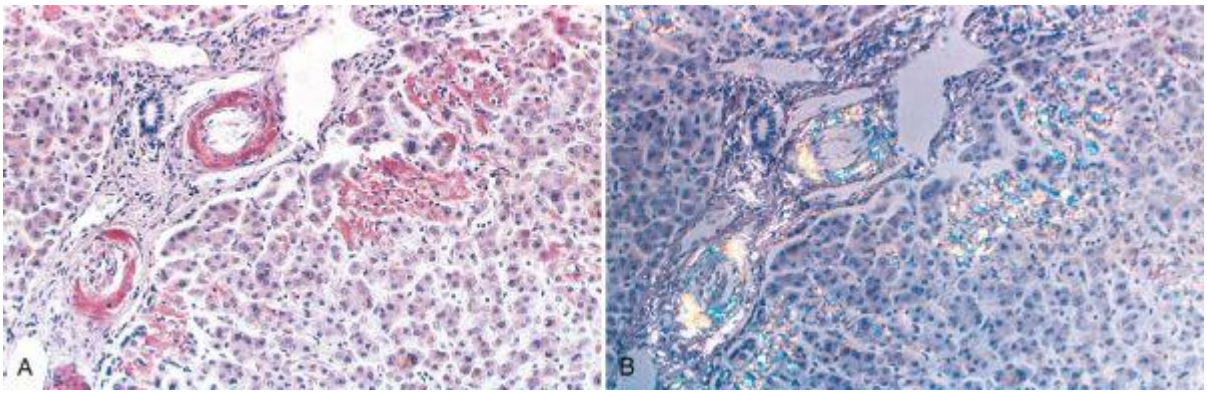

FIGURE 6-50 Amyloidosis. **A**, A section of the liver stained with Congo red reveals pink-red deposits of amyloid in the walls of blood vessels and along sinusoids. **B**, Note the yellow-green birefringence of the deposits when observed by polarizing microscope. *(Courtesy of Dr. Trace Worrell and Sandy Hinton, Department of Pathology, University of Texas Southwestern Medical School, Dallas TX.)*

Even though all deposits have a uniform appearance and staining characteristics, *amyloid is not a chemically distinct entity*.[165] There are three major and several minor biochemical forms. These are deposited by several different pathogenetic mechanisms, and therefore amyloidosis *should not be considered a single disease; rather it is a group of diseases having in common the deposition of similar-appearing proteins*. At the heart of the morphologic similarity is the remarkably uniform physical organization of amyloid protein, which we consider first.

Properties of Amyloid Proteins

Physical Nature of Amyloid

By electron microscopy amyloid is seen to be made up largely of continuous, nonbranching fibrils with a diameter of approximately 7.5 to 10 nm. This electron-microscopic structure is identical in all types of amyloidosis. X-ray crystallography and infrared spectroscopy demonstrate a characteristic cross-β-pleated sheet conformation (Fig. 6-51). This conformation is seen regardless of the clinical setting or chemical composition and is responsible for the distinctive Congo red staining and birefringence of amyloid.

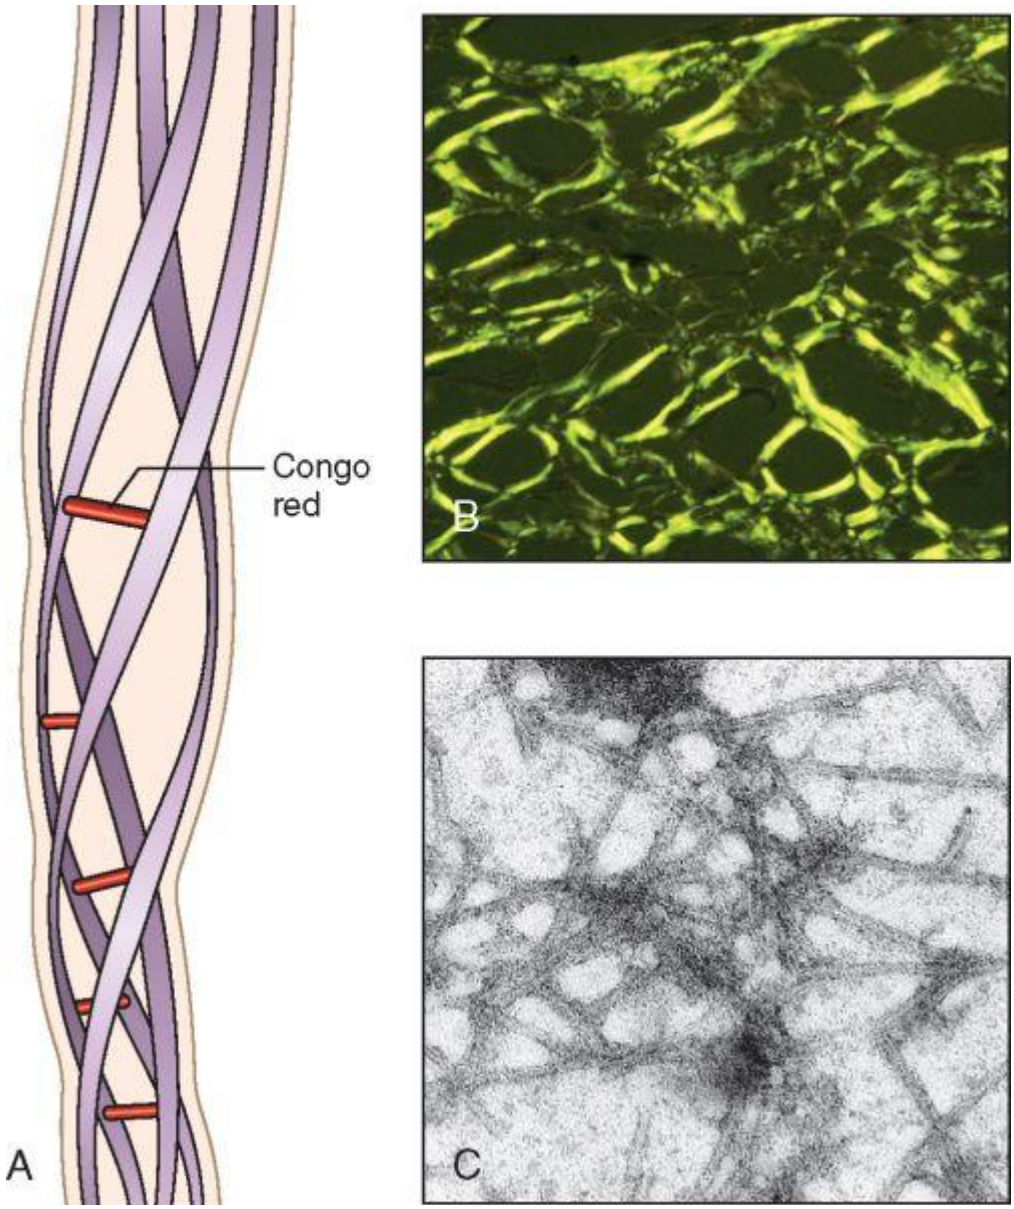

FIGURE 6-51 Structure of amyloid. **A**, An amyloid fiber schematically showing four fibrils (there can be as many as six in each fiber) wound around one another with regularly spaced binding of the Congo red dye. **B**, Congo red staining shows apple-green birefringence under polarized light, a diagnostic feature of amyloid. **C**, Electron micrograph of 7.5- to 10-nm amyloid fibrils. *(Reproduced from Merlini G and Bellotti V. Molecular mechanisms of amyloidosis. N Engl J Med 349:583–596, 2003, with permission of the Massachusetts Medical Society.)*

Chemical Nature of Amyloid

Approximately 95% of the amyloid material consists of fibril proteins, the remaining 5% being the P component and other glycoproteins. *Of the more than 20 biochemically distinct forms of amyloid proteins that have been identified, three are most common:* (1) *AL (amyloid light chain)* is derived from Ig light chains produced in plasma cells; (2) *AA (amyloid-associated)* is derived from a unique non-Ig protein synthesized by the liver; and (3) *Aβ amyloid* is produced from β amyloid precursor protein and is found in the cerebral lesions of Alzheimer disease.

- The AL protein is made up of complete immunoglobulin light chains, the amino-terminal fragments of light chains, or both. Most of the AL proteins analyzed are composed of λ light chains or their fragments, but in some cases κ chains have been identified. The amyloid fibril protein of the AL type is produced from free Ig light chains secreted by a monoclonal population of plasma cells, and its deposition is associated with certain forms of plasma cell tumors (Chapter 13).
- The second major class of amyloid fibril protein (AA) does not have structural homology to immunoglobulins. It has a molecular weight of 8500 and consists of 76 amino acid residues. AA fibrils are derived by proteolysis from a larger (12,000 daltons) precursor in the serum called SAA (serum amyloid–associated) protein that is synthesized in the liver and circulates in association with high density lipoproteins. The production of SAA protein is increased in inflammatory states as part of the “acute phase response”; therefore, this form of amyloidosis is associated with chronic inflammation, and is often called *secondary amyloidosis*.
- β-*amyloid protein* (Aβ) is a 4000-dalton peptide that constitutes the core of cerebral plaques found in Alzheimer disease as well as the amyloid deposited in walls of cerebral blood vessels in individuals with this disease. The Aβ protein is derived by proteolysis from a much larger transmembrane glycoprotein, called *amyloid precursor protein*. This form of amyloid is discussed in Chapter 28 .

Several other biochemically distinct proteins have been found in amyloid deposits in a variety of clinical settings. Some of the more common ones are the following:

- *Transthyretin (TTR)* is a normal serum protein that binds and transports thyroxine and retinol. A mutant form of TTR (and its fragments) is deposited in a group of genetically determined disorders referred to as familial amyloid polyneuropathies.[167] Several mutations have been identified in the TTR protein that contribute to its deposition in tissues in the form of amyloid. TTR is also deposited in the heart of aged individuals (senile systemic amyloidosis), but in such cases the amino acid sequence of the TTR molecule is normal.
- β_2-*microglobulin*, a component of MHC class I molecules and a normal serum protein, has been identified as the amyloid fibril subunit ($A\beta_2m$) in amyloidosis that complicates the course of patients on *long-term hemodialysis*.
- In a minority of cases of prion disease in the central nervous system, the misfolded *prion proteins* aggregate in the extracellular space and acquire the structural and staining characteristics of amyloid protein. Therefore, prion diseases are sometimes considered examples of local amyloidosis.

In addition, other minor components are always present in amyloid. These include serum amyloid P component, proteoglycans, and highly sulfated glycosaminoglycans. Serum amyloid P protein may contribute to amyloid deposition by stabilizing the fibrils and decreasing their clearance.

Pathogenesis of Amyloidosis

Amyloidosis results from abnormal folding of proteins, which are deposited as fibrils in extracellular tissues and disrupt normal function.[165,][166] Misfolded proteins are often unstable and self-associate, ultimately leading to the formation of oligomers and fibrils that are deposited in tissues. The reason diverse conditions are associated with amyloidosis may be that each results in excessive production of proteins that are prone to misfolding (Fig. 6-52). The proteins that form amyloid fall into two general categories: (1) normal proteins that have an inherent tendency to fold improperly, associate and form fibrils, and do so when they are produced in increased amounts; and (2) mutant proteins that are prone to misfolding and subsequent aggregation.

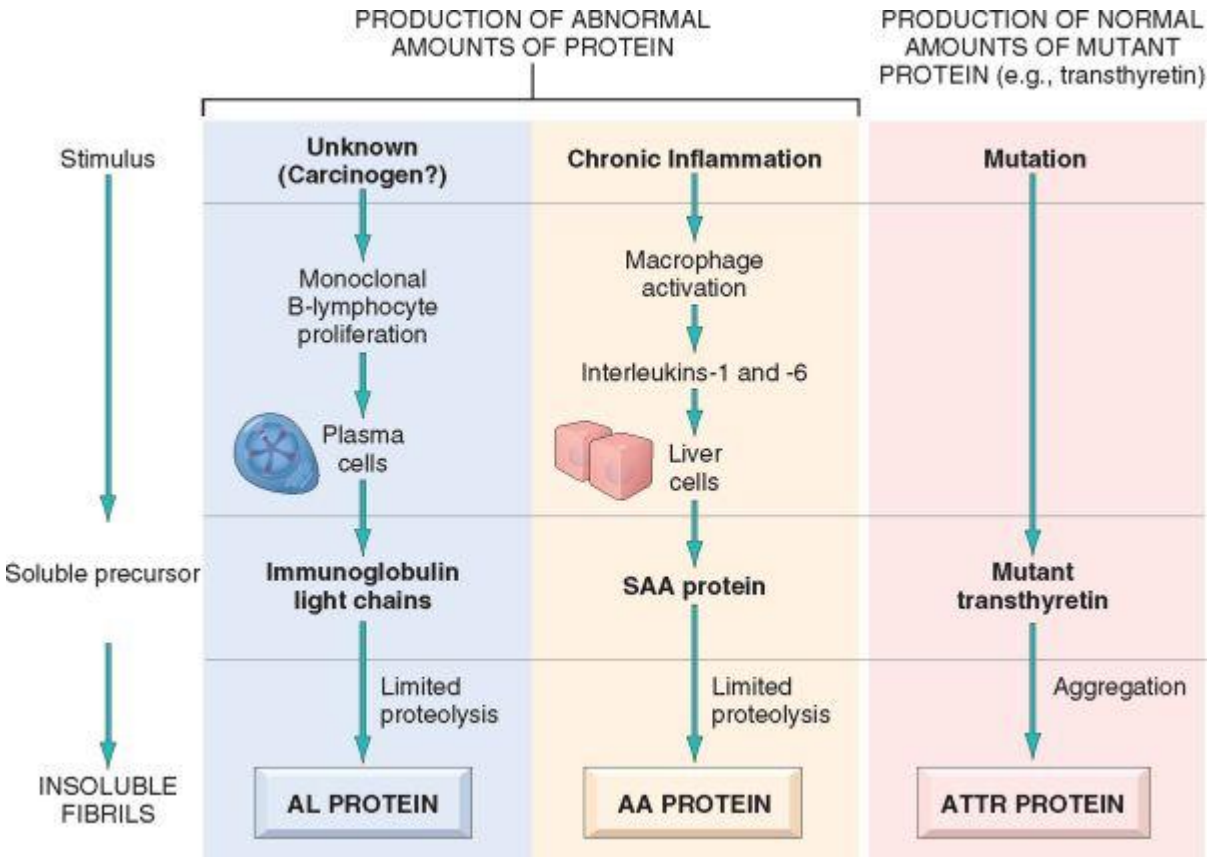

FIGURE 6-52 Pathogenesis of amyloidosis, showing the proposed mechanisms underlying deposition of the major forms of amyloid fibrils. See text for abbreviations.

Normally, misfolded proteins are degraded intracellularly in proteasomes, or extracellularly by macrophages. It seems that in amyloidosis these quality control mechanisms fail so that too much of a misfolded protein accumulates outside cells. This proposed mechanism may explain most forms of amyloidosis. For instance, SAA is synthesized by the liver cells under the influence of cytokines such as IL-6 and IL-1 that are produced during inflammation; thus, longstanding inflammation leads to elevated SAA levels. However, increased production of SAA by itself is not sufficient for the deposition of amyloid. There are two possible explanations for this. According to one view, SAA is normally degraded to soluble end products by the action of monocyte-derived enzymes. Conceivably, individuals who develop amyloidosis have an enzyme defect that results in incomplete breakdown of SAA, thus generating insoluble AA molecules. Alternatively, a genetically determined structural abnormality in the SAA molecule itself renders it resistant to degradation by macrophages.

In familial amyloidosis the deposition of TTRs as amyloid fibrils does not result from overproduction of TTRs. It has been proposed that genetically detemined alterations of structure render the TTRs prone to misfolding and aggregation, and resistant to proteolysis.

Classification of Amyloidosis

Because a given biochemical form of amyloid (e.g., AA) may be associated with amyloid deposition in diverse clinical settings, we follow a combined biochemical-clinical classification for our discussion

(Table 6-15). Amyloid may be *systemic* (generalized), involving several organ systems, or it may be *localized*, when deposits are limited to a single organ, such as the heart.

TABLE 6-15 -- Classification of Amyloidosis

Clinicopathologic Category	Associated Diseases	Major Fibril Protein	Chemically Related Precursor Protein
SYSTEMIC (GENERALIZED) AMYLOIDOSIS			
Immunocyte dyscrasias with amyloidosis (primary amyloidosis)	Multiple myeloma and other monoclonal plasma cell proliferations	AL	Immunoglobulin light chains, chiefly λ type
Reactive systemic amyloidosis (secondary amyloidosis)	Chronic inflammatory conditions	AA	SAA
Hemodialysis-associated amyloidosis	Chronic renal failure	$A\beta_2m$	β_2-microglobulin
HEREDITARY AMYLOIDOSIS			
Familial Mediterranean fever		AA	SAA
Familial amyloidotic neuropathies (several types)		ATTR	Transthyretin
SYSTEMIC SENILE AMYLOIDOSIS		ATTR	Transthyretin
LOCALIZED AMYLOIDOSIS			
Senile cerebral	Alzheimer disease	A*b*	APP
Endocrine		A Cal	Calcitonin
Medullary carcinoma of thyroid	Type 2 diabetes	AIAPP	Islet amyloid peptide
Islets of Langerhans		AANF	Atrial natriuretic factor
Isolated atrial amyloidosis			

On clinical grounds, the systemic, or generalized, pattern is subclassified into *primary amyloidosis*, when associated with some immunocyte disorder, or *secondary amyloidosis*, when it occurs as a complication of an underlying chronic inflammatory or tissue-destructive process.[167] *Hereditary* or *familial amyloidosis* constitutes a separate, albeit heterogeneous group, with several distinctive patterns of organ involvement.

Primary Amyloidosis: Immunocyte Dyscrasias with Amyloidosis

Amyloid in this category is usually systemic in distribution and is of the AL type. With approximately 1275 to 3200 new cases every year in the United States, this is the most common form of amyloidosis. In many of these cases, the patients have some form of plasma cell dyscrasia. Best defined is the occurrence of systemic amyloidosis in 5% to 15% of individuals with multiple myeloma, a plasma-cell tumor characterized by multiple osteolytic lesions throughout the skeletal system (Chapter 13). The malignant B cells characteristically synthesize abnormal amounts of a single specific Ig (monoclonal gammopathy), producing an M (myeloma) protein spike on serum electrophoresis. In addition to the synthesis of whole Ig molecules, only the light chains (referred to as *Bence-Jones protein*) of either the κ or the λ variety may be elaborated and found in the serum. By virtue of the small molecular size of the Bence-Jones protein, it is frequently excreted in the urine. The amyloid deposits contain the same light chain protein. Almost all the individuals with myeloma who develop amyloidosis have Bence-Jones proteins in the serum or urine, or both, but the great majority of myeloma patients who have free light chains do not develop amyloidosis. Clearly, therefore, *the presence of Bence-Jones proteins, though*

necessary, is by itself not enough to produce amyloidosis. Other factors, such as the type of light chain produced *(amyloidogenic potential)* and the susceptibility to degradation, may have a bearing on whether Bence-Jones proteins are deposited as amyloid.

The great majority of persons with AL amyloid do not have classic multiple myeloma or any other overt B-cell neoplasm; such cases have been traditionally classified as primary amyloidosis, because their clinical features derive from the effects of amyloid deposition without any other associated disease. In virtually all such cases, however, monoclonal immunoglobulins or free light chains, or both, can be found in the serum or urine. Most of these patients also have a modest increase in the number of plasma cells in the bone marrow, which presumably secrete the precursors of AL protein. Clearly, these patients have an underlying plasma cell dyscrasia in which production of an abnormal protein, rather than production of tumor masses, is the predominant manifestation.

Reactive Systemic Amyloidosis

The amyloid deposits in this pattern are systemic in distribution and are composed of AA protein. This category was previously referred to as *secondary amyloidosis* because it is secondary to an associated inflammatory condition. At one time, tuberculosis, bronchiectasis, and chronic osteomyelitis were the most important underlying conditions, but with the advent of effective antimicrobial chemotherapy the importance of these conditions has diminished. More commonly now, reactive systemic amyloidosis complicates rheumatoid arthritis, other connective tissue disorders such as ankylosing spondylitis, and inflammatory bowel disease, particularly Crohn disease and ulcerative colitis. Among these the most frequent associated condition is rheumatoid arthritis. Amyloidosis is reported to occur in approximately 3% of patients with rheumatoid arthritis and is clinically significant in one half of those affected. Heroin abusers who inject the drug subcutaneously also have a high occurrence rate of generalized AA amyloidosis. The chronic skin infections associated with “skin-popping” of narcotics seem to be responsible for the amyloidosis. Reactive systemic amyloidosis may also occur in association with non-immunocyte–derived tumors, the two most common being renal cell carcinoma and Hodgkin lymphoma.

Hemodialysis-Associated Amyloidosis

Patients on long-term hemodialysis for renal failure develop amyloidosis as a result of deposition of β_2-microglobulin. This protein is present in high concentrations in the serum of persons with renal disease and is retained in the circulation because it cannot be filtered through dialysis membranes. Patients often present with carpal tunnel syndrome because of β_2-microglobulin deposition. In some series, over half the patients on long-term dialysis (>20 years) developed amyloid deposits in the synovium, joints, or tendon sheaths.

Heredofamilial Amyloidosis

A variety of familial forms of amyloidosis have been described. Most of them are rare and occur in limited geographic areas. The most common and best studied is an autosomal recessive condition called *familial Mediterranean fever*.[168] This is an “autoinflammatory” syndrome associated with abnormally high production of the cytokine IL-1, and characterized clinically by attacks of fever accompanied by inflammation of serosal surfaces, including peritoneum, pleura, and synovial membrane. The gene for familial Mediterranean fever encodes a protein called *pyrin* (for its relation to fever), which is one of a complex of proteins that regulate inflammatory reactions via the production of pro-inflammatory cytokines (Chapter 2).[169,][170] This disorder is encountered largely in individuals of Armenian, Sephardic Jewish, and Arabic origins. It is sometimes associated with widespread amyloidosis. The amyloid fibril proteins are made up of AA proteins, suggesting that this form of amyloidosis is related to the recurrent bouts of inflammation.

In contrast to familial Mediterranean fever, a group of autosomal dominant familial disorders is characterized by deposition of amyloid predominantly in peripheral and autonomic nerves. These familial amyloidotic polyneuropathies have been described in different parts of the world. As mentioned before, in all of these genetic disorders, the fibrils are made up of mutant TTRs.

Localized Amyloidosis

Sometimes, amyloid deposits are limited to a single organ or tissue without involvement of any other site in the body. The deposits may produce grossly detectable nodular masses or be evident only on microscopic examination. Nodular deposits of amyloid are most often encountered in the lung, larynx, skin, urinary bladder, tongue, and the region about the eye. Frequently, there are infiltrates of lymphocytes and plasma cells in the periphery of these amyloid masses. At least in some cases, the amyloid consists of AL protein and may therefore represent a localized form of immunocyte-derived amyloid.

Endocrine Amyloid

Microscopic deposits of localized amyloid may be found in certain endocrine tumors, such as medullary carcinoma of the thyroid gland, islet tumors of the pancreas, pheochromocytomas, and undifferentiated carcinomas of the stomach, and in the islets of Langerhans in individuals with type II diabetes mellitus. In these settings the amyloidogenic proteins seem to be derived either from polypeptide hormones (e.g., medullary carcinoma) or from unique proteins (e.g., islet amyloid polypeptide).

Amyloid of Aging

Several well-documented forms of amyloid deposition occur with aging. *Senile systemic amyloidosis* refers to the systemic deposition of amyloid in elderly patients (usually in their 70s and 80s). Because of the dominant involvement and related dysfunction of the heart, this form was previously called *senile cardiac amyloidosis*. Those who are symptomatic present with a restrictive cardiomyopathy and arrhythmias (Chapter 12). The amyloid in this form is composed of the normal TTR molecule. In addition to the sporadic senile systemic amyloidosis, another form, affecting predominantly the heart, that results from the deposition of a mutant form of TTR has also been recognized. Approximately 4% of the black population in the United States is a carrier of the mutant allele, and cardiomyopathy has been identified in both homozygous and heterozygous patients. The precise prevalence of patients with this mutation who develop clinically manifest cardiac disease is not known.

Morphology. There are no consistent or distinctive patterns of organ or tissue distribution of amyloid deposits in any of the categories cited. Kidneys, liver, spleen, lymph nodes, adrenals, and thyroid as well as many other tissues are classically involved. Macroscopically the affected organs are often enlarged and firm and have a waxy appearance. If the deposits are sufficiently large, painting the cut surface with iodine imparts a yellow color that is transformed to blue violet after application of sulfuric acid.

As noted earlier, the histologic diagnosis of amyloid is based on its staining characteristics. The most commonly used staining technique uses the dye **Congo red**, which under ordinary light imparts a pink or red color to amyloid deposits. Under polarized light, the Congo red–stained amyloid shows a green birefringence (see Fig. 6-50B). This reaction is shared by all forms of amyloid and is due to the cross-β-pleated configuration of amyloid fibrils. Confirmation can be obtained by electron microscopy. AA, AL, and TTR amyloid can be distinguished in histologic sections by specific immunohistochemical staining. Because the pattern of organ involvement in different clinical forms of amyloidosis is variable, each of the major organ involvements is described separately.

Kidney. Amyloidosis of the kidney is the most common and potentially the most serious form of organ involvement. Grossly, the kidneys may be of normal size and color, or, in advanced cases, they may be shrunken because of ischemia caused by vascular narrowing induced by the deposition of amyloid within arterial and arteriolar walls.

Histologically, the amyloid is deposited primarily in the glomeruli, but the interstitial peritubular tissue, arteries, and arterioles are also affected. The glomerular deposits first appear as subtle thickenings of the mesangial matrix, accompanied usually by uneven widening of the basement membranes of the glomerular capillaries. In time the mesangial depositions and the deposits along the basement membranes cause capillary narrowing and distortion of the glomerular vascular tuft. With progression of the glomerular amyloidosis, the capillary lumens are obliterated, and the obsolescent glomerulus is flooded by confluent masses or interlacing broad ribbons of amyloid (Fig. 6-53).

Spleen. Amyloidosis of the spleen may be inapparent grossly or may cause moderate to marked splenomegaly (up to 800 gm). For completely mysterious reasons, one of two patterns of deposition is seen. In one, the deposits are largely limited to the splenic follicles, producing tapioca-like granules on gross inspection, designated **sago spleen**. In the other pattern, the amyloid involves the walls of the splenic sinuses and connective tissue framework in the red pulp. Fusion of the early deposits gives rise to large, maplike areas of amyloidosis, creating what has been designated **lardaceous spleen**.

Liver. The deposits may be inapparent grossly or may cause moderate to marked hepatomegaly. Amyloid appears first in the space of Disse and then progressively encroaches on adjacent hepatic parenchymal cells and sinusoids (see Fig. 6-50). In time, deformity, pressure atrophy, and disappearance of hepatocytes occur, causing total replacement of large areas of liver parenchyma. Vascular involvement and deposits in Kupffer cells are frequent. Normal liver function is usually preserved despite sometimes quite severe involvement of the liver.

Heart. Amyloidosis of the heart (Chapter 12) may occur in any form of systemic amyloidosis. It is also the major organ involved in senile systemic amyloidosis. The heart may be enlarged and firm, but more often it shows no significant changes on gross inspection. Histologically the deposits begin as focal subendocardial accumulations and within the myocardium between the muscle fibers. Expansion of these myocardial deposits eventually causes pressure atrophy of myocardial fibers. When the amyloid deposits are subendocardial, the conduction system may be damaged, accounting for the electrocardiographic abnormalities noted in some patients.

Other Organs. Amyloidosis of other organs is generally encountered in systemic disease. The adrenals, thyroid, and pituitary are common sites of involvement. The gastrointestinal tract may be involved at any level, from the oral cavity (gingiva, tongue) to the anus. The early lesions mainly affect blood vessels but eventually extend to involve the adjacent areas of the submucosa, muscularis, and subserosa.

Nodular depositions in the tongue may cause macroglossia, giving rise to the designation **tumor-forming amyloid of the tongue**. The respiratory tract may be involved focally or diffusely from the larynx down to the smallest bronchioles. It involves so-called plaques as well as blood vessels (Chapter 28). Amyloidosis of peripheral and autonomic nerves is a feature of several familial amyloidotic neuropathies. Depositions of amyloid in patients on long-term hemodialysis are most prominent in the carpal ligament of the wrist, resulting in compression of the median nerve (carpal tunnel syndrome). These patients may also have extensive amyloid deposition in the joints.

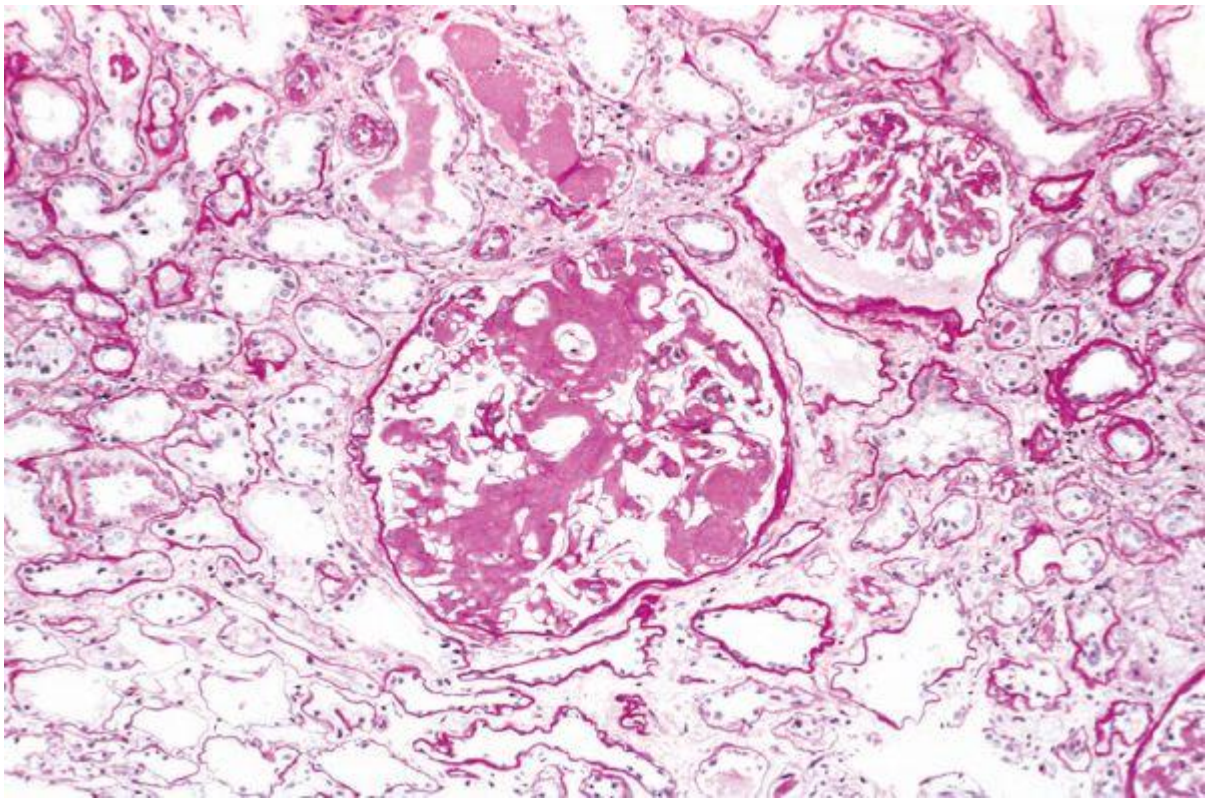

FIGURE 6-53 Amyloidosis of the kidney. The glomerular architecture is almost totally obliterated by the massive accumulation of amyloid.

Clinical Features.

Amyloidosis may be found as an unsuspected anatomic change, having produced no clinical manifestations, or it may cause death. The symptoms depend on the magnitude of the deposits and on the particular sites or organs affected. Clinical manifestations at first are often entirely nonspecific, such as weakness, weight loss, lightheadedness, or syncope. Somewhat more specific findings appear later and most often relate to renal, cardiac, and gastrointestinal involvement.

Renal involvement gives rise to proteinuria that may be severe enough to cause the nephrotic syndrome (Chapter 20). Progressive obliteration of glomeruli in advanced cases ultimately leads to renal failure and uremia. Renal failure is a common cause of death. *Cardiac amyloidosis* may present as an insidious congestive heart failure. The most serious aspects of cardiac amyloidosis are conduction disturbances and arrhythmias, which may prove fatal. Occasionally, cardiac amyloidosis produces a restrictive pattern of cardiomyopathy and masquerades as chronic constrictive pericarditis (Chapter 12). *Gastrointestinal amyloidosis* may be entirely asymptomatic, or it may present in a variety of ways. Amyloidosis of the tongue may cause sufficient enlargement and inelasticity to hamper speech and swallowing. Depositions in the stomach and intestine may lead to malabsorption, diarrhea, and disturbances in digestion.

The diagnosis of amyloidosis depends on the histologic demonstration of amyloid deposits in tissues. The most common sites biopsied are the kidney, when renal manifestations are present, or rectal or gingival tissues in patients suspected of having systemic amyloidosis. Examination of abdominal fat aspirates stained with Congo red can also be used for the diagnosis of systemic amyloidosis. The test is

quite specific, but its sensitivity is low. In suspected cases of immunocyte-associated amyloidosis, serum and urine protein electrophoresis and immunoelectrophoresis should be performed. Bone marrow aspirates in such cases often show monoclonal plasmacytosis, even in the absence of overt multiple myeloma. Scintigraphy with radiolabeled serum amyloid P (SAP) component is a rapid and specific test, since SAP binds to the amyloid deposits and reveals their presence. It also gives a measure of the extent of amyloidosis and can be used to follow patients undergoing treatment.

The prognosis for individuals with generalized amyloidosis is poor. Those with immunocyte-derived amyloidosis (not including multiple myeloma) have a median survival of 2 years after diagnosis. Persons with myeloma-associated amyloidosis have a poorer prognosis. The outlook for individuals with reactive systemic amyloidosis is somewhat better and depends to some extent on the control of the underlying condition. Resorption of amyloid after treatment of the associated condition has been reported, but this is a rare occurrence. New therapeutic strategies aimed at correcting protein misfolding and inhibiting fibrillogenesis are being developed.

2.7 7. Neoplasia

2.7.1 Nomenclature

THOMAS P. STRICKER,
VINAY KUMAR

Cancer is the second leading cause of death in the United States; only cardiovascular diseases exact a higher toll. Even more agonizing than the mortality rate is the emotional and physical suffering inflicted by neoplasms. Patients and the public often ask, "When will there be a cure for cancer?" The answer to this simple question is difficult, because cancer is not one disease but many disorders that share a profound growth dysregulation. Some cancers, such as Hodgkin lymphoma, are curable, whereas others, such as pancreatic adenocarcinoma, have a high mortality. The only hope for controlling cancer lies in learning more about its cause and pathogenesis, and great strides have been made in understanding its molecular basis. Indeed, some good news has emerged: cancer mortality for both men and women in the United States declined during the last decade of the twentieth century and has continued its downward course in the 21st.[1] The discussion that follows deals with both benign and malignant tumors, focusing on the basic morphologic and biologic properties of tumors and the molecular basis of carcinogenesis. We also discuss the interactions of the tumor with the host and the host response to tumors.

Nomenclature

Neoplasia means "new growth," and a new growth is called a *neoplasm. Tumor* originally applied to the swelling caused by inflammation, but the non-neoplastic usage of *tumor* has almost vanished; thus, the term is now equated with neoplasm. *Oncology* (Greek *oncos* = tumor) is the study of tumors or neoplasms.

Although all physicians know what they mean when they use the term *neoplasm*, it has been surprisingly difficult to develop an accurate definition. The eminent British oncologist Willis[2] has come closest: "A neoplasm is an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of the normal tissues and persists in the same excessive manner after cessation of the stimuli which evoked the change." We know that the persistence of tumors, even after the inciting stimulus is gone, results from *genetic alterations that are passed down to the progeny of the tumor cells. These genetic changes allow excessive and unregulated proliferation that becomes autonomous (independent of physiologic growth stimuli)*, although tumors generally remain dependent on the host for their nutrition and blood supply. As we shall discuss later, the entire population of neoplastic cells within an individual tumor arises from a single cell that has incurred genetic change, and hence tumors are said to be *clonal*.

A tumor is said to be *benign* when its microscopic and gross characteristics are considered relatively innocent, implying that it will remain localized, it cannot spread to other sites, and it is generally

amenable to local surgical removal; the patient generally survives. It should be noted, however, that benign tumors can produce more than localized lumps, and sometimes they are responsible for serious disease.

Malignant tumors are collectively referred to as *cancers*, derived from the Latin word for *crab*, because they adhere to any part that they seize on in an obstinate manner, similar to a crab. *Malignant*, as applied to a neoplasm, implies that the lesion can invade and destroy adjacent structures and spread to distant sites (metastasize) to cause death. Not all cancers pursue so deadly a course. Some are discovered early and are treated successfully, but the designation *malignant* always raises a red flag.

All tumors, benign and malignant, have two basic components: (1) clonal neoplastic cells that constitute their *parenchyma* and (2) reactive *stroma* made up of connective tissue, blood vessels, and variable numbers of macrophages and lymphocytes. Although the neoplastic cells largely determine a tumor's behavior and pathologic consequences, their growth and evolution is critically dependent on their stroma. An adequate stromal blood supply is requisite for the tumor cells to live and divide, and the stromal connective tissue provides the structural framework essential for the growing cells. In addition, there is cross-talk between tumor cells and stromal cells that directly influences the growth of tumors. In some tumors, the stromal support is scant and so the neoplasm is soft and fleshy. In other cases the parenchymal cells stimulate the formation of an abundant collagenous stroma, referred to as *desmoplasia*. Some demoplastic tumors—for example, some cancers of the female breast—are stony hard or *scirrhous*. The nomenclature of tumors and their biologic behavior are based primarily on the parenchymal component.

Benign Tumors.

In general, benign tumors are designated by attaching the suffix *-oma* to the cell of origin. Tumors of mesenchymal cells generally follow this rule. For example, a benign tumor arising in fibrous tisssue is called a *fibroma*, whereas a benign cartilaginous tumor is a *chondroma*. In contrast, the nomenclature of benign epithelial tumors is more complex. These are variously classified, some based on their cells of origin, others on microscopic pattern, and still others on their macroscopic architecture.

Adenoma is applied to a benign epithelial neoplasm derived from glands, although they may or may not form glandular structures. On this basis, a benign epithelial neoplasm that arises from renal tubular cells growing in the form of numerous tightly clustered small glands would be termed an *adenoma*, as would a heterogeneous mass of adrenal cortical cells growing as a solid sheet. Benign epithelial neoplasms producing microscopically or macroscopically visible finger-like or warty projections from epithelial surfaces are referred to as *papillomas*. Those that form large cystic masses, as in the ovary, are referred to as *cystadenomas*. Some tumors produce papillary patterns that protrude into cystic spaces and are called *papillary cystadenomas*. When a neoplasm, benign or malignant, produces a macroscopically visible projection above a mucosal surface and projects, for example, into the gastric or colonic lumen, it is termed a *polyp* (Fig. 7-1).

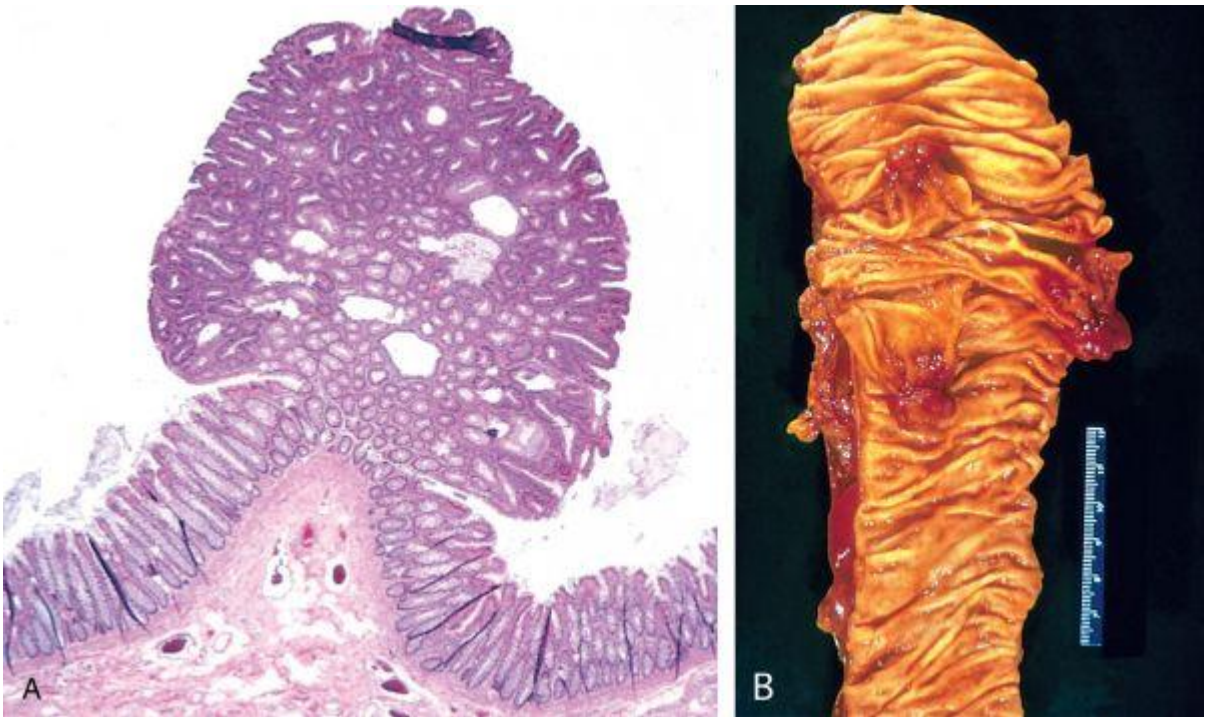

FIGURE 7-1 Colonic polyp. **A**, This benign glandular tumor (adenoma) is projecting into the colonic lumen and is attached to the mucosa by a distinct stalk. **B**, Gross appearance of several colonic polyps.

Malignant Tumors.

The nomenclature of malignant tumors essentially follows the same schema used for benign neoplasms, with certain additions. *Malignant tumors arising in mesenchymal tissue are usually called sarcomas* (Greek *sar* = fleshy), because they have little connective tissue stroma and so are fleshy (e.g., fibrosarcoma, chondrosarcoma, leiomyosarcoma, and rhabdomyosarcoma). Malignant neoplasms of epithelial cell origin, derived from any of the three germ layers, are called *carcinomas*. Thus, cancer arising in the epidermis of ectodermal origin is a carcinoma, as is a cancer arising in the mesodermally derived cells of the renal tubules and the endodermally derived cells of the lining of the gastrointestinal tract. Carcinomas may be further qualified. *Squamous cell carcinoma* would denote a cancer in which the tumor cells resemble stratified squamous epithelium, and *adenocarcinoma* denotes a lesion in which the neoplastic epithelial cells grow in glandular patterns. Sometimes the tissue or organ of origin can be identified, as in the designation of renal cell adenocarcinoma or bronchogenic squamous cell carcinoma. Not infrequently, however, a cancer is composed of undifferentiated cells of unknown tissue origin, and must be designated merely as an undifferentiated malignant tumor.

In many benign and malignant neoplasms, the parenchymal cells bear a close resemblance to each other, as though all were derived from a single cell. Indeed, neoplasms are of monoclonal origin, as is documented later. Infrequently, divergent differentiation of a single neoplastic clone along two lineages creates what are called *mixed tumors*. The best example of this is the *mixed tumor of salivary gland origin*. These tumors contain epithelial components scattered within a myxoid stroma that sometimes contains islands of cartilage or bone (Fig. 7-2). All these elements, it is believed, arise from a single clone capable of giving rise to epithelial and myoepithelial cells; thus, the preferred designation of these neoplasms is *pleomorphic adenoma*. The great majority of neoplasms, even mixed tumors, are composed of cells representative of a single germ layer. The multifaceted mixed tumors should not be

confused with a *teratoma*, which contains recognizable mature or immature cells or tissues representative of more than one germ cell layer and sometimes all three. Teratomas originate from totipotential cells such as those normally present in the ovary and testis and sometimes abnormally present in sequestered midline embryonic rests. Such cells have the capacity to differentiate into any of the cell types found in the adult body and so, not surprisingly, may give rise to neoplasms that mimic, in a helter-skelter fashion, bits of bone, epithelium, muscle, fat, nerve, and other tissues. When all the component parts are well differentiated, it is a *benign (mature) teratoma*; when less well differentiated, it is an immature, potentially or overtly, *malignant teratoma*. A particularly common pattern is seen in the ovarian *cystic teratoma* (dermoid cyst), which differentiates principally along ectodermal lines to create a cystic tumor lined by skin replete with hair, sebaceous glands, and tooth structures (Fig. 7-3).

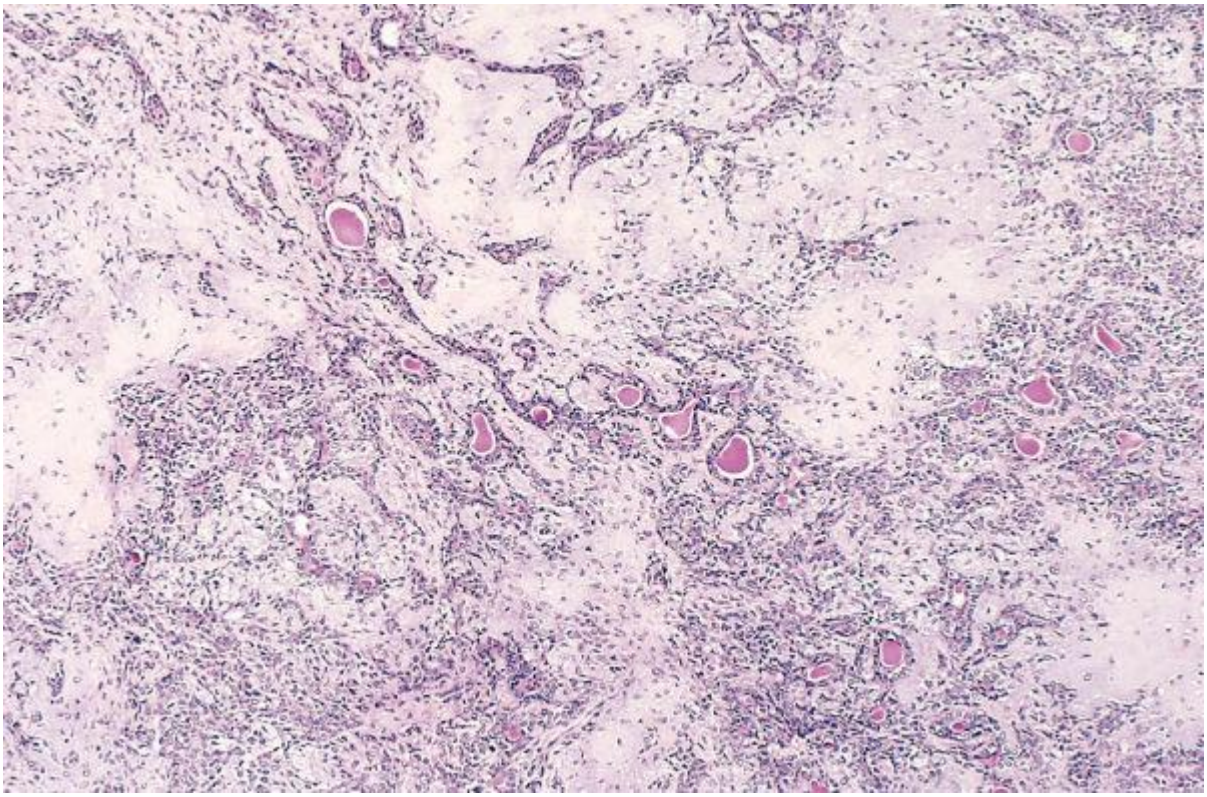

FIGURE 7-2 This mixed tumor of the parotid gland contains epithelial cells forming ducts and myxoid stroma that resembles cartilage. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

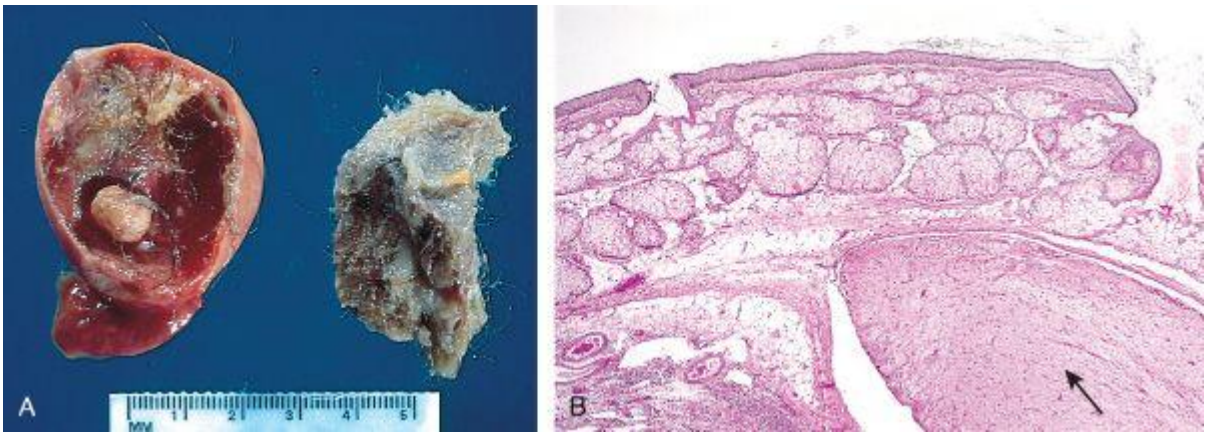

FIGURE 7-3 A, Gross appearance of an opened cystic teratoma of the ovary. Note the presence of hair, sebaceous material, and tooth. **B**, A microscopic view of a similar tumor shows skin, sebaceous glands, fat cells, and a tract of neural tissue *(arrow)*.

The nomenclature of the more common forms of neoplasia is presented in Table 7-1 . It is evident from this compilation that there are some inappropriate but deeply entrenched usages. For generations, benign-sounding designations such as lymphoma, melanoma, mesothelioma, and seminoma have been used for certain malignant neoplasms. The converse is also true; ominous terms may be applied to trivial lesions. *Hamartomas* present as disorganized but benign-appearing masses composed of cells indigenous to the particular site. They were once thought to be a developmental malformation, unworthy of the -oma designation. For example, pulmonary chondroid harmatoma contains islands of disorganized, but histologically normal cartilage, bronchi, and vessels. However, many hamartomas, including pulmonary chondroid hamartoma, have clonal, recurrent translocations involving genes encoding certain chromatin proteins.[3] Thus, through molecular biology they have finally earned their -oma designation. Another misnomer is the term *choristoma*. This congenital anomaly is better described as a *heterotopic rest* of cells. For example, a small nodule of well-developed and normally organized pancreatic substance may be found in the submucosa of the stomach, duodenum, or small intestine. This heterotopic rest may be replete with islets of Langerhans and exocrine glands. The term *choristoma*, connoting a neoplasm, imparts to the heterotopic rest a gravity far beyond its usual trivial significance. Although regrettably the terminology of neoplasms is not simple, it is important because it is the language by which the nature and significance of tumors are categorized.

TABLE 7-1 -- Nomenclature of Tumors

Tissue of Origin	Benign	Malignant
COMPOSED OF ONE PARENCHYMAL CELL TYPE		
Tumors of Mesenchymal Origin		
Connective tissue and derivatives	Fibroma	Fibrosarcoma
	Lipoma	Liposarcoma
	Chondroma	Chondrosarcoma
	Osteoma	Osteogenic sarcoma
Endothelial and Related Tissues		
Blood vessels	Hemangioma	Angiosarcoma

Tissue of Origin	Benign	Malignant
Lymph vessels	Lymphangioma	Lymphangiosarcoma
Synovium		Synovial sarcoma
Mesothelium		Mesothelioma
Brain coverings	Meningioma	Invasive meningioma
Blood Cells and Related Cells		
Hematopoietic cells		Leukemias
Lymphoid tissue		Lymphomas
Muscle		
Smooth	Leiomyoma	Leiomyosarcoma
Striated	Rhabdomyoma	Rhabdomyosarcoma
Tumors of Epithelial Origin		
Stratified squamous	Squamous cell papilloma	Squamous cell carcinoma
Basal cells of skin or adnexa		Basal cell carcinoma
Epithelial lining of glands or ducts	Adenoma	Adenocarcinoma
	Papilloma	Papillary carcinomas
	Cystadenoma	Cystadenocarcinoma
Respiratory passages	Bronchial adenoma	Bronchogenic carcinoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Liver cells	Liver cell adenoma	Hepatocellular carcinoma
Urinary tract epithelium (transitional)	Transitional-cell papilloma	Transitional-cell carcinoma
Placental epithelium	Hydatidiform mole	Choriocarcinoma
Testicular epithelium (germ cells)		Seminoma
		Embryonal carcinoma
Tumors of Melanocytes	Nevus	Malignant melanoma
MORE THAN ONE NEOPLASTIC CELL TYPE—MIXED TUMORS, USUALLY DERIVED FROM ONE GERM CELL LAYER		
Salivary glands	Pleomorphic adenoma (mixed tumor of salivary origin)	Malignant mixed tumor of salivary gland origin
Renal anlage		Wilms tumor
MORE THAN ONE NEOPLASTIC CELL TYPE DERIVED FROM MORE THAN ONE GERM CELL LAYER—TERATOGENOUS		
Totipotential cells in gonads or in embryonic rests	Mature teratoma, dermoid cyst	Immature teratoma, teratocarcinoma

2.7.2 Characteristics of Benign & Malignant Neoplasms

Nothing is more important to the individual with a tumor than being told “It is benign,” and so the differentiation between benign and malignant tumors is one of the most important distinctions a pathologist can make. In the great majority of instances, a benign tumor may be distinguished from a malignant tumor with considerable confidence on the basis of morphology. Occasionally, despite the pathologist's best efforts, a neoplasm defies categorization. Certain anatomic features may suggest

innocence, whereas others point toward cancerous potential. In a few instances there is not perfect concordance between the appearance of a neoplasm and its biologic behavior. In these cases molecular profiling (see below) or other molecular ancillary tests may provide useful information. Although an innocent face may mask an ugly nature, in general, benign and malignant tumors can be distinguished on the basis of differentiation and anaplasia, rate of growth, local invasion, and metastasis.

DIFFERENTIATION AND ANAPLASIA

Differentiation refers to the extent to which neoplastic parenchymal cells resemble the corresponding normal parenchymal cells, both morphologically and functionally; lack of differentiation is called anaplasia. In general, benign tumors are well differentiated (Figs. 7-4 and 7-5). The neoplastic cell in a benign adipocyte tumor—a lipoma—so closely resembles the normal cell that it may be impossible to recognize it as a tumor by microscopic examination of individual cells. Only the growth of these cells into a discrete mass discloses the neoplastic nature of the lesion. One may get so close to the tree that one loses sight of the forest. In well-differentiated benign tumors, mitoses are extremely scant in number and are of normal configuration.

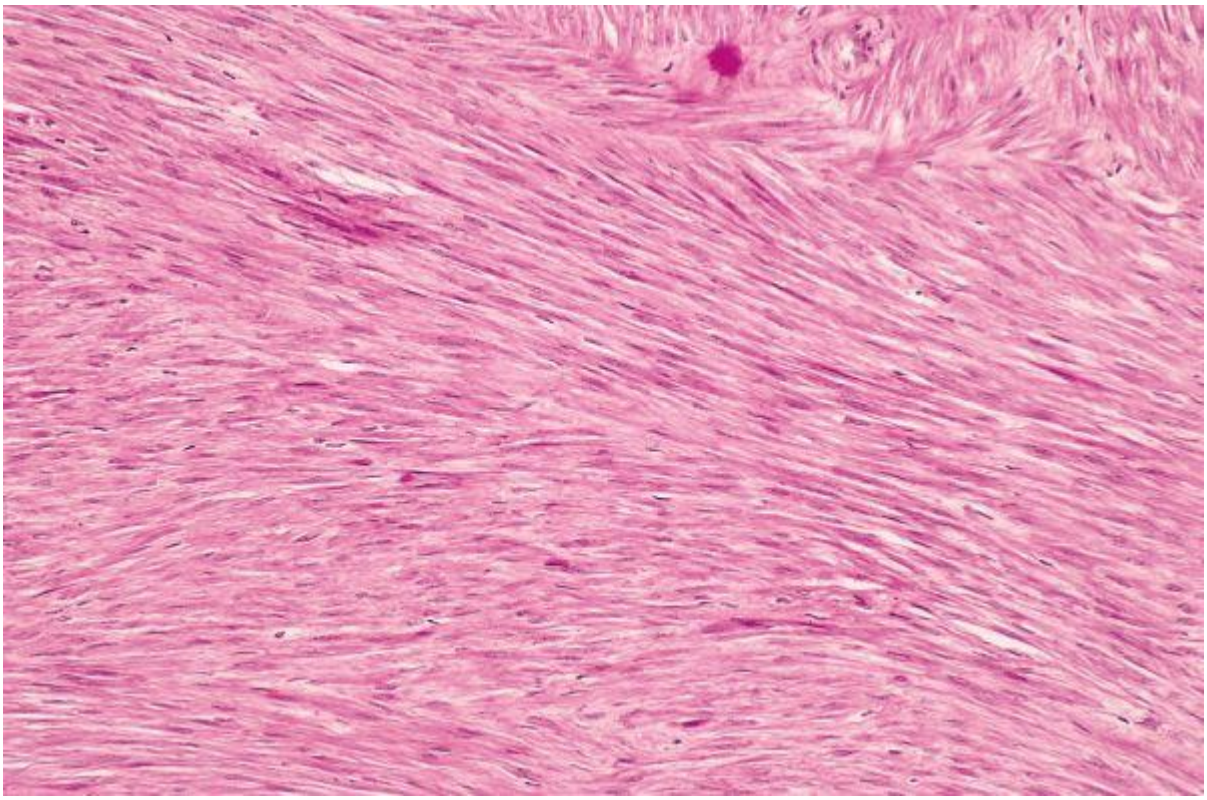

FIGURE 7-4 Leiomyoma of the uterus. This benign, well-differentiated tumor contains interlacing bundles of neoplastic smooth muscle cells that are virtually identical in appearance to normal smooth muscle cells in the myometrium.

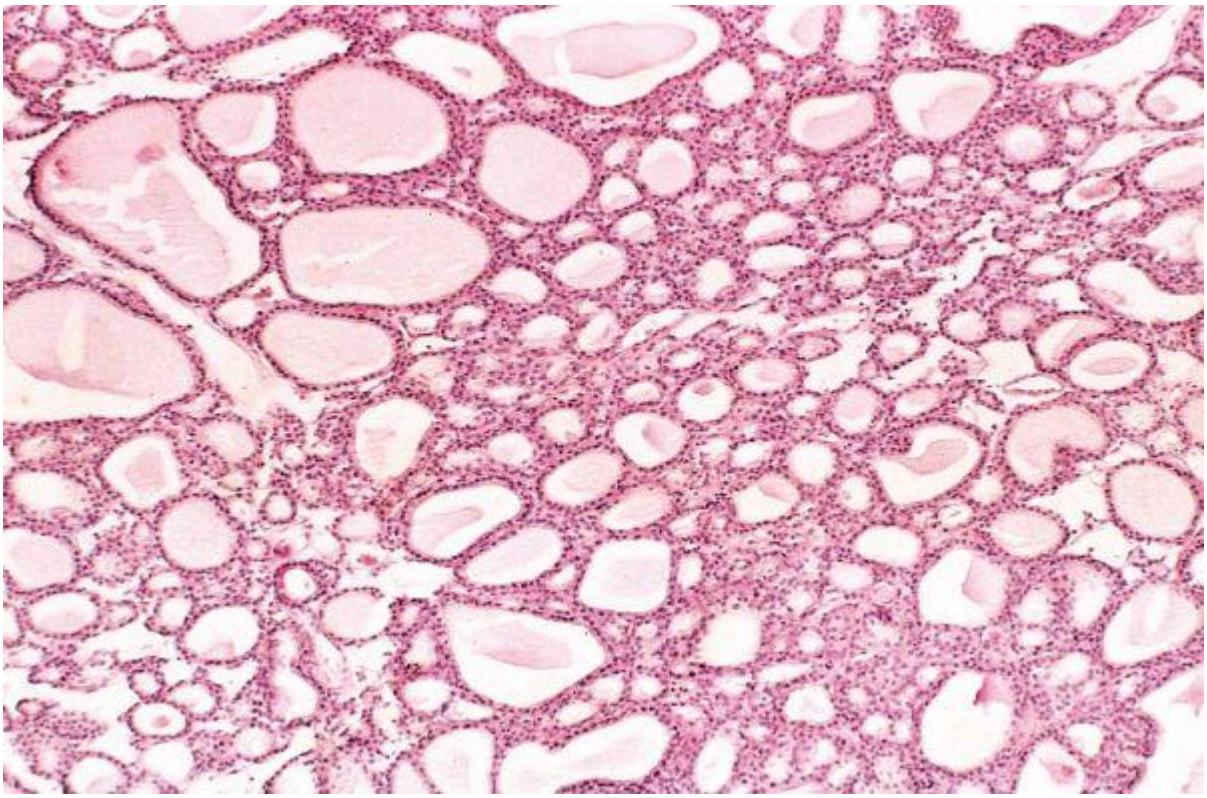

FIGURE 7-5 Benign tumor (adenoma) of the thyroid. Note the normal-looking (well-differentiated), colloid-filled thyroid follicles. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

Malignant neoplasms are characterized by a wide range of parenchymal cell differentiation, from surprisingly well differentiated (Fig. 7-6) to completely undifferentiated. Certain well-differentiated adenocarcinomas of the thyroid, for example, may form normal-appearing follicles, and some squamous cell carcinomas contain cells that do not differ cytologically from normal squamous epithelial cells (Fig. 7-7). Thus, the morphologic diagnosis of malignancy in well-differentiated tumors may sometimes be quite difficult. In between the two extremes lie tumors that are loosely referred to as *moderately well differentiated*.

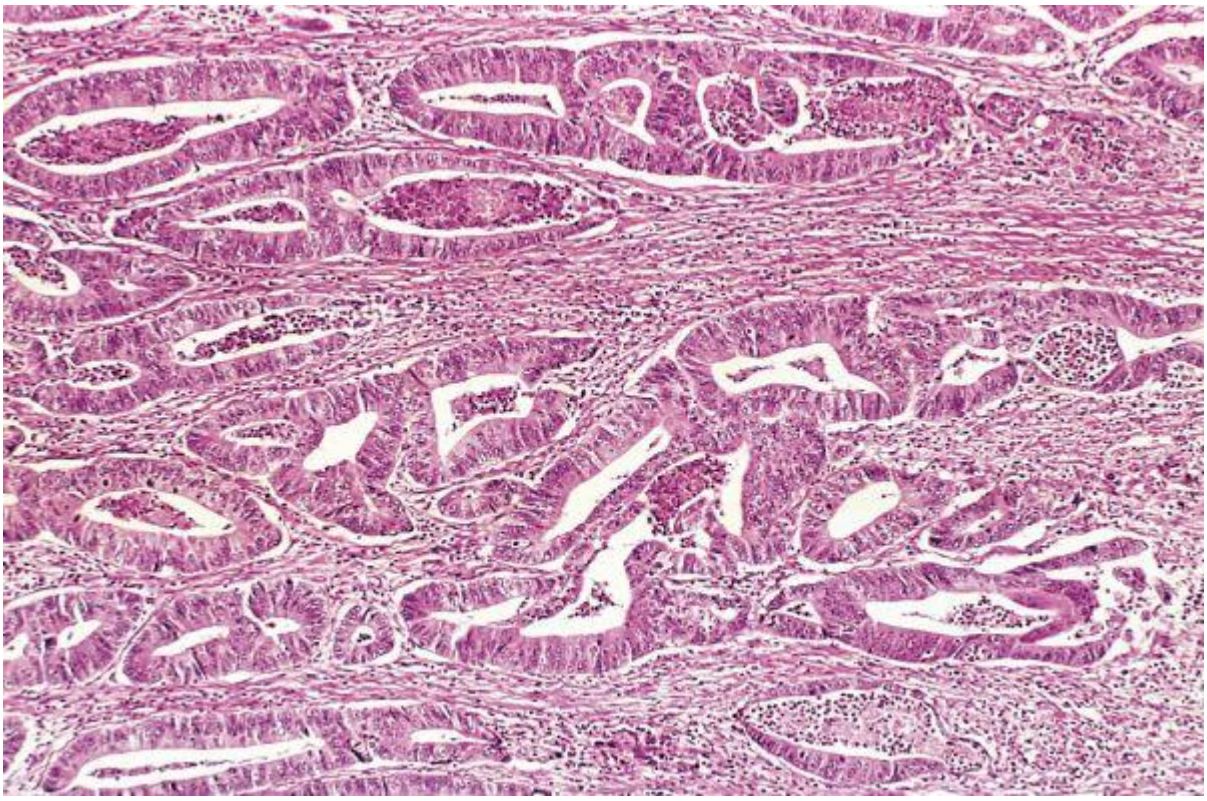

FIGURE 7-6 Malignant tumor (adenocarcinoma) of the colon. Note that compared with the well-formed and normal-looking glands characteristic of a benign tumor (see Fig. 7-5), the cancerous glands are irregular in shape and size and do not resemble the normal colonic glands. This tumor is considered differentiated because gland formation can be seen. The malignant glands have invaded the muscular layer of the colon. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

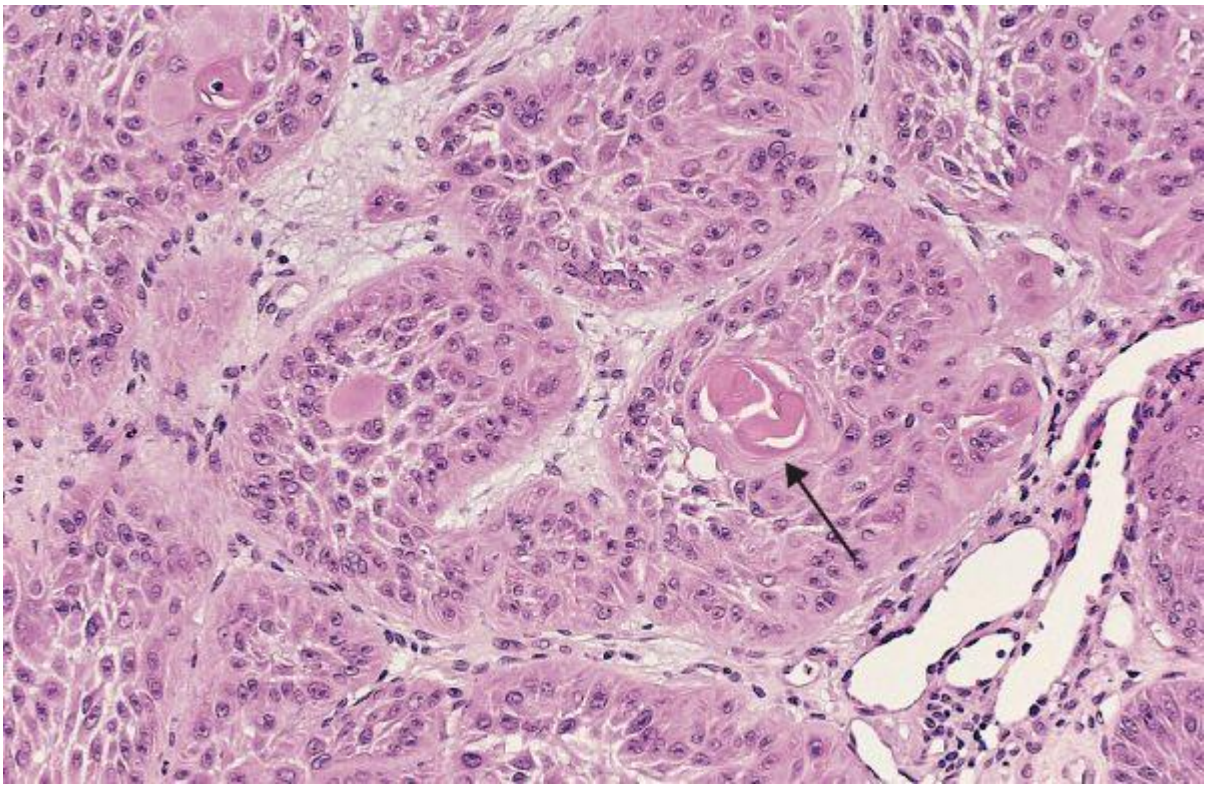

FIGURE 7-7 Well-differentiated squamous cell carcinoma of the skin. The tumor cells are strikingly similar to normal squamous epithelial cells, with intercellular bridges and nests of keratin pearls *(arrow)*. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

Malignant neoplasms that are composed of poorly differentiated cells are said to be *anaplastic*. Lack of differentiation, or anaplasia, is considered a hallmark of malignancy. The term *anaplasia* literally means "to form backward," implying a reversal of differentiation to a more primitive level. It is believed, however, that most cancers do not represent "reverse differentiation" of mature normal cells but, in fact, arise from less mature cells with "stem-cell-like" properties, such as tissue stem cells (Chapter 3). In well-differentiated tumors (Fig. 7-7), daughter cells derived from these "cancer stem cells" retain the capacity for differentiation, whereas in poorly differentiated tumors that capacity is lost.

Lack of differentiation, or anaplasia, is often associated with many other morphologic changes.

- *Pleomorphism*. Both the cells and the nuclei characteristically display *pleomorphism*—variation in size and shape (Fig. 7-8). Thus, cells within the same tumor are not uniform, but range from large cells, many times larger than their neighbors, to extremely small and primitive appearing.
- *Abnormal nuclear morphology*. Characteristically the nuclei contain abundant chromatin and are dark staining *(hyperchromatic)*. The nuclei are disproportionately large for the cell, and the nuclear-to-cytoplasm ratio may approach 1 : 1 instead of the normal 1 : 4 or 1 : 6. The nuclear shape is variable and often irregular, and the chromatin is often coarsely clumped and distributed along the nuclear membrane. Large nucleoli are usually present in these nuclei.
- *Mitoses*. As compared with benign tumors and some well-differentiated malignant neoplasms, undifferentiated tumors usually possess large numbers of mitoses, reflecting the higher proliferative activity of the parenchymal cells. *The presence of mitoses, however, does not necessarily indicate that a tumor is malignant or that the tissue is neoplastic*. Many normal tissues exhibiting rapid turnover, such as bone

marrow, have numerous mitoses, and non-neoplastic proliferations such as hyperplasias contain many cells in mitosis. More important as a morphologic feature of malignancy are atypical, bizarre mitotic figures, sometimes producing tripolar, quadripolar, or multipolar spindles (Fig. 7-9).

- *Loss of polarity*. In addition to the cytologic abnormalities, the *orientation of anaplastic cells is markedly disturbed (i.e., they lose normal polarity)*. Sheets or large masses of tumor cells grow in an anarchic, disorganized fashion.
- *Other changes*. Another feature of anaplasia is the formation of *tumor giant cells*, some possessing only a single huge polymorphic nucleus and others having two or more large, hyperchromatic nuclei (Fig. 7-8). These giant cells are not to be confused with inflammatory Langhans or foreign body giant cells, which are derived from macrophages and contain many small, normal-appearing nuclei. Although growing tumor cells obviously require a blood supply, often the vascular stroma is scant, and in many anaplastic tumors, large central areas undergo ischemic *necrosis*.

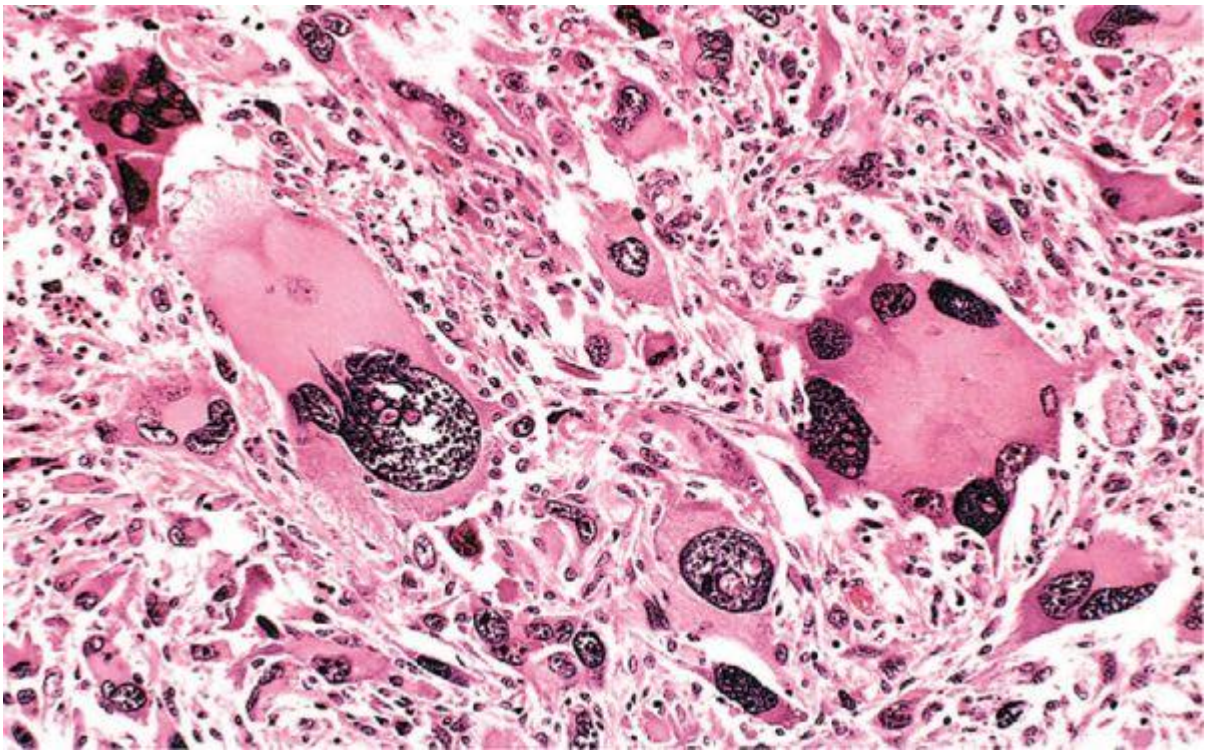

FIGURE 7-8 Anaplastic tumor of the skeletal muscle (rhabdomyosarcoma). Note the marked cellular and nuclear pleomorphism, hyperchromatic nuclei, and tumor giant cells. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

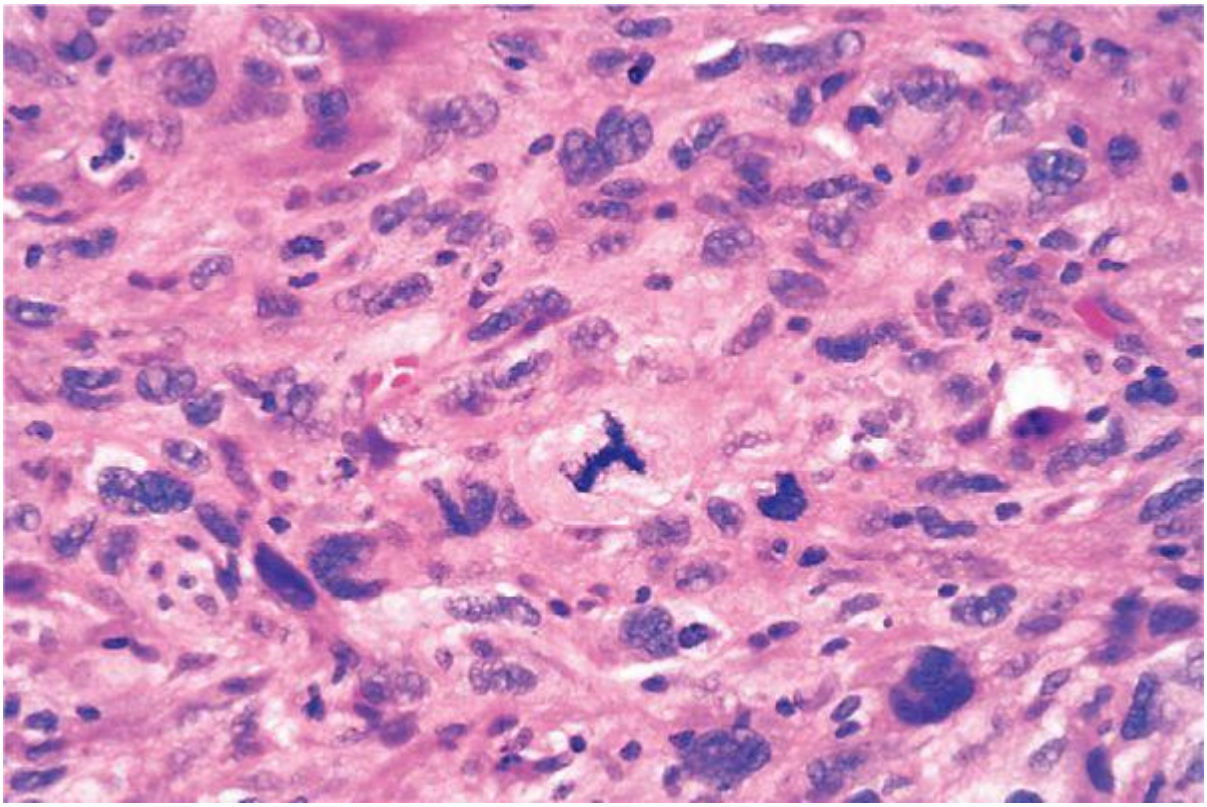

FIGURE 7-9 Anaplastic tumor showing cellular and nuclear variation in size and shape. The prominent cell in the center field has an abnormal tripolar spindle.

Before we leave the subject of differentiation and anaplasia, we should discuss metaplasia and dysplasia. *Metaplasia is defined as the replacement of one type of cell with another type*. Metaplasia is nearly always found in association with tissue damage, repair, and regeneration. Often the replacing cell type is more suited to a change in environment. For example, gastroesophageal reflux damages the squamous epithelium of the esophagus, leading to its replacement by glandular (gastric or intestinal) epithelium, more suited to the acidic environment. *Dysplasia* is a term that literally means disordered growth. Dysplasia often occurs in metaplastic epithelium, but not all metaplastic epithelium is also dysplastic. Dysplasia is encountered principally in epithelia, and it is characterized by a constellation of changes that *include a loss in the uniformity of the individual cells as well as a loss in their architectural orientation*. Dysplastic cells exhibit considerable pleomorphism and often contain large hyperchromatic nuclei with a high nuclearto-cytoplasmic ratio. The architecture of the tissue may be disorderly. For example, in squamous epithelium the usual progressive maturation of tall cells in the basal layer to flattened squames on the surface may be lost and replaced by a scrambling of dark basal-appearing cells throughout the epithelium. Mitotic figures are more abundant than usual, although almost invariably they have a normal configuration. Frequently, however, the mitoses appear in abnormal locations within the epithelium. For example, in dysplastic stratified squamous epithelium, mitoses are not confined to the basal layers but instead may appear at all levels, including surface cells. When dysplastic changes are marked and involve the entire thickness of the epithelium but the lesion remains confined by the basement membrane, it is considered a preinvasive neoplasm and is referred to as *carcinoma in situ* (Fig. 7-10). Once the tumor cells breach the basement membrane, the tumor is said to be *invasive*. Dysplastic changes are often found adjacent to foci of invasive carcinoma, and in some situations, such as in long-term cigarette smokers and persons with Barrett esophagus, severe epithelial dysplasia

frequently antedates the appearance of cancer. However, *dysplasia does not necessarily progress to cancer*. Mild to moderate changes that do not involve the entire thickness of epithelium may be reversible, and with removal of the inciting causes the epithelium may revert to normal. Even carcinoma in situ may take years to become invasive.

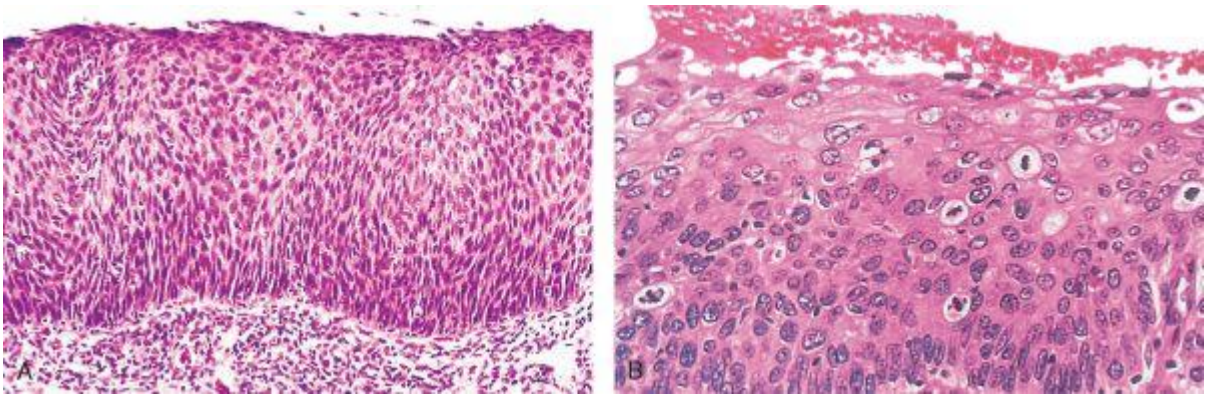

FIGURE 7-10 **A**, Carcinoma in situ. This low-power view shows that the entire thickness of the epithelium is replaced by atypical dysplastic cells. There is no orderly differentiation of squamous cells. The basement membrane is intact, and there is no tumor in the subepithelial stroma. **B**, A high-power view of another region shows failure of normal differentiation, marked nuclear and cellular pleomorphism, and numerous mitotic figures extending toward the surface. The basement membrane is not seen in this section.

As you might presume, the better the differentiation of the transformed cell, the more completely it retains the functional capabilities found in its normal counterparts. Thus, benign neoplasms and well-differentiated carcinomas of endocrine glands frequently elaborate the hormones characteristic of their origin. Increased levels of these hormones in the blood are used clinically to detect and follow such tumors. Welldifferentiated squamous cell carcinomas of the epidermis elaborate keratin, just as well-differentiated hepatocellular carcinomas elaborate bile. Highly anaplastic undifferentiated cells, whatever their tissue of origin, lose their resemblance to the normal cells from which they have arisen. In some instances, new and unanticipated functions emerge. Some tumors may elaborate fetal proteins not produced by comparable cells in the adult. Carcinomas of nonendocrine origin may produce a variety of hormones. For example, bronchogenic carcinomas may produce corticotropin, parathyroid-like hormone, insulin, and glucagon, as well as others. *Despite exceptions, the more rapidly growing and the more anaplastic a tumor, the less likely it will have specialized functional activity. The cells in benign tumors are almost always well differentiated and resemble their normal cells of origin; the cells in cancer are more or less differentiated, but some derangement of differentiation is always present*.

RATES OF GROWTH

A fundamental issue in tumor biology is to understand the factors that affect the growth rates of tumors and their influence on clinical outcome and therapeutic responses. One can begin the consideration of tumor cell kinetics by asking the question: How long does it take to produce a clinically overt tumor mass? It is a reasonable estimate the original transformed cell (approximately 10 μm in diameter) must undergo at least 30 population doublings to produce 10^9 cells (weighing approximately 1 gm), which is the smallest clinically detectable mass. In contrast, only 10 additional doubling cycles are required to produce a tumor containing 10^{12} cells (weighing -1kg), which is usually the maximal size compatible with life. These are minimal estimates, based on the assumption that all descendants of the transformed cell retain the ability to divide and that there is no loss of cells from the replicative pool. This concept of tumor as a “pathologic dynamo” is not entirely correct, as we discuss subsequently. Nevertheless, this

calculation highlights an extremely important concept about tumor growth: *By the time a solid tumor is clinically detected, it has already completed a major portion of its life span*. This is a major impediment in the treatment of cancer and underscores the need to develop diagnostic markers to detect early cancers.

The rate of growth of a tumor is determined by three main factors: the doubling time of tumor cells, the fraction of tumor cells that are in the replicative pool, and the rate at which cells are shed or die. Because cell cycle controls are deranged in most tumors, tumor cells can be triggered to cycle without the usual restraints. The dividing cells, however, do not necessarily complete the cell cycle more rapidly than do normal cells. In reality, total cell cycle time for many tumors is equal to or longer than that of corresponding normal cells. Thus, it can be safely concluded that growth of tumors is not commonly associated with a shortening of cell cycle time.

The proportion of cells within the tumor population that are in the proliferative pool is referred to as the *growth fraction*. Clinical and experimental studies suggest that during the early, submicroscopic phase of tumor growth, the vast majority of transformed cells are in the proliferative pool (Fig. 7-11). As tumors continue to grow, cells leave the proliferative pool in ever-increasing numbers as a result of shedding, lack of nutrients, necrosis, apoptosis, differentiation, and reversion to the nonproliferative phase of the cell cycle (G_0). Thus, by the time a tumor is clinically detectable, most cells are not in the replicative pool. Even in some rapidly growing tumors, the growth fraction is only about 20% or less.

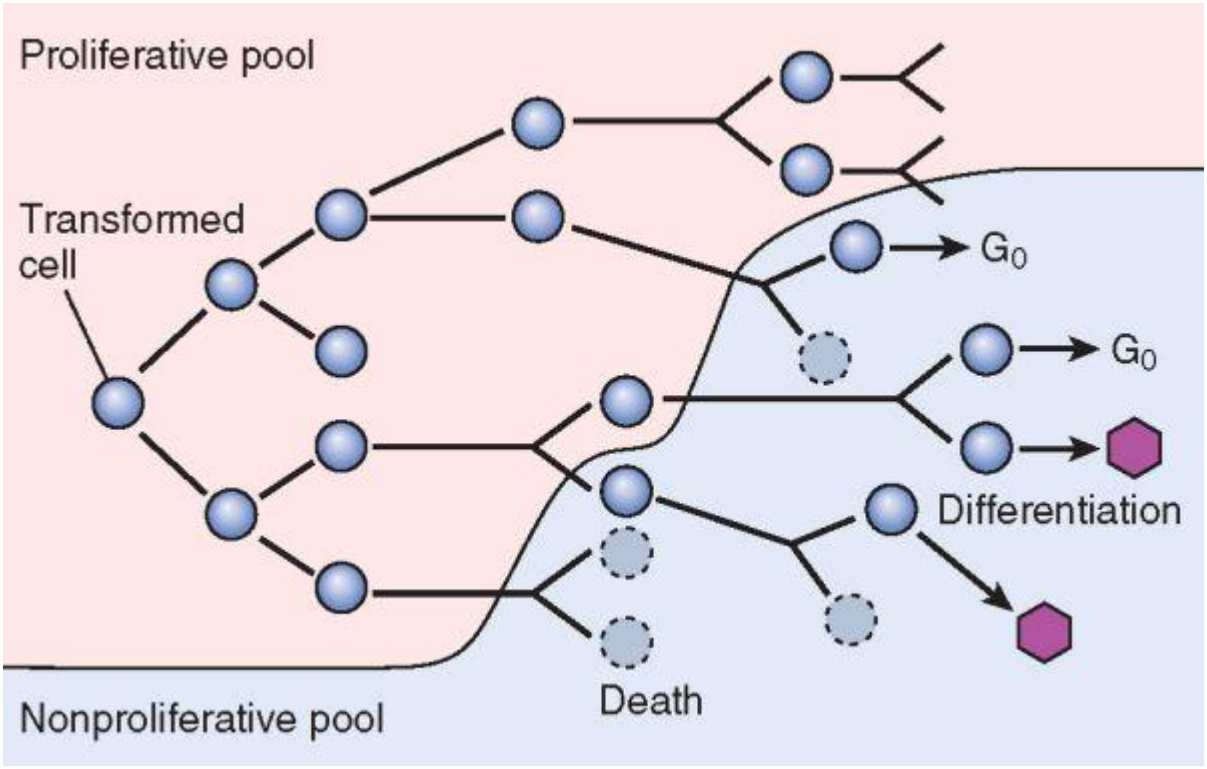

FIGURE 7-11 Schematic representation of tumor growth. As the cell population expands, a progressively higher percentage of tumor cells leaves the replicative pool by reversion to G_0, differentiation, and death.

Ultimately the progressive growth of tumors and the rate at which they grow are determined by an *excess of cell production over cell loss*. In some tumors, especially those with a relatively high growth

fraction, the imbalance is large, resulting in more rapid growth than in those in which cell production exceeds cell loss by only a small margin. Some leukemias and lymphomas and certain lung cancers (i.e., small-cell carcinoma) have a relatively high growth fraction, and their clinical course is rapid. By comparison, many common tumors, such as cancers of the colon and breast, have low growth fractions, and cell production exceeds cell loss by only about 10%; they tend to grow at a much slower pace.

Several important conceptual and practical lessons can be learned from studies of tumor cell kinetics:

- Fast-growing tumors may have a high *cell turnover*, implying that rates of both proliferation and apoptosis are high. Obviously if the tumor is to grow, the rate of proliferation must exceed that of cell death.
- The growth fraction of tumor cells has a profound effect on their susceptibility to cancer chemotherapy. Because most anticancer agents act on cells that are in cycle, it is not difficult to imagine that a tumor that contains 5% of all cells in the replicative pool will be slow growing but relatively refractory to treatment with drugs that kill dividing cells. One strategy used in the treatment of tumors with low growth fraction (e.g., cancer of colon and breast) is first to shift tumor cells from G_0 into the cell cycle. This can be accomplished by debulking the tumor with surgery or radiation. The surviving tumor cells tend to enter the cell cycle and thus become susceptible to drug therapy. Such considerations form the basis of combined-modality treatment. Some aggressive tumors (such as certain lymphomas and leukemias) that contain a large pool of dividing cells literally melt away with chemotherapy and may even be cured.

We can now return to the question posed earlier: How long does it take for one transformed cell to produce a clinically detectable tumor containing 10^9 cells? If every one of the daughter cells remained in cell cycle and no cells were shed or lost, we could anticipate the answer to be 90 days (30 population doublings, with a cell cycle time of 3 days). In reality, *the latent period before which a tumor becomes clinically detectable is unpredictable but typically much longer than 90 days, as long as many years for most solid tumors, emphasizing once again that human cancers are diagnosed only after they are fairly advanced in their life cycle*. After they become clinically detectable, the average volume-doubling time for such common killers as cancer of the lung and colon is about 2 to 3 months. As might be anticipated from the discussion of the variables that affect growth rate, however, the range of doubling time values is extremely broad, varying from less than 1 month for some childhood cancers to more than 1 year for certain salivary gland tumors. Cancer is indeed an unpredictable group of disorders.

In general, *the growth rate of tumors correlates with their level of differentiation, and thus most malignant tumors grow more rapidly than do benign lesions*. There are, however, many exceptions to such an oversimplification. Some benign tumors have a higher growth rate than malignant tumors. Moreover, the rate of growth of benign as well as malignant neoplasms may not be constant over time. Factors such as hormonal stimulation, adequacy of blood supply, and unknown influences may affect their growth. For example, the growth of uterine leiomyomas (benign smooth muscle tumors) may change over time because of hormonal variations. Not infrequently, repeated clinical examination of women bearing such neoplasms over the span of decades discloses no significant increase in size. After menopause the neoplasms may atrophy and may be replaced largely by collagenous, sometimes calcified, tissue. During pregnancy leiomyomas frequently enter a growth spurt. Such changes reflect the responsiveness of the tumor cells to circulating levels of steroid hormones, particularly estrogens. Cancers show a wide range of growth. Some malignant tumors grow slowly for years and then suddenly increase in size, explosively disseminating to cause death within a few months of discovery. It is possible that such behavior results from the emergence of an aggressive subclone of transformed cells. At the other extreme are malignant neoplasms that grow more slowly than do benign tumors and may even enter periods of dormancy lasting for years. On occasion, cancers decrease in size and even spontaneously disappear, but such “miracles” are rare enough that they remain intriguing curiosities.

CANCER STEM CELLS AND CANCER CELL LINEAGES

The continued growth and maintenance of many tissues that contain short-lived cells, such as the formed elements of the blood and the epithelial cells of the gastrointestinal tract and skin, require a resident population of tissue stem cells that are long-lived and capable of self-renewal. Tissue stem cells are rare and exist in a niche created by support cells, which produce paracrine factors that sustain the stem cell.[4] Recall from Chapter 3 that tissue stem cells divide asymmetrically to produce two types of daughter cells—those with limited proliferative potential, which undergo terminal differentiation and die, and those that retain stem cell potential.

Cancers are immortal and have limitless proliferative capacity, indicating that like normal tissues, they also must contain cells with "stemlike" properties.[5,][6] The concept of cancer stem cells has several important implications. Most notably, if cancer stem cells are essential for tumor persistence, it follows that these cells must be eliminated to cure the affected patient. It is hypothesized that like normal stem cells, cancer stem cells have a high intrinsic resistance to conventional therapies, because of their low rate of cell division and the expression of factors, such as multiple drug resistance-1 (MDR1), that counteract the effects of chemotherapeutic drugs.[5,][6] Thus, the limited success of current therapies may in part be explained by their failure to kill the malignant stem cells that lie at the root of cancer. Cancer stem cells could arise from normal tissue stem cells or from more differentiated cells that, as part of the transformation process, acquire the property of self-renewal. Studies of certain leukemias (Chapter 13) support both of these possibilities. For example, chronic myelogenous leukemia (CML) originates from the malignant counterpart of a normal hematopoietic stem cell, whereas certain acute myeloid leukemias (AMLs) are derived from more differentiated myeloid precursors that acquire an abnormal capacity for self-renewal. The identification of "leukemia stem cells" has spurred the search for cancer stem cells in solid tumors. Most such studies have focused on the identification of tumor-initiating cells (T-ICs), which are defined as cells that allow a human tumor to grow and maintain itself indefinitely when transplanted into an immunodeficient mouse. T-ICs have been identified in several human tumors, including breast carcinoma, glioblastoma multiforme, colon cancer, and AML, [5] [6] [7] [8] in which they constitute 0.1% to 2% of the total cellularity.

More recent studies have shown that in some cancers, T-ICs are very common, representing 25% of the total cellularity.[9] Thus some tumors may have a small number of T-ICs that then "differentiate" to form the bulk of the tumor, while other tumors may be primarily composed of T-ICs. In the future, it will be important to identify the tumorigenic population in each tumor to direct therapy against tumor stem cells. An emerging theme is that the genes and pathways that maintain cancer stem cells are the same as those that regulate normal tissue stem cell homeostasis. Examples include BMI1, a component of the polycomb chromatin-remodeling complex that promotes "stem-ness" in both normal hematopoietic and leukemic stem cells; and the WNT pathway, a key regulator of normal colonic crypt stem cells that has been implicated in the maintenance of colonic adenocarcinoma "stem cells."[9,][10] Important remaining questions revolve around whether T-ICs are an accurate measure of cancer stem cells, if cancer stem cells remain dependent on the "niche" that supports normal stem cells, and if it will be possible to selectively target cancer cell "stem-ness" factors.

LOCAL INVASION

Nearly all benign tumors grow as cohesive expansile masses that remain localized to their site of origin and do not have the capacity to infiltrate, invade, or metastasize to distant sites, as do malignant tumors. Because they grow and expand slowly, they usually develop a rim of compressed connective tissue, sometimes called a fibrous *capsule*, which separates them from the host tissue. This capsule is derived largely from the extracellular matrix of the native tissue due to atrophy of normal parenchymal cells under the pressure of an expanding tumor. Such encapsulation does not prevent tumor growth, but it keeps the benign neoplasm as a discrete, readily palpable, and easily movable mass that can be surgically enucleated (Figs. 7-12 and 7-13). Although a well-defined cleavage plane exists around

most benign tumors, in some it is lacking. For example, hemangiomas (neoplasms composed of tangled blood vessels) are often unencapsulated and may appear to permeate the site in which they arise (commonly the dermis of the skin).

FIGURE 7-12 Fibroadenoma of the breast. The tan-colored, encapsulated small tumor is sharply demarcated from the whiter breast tissue.

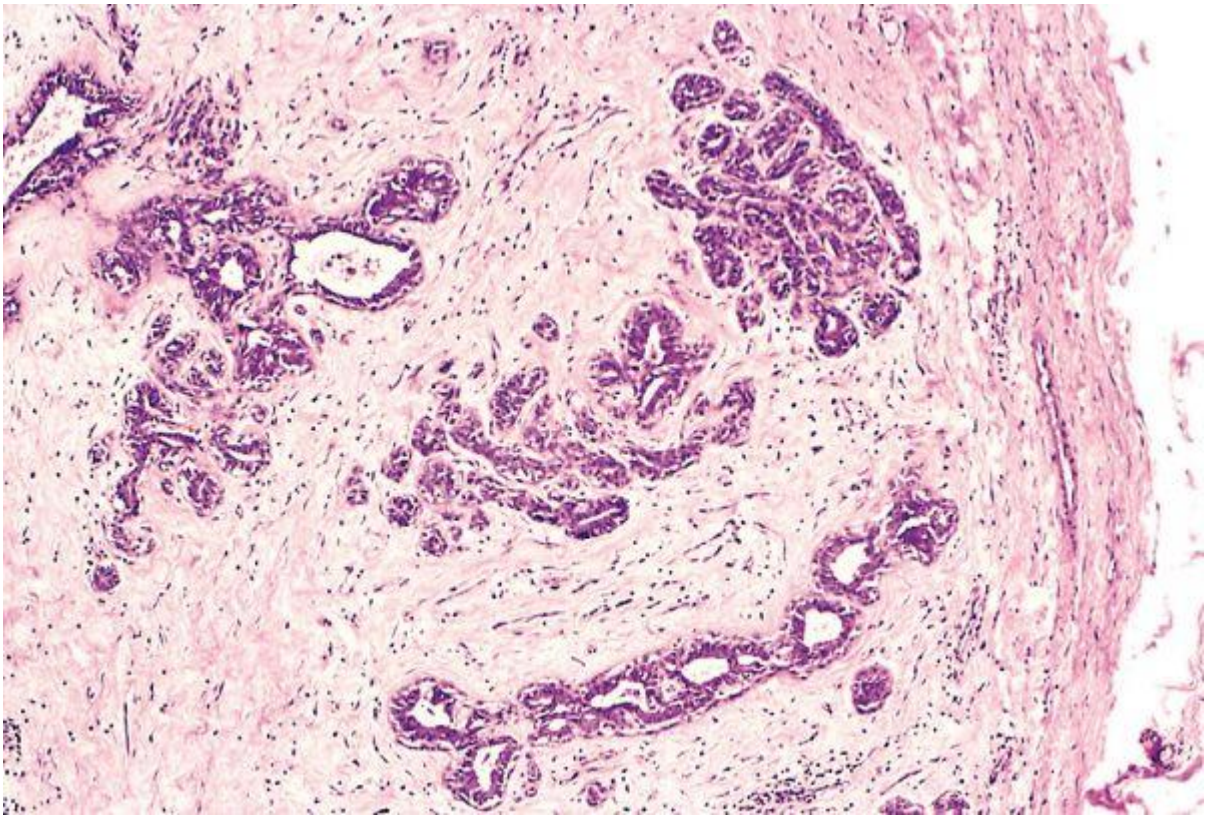

FIGURE 7-13 Microscopic view of fibroadenoma of the breast seen in Figure 7-12 . The fibrous capsule *(right)* delimits the tumor from the

surrounding tissue. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

The growth of cancers is accompanied by progressive infiltration, invasion, and destruction of the surrounding tissue. In general, malignant tumors are poorly demarcated from the surrounding normal tissue, and a well-defined cleavage plane is lacking (Figs. 7-14 and 7-15). Slowly expanding malignant tumors, however, may develop an apparently enclosing fibrous capsule and may push along a broad front into adjacent normal structures. Histologic examination of such pseudo-encapsulated masses almost always shows rows of cells penetrating the margin and infiltrating the adjacent structures, a crablike pattern of growth that constitutes the popular image of cancer.

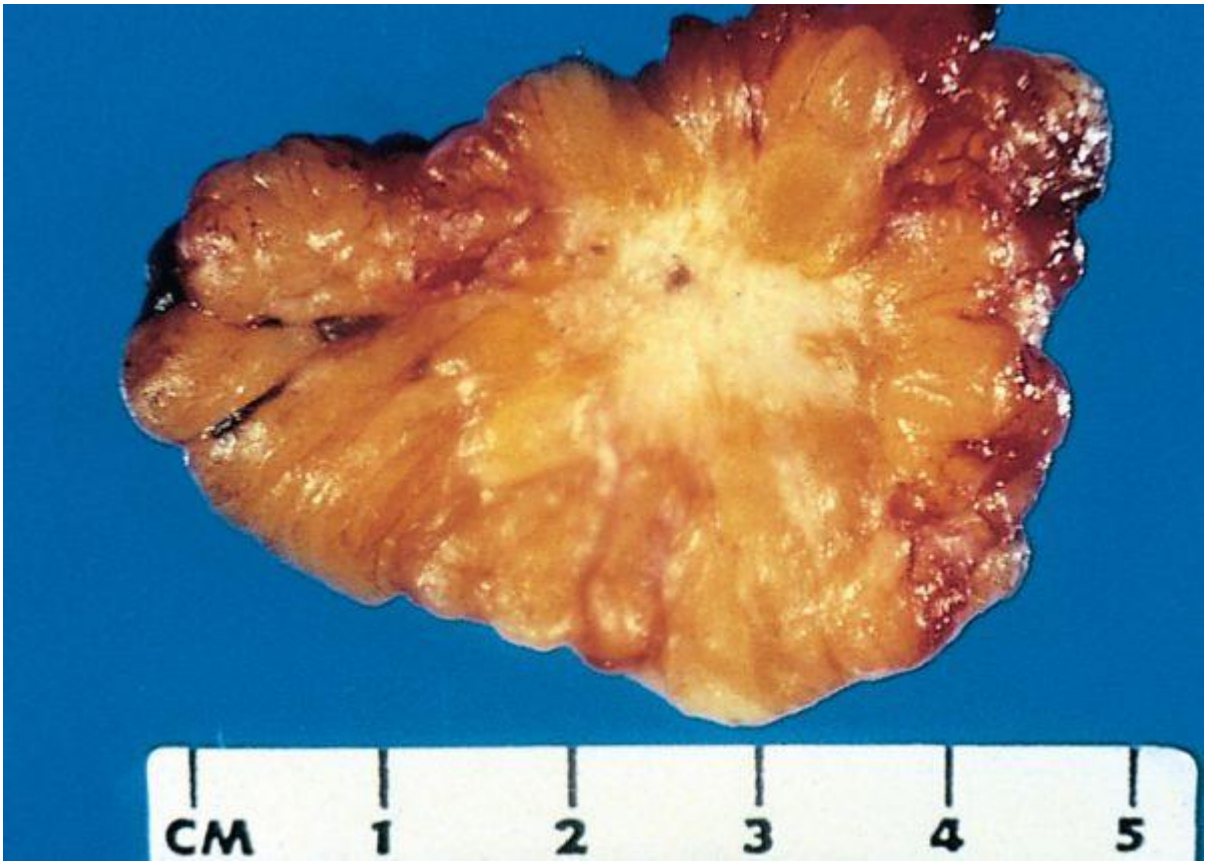

FIGURE 7-14 Cut section of an invasive ductal carcinoma of the breast. The lesion is retracted, infiltrating the surrounding breast substance, and would be stony hard on palpation.

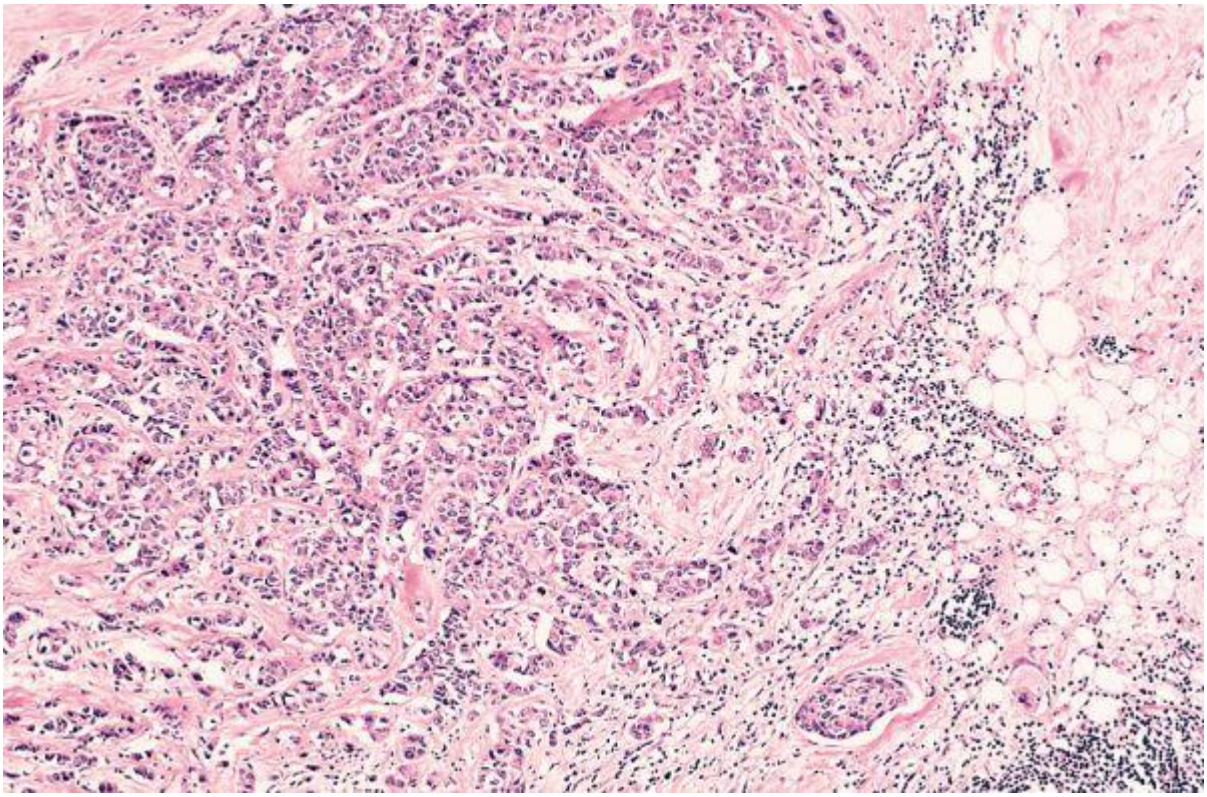

FIGURE 7-15 The microscopic view of the breast carcinoma seen in Figure 7-14 illustrates the invasion of breast stroma and fat by nests and cords of tumor cells (compare with fibroadenoma shown in Fig. 7-13). The absence of a well-defined capsule should be noted. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

Most malignant tumors are obviously invasive and can be expected to penetrate the wall of the colon or uterus, for example, or fungate through the surface of the skin. They recognize no normal anatomic boundaries. Such invasiveness makes their surgical resection difficult or impossible, and even if the tumor appears well circumscribed it is necessary to remove a considerable margin of apparently normal tissues adjacent to the infiltrative neoplasm. *Next to the development of metastases, invasiveness is the most reliable feature that differentiates malignant from benign tumors*. We noted earlier that some cancers seem to evolve from a preinvasive stage referred to as *carcinoma in situ*. This commonly occurs in carcinomas of the skin, breast, and certain other sites and is best illustrated by carcinoma of the uterine cervix (Chapter 22). *In situ epithelial cancers display the cytologic features of malignancy without invasion of the basement membrane*. They may be considered one step removed from invasive cancer; with time, most penetrate the basement membrane and invade the subepithelial stroma.

METASTASIS

Metastases are tumor implants discontinuous with the primary tumor. *Metastasis unequivocally marks a tumor as malignant because benign neoplasms do not metastasize*. The invasiveness of cancers permits them to penetrate into blood vessels, lymphatics, and body cavities, providing the opportunity for spread. *With few exceptions, all malignant tumors can metastasize*. The major exceptions are most malignant neoplasms of the glial cells in the central nervous system, called *gliomas*, and basal cell carcinomas of the skin. Both are locally invasive forms of cancer, but they rarely metastasize. It is evident then that the properties of invasion and metastasis are separable.

In general, the more aggressive, the more rapidly growing, and the larger the primary neoplasm, the greater the likelihood that it will metastasize or already has metastasized. There are innumerable exceptions, however. Small, well-differentiated, slowly growing lesions sometimes metastasize widely; conversely, some rapidly growing, large lesions remain localized for years. Many factors relating to both invader and host are involved.

Approximately 30% of newly diagnosed individuals with solid tumors (excluding skin cancers other than melanomas) present with metastases. Metastatic spread strongly reduces the possibility of cure; hence, short of prevention of cancer, no achievement would be of greater benefit to patients than methods to block metastases.

Pathways of Spread

Dissemination of cancers may occur through one of three pathways: (1) direct seeding of body cavities or surfaces, (2) lymphatic spread, and (3) hematogenous spread. Although direct transplantation of tumor cells, as for example on surgical instruments, may theoretically occur, it is rare and we do not discuss this artificial mode of dissemination further. Each of the three major pathways is described separately.

Seeding of Body Cavities and Surfaces.

Seeding of body cavities and surfaces may occur whenever a malignant neoplasm penetrates into a natural "open field." Most often involved is the peritoneal cavity (Fig. 7-16), but any other cavity—pleural, pericardial, subarachnoid, and joint space—may be affected. Such seeding is particularly characteristic of carcinomas arising in the ovaries, when, not infrequently, all peritoneal surfaces become coated with a heavy layer of cancerous glaze. Remarkably, the tumor cells may remain confined to the surface of the coated abdominal viscera without penetrating into the substance. Sometimes mucus-secreting appendiceal carcinomas fill the peritoneal cavity with a gelatinous neoplastic mass referred to as *pseudomyxoma peritonei*.

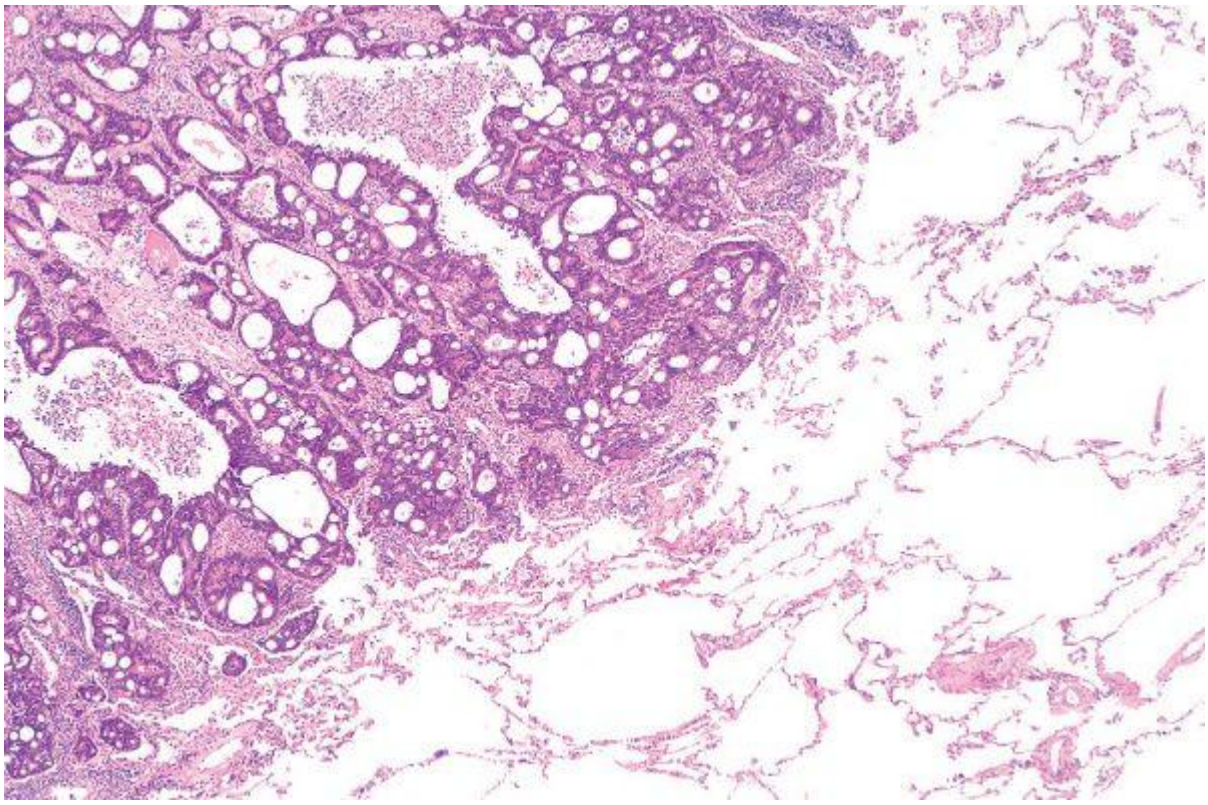

FIGURE 7-16 Colon carcinoma invading pericolonic adipose tissue. *(Courtesy of Dr. Melissa Upton, University of Washington, Seattle, WA.)*

Lymphatic Spread.

Transport through lymphatics is the most common pathway for the initial dissemination of carcinomas (Fig. 7-17), and sarcomas may also use this route. Tumors do not contain functional lymphatics, but lymphatic vessels located at the tumor margins are apparently sufficient for the lymphatic spread of tumor cells.[11] The emphasis on lymphatic spread for carcinomas and hematogenous spread for sarcomas is misleading, because ultimately there are numerous interconnections between the vascular and the lymphatic systems. *The pattern of lymph node involvement follows the natural routes of lymphatic drainage*. Because carcinomas of the breast usually arise in the upper outer quadrants, they generally disseminate first to the axillary lymph nodes. Cancers of the inner quadrants drain to the nodes along the internal mammary arteries. Thereafter the infraclavicular and supraclavicular nodes may become involved. Carcinomas of the lung arising in the major respiratory passages metastasize first to the perihilar tracheobronchial and mediastinal nodes. Local lymph nodes, however, may be bypassed—so-called "skip metastasis"—because of venous-lymphatic anastomoses or because inflammation or radiation has obliterated lymphatic channels.

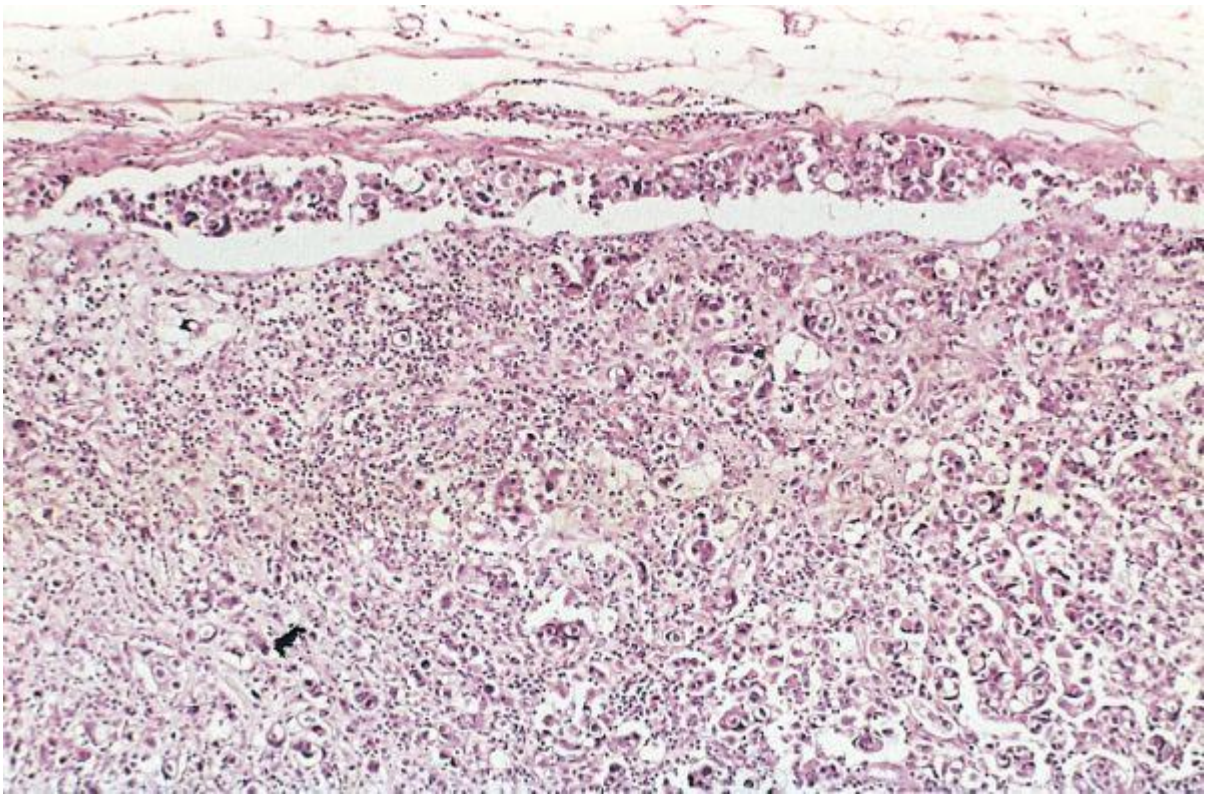

FIGURE 7-17 Axillary lymph node with metastatic breast carcinoma. The subcapsular sinus *(top)* is distended with tumor cells. Nests of tumor cells have also invaded the subcapsular cortex. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallas, TX.)*

In breast cancer, determining the involvement of axillary lymph nodes is very important for assessing the future course of the disease and for selecting suitable therapeutic strategies. To avoid the considerable surgical morbidity associated with a full axillary lymph node dissection, *biopsy of sentinel nodes* is often used to assess the presence or absence of metastatic lesions in the lymph nodes. A sentinel lymph node is defined as "the first node in a regional lymphatic basin that receives lymph flow from the primary tumor."[12] Sentinel node mapping can be done by injection of radiolabeled tracers and blue dyes, and the use of frozen section upon the sentinel lymph node at the time of surgery can guide the surgeon to the appropriate therapy. Sentinel node biopsy has also been used for detecting the spread of melanomas, colon cancers, and other tumors.[12,][13]

In many cases the regional nodes serve as effective barriers to further dissemination of the tumor, at least for a while. Conceivably the cells, after arrest within the node, may be destroyed by a tumor-specific immune response. Drainage of tumor cell debris or tumor antigens, or both, also induces reactive changes within nodes. Thus, enlargement of nodes may be caused by (1) the spread and growth of cancer cells or (2) reactive hyperplasia (Chapter 13). Therefore, *nodal enlargement in proximity to a cancer, while it must arouse suspicion, does not necessarily mean dissemination of the primary lesion*.

Hematogenous Spread.

Hematogenous spread is typical of sarcomas but is also seen with carcinomas. Arteries, with their thicker walls, are less readily penetrated than are veins. Arterial spread may occur, however, when tumor cells pass through the pulmonary capillary beds or pulmonary arteriovenous shunts or when pulmonary metastases themselves give rise to additional tumor emboli. In such vascular spread, several factors influence the patterns of distribution of the metastases. With venous invasion the blood-borne cells follow the venous flow draining the site of the neoplasm, and the tumor cells often come to rest in the first capillary bed they encounter. Understandably the liver and lungs are most frequently involved in such hematogenous dissemination (Figs. 7-18 and 7-19), because all portal area drainage flows to the liver and all caval blood flows to the lungs. Cancers arising in close proximity to the vertebral column often embolize through the paravertebral plexus, and this pathway is involved in the frequent vertebral metastases of carcinomas of the thyroid and prostate.

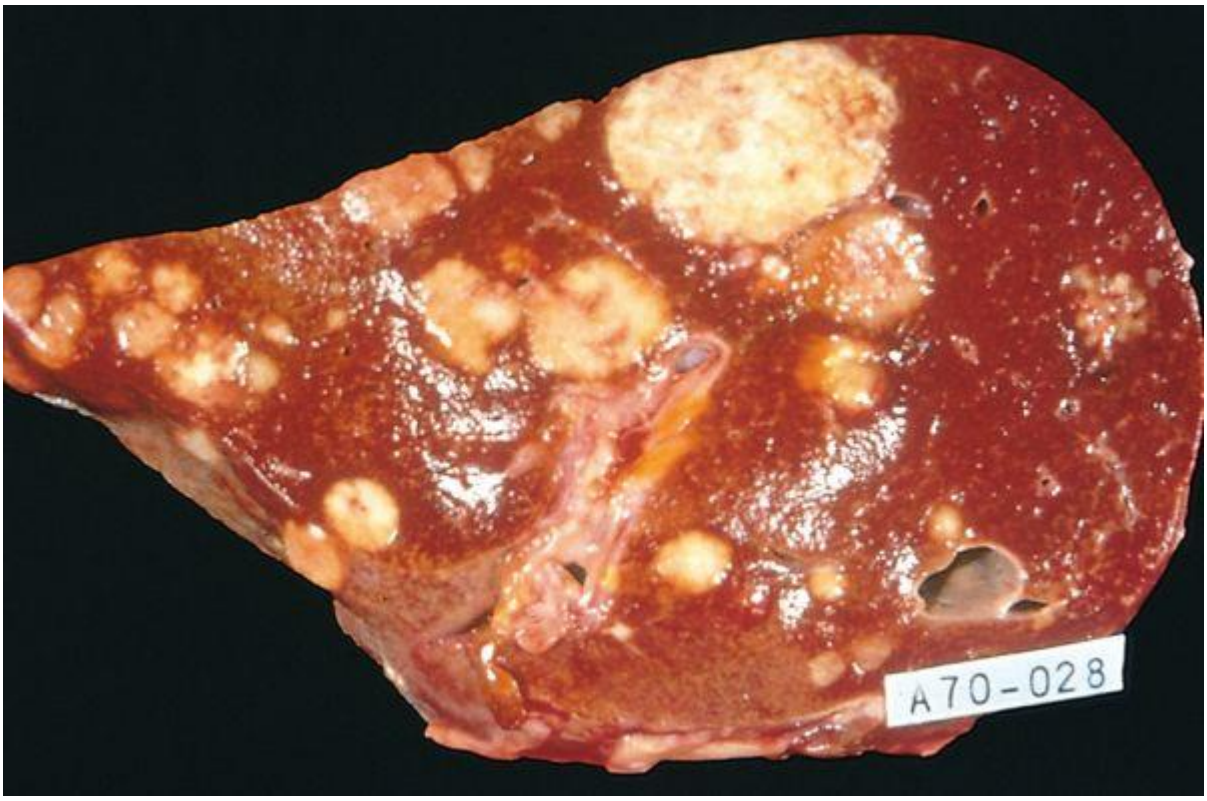

FIGURE 7-18 A liver studded with metastatic cancer.

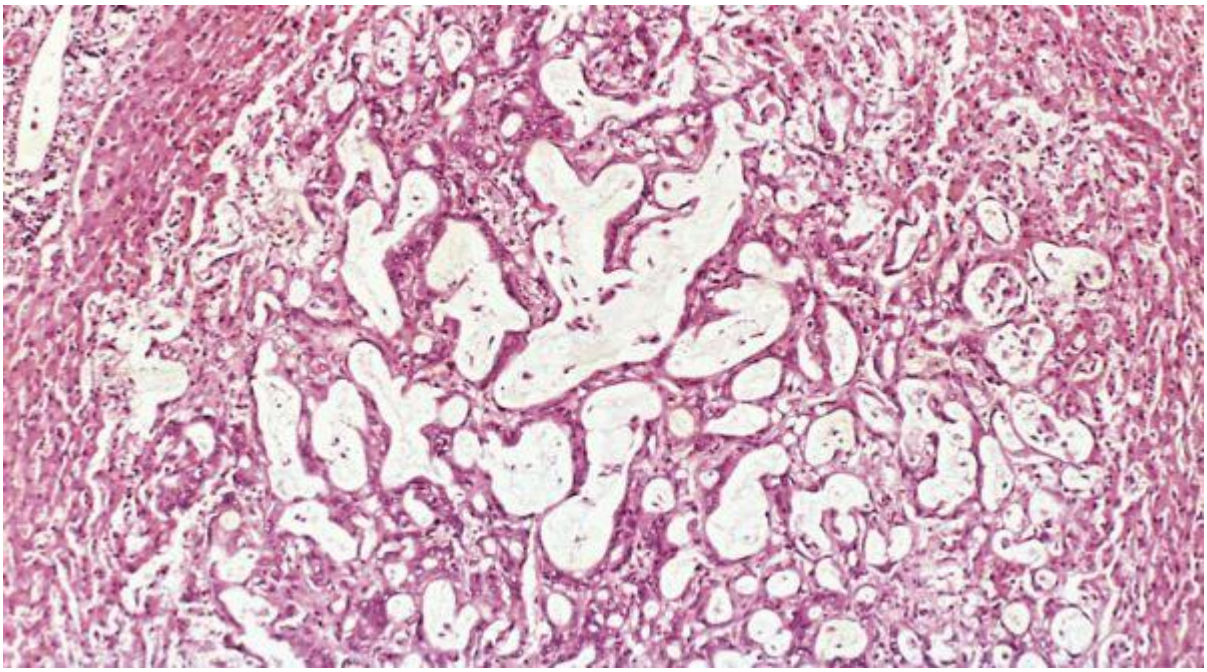

FIGURE 7-19 Microscopic view of liver metastasis. A pancreatic adenocarcinoma has formed a metastatic nodule in the liver. *(Courtesy of Dr. Trace Worrell, University of Texas Southwestern Medical School, Dallax, TX.)*

Certain cancers have a propensity for invasion of veins. Renal cell carcinoma often invades the branches of the renal vein and then the renal vein itself to grow in a snakelike fashion up the inferior vena cava, sometimes reaching the right side of the heart. Hepatocellular carcinomas often penetrate portal and hepatic radicles to grow within them into the main venous channels. Remarkably, such intravenous growth may not be accompanied by widespread dissemination. Histologic evidence of penetration of small vessels at the site of the primary neoplasm is obviously an ominous feature. Such changes, however, must be viewed guardedly because, for reasons discussed later, they do not indicate the inevitable development of metastases.

Many observations suggest that mere anatomic localization of the neoplasm and natural pathways of venous drainage do not wholly explain the systemic distributions of metastases. For example, breast carcinoma preferentially spreads to bone, bronchogenic carcinomas tend to involve the adrenals and the brain, and neuroblastomas spread to the liver and bones. Conversely, skeletal muscles and the spleen, despite the large percentage of blood flow they receive and the enormous vascular beds present, are rarely the site of secondary deposits. The probable basis of such tissue-specific homing of tumor cells is discussed later.

The distinguishing features of benign and malignant tumors discussed in this overview are summarized in Table 7-2 and Figure 7-20 . With this background on the structure and behavior of neoplasms, we now discuss the origin of tumors, starting with insights gained from the epidemiology of cancer and followed by the molecular basis of carcinogenesis.

TABLE 7-2 -- Comparisons between Benign and Malignant Tumors

Characteristics	Benign	Malignant
Differentiation/anaplasia	Well differentiated; structure sometimes typical of tissue of origin	Some lack of differentiation with anaplasia; structure often atypical
Rate of growth	Usually progressive and slow; may come to a standstill or regress; mitotic figures rare and normal	Erratic and may be slow to rapid; mitotic figures may be numerous and abnormal
Local invasion	Usually cohesive expansile well-demarcated masses that do not invade or infiltrate surrounding normal tissues	Locally invasive, infiltrating surrounding tissue; sometimes may be seemingly cohesive and expansile
Metastasis	Absent	Frequently present; the larger and more undifferentiated the primary, the more likely are metastases

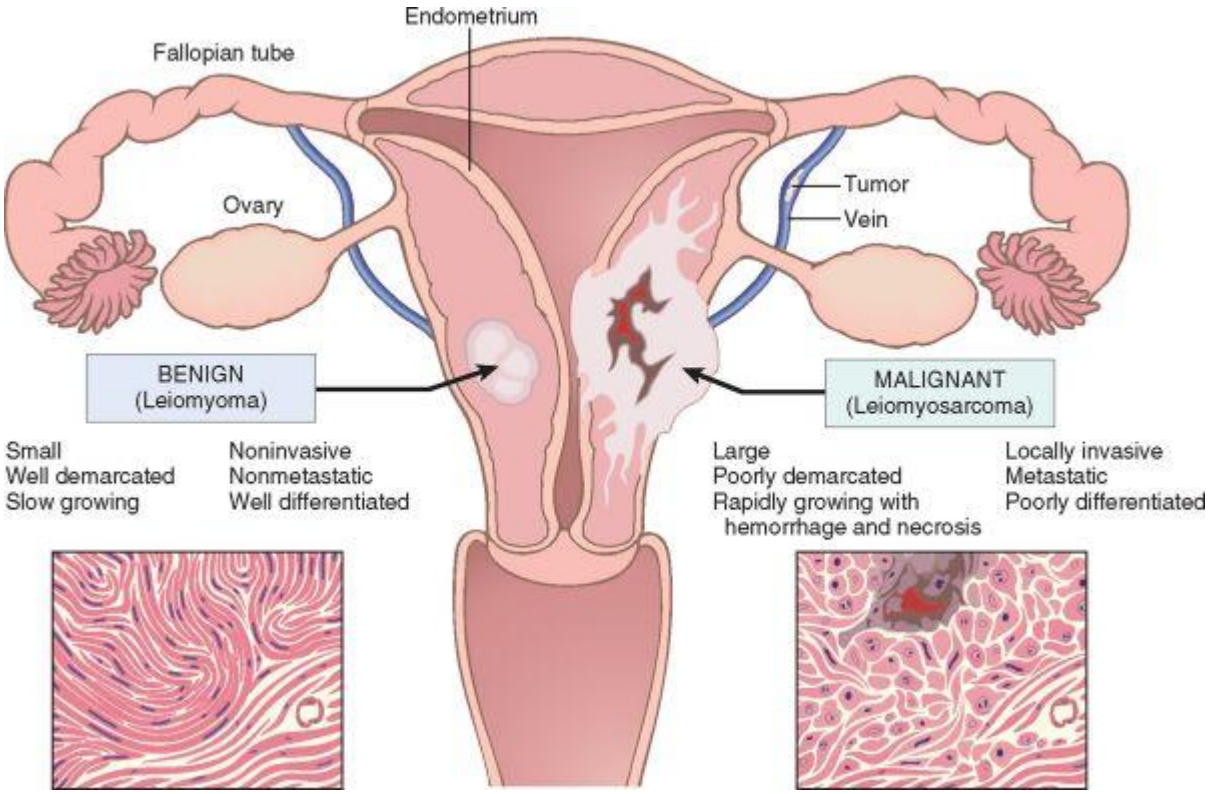

FIGURE 7-20 Comparison between a benign tumor of the myometrium (leiomyoma) and a malignant tumor of the same origin (leiomyosarcoma).

2.7.3 Epidemiology

Because cancer is a disorder of cell growth and behavior, its ultimate cause has to be defined at the cellular and subcellular levels. Study of cancer patterns in populations, however, can contribute substantially to knowledge about the origins of cancer. Epidemiologic studies have established the causative link between smoking and lung cancer, and comparison of diet and cancer rates in the Western world and Africa has implicated high dietary fat and low fiber in the development of colon cancer. Major insights into the causes of cancer can be obtained by epidemiologic studies that relate particular environmental, racial (possibly hereditary), and cultural influences to the occurrence of specific neoplasms. Certain diseases associated with an increased risk of developing cancer (preneoplastic disorders) also provide clues to the pathogenesis of cancer. In the following discussion we first summarize the overall incidence of cancer to gain an insight into the magnitude of the cancer problem, then we review some factors relating to the patient and environment that influence the predisposition to cancer.

CANCER INCIDENCE

In some measure, an individual's likelihood of developing a cancer is expressed by national incidence and mortality rates. For example, residents of the United States have about a one in five chance of dying of cancer. There were, it is estimated, about 1,437,180 new cancer cases and 565,650 deaths from cancer in 2008, representing 23% of all mortality,[1] a frequency surpassed only by deaths caused by cardiovascular diseases. These data do not include an additional 1 million, for the most part readily curable, non-melanoma cancers of the skin and 122,000 cases of carcinoma in situ, largely of the female breast and melanomas.[1] The major organ sites affected and the estimated frequency of cancer deaths

are shown in Figure 7-21 . The most common tumors in men arise in the prostate, lung, and colorectum. In women, cancers of the breast, lung, and colon and rectum are the most frequent. Cancers of the lung, female breast, prostate, and colon/rectum constitute more than 50% of cancer diagnoses and cancer deaths in the U.S. population.[1]

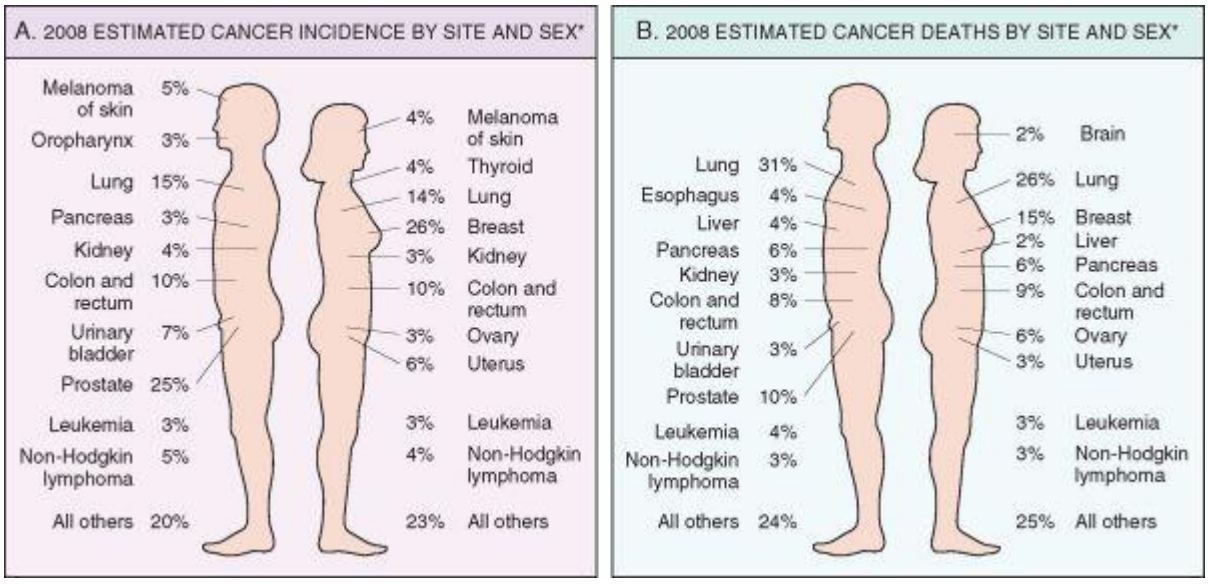

FIGURE 7-21 Cancer incidence and mortality by site and sex. Excludes basal cell and squamous cell skin cancers and in situ carcinomas, except urinary bladder. *(Adapted from Jemal A et al.: Cancer statistics, 2008. CA Cancer J Clin 58:2, 2008.)*

The age-adjusted death rates (number of deaths per 100,000 population) for many forms of cancer have significantly changed over the years. Many of the long-term comparisons are noteworthy. Over the last 50 years of the twentieth century, the overall age-adjusted cancer death rate significantly increased in both men and women. However, since 1995 the cancer incidence rate in men has stabilized and since 1990 the cancer death rate in men has decreased 18.4%.[1] In women the cancer incidence rate stabilized in 1995, and the cancer death rate has decreased 10.4% since 1991.[1] Among men nearly 80% of the total decrease in cancer death rates is accounted for by decreases in death rates from lung, prostate, and colorectal cancers since 1990.[1] Among women nearly 60% of the decrease in cancer death rates is due to reductions in death rates from breast and colorectal cancers.[1] Nearly 40% of the sex-specific decreases in cancer death rates is accounted for by a reduction in lung cancer deaths in men and breast cancer deaths in women.[1] Decreased use of tobacco products is responsible for the reduction in lung cancer deaths, while improved detection and treatment are responsible for the decrease in death rates for colorectal, female breast, and prostate cancer.[1] The last half century has seen a decline in the number of deaths caused by cervical cancer that relates to earlier diagnosis made possible by the Papanicolaou (Pap) smear. The downward trend in deaths from stomach cancer has been attributed to a decrease in some dietary carcinogens, as a consequence of better food preservation or changes in dietary habits. Unfortunately, between 1990–1991 and 2004, lung cancer death rates in women, and liver and intrahepatic bile duct cancer death rates in men, increased substantially, offsetting some of the improvement in survival from other cancers.[1] Indeed, although in women carcinomas of the breast occur about 2.5 times more frequently than those of the lung, lung cancer has become the leading cause of cancer deaths in women. Deaths from primary liver cancers, which declined between 1930 and 1970, have approximately doubled during the past 30 years. This number is expected to increase over the

coming decades, as the large number of individuals infected with the hepatitis C virus (HCV) begin to develop hepatocellular carcinoma.

Although race is not a strict biologic category, it can define groups at risk for certain cancers.[14,][15] The disparity in cancer mortality rates between white and black Americans persists, but African Americans had the largest decline in cancer mortality during the past decade. Hispanics living in the United States have a lower frequency of the most common tumors than the white non-Hispanic population but a higher incidence of tumors of the stomach, liver, uterine cervix, and gallbladder, as well as certain childhood leukemias.

GEOGRAPHIC AND ENVIRONMENTAL FACTORS

Although genetics and environmental triggers both play a role in the pathogenesis of cancer, environmental factors are thought to be the more significant contributors in most common sporadic cancers. In one large study the proportion of risk from environmental causes was found to be 65%, whereas heritable factors contributed 26% to 42% of cancer risk. Remarkable differences found in the incidence and death rates of specific forms of cancer around the world also suggest a role for environmental factors.[16,][17] For example, the death rate for stomach carcinoma in both men and women is seven to eight times higher in Japan than in the United States. In contrast, the death rate from carcinoma of the lung is slightly more than twice as great in the United States as in Japan. Although racial predispositions cannot be ruled out, it is generally believed that most of these geographic differences are the consequence of environmental influences. Indeed, comparing mortality rates for Japanese immigrants to the United States and Japanese born in the United States of immigrant parents (Nisei) with those of long-term residents of both countries shows that cancer mortality rates for first-generation Japanese immigrants are intermediate between those of natives of Japan and natives of California, and the two rates come closer with each passing generation (Fig. 7-22). This points strongly to environmental and cultural factors rather than genetic predisposition.

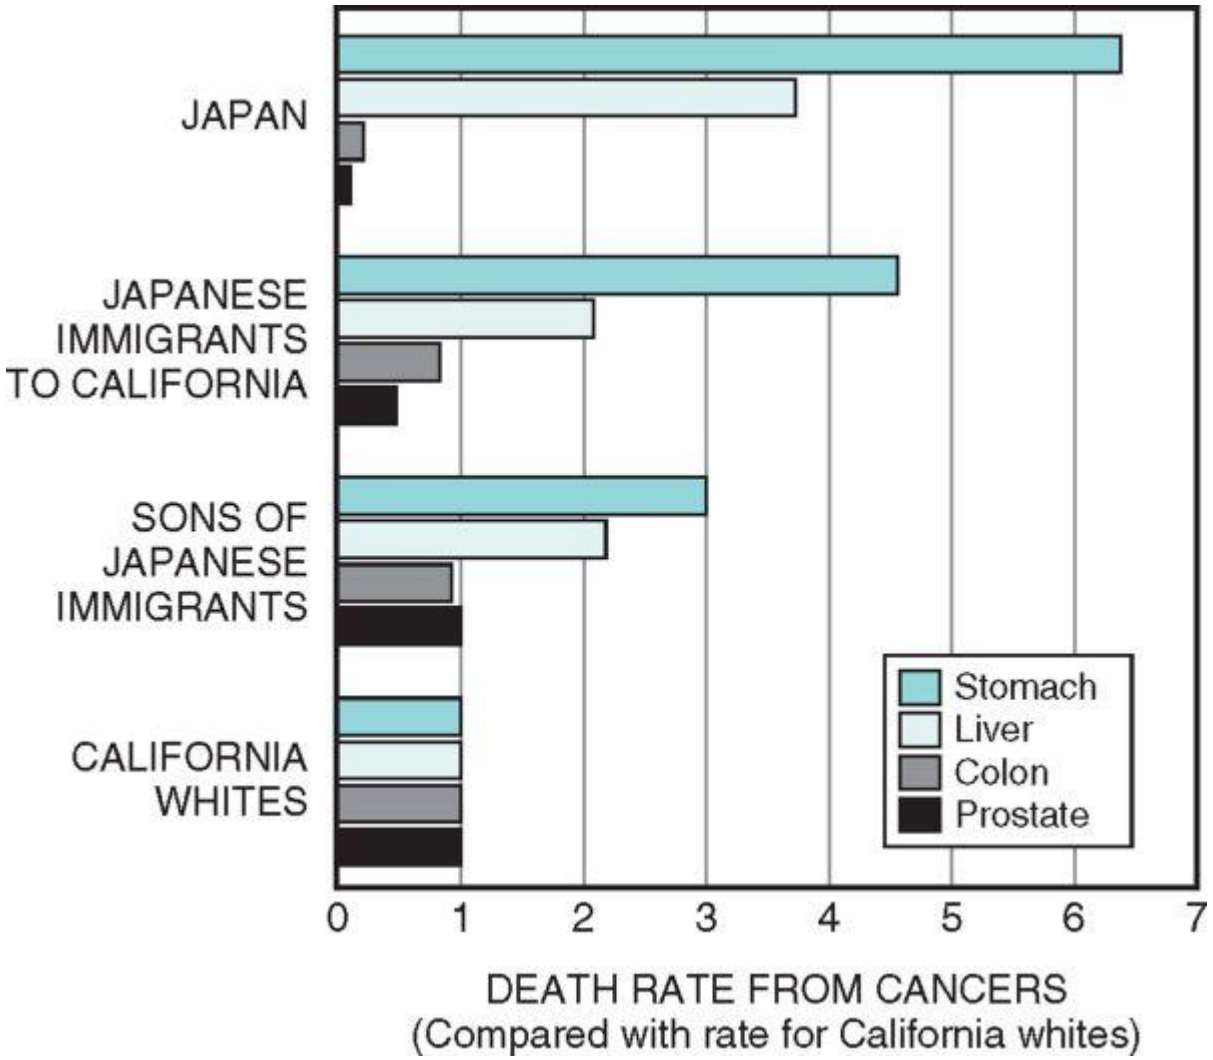

FIGURE 7-22 The change in incidence of various cancers with migration from Japan to the United States provides evidence that the occurrence of cancers is related to components of the environment that differ in the two countries. The incidence of each kind of cancer is expressed as the ratio of the death rate in the population being considered to that in a hypothetical population of California whites with the same age distribution; the death rates for whites are thus defined as 1. The death rates among immigrants and immigrants' sons tend consistently toward California norms. *(From Cairns J: The cancer problem. In Readings from Scientific American—Cancer Biology. New York, WH Freeman, 1986, p 13.)*

There is no paucity of carcinogenic environmental factors: they lurk in the ambient environment, in the workplace, in food, and in personal practices. Individuals may be exposed to carcinogenic factors when they go outside (ultraviolet [UV] rays, smog), in their medication (methotrexate), at work (asbestos, vinyl chloride; Table 7-3), or at home (high-fat diet, alcohol). Overall, mortality data indicate that the most overweight individuals in the U.S. population have a 52% (men) and 62% (women) higher death rate from cancer than do their slimmer counterparts. Indeed, obesity is associated with approximately 14% of cancer deaths in men and 20% in women.[18] Alcohol abuse alone increases the risk of carcinomas of the oropharynx (excluding lip), larynx, and esophagus and, by the development of alcoholic cirrhosis, hepatocellular carcinoma. Smoking, particularly of cigarettes, has been implicated in cancer of the mouth, pharynx, larynx, esophagus, pancreas, bladder, and most significantly, about 90% of lung cancer deaths (Chapter 9). Cigarette smoking has been called the single most important environmental factor

contributing to premature death in the United States. Alcohol and tobacco together synergistically increase the danger of incurring cancers in the upper aerodigestive tract. The risk of cervical cancer is linked to age at first intercourse and the number of sex partners, and it is now known that infection by venereally transmitted human papillomavirus (HPV) contributes to cervical dysplasia and cancer. It appears that almost everything one does to gain a livelihood or for pleasure is fattening, immoral, illegal, or, even worse, oncogenic.

TABLE 7-3 -- Occupational Cancers

Agents or Groups of Agents	Human Cancer Site for Which Reasonable Evidence Is Available	Typical Use or Occurrence
Arsenic and arsenic compounds	Lung, skin, hemangiosarcoma	Byproduct of metal smelting; component of alloys, electrical and semiconductor devices, medications and herbicides, fungicides, and animal dips
Asbestos	Lung, mesothelioma; gastrointestinal tract (esophagus, stomach, large intestine)	Formerly used for many applications because of fire, heat, and friction resistance; still found in existing construction as well as fire-resistant textiles, friction materials (i.e., brake linings), underlayment and roofing papers, and floor tiles
Benzene	Leukemia, Hodgkin lymphoma	Principal component of light oil; despite known risk, many applications exist in printing and lithography, paint, rubber, dry cleaning, adhesives and coatings, and detergents; formerly widely used as solvent and fumigant
Beryllium and beryllium compounds	Lung	Missile fuel and space vehicles; hardener for lightweight metal alloys, particularly in aerospace applications and nuclear reactors
Cadmium and cadmium compounds	Prostate	Uses include yellow pigments and phosphors; found in solders; used in batteries and as alloy and in metal platings and coatings
Chromium compounds	Lung	Component of metal alloys, paints, pigments, and preservatives
Nickel compounds	Nose, lung	Nickel plating; component of ferrous alloys, ceramics, and batteries; by-product of stainless-steel arc welding
Radon and its decay products	Lung	From decay of minerals containing uranium; potentially serious hazard in quarries and underground mines
Vinyl chloride	Angiosarcoma, liver	Refrigerant; monomer for vinyl polymers; adhesive for plastics; formerly inert aerosol propellant in pressurized containers

Modified from Stellman JM, Stellman SD: Cancer and workplace. CA Cancer J Clin 46:70, 1996.

AGE

Age has an important influence on the likelihood of being afflicted with cancer. Most carcinomas occur in the later years of life (>55 years). Cancer is the main cause of death among women aged 40 to 79 and among men aged 60 to 79; the decline in deaths after age 80 is due to the lower number of individuals who reach this age. The rising incidence with age may be explained by the accumulation of somatic mutations associated with the emergence of malignant neoplasms (discussed later). The decline in immune competence that accompanies aging may also be a factor.

However, children are not spared; cancer accounts for slightly more than 10% of all deaths in children under age 15 in the United States, second only to accidents. However, the types of cancers that predominate in children are significantly different from those seen in adults. Carcinomas, the most

common general category of tumor in adults, are extraordinarily rare among children. Instead, acute leukemia and primitive neoplasms of the central nervous system are responsible for approximately 60% of childhood cancer deaths. The common neoplasms of infancy and childhood include the so-called small round blue cell tumors such as neuroblastoma, Wilms tumor, retinoblastoma, acute leukemias, and rhabdomyosarcomas. These are discussed in Chapter 10 and elsewhere in the text.

GENETIC PREDISPOSITION TO CANCER

One frequently asked question is: "My mother and father both died of cancer. Does that mean I am doomed to get it?" Based on current knowledge, the answer must be carefully qualified.[19,][20] Evidence now indicates that for a large number of cancer types, including the most common forms, there exist not only environmental influences but also hereditary predispositions. For example, lung cancer is in most instances clearly related to cigarette smoking, yet mortality from lung cancer has been shown to be four times greater among nonsmoking relatives (parents and siblings) of lung cancer patients than among nonsmoking relatives of controls (the effects of second-hand smoke may confound some of these results). Less than 10% of cancer patients have inherited mutations that predispose to cancer, and the frequency is even lower (around 0.1%) for certain types of tumors. Despite the low frequency, the recognition of inherited predisposition to cancer has had a major impact on the understanding of cancer pathogenesis. Moreover, genes that are causally associated with cancers that have a strong hereditary component are generally also involved in the much more common sporadic forms of the same tumor. Genetic predisposition to cancer can be divided into three categories (Table 7-4).

TABLE 7-4 -- Examples of Inherited Predisposition to Cancer

INHERITED CANCER SYNDROMES (AUTOSOMAL DOMINANT)	
Gene	***Inherited Predisposition***
RB	Retinoblastoma
p53	Li-Fraumeni syndrome (various tumors)
p16/INK4A	Melanoma
APC	Familial adenomatous polyposis/colon cancer
NF1, *NF2*	Neurofibromatosis 1 and 2
BRCA1, *BRCA2*	Breast and ovarian tumors
MEN1, *RET*	Multiple endocrine neoplasia 1 and 2
MSH2, *MLH1*, *MSH6*	Hereditary nonpolyposis colon cancer
PTCH	Nevoid basal cell carcinoma syndrome
PTEN	Cowden syndrome (epithelial cancers)
LKB1	Peutz-Jegher syndrome (epithelial cancers)
VHL	Renal cell carcinomas
INHERITED AUTOSOMAL RECESSIVE SYNDROMES OF DEFECTIVE DNA REPAIR	
Xeroderma pigmentosum	
Ataxia-telangiectasia	
Bloom syndrome	
Fanconi anemia	
FAMILIAL CANCERS	
Familial clustering of cases, but role of inherited predisposition not clear for each individual	

INHERITED CANCER SYNDROMES (AUTOSOMAL DOMINANT)	
Gene	***Inherited Predisposition***
Breast cancer	
Ovarian cancer	
Pancreatic cancer	

Autosomal Dominant Inherited Cancer Syndromes.

Inherited cancer syndromes include several well-defined cancers in which inheritance of a single autosomal dominant mutant gene greatly increases the risk of developing a tumor. The inherited mutation is usually a point mutation occurring in a single allele of a tumor suppressor gene. The silencing of the second allele occurs in somatic cells, generally as a consequence of deletion or recombination. Childhood *retinoblastoma* is the most striking example in this category. Approximately 40% of retinoblastomas are inherited. Carriers of a mutant of the *RB tumor suppressor gene* have a 10,000-fold increased risk of developing retinoblastoma, usually bilateral. They also have a greatly increased risk of developing a second cancer, particularly osteosarcoma. Familial adenomatous polyposis is an autosomal dominant hereditary disorder caused by mutation of the adenomatous polyposis coli (*APC*) tumor suppressor gene. Other autosomal dominant cancer syndromes include Li-Fraumeni syndrome resulting from germ-line mutations of the *p53* gene; multiple endocrine neoplasia types 1 and 2 (MEN-1 and MEN-2) caused by mutation in the genes that encode the menin transcription factor and the RET tyrosine kinase, respectively; hereditary nonpolyposis colon cancer (HNPCC), a condition caused by inactivation of a DNA mismatch repair gene (also listed below among repair defects); and several others listed in Table 7-4 .

There are several features that characterize inherited cancer syndromes:

- In each syndrome, tumors tend to arise in specific sites and tissues, although they may involve more than one site. There is no increase in predisposition to cancers in general. For example, in MEN-2, thyroid, parathyroid, and adrenals are involved, while in MEN-1, the pituitary, parathyroid, and pancreas are involved. Patients with familial adenomatous polyposis develop innumerable polypoid adenomas of the colon, and virtually 100% of those affected develop a colonic adenocarcinoma by age 50. The one exception to this tumor specific tissue involvement is Li-Fraumeni syndrome.
- Tumors within this group are often associated with a specific marker phenotype. For example, there may be multiple benign tumors in the affected tissue, as occurs in familial polyposis of the colon and in MEN. Sometimes, there are abnormalities in tissue that are not the target of transformation (e.g., Lisch nodules and café-au-lait spots in neurofibromatosis type 1; see Chapter 27).

As in other autosomal dominant conditions, both incomplete penetrance and variable expressivity occur.

Defective DNA-Repair Syndromes.

Besides the dominantly inherited precancerous conditions, a group of cancer-predisposing conditions is collectively characterized by defects in DNA repair and resultant DNA instability. These conditions generally have an autosomal recessive pattern of inheritance. Included in this group are xeroderma pigmentosum, ataxia-telangiectasia, and Bloom syndrome, all rare diseases characterized by genetic instability resulting from defects in DNA-repair genes. Also included here is HNPCC, an autosomal dominant condition caused by inactivation of a DNA mismatch repair gene.[21] HNPCC is the most common cancer predisposition syndrome, increasing the susceptibility of cancer of the colon, the small intestine, endometrium, and ovary (Chapter 17).

Familial Cancers.

Besides the inherited syndromes of cancer susceptibility, cancer may occur at higher frequency in certain families without a clearly defined pattern of transmission. Virtually all the common types of cancers that occur sporadically have also been reported to occur in familial forms. Examples include carcinomas of colon, breast, ovary, and brain, as well as melanomas and lymphomas. *Features that characterize familial cancers include early age at onset, tumors arising in two or more close relatives of the index case, and sometimes, multiple or bilateral tumors*. Familial cancers are not associated with specific marker phenotypes. For example, in contrast to the familial adenomatous polyp syndrome, familial colonic cancers do not arise in preexisting benign polyps. The transmission pattern of familial cancers is not clear. In general, siblings have a risk between two and three times greater than unrelated individuals. Segregation analyses of large families usually show that predisposition to the tumors is dominant, but multifactorial inheritance cannot be easily ruled out. It is likely that familial susceptibility to cancer may depend on multiple low-penetrance alleles, each contributing to only a small increase in the risk of tumor development. Genome-wide association studies show great promise in identifying such alleles (Chapter 5).[22] It has been estimated that 10% to 20% of patients with breast or ovarian cancer have a first- or second-degree relative with one of these tumors. Although two breast cancer susceptibility genes, named *BRCA1* and *BRCA2*, have been identified, mutation of these genes occurs in no more than 3% of breast cancers.[20] A similar situation occurs in familial melanomas, in which a mutation of the *p16* tumor suppressor gene has been identified. However, mutation in this gene accounts for only about 20% of familial melanoma kindreds, suggesting that other factors are involved in the familial predisposition.[23]

Interactions between Genetic and Nongenetic Factors.

What can be said about the influence of heredity on the majority of malignant neoplasms? It could be argued that they are largely of environmental origin, but lack of family history does not preclude an inherited component. It is generally difficult to sort out the hereditary and acquired basis of a tumor, because these factors often interact closely. The interaction between genetic and nongenetic factors is particularly complex when tumor development depends on the action of multiple contributory genes. Even in tumors with a well-defined inherited component, the risk of developing the tumor can be greatly influenced by nongenetic factors. For instance, breast cancer risk in female carriers of *BRCA1* or *BRCA2* mutations is almost threefold higher for women born after 1940, as compared with the risks for women born before that year.[20] Furthermore, the genotype can significantly influence the likelihood of developing environmentally induced cancers. Inherited variations (polymorphisms) of enzymes that metabolize procarcinogens to their active carcinogenic forms (see “Initiation of Carcinogenesis”) can influence the susceptibility to cancer. Of interest in this regard are genes that encode the cytochrome P-450 enzymes. As discussed later under “Chemical Carcinogenesis,” polymorphism at one of the P-450 loci confers inherited susceptibility to lung cancers in cigarette smokers. More such associations are likely to be found.

NONHEREDITARY PREDISPOSING CONDITIONS

The only certain way of avoiding cancer is not to be born; to live is to incur the risk. Certain predisposing influences, such as environment, behaviors, and clinical conditions, can increase that risk, however. For example, regenerative, metaplastic, hyperplastic, and dysplastic proliferations are fertile soil for the origin of a malignant tumor, because cell replication is involved in neoplastic transformation. Indeed, proliferation may be required for neoplastic transformation in some settings, since it is proliferating cells that accumulate the genetic lesions required for carcinogenesis.

Chronic Inflammation and Cancer.

In 1863 Virchow proposed that *cancer develops at sites of chronic inflammation*, and the potential relationships between cancer and inflammation have been studied since then.[24] This is exemplified by

the increased risk of cancer in individuals affected by a variety of chronic inflammatory diseases of the gastrointestinal tract (Table 7-5). These include ulcerative colitis, *Helicobacter pylori* gastritis, viral hepatitis, and chronic pancreatitis. Although the precise mechanisms that link inflammation and cancer development have not been established, recent work has demonstrated that in the setting of unresolved chronic inflammation, as occurs in viral hepatitis or chronic gastritis, the immune response may become maladaptive, promoting tumorigenesis.[24] As with any cause of tissue injury, there is a compensatory proliferation of cells so as to repair the damage. This regenerative process is aided and abetted by a plethora of growth factors, cytokines, chemokines, and other bioactive substances produced by activated immune cells that promote cell survival, tissue remodeling, and angiogenesis. In some cases, chronic inflammation may increase the pool of tissue stem cells, which become subject to the effect of mutagens. These mediators also cause genomic stress and mutations; additionally the activated immune cells produce reactive oxygen species that are directly genotoxic. To add insult to injury, many of these mediators promote cell survival, even in the face of genomic damage. In the short term this can be adaptive; the organism must survive, and the damaged cells can be repaired or eliminated later. However, in chronic inflammation such behavior is maladaptive, since it allows the creation and fixation of such mutations, eventually leading to cancer. Whatever the precise mechanism, the link between chronic inflammation and cancer has practical implications. For instance, expression of the enzyme *cyclooxygenase-2 (COX-2)*, which brings about the conversion of arachidonic acid into prostaglandins (Chapter 2), is induced by inflammatory stimuli and is increased in colon cancers and other tumors.[25] The development of COX-2 inhibitors for cancer treatment is an active area of research.[26]

TABLE 7-5 -- Chronic Inflammatory States and Cancer

Pathologic Condition	Associated Neoplasm(s)	Etiologic Agent
Asbestosis, silicosis	Mesothelioma, lung carcinoma	Asbestos fibers, silica particles
Bronchitis	Lung carcinoma	Silica, asbestos, smoking (nitrosamines, peroxides)
Cystitis, bladder inflammation	Bladder carcinoma	Chronic indwelling urinary catheters
Gingivitis, lichen planus	Oral squamous cell carcinoma	
Inflammatory bowel disease	Colorectal carcinoma	
Lichen sclerosis	Vulvar squamous cell carcinoma	
Chronic pancreatitis	Pancreatic carcinoma	Alcoholism
Hereditary pancreatitis	Pancreatic carcinoma	Mutation in trypsinogen gene
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma	Gastric acids
Sialadenitis	Salivary gland carcinoma	
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma	
CANCERS ASSOCIATED WITH INFECTIOUS AGENTS		
Opisthorchis, cholangitis	Cholangiosarcoma, colon carcinoma	Liver flukes (*Opisthorchis viverrini*)
		Bile acids
Chronic cholecystitis	Gallbladder cancer	Bacteria, gallbladder stones
Gastritis/ulcers	Gastric adenocarcinoma, MALT	*Helicobacter pylori*
Hepatitis	Hepatocellular carcinoma	Hepatitis B and/or C virus
Mononucleosis	B-cell non-Hodgkin lymphoma and Hodgkin	Epstein-Barr virus

Pathologic Condition	Associated Neoplasm(s)	Etiologic Agent
	lymphoma	
AIDS	Non-Hodgkin lymphoma, squamous cell carcinoma, Kaposi sarcoma	Human immunodeficiency virus, human herpesvirus type 8
Osteomyelitis	Carcinoma in draining sinuses	Bacterial infection
Pelvic inflammatory disease, chronic cervicitis	Ovrian carcinoma, cervical/anal carcinoma	Gonorrhea, chlamydia, human papillomavirus
Chronic cystitis	Bladder, liver, rectal carcinoma	Schistosomiasis

Adapted from Tlsty TD, Coussens LM: Tumor stroma and regulation of cancer development. Ann Rev Pathol Mech Dis 1:119, 2006.

Precancerous Conditions.

Certain non-neoplastic disorders—*the chronic atrophic gastritis of pernicious anemia, solar keratosis of the skin, chronic ulcerative colitis, and leukoplakia of the oral cavity, vulva, and penis*—have such a well-defined association with cancer that they have been termed *precancerous conditions*. This designation is somewhat unfortunate, because in the great majority of these lesions no malignant neoplasm emerges. Nonetheless, the term persists because it calls attention to the increased risk. Certain forms of benign neoplasia also constitute precancerous conditions. The villous adenoma of the colon, as it increases in size, becomes malignant in up to 50% of cases. It might be asked: Is there not a risk with all benign neoplasms? Although some risk may be inherent, a large cumulative experience indicates that most benign neoplasms do not become cancerous. Nonetheless, numerous examples could be offered of cancers arising, albeit rarely, in benign tumors—for example, a leiomyosarcoma beginning in a leiomyoma, and carcinoma appearing in long-standing pleomorphic adenomas. Generalization is impossible, because each type of benign neoplasm is associated with a particular level of risk ranging from virtually never to frequently. Only follow-up studies of large series of each neoplasm can establish the level of risk, and always the question remains: Did the cancer arise from a nonmalignant cell in the benign tumor, or did the benign tumor contain, from the outset, a silent or indolent malignant focus?

2.7.4 Molecular Basis of Cancer

The literature on the molecular basis of cancer continues to proliferate at such a rapid pace that it is easy to get lost in the growing forest of information. We list some fundamental principles before delving into the details of the molecular basis of cancer.

- *Nonlethal genetic damage lies at the heart of carcinogenesis*. Such genetic damage (or mutation) may be acquired by the action of environmental agents, such as chemicals, radiation, or viruses, or it may be inherited in the germ line.[26] The term *environmental*, used in this context, involves any acquired defect caused by exogenous agents or endogenous products of cell metabolism. Not all mutations, however, are "environmentally" induced. Some may be spontaneous and stochastic, falling into the category of bad luck.
- *A tumor is formed by the clonal expansion of a single precursor cell that has incurred genetic damage (i.e., tumors are monoclonal)*. Clonality of tumors can be assessed in women who are heterozygous for polymorphic X-linked markers, such as the androgen receptor. The principle underlying such an analysis is illustrated in Figure 7-23 . The most commonly used method to determine tumor clonality involves the analysis of methylation patterns adjacent to the highly polymorphic locus of the human androgen receptor gene, *AR*.[27] The frequency of such polymorphisms in the general population is more than 90%, so it is easy to establish clonality by showing that all the cells in a tumor express the same allele. For tumors with acquired cytogenetic aberrations of any type (e.g., a translocation) their presence can be taken as evidence that the proliferation is clonal. Immunoglobulin receptor and T-cell receptor gene rearrangements serve as markers of clonality in B- and T-cell lymphomas, respectively.
- *Four classes of normal regulatory genes—the growth-promoting proto-oncogenes, the growth-inhibiting*

tumor suppressor genes, genes that regulate programmed cell death (apoptosis), and genes involved in DNA repair—are the principal targets of genetic damage. Mutant alleles of proto-oncogenes are considered dominant, because they transform cells despite the presence of a normal counterpart. In contrast, typically, both normal alleles of the tumor suppressor genes must be damaged before transformation can occur. However, there are exceptions to this rule; sometimes, loss of a single allele of a tumor suppressor gene reduces levels or activity of the protein enough that the brakes on cell proliferation and survival are released. Loss of gene function caused by damage to a single allele is called *haploinsufficiency*. Such a finding indicates that dosage of the gene is important, and that two copies are required for normal function.[28] Genes that regulate apoptosis may behave as proto-oncogenes or tumor suppressor genes. Mutations of DNA repair genes do not directly transform cells by affecting proliferation or apoptosis. Instead, DNA-repair genes affect cell proliferation or survival indirectly by influencing the ability of the organism to repair nonlethal damage in other genes, including proto-oncogenes, tumor suppressor genes, and genes that regulate apoptosis. A disability in the DNA-repair genes can predispose cells to widespread mutations in the genome and thus to neoplastic transformation. Cells with mutations in DNA repair genes are said to have developed a *mutator phenotype*.[29] Interestingly, a new class of regulatory molecules, called microRNAs (miRNAs), has recently been discovered (Chapter 5). Even though they do not encode proteins, different families of miRNAs have been shown to act as either oncogenes or tumor suppressors.[29,][30] They do so by affecting the translation of other genes as will be discussed later.

- *Carcinogenesis is a multistep process at both the phenotypic and the genetic levels, resulting from the accumulation of multiple mutations*.[31] As discussed earlier, malignant neoplasms have several phenotypic attributes, such as excessive growth, local invasiveness, and the ability to form distant metastases. Furthermore, it is well established that over a period of time many tumors become more aggressive and acquire greater malignant potential. This phenomenon is referred to as tumor progression and is not simply a function of an increase in tumor size. Careful clinical and experimental studies reveal that increasing malignancy is often acquired in an incremental fashion. At the molecular level, tumor progression and associated heterogeneity most likely result from multiple mutations that accumulate independently in different cells, generating subclones with varying abilities to grow, invade, metastasize, and resist (or respond to) therapy (Fig. 7-24). Some of the mutations may be lethal; others may spur cell growth by affecting additional proto-oncogenes or tumor suppressor genes. *Even though most malignant tumors are monoclonal in origin, by the time they become clinically evident their constituent cells are extremely heterogeneous*. During progression, tumor cells are subjected to immune and nonimmune selection pressures. For example, cells that are highly antigenic are destroyed by host defenses, whereas those with reduced growth factor requirements are positively selected. A growing tumor therefore tends to be enriched for subclones that “beat the odds” and are adept at survival, growth, invasion, and metastasis.

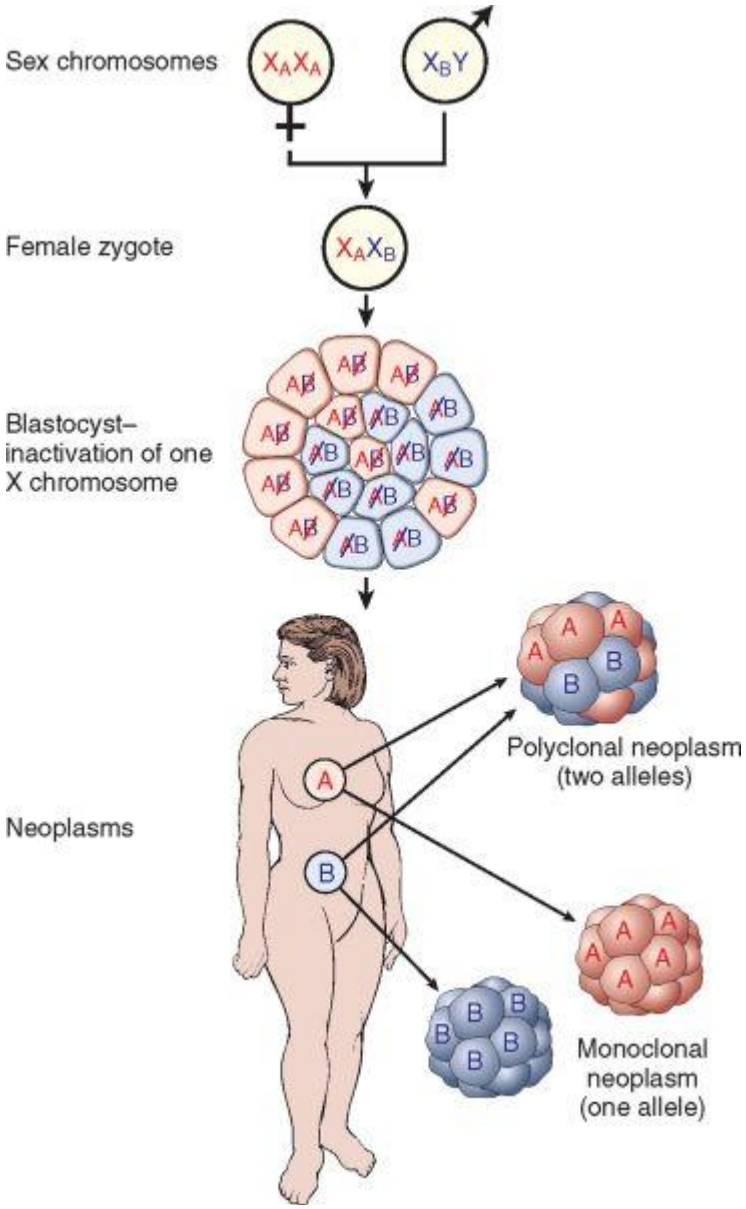

FIGURE 7-23 The use of X-linked markers as evidence of the monoclonality of neoplasms. Because of random X inactivation, all females are mosaics with two cell populations (with different alleles for the androgen receptor labeled A and B in this case). When neoplasms that arise in women who are heterozygous for X-linked markers are analyzed, they are made up of cells that contain the active maternal (X_A) or the paternal (X_B) X chromosome but not both.

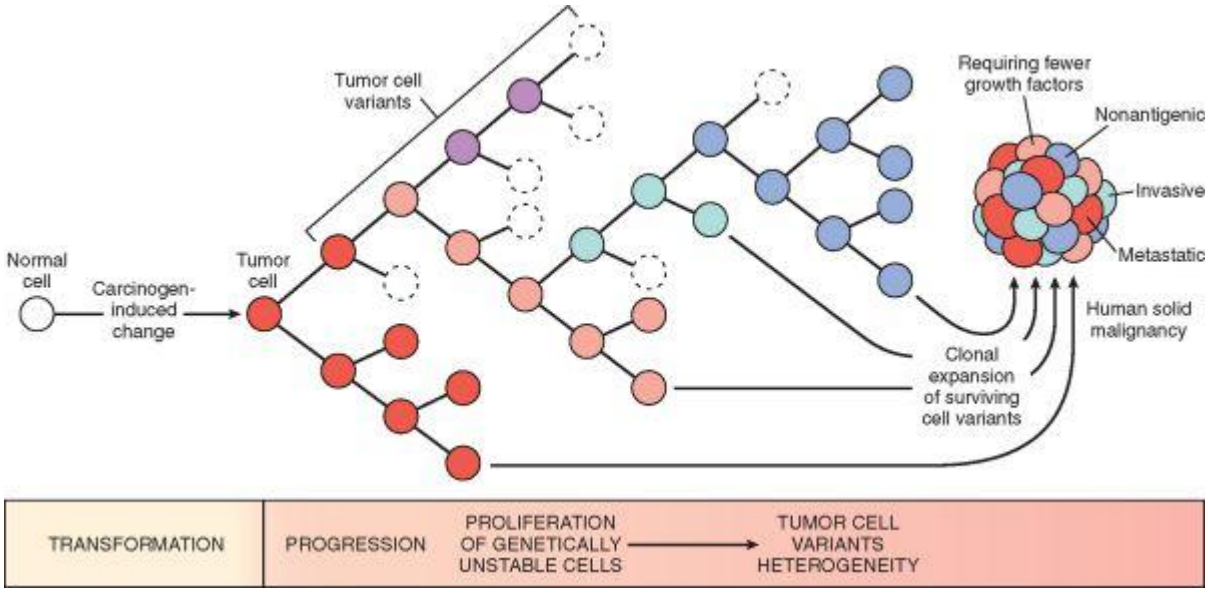

FIGURE 7-24 Tumor progression and generation of heterogeneity. New subclones arise from the descendants of the original transformed cell by multiple mutations. With progression the tumor mass becomes enriched for variants that are more adept at evading host defenses and are likely to be more aggressive.

ESSENTIAL ALTERATIONS FOR MALIGNANT TRANSFORMATION

With this overview we can now address in some detail the molecular pathogenesis of cancer and then discuss the carcinogenic agents that inflict genetic damage. Over the past two decades, hundreds of cancer-associated genes have been discovered. Some, such as *p53*, are mutated in many different cancers; others, such as *ABL1*, are affected only in one or few. Each of the cancer-associated genes has a specific function, the dysregulation of which contributes to the origin or progression of malignancy. It is traditional to describe cancer-associated genes on the basis of their presumed function. It is beneficial, however, to consider cancer-related genes in the context of *seven fundamental changes in cell physiology that together determine malignant phenotype*.[32] (Another important change for tumor development is *escape from immune attack.* This property is discussed later in this chapter.) The seven key changes are the following:

- *Self-sufficiency in growth signals*: Tumors have the capacity to proliferate without external stimuli, usually as a consequence of oncogene activation.
- *Insensitivity to growth-inhibitory signals*: Tumors may not respond to molecules that are inhibitory to the proliferation of normal cells such as transforming growth factor β (TGF-β) and direct inhibitors of cyclin-dependent kinases (CDKIs).
- *Evasion of apoptosis*: Tumors may be resistant to programmed cell death, as a consequence of inactivation of *p53* or activation of anti-apoptotic genes.
- *Limitless replicative potential*: Tumor cells have unrestricted proliferative capacity, avoiding cellular senescence and mitotic catastrophe.
- *Sustained angiogenesis*: Tumor cells, like normal cells, are not able to grow without formation of a vascular supply to bring nutrients and oxygen and remove waste products. Hence, tumors must induce angiogenesis.
- *Ability to invade and metastasize*: Tumor metastases are the cause of the vast majority of cancer deaths and depend on processes that are intrinsic to the cell or are initiated by signals from the tissue environment.
- *Defects in DNA repair*: Tumors may fail to repair DNA damage caused by carcinogens or incurred during

unregulated cellular proliferation, leading to genomic instability and mutations in proto-oncogenes and tumor suppressor genes.

Mutations in one or more genes that regulate these cellular traits are seen in every cancer. However, the precise genetic pathways that give rise to these attributes differ between individual cancers, even within the same organ. It is widely believed that the occurrence of mutations in cancer-related genes is conditioned by the robustness of the DNA-repair machinery, as well as protective mechanisms such as apoptosis and senescence that prevent the proliferation of cells with damaged DNA. Indeed, recent studies in a variety of human tumors, such as melanoma and prostate adenocarcinoma, have shown that oncogene-induced senescence, wherein mutation of a proto-oncogene drives cells into senescence rather than proliferation, is an important barrier to carcinogenesis.[33] Some limits to neoplastic growth are even physical. If a tumor is to grow larger than 1 to 2 mm, mechanisms that allow the delivery of nutrients and the elimination of waste products must be provided (angiogenesis). Furthermore, epithelia are separated from the interstitial matrix by a basement membrane, composed of extracellular matrix molecules, that must be broken down by invasive carcinoma cells. These protective barriers, both intrinsic and extrinsic to the cell, must be breached, and feedback loops that normally prevent uncontrolled cell division must be disabled by mutations before a fully malignant tumor can emerge. The main principles of the molecular basis of cancer are summarized in a simplified form in Figure 7-25 .

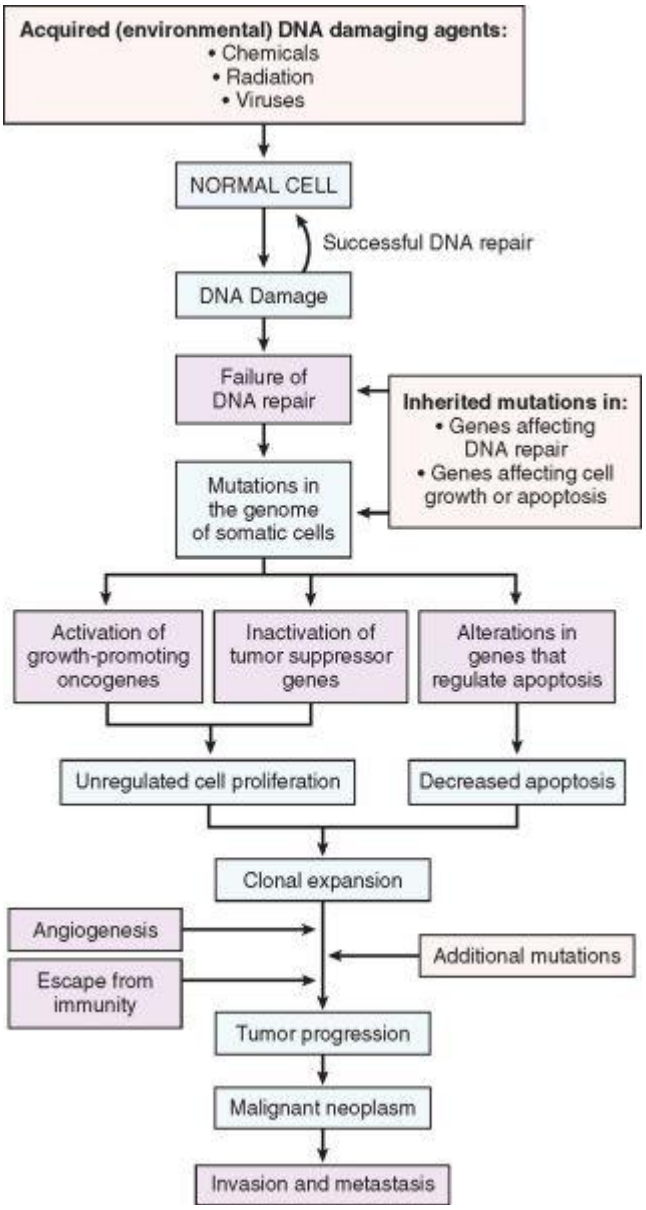

FIGURE 7-25 Flowchart depicting a simplified scheme of the molecular basis of cancer.

In the following sections we discuss the nature of the genes involved in each of the seven biologic alterations listed earlier. We end with a discussion of epigenetic changes and chromosomal abnormalities in cancer.

SELF-SUFFICIENCY IN GROWTH SIGNALS: ONCOGENES

Genes that promote autonomous cell growth in cancer cells are called *oncogenes*, and their unmutated cellular counterparts are called *proto-oncogenes*. Oncogenes are created by mutations in proto-oncogenes and are characterized by the ability to promote cell growth in the absence of normal growth-promoting signals. Their products, called *oncoproteins*, resemble the normal products of proto-oncogenes except that oncoproteins are often devoid of important internal regulatory elements, and their production in the transformed cells does not depend on growth factors or other external signals. In this

way cell growth becomes autonomous, freed from checkpoints and dependence upon external signals. To aid in the understanding of the nature and functions of oncoproteins and their role in cancer, it is necessary to briefly mention the sequential steps that characterize normal cell proliferation. Under physiologic conditions cell proliferation can be readily resolved into the following steps:

- The binding of a growth factor to its specific receptor
- Transient and limited activation of the growth factor receptor, which, in turn, activates several signal-transducing proteins on the inner leaflet of the plasma membrane
- Transmission of the transduced signal across the cytosol to the nucleus via second messengers or by a cascade of signal transduction molecules
- Induction and activation of nuclear regulatory factors that initiate DNA transcription
- Entry and progression of the cell into the cell cycle, ultimately resulting in cell division

With this background we can readily identify the strategies used by cancer cells to acquire self-sufficiency in growth signals. They can be grouped on the basis of their role in growth factor–mediated signal transduction cascades and cell cycle regulation.

Proto-oncogenes, Oncogenes, and Oncoproteins

Proto-oncogenes have multiple roles, participating in cellular functions related to growth and proliferation. Proteins encoded by proto-oncogenes may function as growth factors or their receptors, signal transducers, transcription factors, or cell cycle components. Oncoproteins encoded by oncogenes generally serve functions similar to their normal counterparts (Table 7-6). However, *mutations convert proto-oncogenes into constitutively active cellular oncogenes that are involved in tumor development because the oncoproteins they encode endow the cell with self-sufficiency in growth*.[34]

TABLE 7-6 -- Selected Oncogenes, Their Mode of Activation, and Associated Human Tumors

Category	Proto-oncogene	Mode of Activation	Associated Human Tumor
GROWTH FACTORS			
PDGF-β chain	*SIS* (official name *PBGFB*)	Overexpression	Astrocytoma
			Osteosarcoma
Fibroblast growth factors	*HST1*	Overexpression	Stomach cancer
	INT2 (official name *FGF3*)	Amplification	Bladder cancer
			Breast cancer
			Melanoma
TGF-α	*TGFA*	Overexpression	Astrocytomas
			Hepatocellular carcinomas
HGF	*HGF*	Overexpression	Thyroid cancer
GROWTH FACTOR RECEPTORS			
EGF-receptor family	*ERBB1* (*EGFR*), *ERRB2*	Overexpression	Squamous cell carcinoma of lung, gliomas
FMS-like tyrosine kinase 3	*FLT3*	Amplification	Breast and ovarian cancers
Receptor for neurotrophic factors	*RET*	Point mutation	Leukemia

Category	Proto-oncogene	Mode of Activation	Associated Human Tumor
		Point mutation	Multiple endocrine neoplasia 2A and B, familial medullary thyroid carcinomas
PDGF receptor	*PDGFRB*	Overexpression, translocation	Gliomas, leukemias
Receptor for stem cell (steel) factor	*KIT*	Point mutation	Gastrointestinal stromal tumors, seminomas, leukemias
PROTEINS INVOLVED IN SIGNAL TRANSDUCTION			
GTP-binding	*KRAS*	Point mutation	Colon, lung, and pancreatic tumors
	HRAS	Point mutation	Bladder and kidney tumors
	NRAS	Point mutation	Melanomas, hematologic malignancies
Nonreceptor tyrosine kinase	*ABL*	Translocation	Chronic myeloid leukemia
			Acute lymphoblastic leukemia
RAS signal transduction	*BRAF*	Point mutation	Melanomas
WNT signal transduction	β-catenin	Point mutation	Hepatoblastomas, hepatocellular carcinoma
		Overexpression	
NUCLEAR-REGULATORY PROTEINS			
Transcriptional activators	C-*MYC*	Translocation	Burkitt lymphoma
	N-*MYC*	Amplification	Neuroblastoma, small-cell carcinoma of lung
	L-*MYC*	Amplification	Small-cell carcinoma of lung
CELL CYCLE REGULATORS			
Cyclins	Cyclin D	Translocation	Mantle cell lymphoma
		Amplification	Breast and esophageal cancers
	Cyclin E	Overexpression	Breast cancer
Cyclin-dependent kinase	*CDK4*	Amplification or point mutation	Glioblastoma, melanoma, sarcoma

Two questions follow: (1) What are the functions of oncogene products, the oncoproteins? (2) How do the normally "civilized" proto-oncogenes turn into "enemies within"? These issues are discussed below.

Growth Factors.

Normal cells require stimulation by growth factors to undergo proliferation. Most soluble growth factors are made by one cell type and act on a neighboring cell to stimulate proliferation (paracrine action). Many cancer cells, however, acquire the ability to synthesize the same growth factors to which they are responsive, generating an autocrine loop. For example, many glioblastomas secrete platelet-derived growth factor (PDGF) and express the PDGF receptor, and many sarcomas make both transforming growth factor α (TGF-α) and its receptor. Although an autocrine loop is considered to be an important element in the pathogenesis of several tumors, in most instances the growth factor gene itself is not altered or mutated. More commonly, products of other oncogenes that lie along many signal transduction pathways, such as *RAS*, cause overexpression of growth factor genes, thus forcing the cells to secrete large amounts of growth factors, such as TGF-α. Nevertheless, increased growth factor production is not sufficient for neoplastic transformation. In all likelihood growth factor driven

proliferation contributes to the malignant phenotype by increasing the risk of spontaneous or induced mutations in the proliferating cell population.

Growth Factor Receptors.

Several oncogenes that encode growth factor receptors have been found. To understand how mutations affect the function of these receptors, it should be recalled that one important class of growth factor receptors are transmembrane proteins with an external ligand-binding domain and a cytoplasmic tyrosine kinase domain (Chapter 3). In the normal forms of these receptors, the kinase is *transiently* activated by binding of the specific growth factors, followed rapidly by receptor dimerization and tyrosine phosphorylation of several substrates that are a part of the signaling cascade. *The oncogenic versions of these receptors are associated with constitutive dimerization and activation without binding to the growth factor*. Hence, the mutant receptors deliver continuous mitogenic signals to the cell, even in the absence of growth factor in the environment.

Growth factor receptors can be constitutively activated in tumors by multiple different mechanisms, including mutations, gene rearrangements, and overexpression. The *RET* proto-oncogene, a receptor tyrosine kinase, exemplifies oncogenic conversion via mutations and gene rearrangements.[33] The RET protein is a receptor for the glial cell line–derived neurotrophic factor and structurally related proteins that promote cell survival during neural development. RET is normally expressed in neuroendocrine cells, such as parafollicular C cells of the thyroid, adrenal medulla, and parathyroid cell precursors. Point mutations in the *RET* proto-oncogene are associated with dominantly inherited MEN types 2A and 2B and familial medullary thyroid carcinoma (Chapter 24). In MEN-2A, point mutations in the *RET* extracellular domain cause constitutive dimerization and activation, leading to medullary thyroid carcinomas and adrenal and parathyroid tumors. In MEN-2B, point mutations in the *RET* cytoplasmic catalytic domain alter the substrate specificity of the tyrosine kinase and lead to thyroid and adrenal tumors without involvement of the parathyroid. In all these familial conditions, the affected individuals inherit the *RET* mutation in the germline. Sporadic medullary carcinomas of the thyroid are associated with somatic rearrangements of the *RET* gene, generally similar to those found in MEN-2B.[35,][36]

Oncogenic conversions by mutations and rearrangements have been found in other growth factor receptor genes. Point mutations in *FLT3*, the gene encoding the FMS-like tyrosine kinase 3 receptor, that lead to constitutive signaling have been detected in myeloid leukemias. In certain chronic myelomonocytic leukemias with the (5;12) translocation, the entire cytoplasmic domain of the PDGF receptor is fused with a segment of an ETS family transcription factor, resulting in permanent dimerization of the PDGF receptor. Greater than 90% of gastrointestinal stromal tumors have a constitutively activating mutation in the receptor tyrosine kinase c-KIT or PDGFR, which are the receptors for stem cell factor and PDGF, respectively. These mutations are amenable to specific inhibition by the tyrosine kinase inhibitor imatinib mesylate. This type of therapy, directed to a specific alteration in the cancer cell, is called *targeted therapy*.[37]

Far more common than mutations of these proto-oncogenes is overexpression of normal forms of growth factor receptors. In some tumors increased receptor expression results from gene amplification, but in many cases the molecular basis of increased receptor expression is not fully known. Two members of the epidermal growth factor (EGF) receptor family are the best described. The normal form of *ERBB1*, the EGF receptor gene, is overexpressed in up to 80% of squamous cell carcinomas of the lung, in 50% or more of *glioblastomas* (Chapter 28), and in 80% to 100% of head and neck tumors.[38,][39] Likewise, the *ERBB2* gene (also called *HER-2/NEU*), the second member of the EGF receptor family, is amplified in approximately 25% of breast cancers and in human adenocarcinomas arising within the ovary, lung, stomach, and salivary glands.[36] Because the molecular alteration in *ERBB2* is specific for the cancer cells, new therapeutic agents consisting of monoclonal antibodies

specific to *ERBB2* have been developed and are currently in use clinically, providing yet another example of targeted therapy.[38,][39]

Signal-Transducing Proteins.

Several examples of oncoproteins that mimic the function of normal cytoplasmic signal-transducing proteins have been found. Most such proteins are strategically located on the inner leaflet of the plasma membrane, where they receive signals from outside the cell (e.g., by activation of growth factor receptors) and transmit them to the cell's nucleus. Biochemically, the signal-transducing proteins are heterogeneous. *The most well-studied example of a signal-transducing oncoprotein is the RAS family of guanine triphosphate (GTP)-binding proteins (G proteins).*

The RAS Oncogene.

The *RAS* genes, of which there are three in the human genome (*HRAS*, *KRAS*, *NRAS*), were discovered initially in transforming retroviruses. *Point mutation of RAS family genes is the single most common abnormality of proto-oncogenes in human tumors*. Approximately 15% to 20% of all human tumors contain mutated versions of RAS proteins.[40] The frequency of such mutations varies with different tumors, but in some types of cancers it is very high. For example, 90% of pancreatic adenocarcinomas and cholangiocarcinomas contain a *RAS* point mutation, as do about 50% of colon, endometrial, and thyroid cancers and 30% of lung adenocarcinomas and myeloid leukemias.[41,][42] In general, carcinomas (particularly from colon and pancreas) have mutations of *KRAS*, bladder tumors have *HRAS* mutations, and hematopoietic tumors bear *NRAS* mutations. *RAS* mutations are infrequent in certain other cancers, such as those arising in the uterine cervix or breast.

RAS plays an important role in signaling cascades downstream of growth factor receptors, resulting in mitogenesis. For example, abrogation of RAS function blocks the proliferative response to EGF, PDGF, and CSF-1. Normal RAS proteins are tethered to the cytoplasmic aspect of the plasma membrane, as well as the endoplasmic reticulum and Golgi membranes. They can be activated by growth factor binding to receptors at the plasma membrane.[40] RAS is a member of a family of small G proteins that bind guanosine nucleotides (guanosine triphosphate, GTP and guanosine diphosphate, GDP), similar to the larger trimolecular G proteins. Normally RAS proteins flip back and forth between an excited signal-transmitting state and a quiescent state. In the inactive state, RAS proteins bind GDP. Stimulation of cells by growth factors leads to exchange of GDP for GTP and subsequent conformational changes that generates active RAS (Fig. 7-26). The activated RAS stimulates downstream regulators of proliferation, such as the *mitogen-activated protein (MAP) kinase cascade*, which floods the nucleus with signals for cell proliferation.

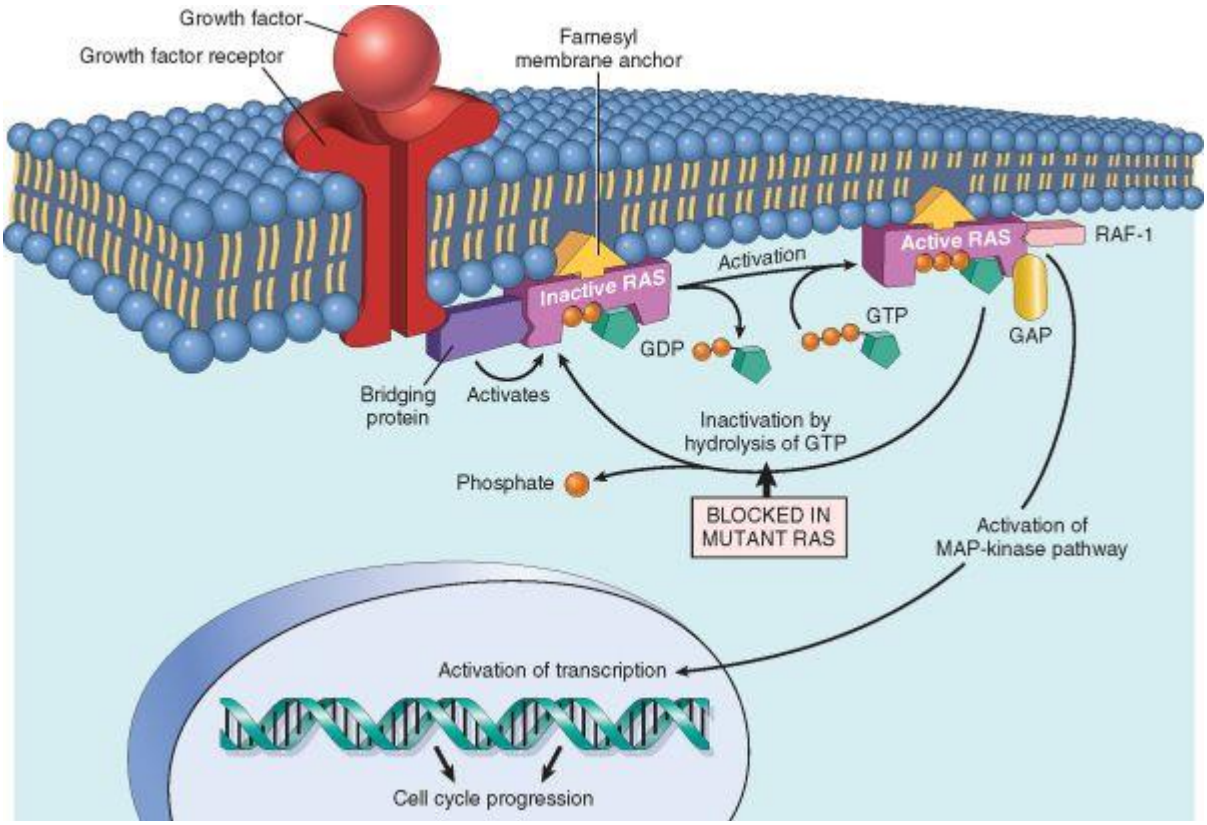

FIGURE 7-26 Model for action of *RAS* genes. When a normal cell is stimulated through a growth factor receptor, inactive (GDP-bound) RAS is activated to a GTP-bound state. Activated RAS recruits RAF and stimulates the MAP-kinase pathway to transmit growth-promoting signals to the nucleus. The mutated RAS protein is permanently activated because of inability to hydrolyze GTP, leading to continuous stimulation of cells without any external trigger. The anchoring of RAS to the cell membrane by the farnesyl moiety is essential for its action. See text for explanation of abbreviations.

The orderly cycling of the RAS protein depends on two reactions: (1) nucleotide exchange (GDP by GTP), which activates RAS protein, and (2) GTP hydrolysis, which converts the GTP-bound, active RAS to the GDP-bound, inactive form. Both these processes are extrinsically regulated by other proteins. The removal of GDP and its replacement by GTP during RAS activation are catalyzed by a family of guanine nucleotide–releasing proteins. Conversely, the GTPase activity intrinsic to normal RAS proteins is dramatically accelerated by *GTPase-activating proteins (GAPs)*. These widely distributed proteins bind to the active RAS and augment its GTPase activity by more than 1000-fold, leading to termination of signal transduction. Thus, GAPs function as "brakes" that prevent uncontrolled RAS activity.

Several distinct point mutations of *RAS* have been identified in cancer cells. The affected residues lie within either the GTP-binding pocket or the enzymatic region essential for GTP hydrolysis, and thus markedly reduce the GTPase activity of the RAS protein. Mutated RAS is trapped in its activated GTP-bound form, and the cell is forced into a continuously proliferating state. It follows from this scenario that the consequences of mutations in RAS protein would be mimicked by mutations in the GAPs that fail to activate the GTPase activity and thus restrain normal RAS proteins. Indeed, disabling mutation of neurofibromin 1, a GAP, is associated with the inherited cancer syndrome familial neurofibromatosis type 1 (Chapter 27).

In addition to RAS, downstream members of the RAS signaling cascade (RAS/RAF/MAP kinase) may also be altered in cancer cells, resulting in a similar phenotype. Thus, mutations in *BRAF*, one of the members of the *RAF* family, have been detected in more than 60% of melanomas and in more than 80% of benign nevi.[44,][45] This suggests that dysregulation of the RAS/RAF/MAP kinase pathway may be one of the initiating events in the development of melanomas, although it is not sufficient by itself to cause tumorigenesis. Indeed, *BRAF* mutations alone lead to oncogene-induced senescence giving rise to benign nevi rather than malignant melanoma. Thus, oncogene-induced senescence is a barrier to carcinogenesis that must be overcome by mutation and disabling of key protective mechanisms, such as those provided by the *p53* gene (discussed later).[33]

Because *RAS* is so frequently mutated in human cancers, much effort has been spent to develop anti-RAS modalities of targeted therapy. Unfortunately, none of these strategies has so far proven to be successful for clinical use.

Alterations in Nonreceptor Tyrosine Kinases

Mutations that unleash latent oncogenic activity occur in several non-receptor-associated tyrosine kinases, which normally function in signal transduction pathways that regulate cell growth (Chapter 3). As with receptor tyrosine kinases, in some instances the mutations take the form of chromosomal translocations or rearrangements that create fusion genes encoding constitutively active tyrosine kinases. An important example of this oncogenic mechanism involves the c-ABL tyrosine kinase. In CML and some acute lymphoblastic leukemias, the *ABL* gene is translocated from its normal abode on chromosome 9 to chromosome 22 (Fig. 7-27), where it fuses with the *BCR* gene (see discussion of chromosomal translocations, later in this chapter). The resultant chimeric gene encodes a constitutively active, oncogenic BCR-ABL tyrosine kinase. Several structural features of the BCR-ABL fusion protein contribute to the increased kinase activity, but the most important is that the BCR moiety promotes the self-association of BCR-ABL. This is a common theme, since many different oncogenic tyrosine kinases consist of fusion proteins in which the non–tyrosine kinase partner drives self-association.[46] Treatment of CML has been revolutionized by the development of imatinib mesylate, a “designer” drug with low toxicity and high therapeutic efficacy that inhibits the BCR-ABL kinase. [47] [48] [49] This is another example of rational drug design emerging from an understanding of the molecular basis of cancer. It is also an example of the concept of oncogene addiction.[50] Despite accumulation of numerous mutations throughout the genome, signaling through the BCR-ABL gene is required for the tumor to persist, hence inhibition of its activity is effective therapy. BCR-ABL translocation is an early, perhaps initiating event, during leukemogenesis. The remaining mutations are selected for, and built around, the constant signaling through BCR-ABL. BCR-ABL signaling can be seen as the central lodgepole around which the structure is built. Remove the lodgepole by inhibition of the BCR-ABL kinase, and the structure collapses.

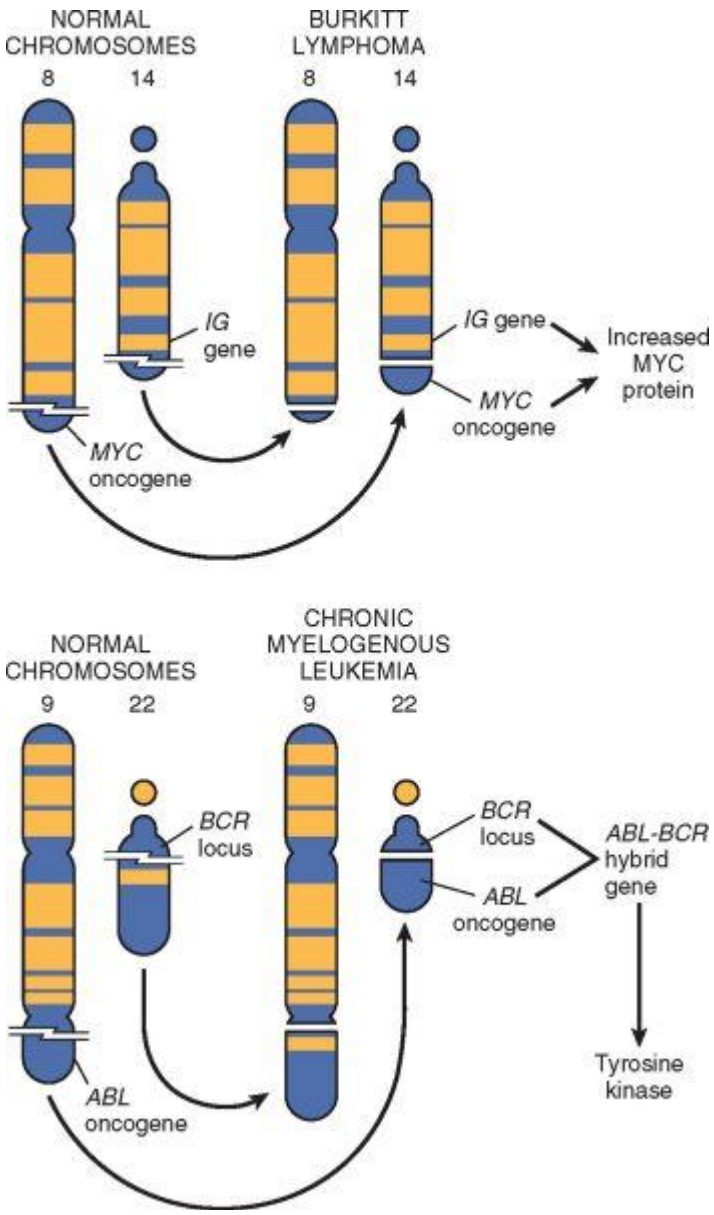

FIGURE 7-27 The chromosomal translocation and associated oncogenes in Burkitt lymphoma and chronic myelogenous leukemia.

In other instances, nonreceptor tyrosine kinases are activated by point mutations that abrogate the function of negative regulatory domains that normally hold enzyme activity in check. For example, several myeloproliferative disorders, particularly polycythemia vera and primary myelofibrosis, are highly associated with activating point mutations in the tyrosine kinase JAK2 (Chapter 13).[51] The aberrant JAK2 kinase in turn activates transcription factors of the STAT family, which promote the growth factor–independent proliferation and survival of the tumor cells. Recognition of this molecular lesion has led to trials of JAK2 inhibitors in myeloproliferative disorders, and stimulated searches for activating mutations in other nonreceptor tyrosine kinases in a wide variety of human cancers.

Transcription Factors.

Just as all roads lead to Rome, all signal transduction pathways converge to the nucleus, where a large bank of responder genes that orchestrate the cell's orderly advance through the mitotic cycle are activated. Indeed, the ultimate consequence of signaling through oncogenes like *RAS* or *ABL* is inappropriate and continuous stimulation of nuclear transcription factors that drive growth-promoting genes. Transcription factors contain specific amino acid sequences or motifs that allow them to bind DNA or to dimerize for DNA binding. Binding of these proteins to specific sequences in the genomic DNA activates transcription of genes. Growth autonomy may thus occur as a consequence of mutations affecting genes that regulate transcription. A host of oncoproteins, including products of the *MYC*, *MYB*, *JUN*, *FOS*, and *REL* oncogenes, are transcription factors that regulate the expression of growth-promoting genes, such as cyclins. *Of these, MYC is most commonly involved in human tumors*, and hence a brief overview of its function is warranted.

The MYC Oncogene.

The *MYC* proto-oncogene is expressed in virtually all eukaryotic cells and belongs to the immediate early response genes, which are rapidly induced when quiescent cells receive a signal to divide (see discussion of liver regeneration in Chapter 3). After a transient increase of *MYC* messenger RNA, the expression declines to a basal level. The molecular basis of MYC function in cell replication is not entirely clear. As with many transcription factors, it is thought that MYC is involved in carcinogenesis by activating genes that are involved in proliferation. Indeed, some of its target genes, such as ornithine decarboxylase and cyclin D2, are known to be associated with cell proliferation. However, the range of activities modulated by MYC is very broad and includes histone acetylation, reduced cell adhesion, increased cell motility, increased telomerase activity, increased protein synthesis, decreased proteinase activity, and other changes in cellular matbolism that enable a high rate of cell division.[52] Genomic mapping of MYC binding sites has identified thousands of different sites and an equivalent number of genes that might be regulated.[53] However, there is little overlap in the MYC target genes in different cancers, preventing identification of a canonical MYC carcinogenesis program. Interestingly, it has been recently suggested that MYC interacts with components of the DNA-replication machinery, and plays a role in the selection of origins of replication.[54] Thus, overexpression of MYC may drive activation of more origins than needed for normal cell division, or bypass checkpoints involved in replication, leading to genomic damage and accumulation of mutations. Finally, MYC is one of a handful of transcription factors that can act in concert to reprogram somatic cells into pluripotent stem cells (Chapter 3); MYC may also enhance self-renewal, block differentiation, or both.

While on one hand *MYC* activation is linked to proliferation, on the other hand, cells in culture undergo apoptosis if *MYC* activation occurs in the absence of survival signals (growth factors).[55] The *MYC* proto-oncogene contains separate domains that encode the growth-promoting and apoptotic activities, but it is not clear whether MYC-induced apoptosis occurs in vivo.

In contrast to the regulated expression of *MYC* during normal cell proliferation, persistent expression, and in some cases overexpression, of the MYC protein are commonly found in tumors. Dysregulation of *MYC* expression resulting from translocation of the gene occurs in Burkitt lymphoma, a B-cell tumor (see Fig. 7-27). *MYC* is amplified in some cases of breast, colon, lung, and many other carcinomas. The related N-*MYC* and L-*MYC* genes are amplified in neuroblastomas (Fig. 7-28) and small-cell cancers of the lung, respectively.

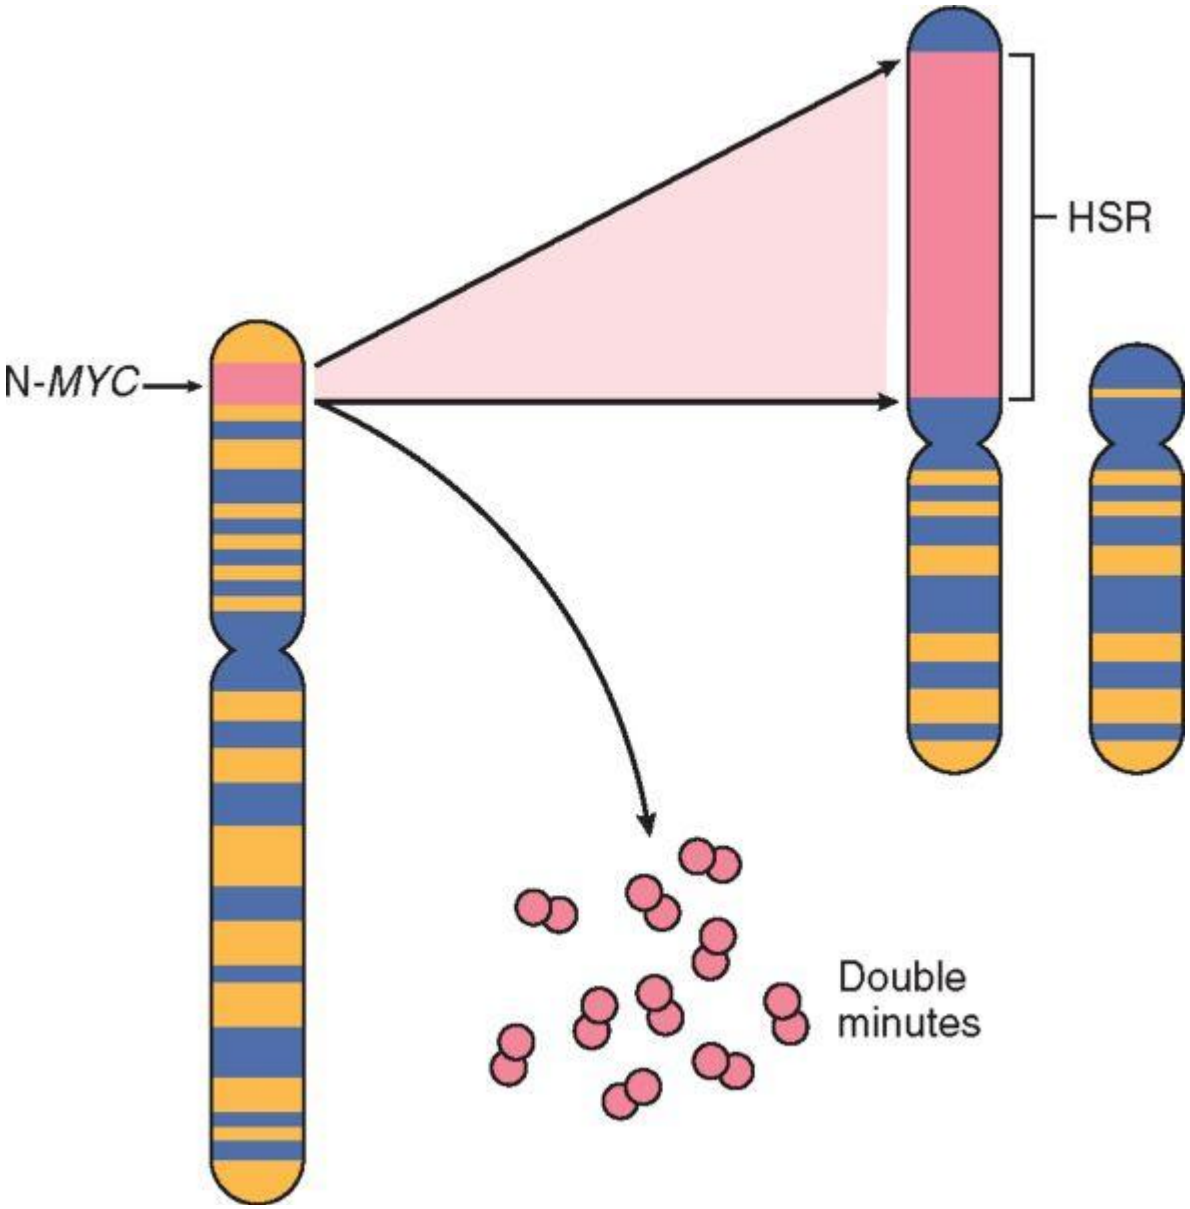

FIGURE 7-28 Amplification of the N-*MYC* gene in human neuroblastomas. The N-*MYC* gene, normally present on chromosome 2p, becomes amplified and is seen either as extra chromosomal double minutes or as a chromosomally integrated, homogeneous staining region (HSR). The integration involves other autosomes, such as 4, 9, or 13. *(Modified from Brodeur GM: Molecular correlates of cytogenetic abnormalities in human cancer cells: implications for oncogene activation. In Brown EB (ed): Progress in Hematology, Vol 14. Orlando, FL, Grune & Stratton, 1986, p 229–256.)*

Cyclins and Cyclin-Dependent Kinases.

The ultimate outcome of all growth-promoting stimuli is the entry of quiescent cells into the cell cycle. Cancers may grow autonomously if the genes that drive the cell cycle become dysregulated by mutations or amplification. As described in Chapter 3 , the orderly progression of cells through the various phases of the cell cycle is orchestrated by cyclin-dependent kinases (CDKs), which are activated by binding to *cyclins*, so called because of the cyclic nature of their production and degradation. The CDK-cyclin complexes phosphorylate crucial target proteins that drive the cell through the cell cycle. On completion of this task, cyclin levels decline rapidly. More than 15 cyclins have been identified;

cyclins D, E, A, and B appear sequentially during the cell cycle and bind to one or more CDK. The cell cycle may thus be seen as a relay race in which each lap is regulated by a distinct set of cyclins, and as one set of cyclins leaves the track, the next set takes over (Fig. 7-29 and Table 7-7).

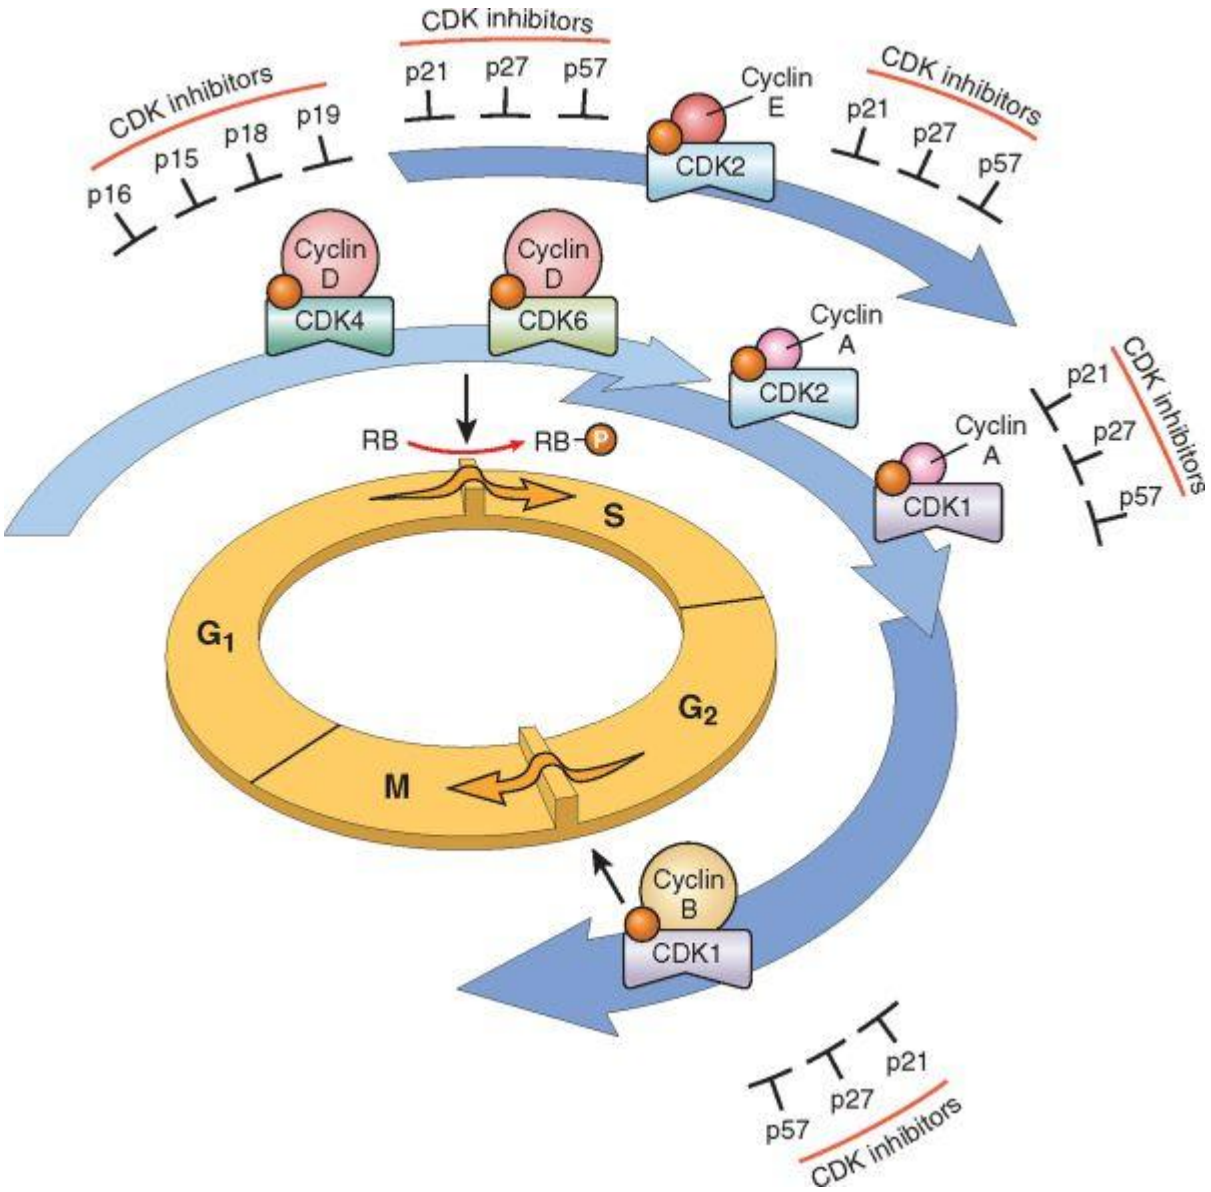

FIGURE 7-29 Schematic illustration of the role of cyclins, CDKs, and CDK inhibitors (CDKIs) in regulating the cell cycle. The shaded arrows represent the phases of the cell cycle during which specific cyclin-CDK complexes are active. As illustrated, cyclin D–CDK4, cyclin D–CDK6, and cyclin E–CDK2 regulate the G_1-to-S transition by phosphorylation of the RB protein (pRB). Cyclin A–CDK2 and cyclin A–CDK1 are active in the S phase. Cyclin B–CDK1 is essential for the G_2-to-M transition. Two families of CDKIs can block activity of CDKs and progression through the cell cycle. The so-called INK4 inhibitors, composed of p16, p15, p18, and p19, act on cyclin D–CDK4 and cyclin D–CDK6. The other family of three inhibitors, p21, p27, and p57, can inhibit all CDKs.

TABLE 7-7 -- Main Cell Cycle Components and Their Inhibitors

Cell Cycle Component	Main Function
CYCLIN-DEPENDENT KINASES	

Cell Cycle Component	Main Function
CDK4	Forms a complex with cyclin D that phosphorylates RB, allowing the cell to progress through the G_1 restriction point.
CDK2	Forms a complex with cyclin E in late G_1, which is involved in G_1/S transition. Forms a complex with cyclin A at the S phase that facilitates G_2/M transition.
CDK1	Forms a complex with cyclin B that facilitates G_2/M transition.
INHIBITORS	
CIP/KIP family: p21, p27 (CDKN2A-C)	Block the cell cycle by binding to cyclin-CDK complexes; p21 is induced by the tumor suppressor p53; p27 responds to growth suppressors such as TGF-β.
INK4/ARF family (CDKN1A-D)	p16/INK4a binds to cyclin D–CDK4 and promotes the inhibitory effects of RB; p14/ARF increases p53 levels by inhibiting MDM2 activity.
CHECKPOINT COMPONENTS	
p53	Tumor suppressor gene altered in the majority of cancers; causes cell cycle arrest and apoptosis. Acts mainly through p21 to cause cell cycle arrest. Causes apoptosis by inducing the transcription of pro-apoptotic genes such as *BAX*. Levels of p53 are negatively regulated by MDM2 through a feedback loop. p53 is required for the G_1/S checkpoint and is a main component of the G_2/M checkpoint.
Ataxia-telangiectasia mutated	Activated by mechanisms that sense double-stranded DNA breaks. Transmits signals to arrest the cell cycle after DNA damage. Acts through p53 in the G_1/S checkpoint. At the G_2/M checkpoint, it acts both through p53-dependent mechanisms and through the inactivation of CDC25 phosphatase, which disrupts the cyclin B–CDK1 complex. Component of a network of genes that include *BRCA1* and *BRCA2*, which link DNA damage with cell cycle arrest and apoptosis.

With this background it is easy to appreciate that mutations that dysregulate the activity of cyclins and CDKs favor cell proliferation. Mishaps affecting the expression of cyclin D or CDK4 seem to be a common event in neoplastic transformation. The cyclin D genes are overexpressed in many cancers, including those affecting the breast, esophagus, liver, and a subset of lymphomas. Amplification of the *CDK4* gene occurs in melanomas, sarcomas, and glioblastomas. Mutations affecting cyclin B and cyclin E and other CDKs also occur, but they are much less frequent.

While cyclins arouse the CDKs, their inhibitors (CDKIs), of which there are many, silence the CDKs and exert negative control over the cell cycle. The CIP/WAF family of CDKIs, composed of three proteins, called p21 (CDKN1A), p27 (CDKN1B), and p57 (CDKN1C), inhibits the CDKs broadly, whereas the INK4 family of CDK1s, made up of p15 (CDKN2B), p16 (CDKN2A), p18 (CDKN2C), and p19 (CDKN2D), has selective effects on cyclin D/CDK4 and cyclin D/CDK6. Expression of these inhibitors is down-regulated by mitogenic signaling pathways, thus promoting the progression of the cell cycle. For example, p27 (CDKN1B), a CDKI that inhibits cyclin E, is expressed throughout G_1. Mitogenic signals dampen the activity of p27 in a variety of ways, relieving inhibition of cyclin E-CDK2 and thus allowing the cell cycle to proceed.[56] The CDKIs are frequently mutated or otherwise silenced in many human malignancies. Germline mutations of *p16* (*CDKN2A*) are associated with 25% of melanoma-prone kindreds.[23] Somatically acquired deletion or inactivation of *p16* is seen in 75% of pancreatic carcinomas, 40% to 70% of glioblastomas, 50% of esophageal cancers, 20% to 70% of acute lymphoblastic leukemias, and 20% of non-small-cell lung carcinomas, soft-tissue sarcomas, and bladder cancers.[57]

Before closing this discussion of the cell cycle and its regulation, we should briefly discuss the internal controls of the cell cycle called *checkpoints*, since later discussion of tumor suppressor genes will

illustrate the importance of cell cycle checkpoints in maintaining genomic integrity. There are two main cell cycle checkpoints, one at the G_1/S transition and the other at G_2/M. The S phase is the point of no return in the cell cycle. Before a cell makes the final commitment to replicate, the G_1/S checkpoint checks for DNA damage; if damage is present, the DNA-repair machinery and mechanisms that arrest the cell cycle are put in motion. The delay in cell cycle progression provides the time needed for DNA repair; if the damage is not repairable, apoptotic pathways are activated to kill the cell. Thus, the G_1/S checkpoint prevents the replication of cells that have defects in DNA, which would be perpetuated as mutations or chromosomal breaks in the progeny of the cell. DNA damaged after its replication can still be repaired as long as the chromatids have not separated. The G_2/M checkpoint monitors the completion of DNA replication and checks whether the cell can safely initiate mitosis and separate sister chromatids. This checkpoint is particularly important in cells exposed to ionizing radiation. Cells damaged by ionizing radiation activate the G_2/M checkpoint and arrest in G_2; defects in this checkpoint give rise to chromosomal abnormalities. To function properly, cell cycle checkpoints require sensors of DNA damage, signal transducers, and effector molecules.[58] The sensors and transducers of DNA damage seem to be similar for the G_1/S and G_2/M checkpoints. They include, as sensors, proteins of the RAD family and ataxia telangiectasia mutated (ATM) and as transducers, the CHK kinase families.[59] The checkpoint effector molecules differ, depending on the cell cycle stage at which they act. In the G_1/S checkpoint, cell cycle arrest is mostly mediated through p53, which induces the cell cycle inhibitor p21. Arrest of the cell cycle by the G_2/M checkpoint involves both p53-dependent and p53-independent mechanisms. *Defects in cell cycle checkpoint components are a major cause of genetic instability in cancer cells*.

INSENSITIVITY TO GROWTH INHIBITION AND ESCAPE FROM SENESCENCE: TUMOR SUPPRESSOR GENES

Failure of growth inhibition is one of the fundamental alterations in the process of carcinogenesis. Whereas oncogenes drive the proliferation of cells, the products of *tumor suppressor genes apply brakes to cell proliferation* (Table 7-8). It has become apparent that the tumor suppressor proteins form a network of checkpoints that prevent uncontrolled growth. Many tumor suppressors, such as RB and p53, are part of a regulatory network that recognizes genotoxic stress from any source, and responds by shutting down proliferation. Indeed, expression of an oncogene in an otherwise completely normal cell leads to quiescence, or to permanent cell cycle arrest (oncogene-induced senescence), rather than uncontrolled proliferation. Ultimately, the growth-inhibitory pathways may prod the cells into apoptosis. Another set of tumor suppressors seem to be involved in cell differentiation, causing cells to enter a postmitotic, differentiated pool without replicative potential. Similar to mitogenic signals, growth-inhibitory, pro-differentiation signals originate outside the cell and use receptors, signal transducers, and nuclear transcription regulators to accomplish their effects; tumor suppressors form a portion of these networks.

TABLE 7-8 -- Selected Tumor Suppressor Genes Involved in Human Neoplasms

Subcellular Locations	Gene	Function	Tumors Associated with Somatic Mutations	Tumors Assocated with Inherited Mutations
Cell surface	TGF-β receptor	Growth inhibition	Carcinomas of colon	Unknown
	E-cadherin	Cell adhesion	Carcinoma of stomach	Familial gastric cancer
Inner aspect of plasma membrane	*NF1*	Inhibition of RAS signal transduction and of p21 cell cycle inhibitor	Neuroblastomas	Neurofibromatosis type 1 and sarcomas
Cytoskeleton	*NF2*	Cytoskeletal stability	Schwannomas and meningiomas	Neurofibromastosis type 2, acoustic schwannomas, and

Subcellular Locations	Gene	Function	Tumors Associated with Somatic Mutations	Tumors Assocated with Inherited Mutations
				meningiomas
Cytosol	*APC*/β-catenin	Inhibition of signal transduction	Carcinomas of stomach, colon, pancreas; melanoma	Familial adenomatous polyposis coli/colon cancer
	PTEN	PI3 kinase signal transduction	Endometrial and prostate cancers	Cowden syndrome
	SMAD2 and *SMAD4*	TGF-β signal transduction	Colon, pancreas tumors	Unknown
Nucleus	*RB1*	Regulation of cell cycle	Retinoblastoma; osteosarcoma carcinomas of breast, colon, lung	Retinoblastomas, osteosarcoma
	p53	Cell cycle arrest and apoptosis in response to DNA damage	Most human cancers	Li-Fraumeni syndrome; multiple carcinomas and sarcomas
	WT1	Nuclear transcription	Wilms' tumor	Wilms' tumor
	P16/INK4a	Regulation of cell cycle by inhibition of cyclindependent kinases	Pancreatic, breast, and esophageal cancers	Malignant melanoma
	BRCA1 and *BRCA2*	DNA repair	Unknown	Carcinomas of female breast and ovary; carcinomas of male breast

PI3 kinase, phosphatidylinositol 3-kinase.

In this section we describe tumor suppressor genes, their products, and possible mechanisms by which loss of their function contributes to unregulated cell growth. The protein products of tumor suppressor genes may function as transcription factors, cell cycle inhibitors, signal transduction molecules, cell surface receptors, and regulators of cellular responses to DNA damage. In the following section we discuss the functions of the most important tumor suppressor genes, and how their defects contribute to carcinogenesis.

We begin our discussion with *RB*, the first, and prototypic, tumor suppressor gene discovered. Like many discoveries in medicine, *RB* was discovered by studying a rare disease, in this case retinoblastoma. Approximately 60% of retinoblastomas are sporadic, and the remaining are familial, with the predisposition to develop the tumor being transmitted as an autosomal dominant trait. Patients with familial retinoblastoma are also at greatly increased risk of developing osteosarcoma and other soft-tissue sarcomas. To explain the inherited and sporadic occurrence of an apparently identical tumor, Knudson proposed his now canonical *"two-hit" hypothesis of oncogenesis*.[19,][60] In molecular terms, Knudson's hypothesis can be stated as follows (Fig. 7-30):

- Two mutations (hits), involving both alleles of *RB* at chromosome locus 13q14, are required to produce retinoblastoma. In some cases, the genetic damage is large enough to be visible in the form of a deletion of 13q14.
- In familial cases, children inherit one defective copy of the *RB* gene in the germ line (one hit); the other copy

is normal (Fig. 7-30). Retinoblastoma develops when the normal *RB* allele is mutated in retinoblasts as a result of spontaneous somatic mutation (second hit). Because only a single somatic mutation is required for loss of RB function in retinoblastoma families, familial retinoblastoma is inherited as an autosomal dominant trait.

- In sporadic cases both normal *RB* alleles must undergo somatic mutation in the same retinoblast (two hits). The end result is the same: a retinal cell that has completely lost *RB* function becomes cancerous.

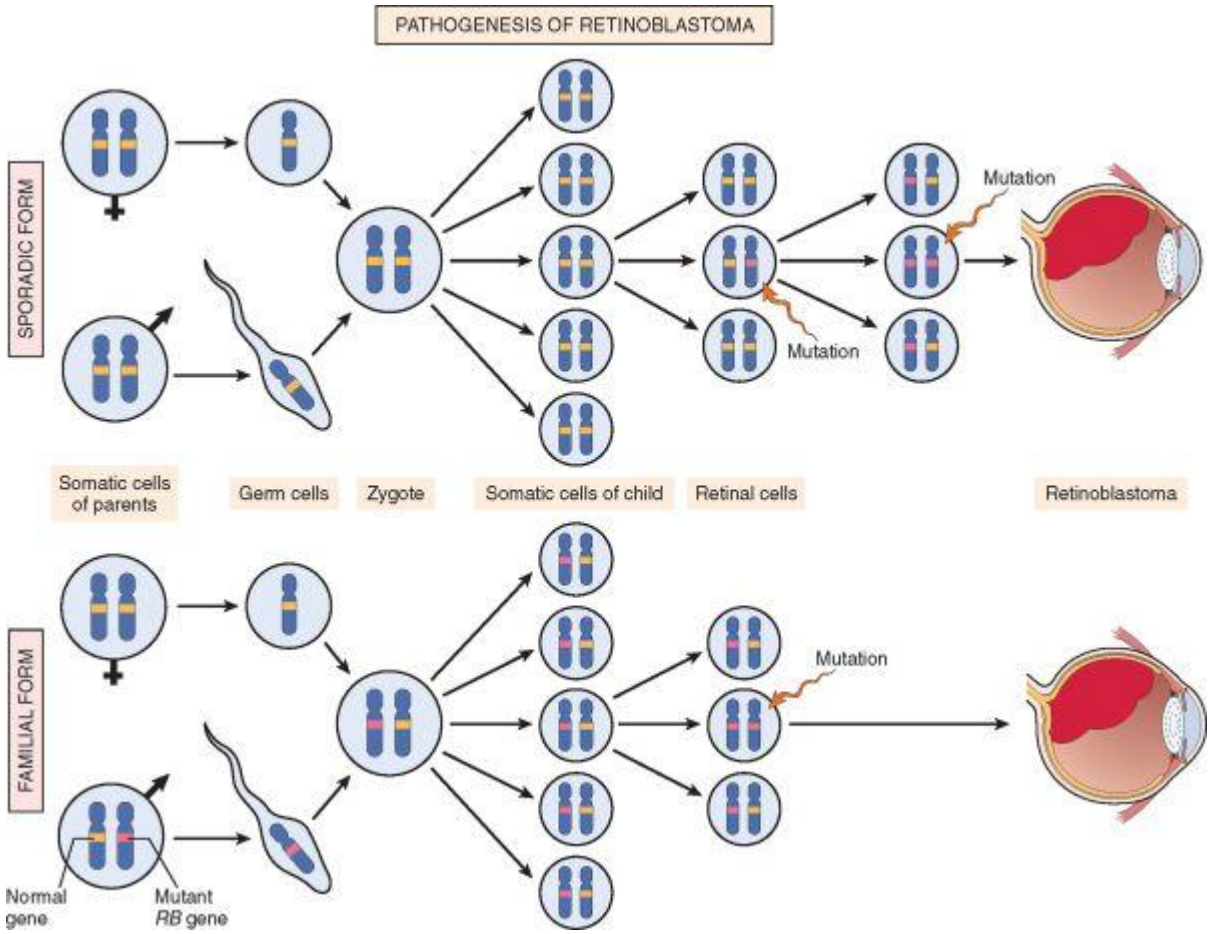

FIGURE 7-30 Pathogenesis of retinoblastoma. Two mutations of the *RB* locus on chromosome 13q14 lead to neoplastic proliferation of the retinal cells. In the sporadic form both mutations at the *RB* locus are acquired by the retinal cells after birth. In the familial form, all somatic cells inherit one mutant *RB* gene from a carrier parent. The second mutation affects the *RB* locus in one of the retinal cells after birth.

At this point we should clarify some terminology. A child carrying an inherited mutant *RB* allele in all somatic cells is perfectly normal (except for the increased risk of developing cancer). Because such a child is heterozygous at the *RB* locus, this implies that heterozygosity for the *RB* gene does not affect cell behavior. *Cancer develops when the cell becomes homozygous for the mutant allele or, put another way, when the cell loses heterozygosity for the normal RB gene (a condition known as LOH, for loss of heterozygosity).* The *RB* gene stands as a paradigm for several other genes that act similarly. For example, one or more genes on the short arm of chromosome 11 play a role in the formation of Wilms' tumor, hepatoblastoma, and rhabdomyosarcoma. The von Hippel-Lindau (*VHL*) gene is a tumor suppressor gene that causes familial clear cell renal carcinomas and is also involved in sporadic forms of the same tumor.[61] *Consistent and nonrandom LOH has provided important clues to the location of several tumor suppressor genes*.

RB.

RB protein, the product of the *RB* gene, is a ubiquitously expressed nuclear phosphoprotein that plays a key role in regulating the cell cycle. RB exists in an active hypophosphorylated state in quiescent cells and an inactive hyperphosphorylated state in the G_1/S cell cycle transition (Fig. 7-31). The importance of RB lies in its enforcement of G_1, or the gap between mitosis (M) and DNA replication (S). In embryos, cell divisions proceed at an amazing clip, with DNA replication beginning immediately after mitosis ends. However, as development proceeds, two gaps are incorporated into the cell cycle: Gap 1 (G_1) between mitosis (M) and DNA replication (S), and Gap 2 (G_2) between DNA replication (S) and mitosis (M) (see Fig. 7-29). Although each phase of the cell cycle circuitry is monitored carefully, the transition from G_1 to S is believed to be an extremely important checkpoint in the cell cycle clock. Once cells cross the G_1 checkpoint they can pause the cell cycle for a time, but they are obligated to complete mitosis. In G_1, however, cells can exit the cell cycle, either temporarily, called quiescence, or permanently, called senescence. In G_1, therefore, diverse signals are integrated to determine whether the cell should enter the cell cycle, exit the cell cycle and differentiate, or die. RB is a key node in this decision process. To understand why RB is such a crucial player, we must review the mechanisms that police the G_1 phase.[62]

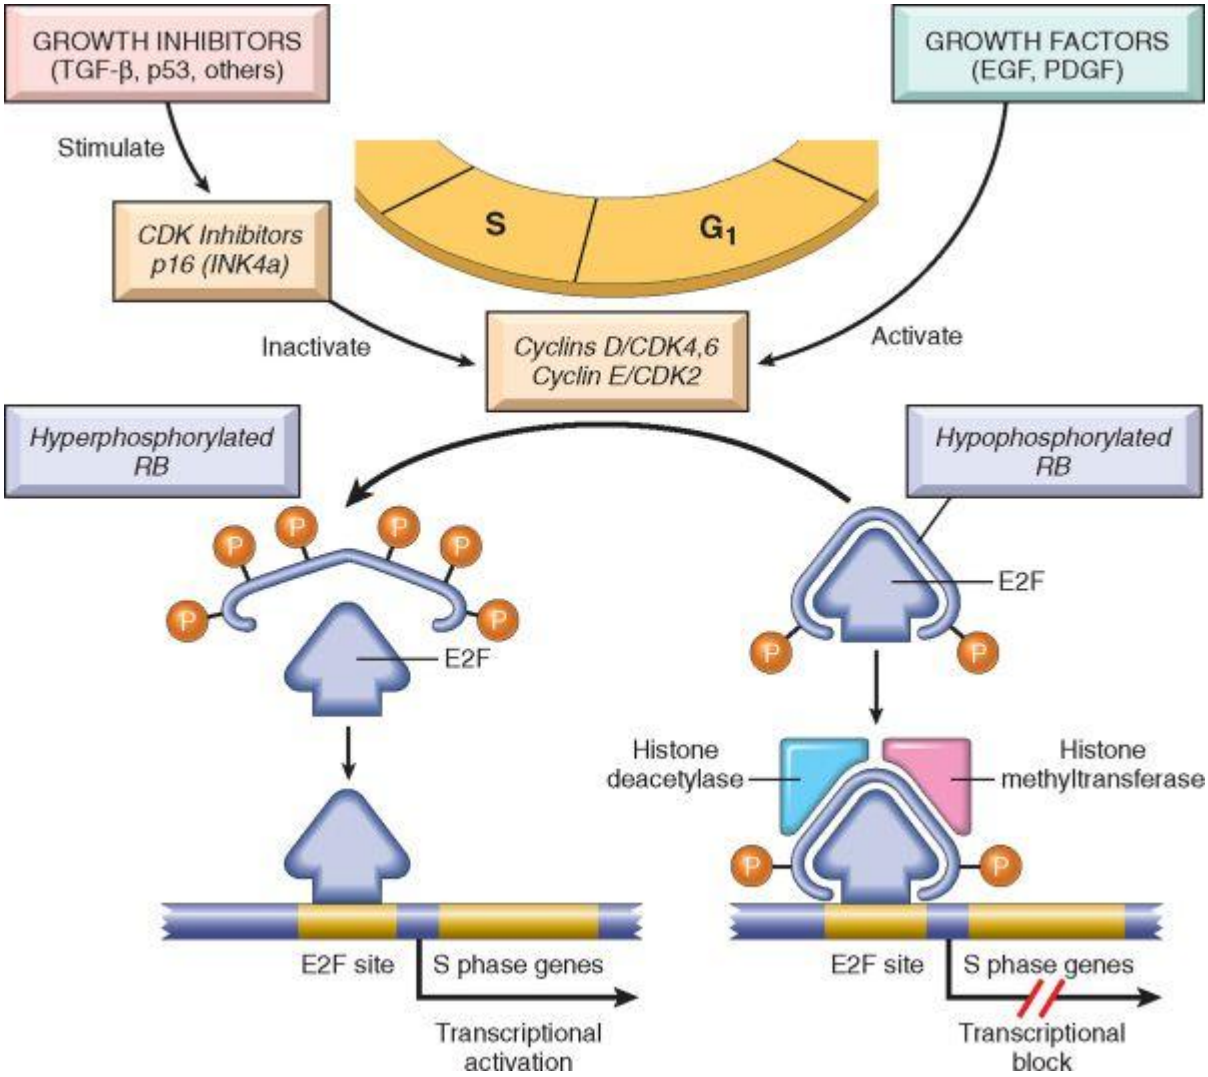

FIGURE 7-31 The role of RB in regulating the G_1-S checkpoint of the cell cycle. Hypophosphorylated RB in complex with the E2F transcription factors binds to DNA, recruits chromatin-remodeling factors (histone deacetylases and histone methyltransferases), and inhibits transcription of genes whose products are required for the S phase of the cell cycle. When RB is phosphorylated by the cyclin D–CDK4, cyclin

D–CDK6, and cyclin E–CDK2 complexes, it releases E2F. The latter then activates transcription of S-phase genes. The phosphorylation of RB is inhibited by CDKIs, because they inactivate cyclin-CDK complexes. Virtually all cancer cells show dysregulation of the G_1-S checkpoint as a result of mutation in one of four genes that regulate the phosphorylation of RB; these genes are *RB1*, *CDK4*, the genes encoding cyclin D proteins, and *CDKN2A* (p16). EGF, epidermal growth factor; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-beta.

The initiation of DNA replication requires the activity of cyclin E–CDK2 complexes, and expression of cyclin E is dependent on the E2F family of transcription factors. Early in G_1, RB is in its hypophosphorylated active form, and it binds to and inhibits the E2F family of transcription factors, preventing transcription of cyclin E. Hypophosphorylated RB blocks E2F-mediated transcription in at least two ways (see Fig. 7-31). First, it sequesters E2F, preventing it from interacting with other transcriptional activators. Second, RB recruits chromatin-remodeling proteins, such as histone deacetylases and histone methyltransferases, which bind to the promoters of E2F-responsive genes such as cyclin E. These enzymes modify chromatin so as to make promoters insensitive to transcription factors. Mitogenic signaling leads to cyclin D expression and activation of cyclin D–CDK4/6 complexes. These complexes phosphorylate RB, inactivating the protein and releasing E2F to induce target genes such as cyclin E. Expression of cyclin E then stimulates DNA replication and progression through the cell cycle. When the cells enter S phase, they are committed to divide without additional growth factor stimulation. During the ensuing M phase the phosphate groups are removed from RB by cellular phosphatases, regenerating the hypophosphorylated form of RB. E2Fs are not the sole effectors of Rb-mediated G_1 arrest. Rb also controls the stability of the cell cycle inhibitor p27.[63,][64]

If RB is absent (as a result of gene mutations) or its ability to regulate E2F transcription factors is derailed, the molecular brakes on the cell cycle are released, and the cells move through the cell cycle. The mutations of *RB* genes found in tumors are localized to a region of the RB protein, called the "RB pocket," that is involved in binding to E2F. However, the versatile RB protein has also been shown to bind to a variety of other transcription factors that regulate cell differentiation.[65] For example, RB stimulates myocyte-, adipocyte-, melanocyte-, and macrophage-specific transcription factors. Thus, the RB pathway couples control of cell cycle progression at G_1 with differentiation, which may explain how differentiation is associated with exit from the cell cycle. In addition to these dual activities, RB can also induce senescence, discussed below.

It was mentioned previously that germline loss or mutations of the *RB* gene predispose to occurrence of retinoblastomas and to a lesser extent osteosarcomas. Furthermore, somatically acquired RB mutations have been described in glioblastomas, small-cell carcinomas of lung, breast cancers, and bladder carcinomas. Given the presence of RB in every cell and its importance in cell cycle control, two questions arise: (1) Why do patients with germline mutation of the *RB* locus develop mainly retinoblastomas? (2) Why are inactivating mutations of *RB* not much more common in human cancers? The reason for the occurrence of tumors restricted to the retina in persons who inherit one defective allele of *RB* is not fully understood, but some possible explanations have emerged from the study of mice with targeted disruption of the *rb* locus. For instance, RB family members may partially complement its function in cell types other than retinoblasts. Indeed, RB is a member of a small family of proteins, so-called pocket proteins, which also include p107 and p130.[66] All three proteins bind to E2F transcription factors. The complexity grows; there are seven E2F proteins (named E2F1 through E2F7), which function as either transcriptional activators or repressors. The pocket proteins are all thought to regulate progression through the cell cycle as well as differentiation in a manner similar to that described for RB above. However, each member of this protein family binds a different set of E2F proteins and is also expressed at different times in the cell cycle. Thus, although there is some redundancy in the network, their functions are not completely overlapping. The complexity of the pocket protein–E2F network is just now being unraveled. For example, in a mouse model of

retinoblastoma, it has been shown that mutation of different members of the network in various combinations generates retinoblastomas not just from retinoblasts, but also from differentiated cells in the retina, such as horizontal interneurons.[67]

With respect to the second question (i.e., why the loss of *RB* is not more common in human tumors), the answer is much simpler: Mutations in other genes that control RB phosphorylation can mimic the effect of *RB* loss, and such genes are mutated in many cancers that may have normal *RB* genes. Thus, for example, mutational activation of cyclin D or CDK4 would favor cell proliferation by facilitating RB phosphorylation. As previously discussed, cyclin D is overexpressed in many tumors because of gene amplification or translocation. Mutational inactivation of CDKIs would also drive the cell cycle by unregulated activation of cyclins and CDKs. Thus, *the emerging paradigm is that loss of normal cell cycle control is central to malignant transformation and that at least one of four key regulators of the cell cycle (*p16/INK4a, cyclin D, CDK4, RB) *is dysregulated in the vast majority of human cancers*.[68] In cells that harbor mutations in any one of these other genes, the function of RB is disrupted even if the *RB* gene itself is not mutated.[34]

The transforming proteins of several oncogenic animal and human DNA viruses seem to act, in part, by neutralizing the growth-inhibitory activities of RB. In these cases, RB protein is functionally inactivated by the binding of a viral protein and no longer acts as a cell cycle inhibitor. Simian virus 40 and polyomavirus large T antigens, adenoviruses EIA protein, and HPV E7 protein all bind to the hypophosphorylated form of RB. The binding occurs in the same RB pocket that normally sequesters E2F transcription factors; in the case of HPV the binding is particularly strong for viral types, such as HPV type 16, that confer high risk for the development of cervical carcinomas. Thus, the RB protein, unable to bind the E2F transcription factors, is functionally inactivated, and the transcription factors are free to cause cell cycle progression.

Several other pathways of cell growth regulation, some to be discussed in more detail later, also converge on RB (see Fig. 7-31):

p53: Guardian of the Genome.

The *p53* gene is located on chromosome 17p13.1, and it is the most common target for genetic alteration in human tumors.[69] (The official name of the gene is *TP53* and the protein is p53; for the sake of simplicity, we refer to both as "p53".) *A little over 50% of human tumors contain mutations in this gene*. Homozygous loss of *p53* occurs in virtually every type of cancer, including carcinomas of the lung, colon, and breast—the three leading causes of cancer death. In most cases, the inactivating mutations affect both *p53* alleles and are acquired in somatic cells (not inherited in the germ line). Less commonly, some individuals inherit one mutant *p53* allele. As with the *RB* gene, inheritance of one mutant allele predisposes individuals to develop malignant tumors because only one additional "hit" is needed to inactivate the second, normal allele. Such individuals, said to have the *Li-Fraumeni syndrome*, have a 25-fold greater chance of developing a malignant tumor by age 50 than the general population.[70] In contrast to individuals who inherit a mutant *RB* allele, the spectrum of tumors that develop in persons with the Li-Fraumeni syndrome is quite varied; the most common types of tumors are sarcomas, breast cancer, leukemia, brain tumors, and carcinomas of the adrenal cortex. As compared with sporadic tumors, those that afflict patients with the Li-Fraumeni syndrome occur at a younger age, and a given individual may develop multiple primary tumors.[71]

The fact that *p53* mutations are common in a variety of human tumors suggests that the p53 protein functions as a critical gatekeeper against the formation of cancer. Indeed, it is evident that p53 acts as a "*molecular policeman*" that prevents the propagation of genetically damaged cells. p53 is a transcription factor that is at the center of a large network of signals that sense cellular stress, such as DNA damage, shortened telomeres, and hypoxia. Many activities of the p53 protein are related to its function as a

transcription factor. Several hundred genes have been shown to be regulated by p53 in numerous different contexts, but which genes are the key for the p53 response is not yet clear. Approximately 80% of the *p53* point mutations present in human cancers are located in the DNA-binding domain of the protein. However, the effects of different point mutations vary considerably; in some cases there is complete abrogation of transcriptional capabilities, whereas other mutants retain the ability to bind to and activate a subset of genes. In addition to somatic and inherited mutations, p53 functions can be inactivated by other mechanisms. As with RB, the transforming proteins of several DNA viruses, including the E6 protein of HPV, can bind to and promote the degradation of p53. Also, analagous to RB, it is thought that in the majority of tumors without a *p53* mutation, the function of the p53 pathway is blocked by mutation in another gene that regulates p53 function. For example, MDM2 and MDMX stimulate the degradation of p53; these proteins are frequently overexpressed in malignancies in which the gene encoding p53 is not mutated. Indeed, MDM2 is amplified in 33% of human sarcomas, thereby causing functional loss of p53 in these tumors.[72,][73]

p53 thwarts neoplastic transformation by three interlocking mechanisms: activation of temporary cell cycle arrest (quiescence), induction of permanent cell cycle arrest (senescence), or triggering of programmed cell death (apoptosis).

In nonstressed, healthy cells, p53 has a short half-life (20 minutes), because of its association with MDM2, a protein that targets it for destruction. When the cell is stressed, for example by an assault on its DNA, p53 undergoes post-transcriptional modifications that release it from MDM2 and increase its half-life. Unshackled from MDM2, p53 also becomes activated as a transcription factor. Hundreds of genes whose transcription is triggered by p53 have been found.[74,][75] They can be grouped into two broad categories: those that cause cell cycle arrest and those that cause apoptosis. If DNA damage can be repaired during cell cycle arrest, the cell reverts to a normal state; if the repair fails, p53 induces apoptosis or senescence. Recently, however, the plot has thickened. It has been known that repression of a subset of pro-proliferative and anti-apoptotic genes is key to the p53 response, but it was not clear how p53 achieved repression, since in most assays it seemed to be an activator of transcription. At this point enter the recently famous miRNAs, the small guys with big clubs. It has been shown that p53 activates transcription of the mir34 family of miRNAs (mir34a–mir34c).[76] miRNAs, as discussed in Chapter 5 , bind to cognate sequences in the 3′ untranslated region of mRNAs, preventing translation (Fig. 7-32B). Interestingly, blocking mir34 severely hampered the p53 response in cells, while ectopic expression of mir34 without p53 activation is sufficient to induce growth arrest and apoptosis. Thus, mir34 microRNAs are able to recapitulate many of the functions of p53 and are necessary for these functions, demonstrating the importance of mir34 to the p53 response. Targets of mir34s include pro-proliferative genes such as cyclins, and anti-apoptotic genes such as *BCL2*. p53 regulation of mir34 explains, at least in part, how p53 is able to repress gene expression, and it seems that regulation of this miRNA is crucial for the p53 response.

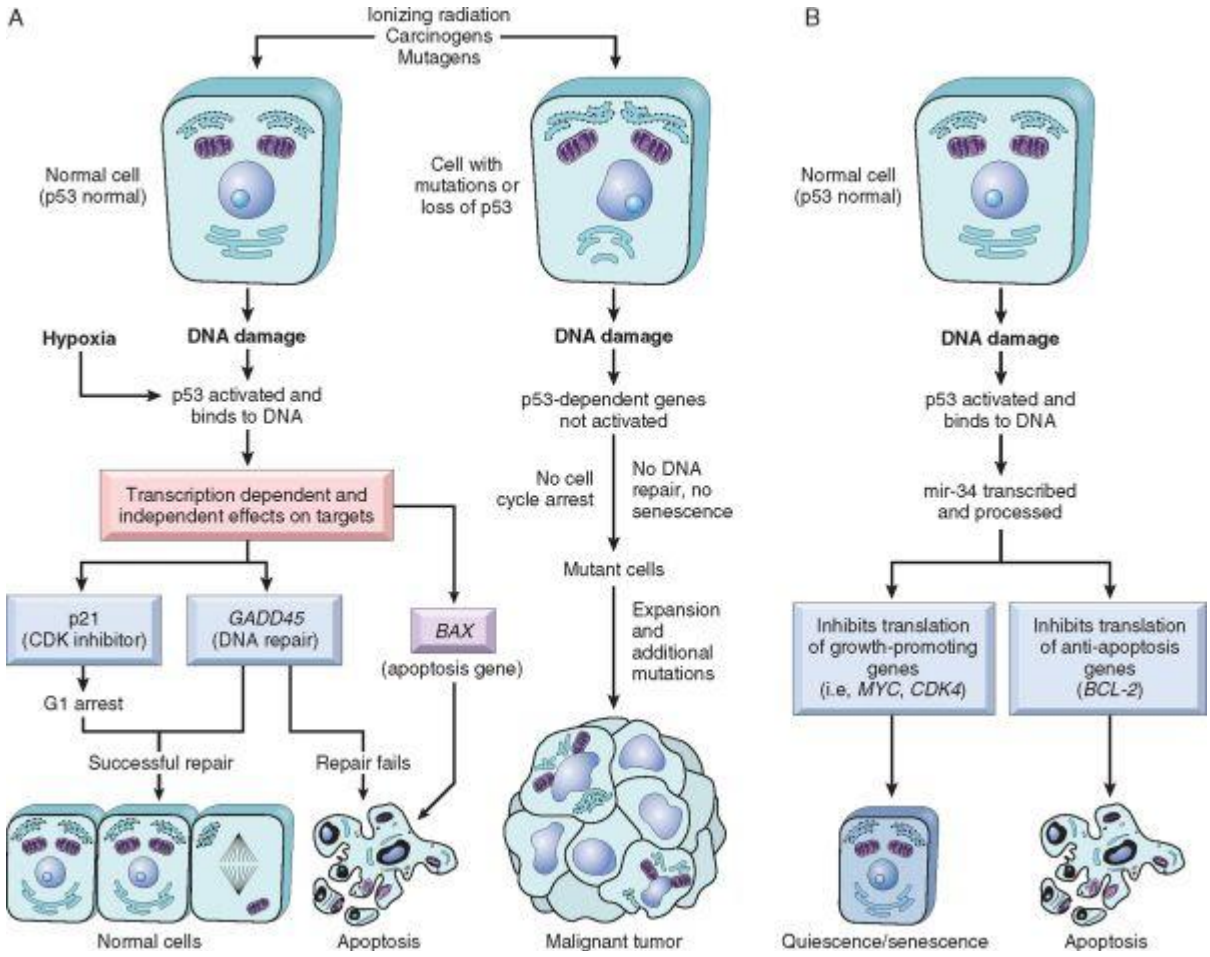

FIGURE 7-32 **A**, The role of *p53* in maintaining the integrity of the genome. Activation of normal *p53* by DNA-damaging agents or by hypoxia leads to cell cycle arrest in G_1 and induction of DNA repair, by transcriptional up-regulation of the cyclin-dependent kinase inhibitor *CDKN1A* (p21) and the *GADD45* genes. Successful repair of DNA allows cells to proceed with the cell cycle; if DNA repair fails, *p53* triggers either apoptosis or senescence. In cells with loss or mutations of *p53*, DNA damage does not induce cell cycle arrest or DNA repair, and genetically damaged cells proliferate, giving rise eventually to malignant neoplasms. **B**, p53 mediates gene repression by activating transcription of miRNAs. p53 activates transcription of the mir34 family of miRNAs. mir34s repress translation of both proliferative genes, such as cyclins, and anti-apoptotic genes, such as *BCL2*. Repression of these genes can promote either quiescence or senescence as well as apoptosis.

The manner in which p53 senses DNA damage and determines the adequacy of DNA repair is beginning to be understood. The key initiators of the DNA-damage pathway are two related protein kinases: *ataxia-telangiectasia mutated (ATM) and ataxia-telangiectasia and Rad3 related (ATR)*.[77,][78] As the name implies, the *ATM* gene was originally identified as the germ-line mutation in individuals with ataxia-telangiectasia. Persons with this disease, which is characterized by an inability to repair certain kinds of DNA damage, suffer from an increased incidence of cancer. The types of damage sensed by ATM and ATR are different, but the downstream pathways they activate are similar. Once triggered, both ATM and ATR phosphorylate a variety of targets, including p53 and DNA-repair proteins. Phosphorylation of these two targets leads to a pause in the cell cycle and stimulation of DNA-repair pathways, respectively.

p53-*mediated cell cycle arrest may be considered the primordial response to DNA damage* (Fig. 7-32). It occurs late in the G_1 phase and is caused mainly by p53-dependent transcription of the CDK inhibitor *CDKN1A* (*p21*). As discussed, p21 inhibits cyclin-CDK complexes and phosphorylation of RB, thereby

preventing cells from entering G_1 phase. Such a pause in cell cycling is welcome, because it gives the cells "breathing time" to repair DNA damage. p53 also helps the process by inducing certain proteins, such as GADD45 (growth arrest and DNA damage), that help in DNA repair.[75] p53 can stimulate DNA-repair pathways by transcription-independent mechanisms as well. If DNA damage is repaired successfully, p53 up-regulates transcription of MDM2, leading to its own destruction and thus releasing the cell cycle block. If the damage cannot be repaired, the cell may enter p53-induced senescence or undergo p53-directed apoptosis.

p53-induced senescence is a permanent cell cycle arrest characterized by specific changes in morphology and gene expression that differentiate it from quiescence or reversible cell cycle arrest. Senescence requires activation of p53 and/or RB and expression of their mediators, such as the CDK inhibitors, and is generally irreversible, although it may require the continued expression of p53. The mechanisms of senescence are unclear but involve epigenetic changes that result in the formation of heterochromatin at different loci throughout the genome.[80] These senescence-associated heterochromatin foci include pro-proliferative genes regulated by E2F; this drastically and permanently alters expression of these E2F targets. Like all p53 responses, senescence may be stimulated in response to a variety of stresses, such as unopposed oncogene signaling, hypoxia, and shortened telomeres.

p53-induced apoptosis of cells with irreversible DNA damage is the ultimate protective mechanism against neoplastic transformation. p53 directs the transcription of several pro-apoptotic genes such as *BAX* and *PUMA* (approved name *BBC3*; described later). Exactly how a cell decides whether to repair its DNA or to enter apoptosis is unclear. It appears that the affinity of p53 for the promoters and enhancers of DNA-repair genes is stronger than its affinity for pro-apoptotic genes.[80] Thus, the DNA-repair pathway is stimulated first, while p53 continues to accumulate. Eventually, if the DNA damage is not repaired, enough p53 accumulates to stimulate transcription of the pro-apoptotic genes and the cell dies. While this scheme is generally correct, there seem to be important cell type–specific responses as well, with some cell types succumbing to apoptosis early, while others opt for senescence.[80] Such differential responses may be related to the functions of other p53 family members expressed in different cell types (see below).

To summarize, p53 links cell damage with DNA repair, cell cycle arrest, and apoptosis. In response to DNA damage, p53 is phosphorylated by genes that sense the damage and are involved in DNA repair. p53 assists in DNA repair by causing G_1 arrest and inducing DNA-repair genes. A cell with damaged DNA that cannot be repaired is directed by p53 to undergo apoptosis (see Fig. 7-32 *). In view of these activities, p53 has been rightfully called a "guardian of the genome." With loss of function of p53, DNA damage goes unrepaired, mutations accumulate in dividing cells, and the cell marches along a one-way street leading to malignant transformation*.

The ability of p53 to control apoptosis in response to DNA damage has important practical therapeutic implications. Irradiation and chemotherapy, the two common modalities of cancer treatment, mediate their effects by inducing DNA damage and subsequent apoptosis. Tumors that retain normal p53 are more likely to respond to such therapy than tumors that carry mutated alleles of the gene. Such is the case with testicular teratocarcinomas and childhood acute lymphoblastic leukemias. By contrast, tumors such as lung cancers and colorectal cancers, which frequently carry *p53* mutations, are relatively resistant to chemotherapy and irradiation. Various therapeutic modalities aimed at increasing normal p53 activity in tumor cells that retain this type of activity or selectively killing cells with defective p53 function are being investigated.

The discovery of p53 family members p63 and p73 has revealed that p53 has collaborators. Indeed, p53, p63, and p73 are players in a complex network with significant cross-talk that is only beginning to be unraveled.[81,][82] p53 is ubiquitously expressed, while p63 and p73 show more tissue specificity. For

example, p63 is essential for the differentiation of stratified squamous epithelia, while p73 has strong pro-apoptotic effects after DNA damage induced by chemotheraputic agents. Furthermore, both p63 and p73, and probably p53 as well, are expressed as different isoforms, some of which act as transcriptional activators and others that function as dominant negatives. An illustrative example of the concerted actions of these three musketeers is seen in the so-called basal subset of breast cancers, which have a poor prognosis. These tumors have been shown to have mutations in *p53* and additionally express a dominant-negative version of p63 that antagonizes the apoptotic activity of p73. This perturbation of the p53p63-p73 network contributes to the chemoresistance and poor prognosis of these tumors.[83]

APC/β-Catenin Pathway.

Adenomatous polyposis coli genes (APC) represents a class of tumor suppressors whose main function is to down-regulate growth-promoting signals. Germ-line mutations at the *APC* (5q21) loci are associated with familial adenomatous polyposis, in which all individuals born with one mutant allele develop thousands of adenomatous polyps in the colon during their teens or 20s (familial adenomatous polyposis; Chapter 17). Almost invariably, one or more of these polyps undergoes malignant transformation, giving rise to colon cancer. As with other tumor suppressor genes, both copies of the *APC* gene must be lost for a tumor to arise. This conclusion is supported by the development of colon adenomas in mice with targeted disruption of *apc* genes in the colonic mucosa.[84] As discussed later, several additional mutations must occur if cancers are to develop in the adenomas. In addition to these tumors, which have a strong hereditary predisposition, 70% to 80% of nonfamilial colorectal carcinomas and sporadic adenomas also show homozygous loss of the *APC* gene, thus firmly implicating *APC* loss in the pathogenesis of colonic tumors.[85]

APC is a component of the WNT signaling pathway, which has a major role in controlling cell fate, adhesion, and cell polarity during embryonic development (Fig. 7-33). WNT signaling is also required for self-renewal of hematopoietic stem cells. WNT signals through a family of cell surface receptors called frizzled (FRZ), and stimulates several pathways, the central one involving β-catenin and APC.

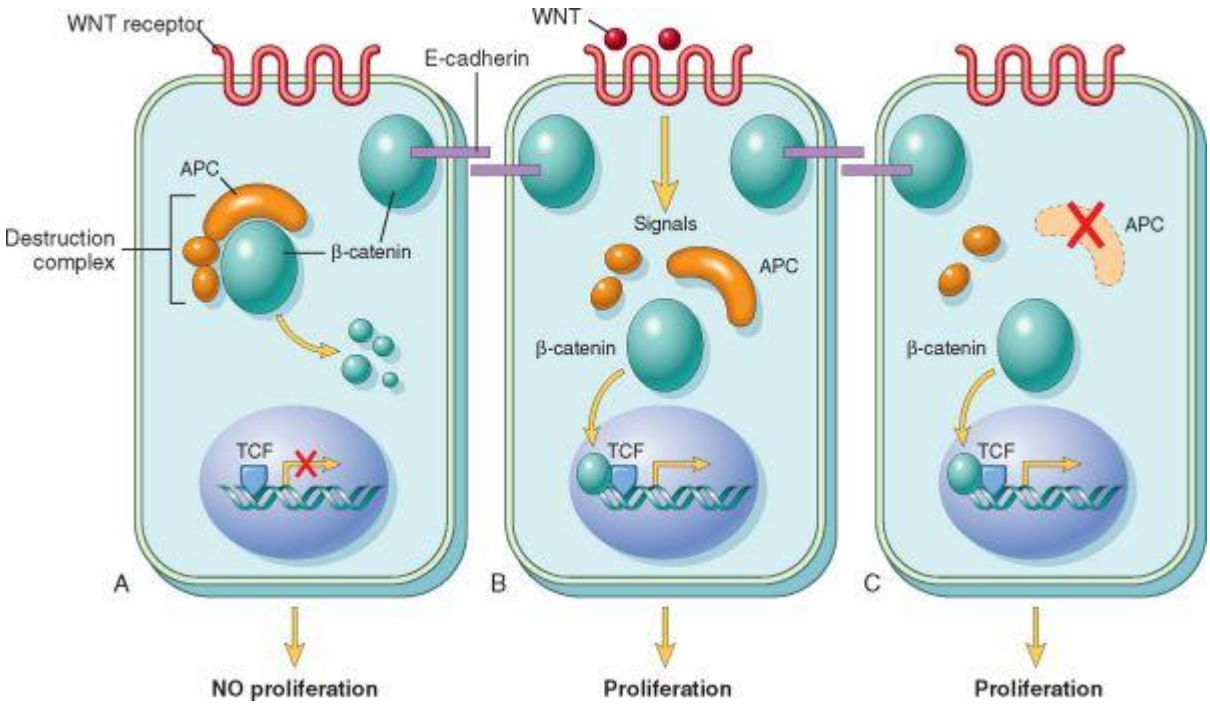

FIGURE 7-33 A, The role of APC in regulating the stability and function of β-catenin. APC and β-catenin are components of the WNT signaling pathway. In resting cells (not exposed to WNT), β-catenin forms a macromolecular complex containing the APC protein. This

complex leads to the destruction of β-catenin, and intracellular levels of β-catenin are low. **B**, When cells are stimulated by WNT molecules, the *destruction complex* is deactivated, β-catenin degradation does not occur, and cytoplasmic levels increase. β-catenin translocates to the nucleus, where it binds to TCF, a transcription factor that activates genes involved in cell cycle progression. **C**, When *APC* is mutated or absent, the destruction of β-catenin cannot occur. β-catenin translocates to the nucleus and coactivates genes that promote entry into the cell cycle, and cells behave as if they are under constant stimulation by the WNT pathway.

An important function of the APC protein is to down-regulate β-catenin. In the absence of WNT signaling APC causes degradation of β-catenin, preventing its accumulation in the cytoplasm.[85] It does so by forming a macromolecular complex with β-catenin, axin, and GSK3β, which leads to the phosphorylation and eventually ubiquitination of β-catenin and destruction by the proteasome. Signaling by WNT blocks the APC-AXIN-GSK3β destruction complex, allowing β-catenin to translocate from the cytoplasm to the nucleus. In the cell nucleus, β-catenin forms a complex with TCF, a transcription factor that up-regulates cellular proliferation by increasing the transcription of c-*MYC*, *cyclin D1*, and other genes. Since inactivation of the *APC* gene disrupts the destruction complex, β-catenin survives and translocates to the nucleus, where it can activate transcription in cooperation with TCF.[85] Thus, cells with loss of APC behave as if they are under continuous WNT signaling. The importance of the APC/β-catenin signaling pathway in tumorigenesis is attested to by the fact that colon tumors that have normal *APC* genes harbor mutations in β-catenin that prevent its destruction by APC, allowing the mutant protein to accumulate in the nucleus. Dysregulation of the APC/β-catenin pathway is not restricted to colon cancers; mutations in the β-catenin gene are present in more than 50% of hepatoblastomas and in approximately 20% of hepatocellular carcinomas.[86] As mentioned in Chapter 3 , β-catenin binds to the cytoplasmic tail of E-cadherin, a cell surface protein that maintains intercellular adhesiveness. Loss of cell-cell contact, such as in a wound or injury to the epithelium, disrupts the interaction between E-cadherin and β-catenin, and allows β-catenin to travel to the nucleus and stimulate proliferation; this is an appropriate response to injury that can help repair the wound. Re-establishment of these E-cadherin contacts as the wound heals leads to β-catenin again being sequestered at the membrane and reduction in the proliferative signal; these cells are said to be "contact-inhibited." Loss of contact inhibition, by mutation of the E-cadherin/β-catenin axis, or by other methods, is a key characteristic of carcinomas. Furthermore, loss of cadherins can favor the malignant phenotype by allowing easy disaggregation of cells, which can then invade locally or metastasize. Reduced cell surface expression of E-cadherin has been noted in many types of cancers, including those that arise in the esophagus, colon, breast, ovary, and prostate.[87] Germline mutations of the E-cadherin gene can predispose to familial gastric carcinoma, and mutation of the gene and decreased E-cadherin expression are present in a variable proportion of gastric cancers of the diffuse type. The molecular basis of reduced E-cadherin expression is varied. In a small proportion of cases, there are mutations in the E-cadherin gene (located on 16q); in other cancers, E-cadherin expression is reduced as a secondary effect of mutations in β-catenin genes. Additionally, E-cadherin may be down-regulated by transcription repressors, such as SNAIL, which have been implicated in epithelial-to-mesenchymal transition and metastasis[88] (discussed below).

Other Genes That Function as Tumor Suppressors.

There is little doubt that many more tumor suppressor genes remain to be discovered. Often, their location is suspected by the detection of consistent sites of *chromosomal deletions* or by analysis of *LOH*. Some of the tumor suppressor genes that are associated with well-defined clinical syndromes are briefly described below (see Table 7-8):

INK4a/ARF.

Also called the *CDKN2A* gene locus, the *INK4a/ARF* locus encodes two protein products; the p16/INK4a CDKI, which blocks cyclin D/CDK2-mediated phosphorylation of RB, keeping the RB checkpoint in place. The second gene product, p14/ARF, activates the p53 pathway by inhibiting MDM2 and preventing destruction of p53. Both protein products function as tumor suppressors, and thus mutation or silencing of this locus impacts both the RB and p53 pathways. p16 in particular is crucial for the induction of senescence. Mutations at this locus have been detected in bladder, head and neck tumors, acute lymphoblastic leukemias, and cholangiocarcinomas. In some tumors, such as cervical cancer, p16/INK4a is frequently silenced by hypermethylation of the gene, without the presence of a mutation (see discussion of epigenetic changes). The other CDKIs also function as tumor suppressors and are frequently mutated or otherwise silenced in many human malignancies, including 20% of familial melanomas, 50% of sporadic pancreatic adenocarcinomas, and squamous cell carcinomas of the esophagus.

The TGF-β Pathway.

In most normal epithelial, endothelial, and hematopoietic cells, TGF-β is a potent inhibitor of proliferation. It regulates cellular processes by binding to a serine-threonine kinase complex composed of TGF-β receptors I and II. Dimerization of the receptor upon ligand binding leads to activation of the kinase and phosphorylation of receptor SMADs (R-SMADs). Upon phosphorylation, R-SMADs can enter the nucleus, bind to SMAD-4, and activate transcription of genes, including the CDKIs p21 and p15/INK4b. In addition, TGF-β signaling leads to repression of c-MYC, CDK2, CDK4, and cyclins A and E. As can be inferred from our earlier discussion, these changes result in decreased phosphorylation of RB and cell cycle arrest.

In many forms of cancer the growth-inhibiting effects of TGF-β pathways are impaired by mutations in the TGF-β signaling pathway. These mutations may affect the type II TGF-β receptor or interfere with SMAD molecules that serve to transduce antiproliferative signals from the receptor to the nucleus. Mutations affecting the type II receptor are seen in cancers of the colon, stomach, and endometrium. Mutational inactivation of SMAD4 is common in pancreatic cancers. *In 100% of pancreatic cancers and 83% of colon cancers, at least one component of the TGF*-β *pathway is mutated*. However, in many cancers, loss of TGF-β-mediated growth inhibition occurs at a level downstream of the core signaling pathway, for example, loss of p21 and/or persistent expression of c-Myc. These tumor cells can then use other elements of the TGFβ–induced program, including immune system suppression/evasion or promotion of angiogenesis, to facilitate tumor progression.[89] Thus TGF-β can function to prevent or promote tumor growth, depending on the state of other genes in the cell.

PTEN.

PTEN (*P*hosphatase and *ten*sin homologue) is a membrane-associated phosphatase encoded by a gene on chromosome 10q23 that is mutated in Cowden syndrome, an autosomal dominant disorder marked by frequent benign growths, such as tumors of the skin appendages, and an increased incidence of epithelial cancers, particularly of the breast (Chapter 23), endometrium, and thyroid. PTEN acts as a tumor suppressor by serving as a brake on the pro-survival/pro-growth PI3K/AKT pathway.[90,][91] As you will recall from Chapter 3 , this pathway is normally stimulated (along with the RAS and JAK/STAT pathways) when ligands bind to receptor tyrosine kinases and involves a cascade of phosphorylation events. First, PI3K (phosphoinositide 3-kinase) phosphorylates the lipid inositide-3-phosphate to give rise to inositide-3,4,5-triphosphate, which binds and activates the kinase PDK1. PDK1 and other factors in turn phosphorylate and activate the serine/threonine kinase AKT, which is a major node in the pathway with several important functions. By phosphorylating a number of substrates, including BAD and MDM2, AKT enhances cell survival. AKT also inactivates the TSC1/TSC2 complex. TSC1 and TSC2 are the products of two tumor suppressor genes that are mutated in tuberous sclerosis (Chapter 28), an autosomal dominant disorder associated with developmental malformations

and unusual benign neoplasms such as cardiac rhabdomyomas (Chapter 12), renal angiomyolipomas, and giant cell astrocytomas. Inactivation of TSC1/TSC2 unleashes the activity of yet another kinase called mTOR (mammalian target of rapamycin, a potent immunosuppressive drug), which stimulates the uptake of nutrients such as glucose and amino acids that are needed for growth and augments the activity of several factors that are required for protein synthesis. Although acquired loss of PTEN function is one of the most common ways that PI3K/AKT signaling is upregulated in various cancers, many other components of the pathway, including PI3K itself, may also be mutated so as to increase signaling. Considering all of these molecular lesions collectively, it is said that this may be the most commonly mutated pathway in human cancer. As a result there is great interest in targeting the PI3K/AKT pathway with inhibitors of mTOR, AKT, and other kinases in the pathway.

NF1.

Individuals who inherit one mutant allele of the *NF1* gene develop numerous benign neurofibromas and optic nerve gliomas as a result of inactivation of the second copy of the gene.[92] This condition is called *neurofibromatosis type 1* (Chapter 27). Some of the neurofibromas later develop into malignant peripheral nerve sheath tumors. *Neurofibromin*, the protein product of the *NF1* gene, contains a GTPase-activating domain, which regulates signal transduction through RAS proteins. Recall that RAS transmits growth-promoting signals and flips back and forth between GDP-binding (inactive) and GTP-binding (active) states. Neurofibromin facilitates conversion of RAS from an active to an inactive state. With loss of neurofibromin function, RAS is trapped in an active, signal-emitting state.

NF2.

Germline mutations in the *NF2* gene predispose to the development of *neurofibromatosis type 2*.[93] As discussed in Chapter 27 , individuals with mutations in *NF2* develop benign bilateral schwannomas of the acoustic nerve. In addition, somatic mutations affecting both alleles of *NF2* have also been found in sporadic meningiomas and ependymomas. The product of the *NF2* gene, called *neurofibromin 2* or *merlin*, shows a great deal of homology with the red cell membrane cytoskeletal protein 4.1 (Chapter 14), and is related to the ERM (ezrin, radixin, and moesin) family of membrane cytoskeleton-associated proteins. Although the mechanism by which *merlin* deficiency leads to carcinogenesis is not known, cells lacking this protein are not capable of establishing stable cell-to-cell junctions and are insensitive to normal growth arrest signals generated by cell-to-cell contact. Merlin is a key member of the Salvador-Warts-Hippo (SWH) tumor suppressor pathway, originally described in *Drosophila*. The signaling pathway controls organ size by modulating cell growth, proliferation, and apoptosis. Many human homologues of genes in the SWH pathway have been implicated in human cancers.[94]

VHL.

Germline mutations of the von Hippel-Lindau (*VHL*) gene on chromosome 3p are associated with hereditary renal cell cancers, pheochromocytomas, hemangioblastomas of the central nervous system, retinal angiomas, and renal cysts.[60] Mutations of the *VHL* gene have also been noted in sporadic renal cell cancers (Chapter 20). The VHL protein is part of a ubiquitin ligase complex. A critical substrate for this activity is HIF1α (hypoxia-inducible transcription factor 1α). In the presence of oxygen, HIF1α is hydroxylated and binds to the VHL protein, leading to ubiquitination and proteasomal degradation. This hydroxylation reaction requires oxygen; in hypoxic environments the reaction cannot occur, and HIF1α escapes recognition by VHL and subsequent degradation. HIF1α can then translocate to the nucleus and turn on many genes, such as the growth/angiogenic factors vascular endothelial growth factor (VEGF) and PDGF. Lack of VHL activity prevents ubiquitination and degradation of HIF1α and is associated with increased levels of angiogenic growth factors.

WT1.

The *WT1* gene, located on chromosome 11p13, is associated with the development of Wilms' tumor, a pediatric kidney cancer.[95] Both inherited and sporadic forms of Wilms' tumor occur, and mutational inactivation of the *WT1* locus has been seen in both forms. The WT1 protein is a transcriptional activator of genes involved in renal and gonadal differentiation. It regulates the mesenchymal-to-epithelial transition that occurs in kidney development. Though not precisely known, it is likely that the tumorigenic effect of WT1 deficiency is intimately connected with the role of the gene in the differentiation of genitourinary tissues. Interestingly, although WT1 is a tumor suppressor in Wilms' tumor, a variety of adult cancers, including leukemias and breast carcinomas, have also been shown to overexpress WT1. Since these tissues do not normally express WT1 at all, it has been suggested that WT1 may function as an oncogene in these cancers. Another Wilms' gene, *WT2*, located on 11p15, is associated with the Beckwith-Wiedemann syndrome (Chapter 10).

Patched (PTCH).

PTCH1 and *PTCH2* are tumor suppressor genes that encode a cell membrane protein (PATCHED), which functions as a receptor for a family of proteins called *Hedgehog*.[96] The Hedgehog/PATCHED pathway regulates several genes, including *TGF*-β and *PDGFRA* and *PDGFRB*. Mutations in *PTCH* are related to Gorlin syndrome, an inherited condition also known as nevoid basal cell carcinoma syndrome (see Chapter 26). *PTCH* mutations are present in 20% to 50% of sporadic cases of basal cell carcinoma. About one half of such mutations are of the type caused by UV exposure.

EVASION OF APOPTOSIS

Accumulation of neoplastic cells may result not only from activation of growth-promoting oncogenes or inactivation of growth-suppressing tumor suppressor genes, but also from mutations in the genes that regulate apoptosis. [97] [98] [99] Thus, apoptosis represents a barrier that must be surmounted for cancer to occur. In the adult, cell death by apoptosis is a physiologic response to several pathologic conditions that might contribute to malignancy if the cells remained viable. A cell with genomic injury can be induced to die, preventing the accumulation of cells with mutations. A variety of signals, ranging from DNA damage to loss of adhesion to the basement membrane (termed *anoikis*), can trigger apoptosis. A large family of genes that regulate apoptosis has been identified. Before we can understand how tumor cells evade apoptosis, it is essential to review briefly the biochemical pathways to apoptosis.

As discussed in Chapter 1 , there are two distinct programs that activate apoptosis, the extrinsic and intrinsic pathways. Figure 7-34 shows, in simplified form, the sequence of events that lead to apoptosis by signaling through the death receptor CD95/Fas (extrinsic pathway) and by DNA damage (intrinsic pathway). The extrinsic pathway is initiated when CD95/Fas binds to its ligand, CD95L/FasL, leading to trimerization of the receptor and its cytoplasmic *death domains*, which attract the intracellular adaptor protein FADD. This protein recruits procaspase 8 to form the death-inducing signaling complex. Procaspase 8 is activated by cleavage into smaller subunits, generating caspase 8. Caspase 8 then activates downstream caspases such as caspase 3, a typical *executioner caspase* that cleaves DNA and other substrates to cause cell death. Additionally, caspase 8 can cleave and activate the BH3-only protein BID, activating the intrinsic pathway as well. The intrinsic pathway of apoptosis is triggered by a variety of stimuli, including withdrawal of survival factors, stress, and injury. Activation of this pathway leads to permeabilization of the mitochondrial outer membrane, with resultant release of molecules, such as cytochrome *c*, that initiate apoptosis. The integrity of the mitochondrial outer membrane is regulated by pro-apoptotic and anti-apoptotic members of the BCL2 family of proteins.[100] The pro-apoptotic proteins BAX and BAK are required for apoptosis and directly promote mitochondrial permeabilization. Their action is inhibited by the anti-apoptotic members of this family exemplified by BCL2 and BCL-XL. A third set of proteins (so-called BH3-only proteins), including BAD, BID, and PUMA, regulate the balance between the pro- and anti-apoptotic members of the BCL2 family. The BH3-only proteins sense death-inducing stimuli and promote apoptosis by neutralizing the

actions of anti-apoptotic proteins like BCL2 and BCL-XL. When the sum total of all BH3 proteins expressed "overwhelms" the anti-apoptotic BCL2/BCL-XL protein barrier, BAX and BAK are activated and form pores in the mitochondrial membrane. Cytochrome *c* leaks into the cytosol, where it binds to APAF1, activating caspase 9. Like caspase 8 of the extrinsic pathway, caspase 9 can cleave and activate the executioner caspases. The caspases can be inhibited by a family of proteins called Inhibitors of Apoptosis Proteins (IAPs). Some tumors avoid apoptosis by upregulating these proteins, and there is interest in developing drugs that can block the interaction between IAPs and caspases. Because of the pro-apoptotic effect of BH3-only proteins, efforts are underway to develop BH3 mimetic drugs.

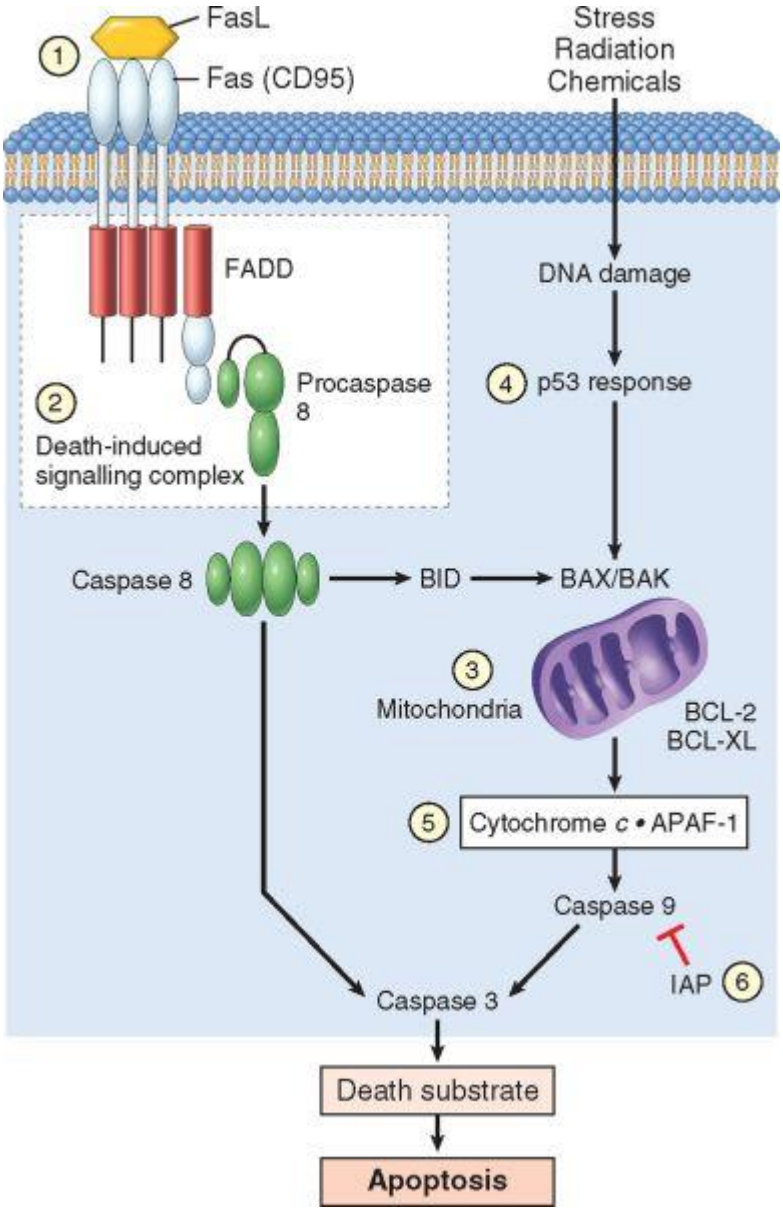

FIGURE 7-34 CD95 receptor–induced and DNA damage–triggered pathways of apoptosis and mechanisms used by tumor cells to evade cell death. (1) Reduced CD95 level. (2) Inactivation of death-induced signaling complex by FLICE protein (caspase 8; apoptosis-related cysteine peptidase). (3) Reduced egress of cytochrome *c* from mitochondrion as a result of up-regulation of BCL2. (4) Reduced levels of pro-apoptotic BAX resulting from loss of p53. (5) Loss of apoptotic peptidase activating factor 1 (APAF1). (6) Up-regulation of inhibitors of apoptosis (IAP). FADD, Fas-associated via death domain.

Within this framework it is possible to illustrate the multiple sites at which apoptosis is frustrated by cancer cells[101] (see Fig. 7-34). Starting from the surface, reduced levels of CD95/Fas may render the tumor cells less susceptible to apoptosis by CD95L/FasL. Some tumors have high levels of FLIP, a protein that can bind death-inducing signaling complex and prevent activation of caspase 8. Of all these genes, perhaps *best established is the role of BCL2 in protecting tumor cells from apoptosis*. As discussed later, approximately 85% of B-cell lymphomas of the follicular type (Chapter 13) carry a characteristic t(14;18)(q32;q21) translocation. Recall that 14q32, the site where immunoglobulin heavy-chain (IgH) genes are found, is also involved in the pathogenesis of Burkitt lymphoma. Juxtaposition of this transcriptionally active locus with *BCL2* (located at 18q21) causes overexpression of the BCL2 protein. This in turn increases the BCL2/BCL-XL buffer, protecting lymphocytes from apoptosis and allowing them to survive for long periods; there is therefore a steady accumulation of B lymphocytes, resulting in lymphadenopathy and marrow infiltration. Because BCL2-overexpressing lymphomas arise in large part from reduced cell death rather than explosive cell proliferation, they tend to be indolent (slow growing) compared with many other lymphomas.

As mentioned before, *p53 is an important pro-apoptotic gene that induces apoptosis in cells that are unable to repair DNA damage*. The actions of p53 are mediated in part by transcriptional activation of BAX, but there are other connections as well between p53 and the apoptotic machinery. Thus, the apoptotic machinery in cancer may be thwarted by mutations affecting the component proteins directly, as well as by loss of sensors of genomic integrity such as p53.

LIMITLESS REPLICATIVE POTENTIAL: TELOMERASE

As was discussed in the section on cellular aging (Chapter 1), most normal human cells have a capacity of 60 to 70 doublings. After this, the cells lose their ability to divide and become senescent. This phenomenon has been ascribed to progressive shortening of *telomeres* at the ends of chromosomes. Indeed, short telomeres seem to be recognized by the DNA-repair machinery as double-stranded DNA breaks, and this leads to cell cycle arrest mediated by p53 and RB.[102] In cells in which the checkpoints are disabled by *p53* or *RB1* mutations, the nonhomologous end-joining pathway is activated as a last-ditch effort to save the cell, joining the shortened ends of two chromosomes.[103] This inappropriately activated repair system results in dicentric chromosomes that are pulled apart at anaphase, resulting in new double-stranded DNA breaks. The resulting genomic instability from the repeated bridge-fusion-breakage cycles eventually produces mitotic catastrophe, characterized by massive cell death. *It follows that for tumors to grow indefinitely, as they often do, loss of growth restraints is not enough. Tumor cells must also develop ways to avoid both cellular senescence and mitotic catastrophe* (Fig. 7-35). If during crisis a cell manages to reactivate telomerase, the bridge-fusion-breakage cycles cease and the cell is able to avoid death. However, during the period of genomic instability that precedes telomerase activation, numerous mutations could accumulate, helping the cell march toward malignancy. Passage through a period of genomic instability may explain the complex karyotypes frequently seen in human carcinomas. Telomerase, active in normal stem cells, is normally absent, or expressed at very low levels in most somatic cells. By contrast, telomere maintenance is seen in virtually all types of cancers. In 85% to 95% of cancers, this is due to up-regulation of the enzyme telomerase. A few tumors use other mechanisms, termed *alternative lengthening of telomeres*, which probably depend on DNA recombination. Interestingly, in the progression from colonic adenoma to colonic adenocarcinoma, early lesions had a high degree of genomic instability with low telomerase expression, whereas malignant lesions had complex karyotypes with high levels of telomerase activity, consistent with a model of telomere-driven tumorigenesis in human cancer. Several other mechanisms of genomic instability are discussed later.

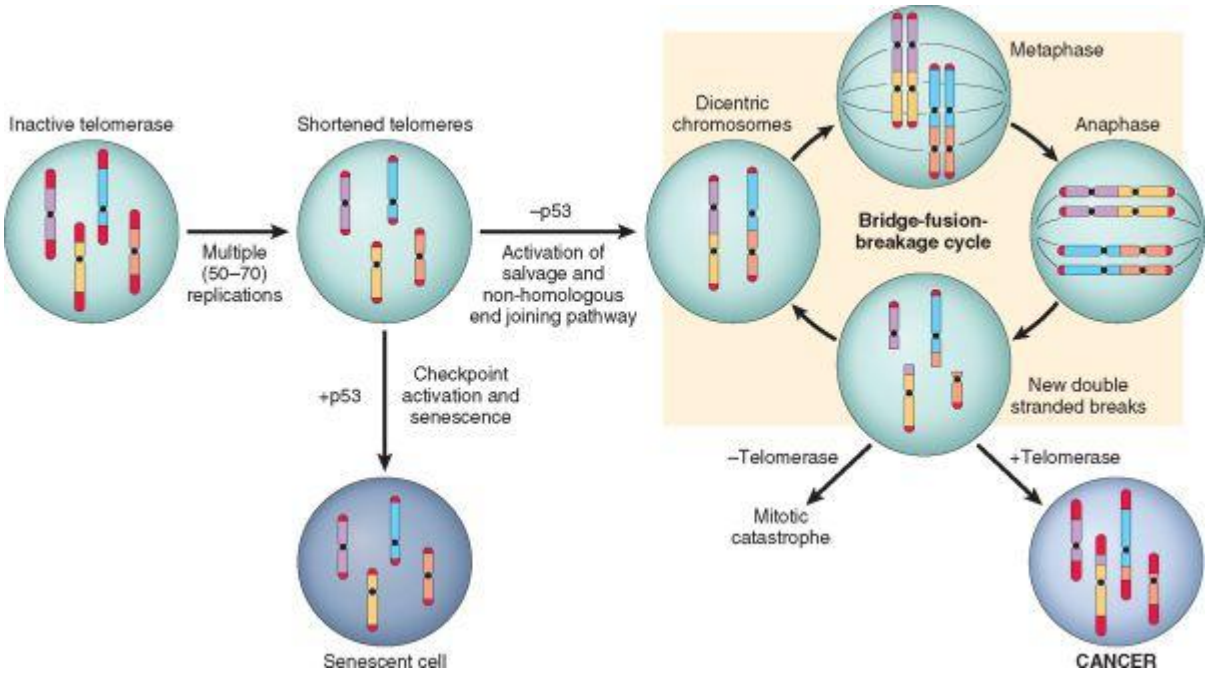

FIGURE 7-35 Sequence of events in the development of limitless replicative potential. Replication of somatic cells, which do not express telomerase, leads to shortened telomeres. In the presence of competent checkpoints, cells undergo arrest and enter nonreplicative senescence. In the absence of checkpoints, DNA-repair pathways are inappropriately activated, leading to the formation of dicentric chromosomes. At mitosis the dicentric chromosomes are pulled apart, generating random double-stranded breaks, which then activate DNA-repair pathways, leading to the random association of double-stranded ends and the formation, again, of dicentric chromosomes. Cells undergo numerous rounds of this bridge-fusion-breakage cycle, which generates massive chromosomal instability and numerous mutations. If cells fail to re-express telomerase, they eventually undergo mitotic catastrophe and death. Re-expression of telomerase allows the cells to escape the bridge-fusion-breakage cycle, thus promoting their survival and tumorigenesis.

ANGIOGENESIS

Even with all the genetic abnormalities discussed above, solid tumors cannot enlarge beyond 1 to 2 mm in diameter unless they are vascularized. Like normal tissues, tumors require delivery of oxygen and nutrients and removal of waste products; presumably the 1- to 2-mm zone represents the maximal distance across which oxygen, nutrients, and waste can diffuse from blood vessels. Cancer cells can stimulate neo-angiogenesis, during which new vessels sprout from previously existing capillaries, or, in some cases, vasculogenesis, in which endothelial cells are recruited from the bone marrow (Chapter 3). Tumor vasculature is abnormal, however. The vessels are leaky and dilated, and have a haphazard pattern of connection. Neovascularization has a dual effect on tumor growth: perfusion supplies needed nutrients and oxygen, and newly formed endothelial cells stimulate the growth of adjacent tumor cells by secreting growth factors, such as insulin-like growth factors (IGFs), PDGF, and granulocyte-macrophage colony-stimulating factor. Angiogenesis is required not only for continued tumor growth but also for access to the vasculature and hence for metastasis. *Angiogenesis is thus a necessary biologic correlate of malignancy*.[104]

How do growing tumors develop a blood supply? The emerging paradigm is that tumor angiogenesis is controlled by the balance between angiogenesis promoters and inhibitors. Early in their growth, most human tumors do not induce angiogenesis. They remain small or in situ, possibly for years, until the *angiogenic switch* terminates this stage of vascular quiescence.[105] The molecular basis of the angiogenic switch involves increased production of angiogenic factors and/or loss of angiogenic inhibitors. These factors may be produced directly by the tumor cells themselves or by inflammatory

cells (e.g., macrophages) or other stromal cells associated with the tumors. Proteases, either elaborated by the tumor cells directly or from stromal cells in response to the tumor, are also involved in regulating the balance between angiogenic and anti-angiogenic factors. Many proteases can release the proangiogenic basic fibroblast growth factors (bFGF) stored in the ECM; conversely, three potent angiogenesis inhibitors—angiostatin, endostatin, and vasculostatin—are produced by proteolytic cleavage of plasminogen, collagen, and transthyretin, respectively. The angiogenic switch is controlled by several physiologic stimuli, such as hypoxia. Relative lack of oxygen stimulates HIF1α, an oxygen-sensitive transcription factor mentioned above, which then activates transcription of a variety of pro-angiogenic cytokines, such as VEGF and bFGF. These factors create an angiogenic gradient that stimulates the proliferation of endothelial cells and guides the growth of new vessels toward the tumor. VEGF also increases the expression of ligands that activate the Notch signaling pathway, which plays a crucial role in regulating the branching and density of the new vessels (Chapter 3). Both pro- and anti-angiogenic factors are regulated by many other genes frequently mutated in cancer. For example, in normal cells, p53 can stimulate expression of anti-angiogenic molecules such as thrombospondin-1, and repress expression of pro-angiogenic molecules such as VEGF. Thus, loss of p53 in tumor cells not only removes the cell cycle checkpoints listed above but also provides a more permissive environment for angiogenesis. The transcription of VEGF is also influenced by signals from the RAS-MAP kinase pathway, and mutations of *RAS* or *MYC* up-regulate the production of VEGF. The mechanisms whereby bFGF, VEGF, and the Notch pathway work together to coordinate angiogenesis were discussed in Chapter 3 . bFGF and VEGF are commonly expressed in a wide variety of tumor cells, and elevated levels can be detected in the serum and urine of a significant fraction of cancer patients. Indeed, an anti-VEGF monoclonal antibody, bevacizumab, has recently been approved for use in the treatment of multiple cancers.[106] Another emerging strategy involves the use of antibodies that inhibit Notch activation. These antibodies cause new vessels to be so malformed that they cannot deliver blood to the tumor effectively.[107,][108]

INVASION AND METASTASIS

Invasion and metastasis are biologic hallmarks of malignant tumors. They are the major cause of cancer-related morbidity and mortality and hence are the subjects of intense scrutiny. Studies in mice and humans reveal that although millions of cells are released into the circulation each day from a primary tumor, only a few metastases are produced. Indeed, tumor cells can be frequently detected in the blood and marrow of patients with breast cancer who have not, and do not ever, develop gross metastatic disease. Why is the metastatic process so inefficient? Each step in the process is subject to a multitude of controls; hence, at any point in the sequence the breakaway cell may not survive.[109] For tumor cells to break loose from a primary mass, enter blood vessels or lymphatics, and produce a secondary growth at a distant site, they must go through a series of steps (summarized in Fig. 7-36). For the purpose of this discussion, the metastatic cascade will be divided into two phases: (1) invasion of the extracellular matrix (ECM); (2) vascular dissemination, homing of tumor cells, and colonization. Subsequently, the molecular genetics of the metastatic cascade, as currently understood, will be presented.

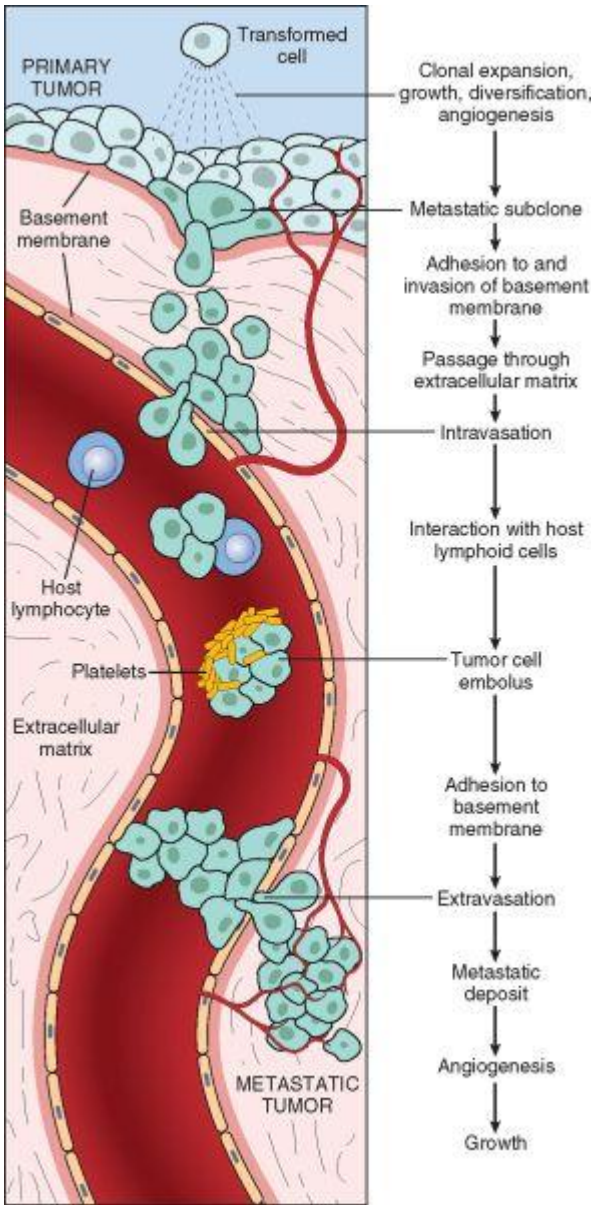

FIGURE 7-36 The metastatic cascade. Sequential steps involved in the hematogenous spread of a tumor.

Invasion of Extracellular Matrix

The structural organization and function of normal tissues is to a great extent determined by interactions between cells and the ECM.[110] As we discussed in Chapter 3 , tissues are organized into compartments separated from each other by two types of ECM: basement membrane and interstitial connective tissue. Though organized differently, each of these components of ECM is made up of collagens, glycoproteins, and proteoglycans. As shown in Figure 7-36 , tumor cells must interact with the ECM at several stages in the metastatic cascade. A carcinoma must first breach the underlying basement membrane, then traverse the interstitial connective tissue, and ultimately gain access to the circulation by penetrating the vascular basement membrane. This process is repeated in reverse when tumor cell emboli extravasate at a distant site. Invasion of the ECM initiates the metastatic cascade and *is an active process that can be resolved into several steps* (Fig. 7-37):

- Changes (“loosening up”) of tumor cell-cell interactions
- Degradation of ECM
- Attachment to novel ECM components
- Migration of tumor cells

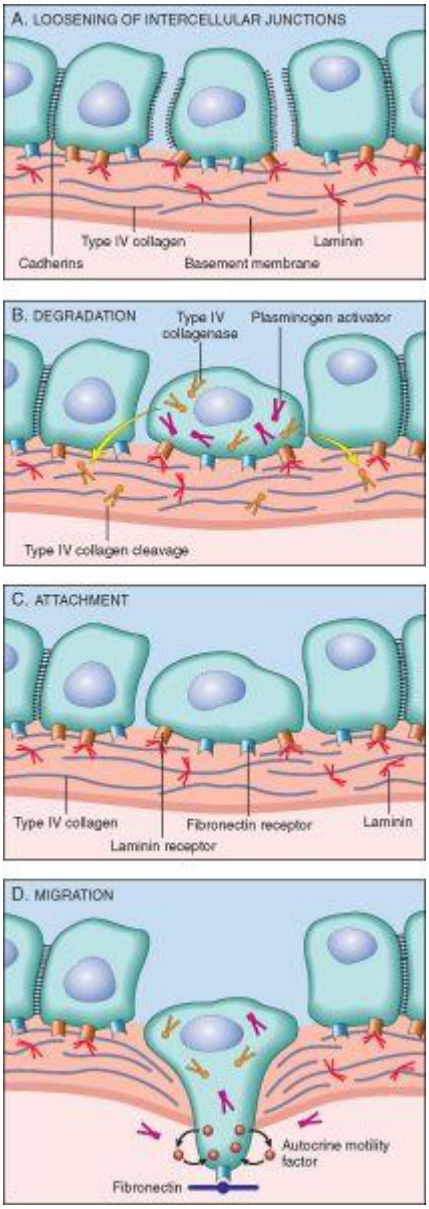

FIGURE 7-37 A–D, Sequence of events in the invasion of epithelial basement membranes by tumor cells. Tumor cells detach from each other because of reduced adhesiveness, then secrete proteolytic enzymes, degrading the basement membrane. Binding to proteolytically generated binding sites and tumor cell migration follow.

Dissociation of cells from one another is often the result of alterations in intercellular adhesion molecules. Normal cells are neatly glued to each other and their surroundings by a variety of adhesion molecules.[111] Cell-cell interactions are mediated by the cadherin family of transmembrane glycoproteins. E-cadherins mediate homotypic adhesions in epithelial tissue, thus serving to keep the epithelial cells together and to relay signals between the cells; intracellularly the E-cadherins are

connected to β-catenin and the actin cytoskeleton. In several epithelial tumors, including adenocarcinomas of the colon and breast, there is a down-regulation of E-cadherin expression. Presumably, this down-regulation reduces the ability of cells to adhere to each other and facilitates their detachment from the primary tumor and their advance into the surrounding tissues. E-cadherins are linked to the cytoskeleton by the *catenins*, proteins that lie under the plasma membrane (see Fig. 7-33). The normal function of E-cadherin is dependent on its linkage to catenins. In some tumors E-cadherin is normal, but its expression is reduced because of mutations in the gene for α catenin.

The second step in invasion is local *degradation of the basement membrane and interstitial connective tissue*. Tumor cells may either secrete proteolytic enzymes themselves or induce stromal cells (e.g., fibroblasts and inflammatory cells) to elaborate proteases. Many different families of proteases, such as matrix metalloproteinases (MMPs), cathepsin D, and urokinase plasminogen activator, have been implicated in tumor cell invasion. MMPs regulate tumor invasion not only by remodeling insoluble components of the basement membrane and interstitial matrix but also by releasing ECM-sequestered growth factors. Indeed, cleavage products of collagen and proteoglycans also have chemotactic, angiogenic, and growth-promoting effects.[112] For example, MMP9 is a gelatinase that cleaves type IV collagen of the epithelial and vascular basement membrane and also stimulates release of VEGF from ECM-sequestered pools. Benign tumors of the breast, colon, and stomach show little type IV collagenase activity, whereas their malignant counterparts overexpress this enzyme. Concurrently, the concentrations of metalloproteinase inhibitors are reduced so that the balance is tilted greatly toward tissue degradation. Indeed, overexpression of MMPs and other proteases has been reported for many tumors. However, recent in vivo imaging experiments have shown that tumor cells can adopt a second mode of invasion, termed *ameboid migration*.[113] In this type of migration the cell squeezes through spaces in the matrix instead of cutting its way through it. This ameboid migration is much quicker, and tumor cells seem to be able to use collagen fibers as high-speed railways in their travels. Tumor cells, in vitro at least, seem to be able to switch between the two forms of migration, perhaps explaining the disappointing performance of MMP inhibitors in clinical trials.

The third step in invasion involves *changes in attachment of tumor cells to ECM proteins*. Normal epithelial cells have receptors, such as integrins, for basement membrane laminin and collagens that are polarized at their basal surface; these receptors help to maintain the cells in a resting, differentiated state. Loss of adhesion in normal cells leads to induction of apoptosis, while, not surprisingly, tumor cells are resistant to this form of cell death. Additionally, the matrix itself is modified in ways that promote invasion and metastasis. For example, cleavage of the basement membrane proteins collagen IV and laminin by MMP2 or MMP9 generates novel sites that bind to receptors on tumor cells and stimulate migration.

Locomotion is the final step of invasion, propelling tumor cells through the degraded basement membranes and zones of matrix proteolysis. Migration is a complex, multistep process that involves many families of receptors and signaling proteins that eventually impinge on the actin cytoskeleton. Cells must attach to the matrix at the leading edge, detach from the matrix at the trailing edge, and contract the actin cytoskeleton to ratchet forward. Such movement seems to be potentiated and directed by tumor cell–derived cytokines, such as autocrine motility factors. In addition, cleavage products of matrix components (e.g., collagen, laminin) and some growth factors (e.g., IGFs I and II) have chemotactic activity for tumor cells. Furthermore, proteolytic cleavage liberates growth factors bound to matrix molecules. Stromal cells also produce paracrine effectors of cell motility, such as hepatocyte growth factor–scatter factor, which bind to receptors on tumor cells. Concentrations of hepatocyte growth factor–scatter factor are elevated at the advancing edges of the highly invasive brain tumor glioblastoma multiforme, supporting their role in motility.

It has become clear in recent years that the ECM and stromal cells surrounding tumor cells do not merely represent a static barrier for tumor cells to traverse but instead represent a varied environment in which reciprocal signaling between tumor cells and stromal cells may either promote or prevent tumorigenesis and/or tumor progression.[24] Stromal cells that interact with tumors include innate and adaptive immune cells (discussed later), as well as fibroblasts. A variety of studies have demonstrated that tumor-associated fibroblasts exhibit altered expression of genes that encode ECM molecules, proteases, protease inhibitors, and various growth factors. Thus, tumor cells live in a complex and ever-changing milieu composed of ECM, growth factors, fibroblasts, and immune cells, with significant cross-talk among all the components. The most successful tumors may be those that can co-opt and adapt this environment to their own nefarious ends.

Vascular Dissemination and Homing of Tumor Cells

Once in the circulation, tumor cells are vulnerable to destruction by a variety of mechanisms, including mechanical shear stress, apoptosis stimulated by loss of adhesion, (which has been termed *anoikis*), and innate and adaptive immune defenses. The details of tumor immunity are considered later.

Within the circulation, tumor cells tend to aggregate in clumps. This is favored by homotypic adhesions among tumor cells as well as heterotypic adhesion between tumor cells and blood cells, particularly platelets (see Fig. 7-36). Formation of platelet-tumor aggregates may enhance tumor cell survival and implantability. Tumor cells may also bind and activate coagulation factors, resulting in the formation of emboli. Arrest and extravasation of tumor emboli at distant sites involves adhesion to the endothelium, followed by egress through the basement membrane. Involved in these processes are adhesion molecules (integrins, laminin receptors) and proteolytic enzymes, discussed earlier. Of particular interest is the CD44 adhesion molecule, which is expressed on normal T lymphocytes and is used by these cells to migrate to selective sites in the lymphoid tissue. Such migration is accomplished by the binding of CD44 to hyaluronate on high endothelial venules, and overexpression of CD44 may favor metastatic spread. At the new site, tumor cells must proliferate, develop a vascular supply, and evade the host defenses.[109]

The site at which circulating tumor cells leave the capillaries to form secondary deposits is related, in part, to the anatomic location of the primary tumor, with most metastases occurring in the first capillary bed available to the tumor. Many observations, however, suggest that natural pathways of drainage do not wholly explain the distribution of metastases. For example, prostatic carcinoma preferentially spreads to bone, bronchogenic carcinomas tend to involve the adrenals and the brain, and neuroblastomas spread to the liver and bones. Such organ tropism may be related to the following mechanisms:

- Because the first step in extravasation is adhesion to the endothelium, tumor cells may have adhesion molecules whose ligands are expressed preferentially on the endothelial cells of the target organ. Indeed, it has been shown that the endothelial cells of the vascular beds of various tissues differ in their expression of ligands for adhesion molecules.
- Chemokines have an important role in determining the target tissues for metastasis. For instance, some breast cancer cells express the chemokine receptors CXCR4 and CCR7.[114] The chemokines that bind to these receptors are highly expressed in tissues to which breast cancers commonly metastasize. Blockage of the interaction between CXCR4 and its receptor decreases breast cancer metastasis to lymph nodes and lungs. Some target organs may liberate chemoattractants that recruit tumor cells to the site. Examples include IGFs I and II.
- In some cases, the target tissue may be a nonpermissive environment—unfavorable soil, so to speak, for the growth of tumor seedlings. For example, though well vascularized, skeletal muscles are rarely the site of metastases.

Despite their “cleverness” in escaping their sites of origin, tumor cells are quite inefficient in colonizing distant organs. Millions of tumors cells are shed daily from even small tumors. These cells can be detected in the bloodstream and in small foci in the bone marrow, even in patients that never develop gross metastatic lesions. Indeed, the concept of dormancy, referring to the prolonged survival of micrometastases without progression, is well described in melanoma and in breast and prostate cancer. Although the molecular mechanisms of colonization are just beginning to be unraveled in mouse models, a constant pattern seems to be that tumor cells secrete cytokines, growth factors, and ECM molecules that act on the resident stromal cells, which in turn make the metastatic site habitable for the cancer cell.[115] For example, breast cancer metastases to bone are osteolytic because of the activation of osteoclasts in the metastatic site. Breast cancer cells secrete parathyroid hormone–related protein (PTHRP), which stimulates osteoblasts to make RANK ligand (RANKL). RANKL then activates osteoclasts, which degrade the bone matrix and release growth factors embedded within it, like IGF and TGF-β. With a better molecular understanding of the mechanisms of metastasis our ability to target them therapeutically will be greatly enhanced.

Molecular Genetics of Metastasis Development

Why do only some tumors metastasize? What are the genetic changes that allow metastases? Why is the metastatic process so inefficient? Several competing theories have been proposed to explain how the metastatic phenotype arises. The clonal evolution model suggest that, as mutations accumulate in genetically unstable cancer cells and the tumor become heterogeneous (Fig. 7-38A), a subset of tumor cell subclones develop the right combination of gene products to complete all the steps involved in metastasis. Thus, metastatic subclones result from clonal evolution, and it is only the rare cell that acquires all the necessary genetic alterations and can complete all the steps. However, recent experiments, in which gene expression profiles of primary tumors and metastatic deposits have been compared, challenge this hypothesis. For example, a subset of breast cancers has a gene expression signature similar to that found in metastases, although no clinical evidence for metastasis is apparent. In these tumors it seems that most if not all cells develop a predilection for metastatic spread during early stages of carcinogenesis. Metastases, according to this view, are not dependent on the stochastic generation of metastatic subclones postulated above. The alternative hypothesis suggested by these data is that metastasis is the result of multiple abnormalities that occur in many, perhaps most, cells of a primary tumor, and perhaps early in the development of the tumor (Fig. 7-38B and C). Such abnormalities give most cells within the tumor a general predisposition for metastasis, often called the “metastasis signature.”[116] This signature may involve not only properties intrinsic to the cancer cells but also the characteristics of their microenvironment, such as the components of the stroma, the presence of infiltrating immune cells, and angiogenesis (Fig. 7-38D). It should be noted, however, that gene expression analyses like those described above would not detect a small subset of metastatic subclones within a large tumor. Perhaps both mechanisms are operative, with aggressive tumors acquiring a metastases-permissive gene expression pattern early in tumorigenesis that requires some additional random mutations to complete the metastatic phenotype. A third hypothesis suggests that background genetic variation, and the resulting variation in gene expression, in the human population contributes to the generation of metastases. In mouse models, cancers induced with the same oncogenic mutations can have very different metastatic outcomes depending on the strain (i.e., background genetics) of the mouse used. Even very strong oncogenes can be significantly affected by background genetics. The fourth hypothesis is a corollary of the tumor stem cell hypothesis, which suggests that if tumors derive from rare tumor stem cells, metastases require the spread of the tumor stem cells themselves.

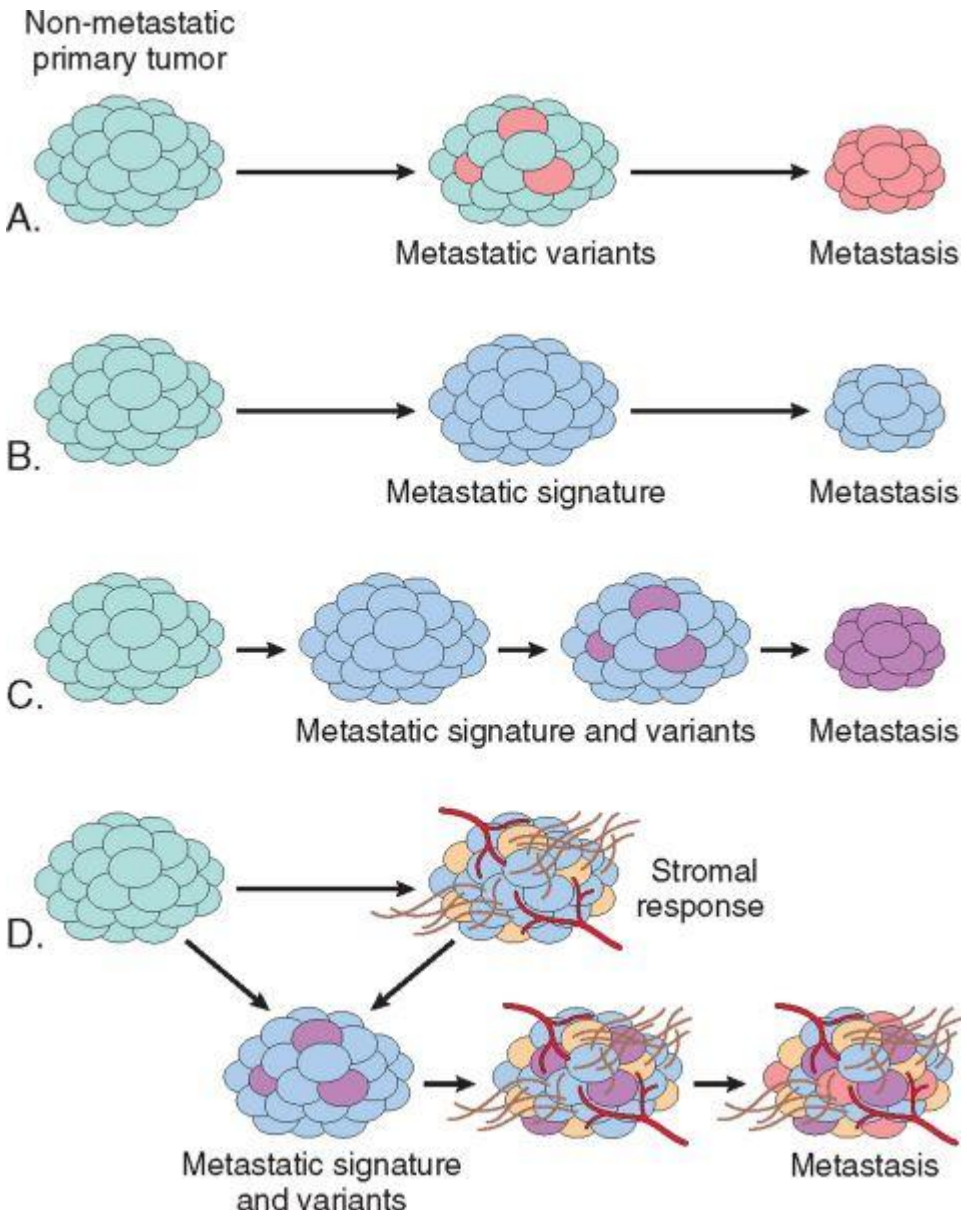

FIGURE 7-38 Mechanisms of metastasis development within a primary tumor. A nonmetastatic primary tumor is shown (light blue) on the left side of all diagrams. Four models are presented: **A**, Metastasis is caused by rare variant clones that develop in the primary tumor; **B**, Metastasis is caused by the gene expression pattern of most cells of the primary tumor, referred to as a metastatic signature; **C**, A combination of **A** and **B**, in which metastatic variants appear in a tumor with a metastatic gene signature; **D**, Metastasis development is greatly influenced by the tumor stroma, which may regulate angiogenesis, local invasiveness, and resistance to immune elimination, allowing cells of the primary tumor, as in **C**, to become metastatic.

One open question in the field is, are there genes whose principal or sole contribution to tumorigenesis is to control metastasis? This question is of more than academic interest, because if altered forms of certain genes promote or suppress the metastatic phenotype, their detection in a primary tumor would have both prognostic and therapeutic implications. Since metastasis is a complex phenomenon involving a variety of steps and pathways described above, it is thought that, unlike transformation, in which a subset of proteins like p53 and RB seem to play a key role, genes that function as “metastasis oncogenes” or “metastatic suppressors” are rare. A metastasis suppressor gene is defined as a gene whose loss promotes the development of metastasis without an effect on the primary tumor.

Accordingly, expression of a metastasis oncogene favors the development of metastasis without effect upon the primary tumor. At least a dozen genes lost in metastatic lesions have been confirmed to function as "metastasis suppressors".[117,][118] Their molecular functions are varied and not yet completely clear; however, most appear to affect various signaling pathways. Interestingly, recent work has suggested that two miRNAs, mir335 and mir126, suppress the metastasis of breast cancer, while a second set (mir10b) promotes metastasis.[119,][120]

Among candidates for metastasis oncogenes are SNAIL and TWIST, which encode transcription factors whose primary function is to promote a process called epithelial-tomesenchymal transition (EMT).[88] In EMT, carcinoma cells down-regulate certain epithelial markers (e.g., E-cadherin) and up-regulate certain mesenchymal markers (e.g., vimentin and smooth muscle actin). These changes are believed to favor the development of a promigratory phenotype that is essential for metastasis. Loss of E-cadherin expression seems to be a key event in EMT, and SNAIL and TWIST are transcriptional repressors that down-regulate E-cadherin expression.[121] EMT has been documented mainly in breast cancers; whether this is a general phenomenon remains to be established.

GENOMIC INSTABILITY—ENABLER OF MALIGNANCY

Although humans literally swim in environmental agents that are mutagenic (e.g., chemicals, radiation, sunlight), cancers are relatively rare outcomes of these encounters. This state of affairs results from the ability of normal cells to repair DNA damage, the death of cells with unrepairable damage[122] (see "Evasion of Apoptosis" above), and other mechanisms, such as oncogene-induced senescence and immune surveillance (discussed later). The importance of DNA repair in maintaining the integrity of the genome is highlighted by several inherited disorders in which genes that encode proteins involved in DNA repair are defective. *Individuals born with such inherited defects in DNA-repair proteins are at a greatly increased risk of developing cancer*. Moreover, defects in repair mechanisms are present in sporadic human cancers. *DNA-repair genes themselves are not oncogenic, but their abnormalities allow mutations in other genes during the process of normal cell division*. Typically, genomic instability occurs when both copies of the DNA repair gene are lost; however, recent work has suggested that at least a subset of these genes may promote cancer in a haploinsufficient manner. Defects in three types of DNA-repair systems—mismatch repair, nucleotide excision repair, and recombination repair—contribute to different types of cancers.

Hereditary Nonpolyposis Colon Cancer Syndrome.

HNPCC syndrome, characterized by familial carcinomas of the colon affecting predominantly the cecum and proximal colon (Chapter 17), results from defects in genes involved in DNA mismatch repair.[123] When a strand of DNA is being replicated, these genes act as "spell checkers." For example, if there is an erroneous pairing of G with T rather than the normal A with T, the mismatch-repair genes correct the defect. Without these "proofreaders," errors gradually accumulate randomly in the genome, and some of these errors may involve proto-oncogenes and tumor suppressor genes. One of the hallmarks of patients with mismatch-repair defects is microsatellite instability.[21] Microsatellites are tandem repeats of one to six nucleotides found throughout the genome. In normal people the length of these microsatellites remains constant. However, in people with HNPCC, these satellites are unstable and increase or decrease in length in tumor cells, creating alleles not found in normal cells of the same patient. Of the various DNA mismatch-repair genes, at least four are involved in the pathogenesis of HNPCC, but germline mutations in the *MSH2* (2p16) and *MLH1* (3p21) genes each account for approximately 30% of cases. The remaining cases have mutations in other mismatch repair genes. Each affected individual inherits one defective copy of a DNA mismatch-repair gene and acquires the second hit in colonic epithelial cells. Thus, DNA-repair genes behave like tumor suppressor genes in their mode of inheritance, but in contrast to tumor suppressor genes (and oncogenes), they affect cell growth only indirectly—by allowing mutations in other genes during the process of normal cell division. Although

HNPCC accounts only for 2% to 4% of all colonic cancers, microsatellite instability can be detected in about 15% of sporadic colon cancers. The growth-regulating genes that are mutated in HNPCC tumors have not yet been fully characterized but include the genes encoding TGF-β receptor II, the TCF component of the β-catenin pathway, *BAX*, and other oncogenes and tumor suppressor genes.[124]

Xeroderma Pigmentosum.

Individuals with another inherited disorder of defective DNA repair, xeroderma pigmentosum, are at increased risk for the development of cancers of the skin particularly following exposure to the UV light contained in sun rays.[125] UV radiation causes cross-linking of pyrimidine residues, preventing normal DNA replication. Such DNA damage is repaired by the nucleotide excision repair system. Several proteins are involved in nucleotide excision repair, and an inherited loss of any one can give rise to xeroderma pigmentosum.

Diseases with Defects in DNA Repair by Homologous Recombination.

A group of autosomal recessive disorders comprising Bloom syndrome, ataxia-telangiectasia, and Fanconi anemia is characterized by hypersensitivity to other DNA-damaging agents, such as ionizing radiation (Bloom syndrome and ataxia-telangiectasia), or DNA cross-linking agents, such as many chemotherapeutic agents (Fanconi anemia).[126,][127] Their phenotype is complex and includes, in addition to predisposition to cancer, features such as neural symptoms (ataxia-telangiectasia), bone marrow aplasia (Fanconi anemia), and developmental defects (Bloom syndrome). As mentioned earlier, the gene mutated in ataxia-telangiectasia, *ATM*, is important in recognizing and responding to DNA damage caused by ionizing radiation. Persons with Bloom syndrome have a predisposition to a very broad spectrum of tumors. The defective gene is located on chromosome 15 and encodes a helicase that participates in DNA repair by homologous recombination. There are 13 genes that make up the Fanconi anemia complex; mutation of any one of these genes can result in the phenotype.[126,][128] Interestingly, *BRCA2*, which is mutated in some individuals with familial breast cancer, is also mutated in a subset of persons with Fanconi anemia. Evidence for the role of DNA-repair genes in the origin of cancer also comes from the study of hereditary breast cancer. Mutations in two genes, *BRCA1* (chromosome 17q21) and *BRCA2* (chromosome 13q12–13), account for 25% of cases of familial breast cancer. In addition to breast cancer, women with *BRCA1* mutations have a substantially higher risk of epithelial ovarian cancers, and men have a slightly higher risk of prostate cancer. Likewise, mutations in the *BRCA2* gene increase the risk of breast cancer in both men and women as well as cancer of the ovary, prostate, pancreas, bile ducts, stomach, and melanocytes. Although the functions of these genes have not been elucidated fully, cells that lack these genes develop chromosomal breaks and severe aneuploidy. Indeed, both *BRCA1* and *BRCA2* have been shown to associate with a variety of proteins involved in the homologous recombination repair pathway. The Fanconi anemia proteins and the BRCA proteins form a DNA-damage response network whose purpose is to resolve and repair intrastrand and interstrand DNA cross-links induced by chemical cross-linking agents. Failure to resolve these cross-links before separation of the two strands would lead to chromosome breakage and exposed chromosome ends. Generation of such ends would, as with short telomeres (see above), lead to the activation of the salvage nonhomologous end joining pathway, formation of dicentric chromosomes, bridge-fusion-breakage cycles, and massive aneuploidy. Similar to other tumor suppressor genes, both copies of *BRCA1* and *BRCA2* must be inactivated for cancer to develop. Although linkage of *BRCA1* and *BRCA2* to familial breast cancers is established, these genes are rarely inactivated in sporadic cases of breast cancer. In this regard, *BRCA1* and *BRCA2* are different from other tumor suppressor genes, such as *APC* and *p53*, which are inactivated in both familial and sporadic cancers.

STROMAL MICROENVIRONMENT AND CARCINOGENESIS

Although we have mostly focused on the neoplastic parenchymal cells in our discussion, tumors are not composed of a single cell type. Indeed, tumors are comprised of a complex mixture of cells of numerous lineages, including the tumor cells themselves, innate and adaptive immune cells, fibroblasts, endothelial cells, and others. Additionally, numerous examples of cross-talk between the ECM and tumor cells have been described. For example, cleavage of matrix components such as type IV collagen releases angiogenic factors (VEGF), and enzymatic degradation of laminin-5 by MMP2 reveals a cryptic proteolytic fragment that favors cancer cell motility.[112] The ECM also stores growth factors in inactive forms, which are released by active matrix proteases. Such factors include PDGF, TGF-β, and bFGF, which in turn affect the growth of tumor cells in a paracrine manner. Successful tumor cells must co-opt these and other interactions and use them to promote their growth and invasion. More interesting is whether tumor cells are dependent upon these interactions for proliferation, survival, or metastases. If so, these interactions, and the stromal cells themselves, become potential therapeutic targets.

Both the inflammatory cells and fibroblasts within the tumor have been shown to have a complex relationship to the cancer cells and to each other. The role of chronic inflammation in the development of cancer has already been described (see above). Various mechanisms, such as the expression of pro-survival and pro-proliferation cytokines by immune cells, not only promote the development of cancer, but also promote survival and progression of tumor cells. Additionally, it has been suggested that macrophages infiltrating the tumor can be induced by the tumor cells to secrete factors that promote metastasis.[129] In a mouse model of breast cancer, genetic deletion of macrophages prevented metastases. Furthermore, in vivo imaging of tumors in animal models has shown that macrophages surrounding blood vessels secrete EGF, resulting in chemotactic migration of tumor cells toward the vasculature.[113] Fibroblasts play an important role in tumors as well. Fibroblasts secrete the matrix that results in the desmoplastic response to tumors. Interestingly, in vitro experiments that altered the stiffness of the matrix alone could change the aggressiveness of a cancer cell line. Thus, the desmoplastic response to cancer may be stimulated by the cancer cells and may promote their growth. On the other hand, in a prostate cancer model, injection of immortalized, but nontumorigenic cells, together with fibroblasts derived from a tumor (cancer-associated fibroblasts) led to the development of poorly differentiated tumors in athymic mice.[130] These carcinomas had multiple genetic abnormalities that were not present in the parent cell line, suggesting that the stroma can drive genetic changes that promote carcinogenesis. Indeed, some of the predictions of tumor behavior based on gene expression profiling are turning out to be based on genes highly expressed in stromal cells, rather than tumor cells. How such changes come about remains mysterious, as does their relevance to carcinogenesis in vivo. However, the results are sufficiently intriguing to merit attention, since they suggest a novel form of cancer therapy that could be targeted to stromal cells. The role of stromal cells in tumor growth and progression is highlighted by recent studies in which gene expression profiles of stroma cells predicted clinical outcome in human breast cancer.[131]

METABOLIC ALTERATIONS: THE WARBURG EFFECT

Even in the presence of ample oxygen, cancer cells shift their glucose metabolism away from the oxygen hungry, but efficient, mitochondria to glycolysis. [132] [133] [134] This phenomenon, called the Warburg effect and also known as aerobic glycolysis, has been recognized for many years (indeed, Otto Warburg received the Nobel Prize for discovery of the effect that bears his name in 1931), but was largely neglected until recently. This metabolic alteration is so common to tumors that some would call it the eighth hallmark of cancer. Indeed, clinically, the “glucose-hunger” of tumors is used to visualize tumors via positron emission tomography (PET) scanning, in which patients are injected with 18F-fluorodeoxyglucose, a non-metabolizable derivative of glucose that is preferentially taken up into tumor cells (as well as normal, actively dividing tissues such as the bone marrow). Most tumors are PETpositive, and rapidly growing ones are markedly so. However, the causal relationship between

aerobic glycolysis and tumor progression is not entirely clear, nor is the initial insult that drives these metabolic changes.

Indeed, as is well known, glycolysis generates 2 ATP molecules per molecule of glucose, while oxidative phosphorylation in the mitochondria generates more than 20. How does a switch to the less efficient glycolysis lead to a growth advantage for a tumor? Several mutually non-exclusive hypotheses have been offered. One attractive hypothesis to explain the Warburg effect is that altered metabolism confers a growth advantage in the hypoxic tumor microenvironment. [133] [134] Although angiogenesis generates increased vasculature, the vessels are poorly formed, and tumors are still relatively hypoxic compared to normal tissues. Indeed, the activation of HIF1α by hypoxia not only stimulates angiogenesis, but also increases the expression of numerous metabolic enzymes in the glycolytic pathway as well as downregulates genes involved in oxidative phosphorylation. So the simplest explanation is basic economics: supply and demand. Decreased demand by individual tumor cells increases the oxygen supply, thus increasing the number of tumor cells that can be supported by the vasculature and increasing the size of the tumor.

However, the Warburg effect refers to aerobic glycolysis; glycolysis that occurs in the face of adequate oxygen for oxidative phosphorylation. Thus, the changes that promote the switch in metabolism during hypoxia must become fixed in the tumor cell. It may be that continuous rounds of hypoxia followed by normoxia, as is frequently seen in tumors, select for tumor cells that constitutively upregulate glycolysis. Additionally, or perhaps alternatively, mutations in oncogenes and tumor suppressors that favor growth, such as *RAS, p53* and *PTEN*, also stimulate metabolic changes in the cell. Which brings us to the second part of the supply and demand equation that may help explain why tumor cells opt for a less efficient energy production pipeline.

In addition to doubling its DNA content prior to division, an actively dividing cell (whether normal or transformed) must also double all of its other components, including membranes, proteins, and organelles. This task requires increased uptake of nutrients, particularly glucose (which produces the energy needed for biosynthesis of these components) and amino acids (which provide the building blocks used for protein synthesis) as well as increased synthesis of the necessary building blocks. Halting the breakdown of glucose at pyruvate allows these carbons to be shunted to anabolic pathways, such as lipid and nucleotide production; additionally, tumor cells are able to shunt glutamine into both the glycolytic as well as anabolic pathways. [134] [135] Thus, the metabolic changes that tumor cells undergo increase their ability to synthesize the building blocks they need for cell division. Indeed, alterations in signaling pathways involved in cancer also stimulate the uptake of glucose and other nutrients, favor glycolysis over oxidative phosphorylation, and increase anabolic pathways in the cell. Normally, growth factors stimulate glucose and amino acid uptake through the PI3K/AKT/mTOR pathway, which is downstream of receptor tyrosine kinases and other growth factor receptors; in tumors, these signals are cell autonomous. Thus, mutation of tumor suppressors and oncogenes not only leads to constitutive activation of pathways that favor survival and proliferation, but they also make glycolysis and anabolic biosynthesis a permanent fixture of the tumor cell. [135] [136]

Now that the Warburg effect has been “rediscovered,” other fascinating connections between metabolism and neoplasia are emerging that involve both tumor suppressors and oncoproteins. One example of the former involves *LKB1*, a tumor suppressor gene encoding a threonine kinase that is mutated in Peutz-Jegher syndrome (Chapter 17), which is associated with benign and malignant epithelial proliferations of the gastrointestinal tract. At least one aspect of LKB1's tumor suppressive activity is mediated through its ability to activate AMP-dependent protein kinase (AMPK), a conserved sensor of cellular energy status that is an important negative regulator of mTOR. Thus LKB1 suppresses tumor formation, at least in part, by putting the brakes on anabolic metabolism. Of note, two other tumor suppressors that are mutated in tuberous sclerosis, TSC1 and TSC2 (Chapter 28), also

negatively regulate mTOR. On the other side of the ledger, it has been claimed that the transforming effects of many oncoproteins, including mutated receptor tyrosine kinases and the notorious oncogenic transcription factor c-MYC, are mediated in part through induction of the "Warburg effect." These kinds of insights have spurred many recent attempts to target signaling pathways that drive anabolic metabolism in cancer cells, such as the PI3K/AKT/mTOR pathway.

As we have discussed earlier, cells have many regulatory barriers to prevent inappropriate growth. One adaptive response of normal cells to oxygen and glucose deprivation is *autophagy*, a state in which cells arrest their growth and cannibalize their own organelles, proteins, and membranes as carbon sources for energy production (Chapter 1). If this adaptation fails, the cells die. Tumor cells often seem to be able to grow under marginal environmental conditions without triggering autophagy, suggesting that the pathways that induce autophagy are deranged. In keeping with this, several genes that promote autophagy are tumor suppressors, most notable PTEN (a negative regulator of the PI3K/AKT pathway), which is mutated or epigenetically silenced in a wide variety of human cancers. Whether autophagy is always bad from the vantage point of the tumor, however, is a matter of active investigation and debate. For example, under conditions of severe nutrient deprivation tumor cells may use autophagy to become "dormant," a state of metabolic hibernation that allows cells to survive hard times for long periods. Such cells are believed to be resistant to therapies that kill actively dividing cells, and could therefore be responsible for therapeutic failures. Thus, autophagy may be a tumor's friend or foe depending on how the signaling pathways that regulate it are "wired" in a given tumor.

DYSREGULATION OF CANCER-ASSOCIATED GENES

The genetic damage that activates oncogenes or inactivates tumor suppressor genes may be subtle (e.g., point mutations) or may involve segments of chromosomes large enough to be detected in a routine karyotype. Activation of oncogenes and loss of function of tumor suppressor genes by mutations were discussed earlier in this chapter. Here we discuss chromosomal abnormalities. We end this section by discussing the epigenetic changes that contribute to carcinogenesis.

Chromosomal Changes

In certain neoplasms, karyotypic abnormalities are nonrandom and common. Specific chromosomal abnormalities have been identified in most leukemias and lymphomas, many sarcomas, and an increasing number of carcinomas. In addition, whole chromosomes may be gained or lost. Although changes in chromosome number (aneuploidy) and structure are generally considered to be late phenomena in cancer progression, it has been suggested that aneuploidy and chromosomal instability may be the initiating events in tumor growth.

The study of chromosomal changes in tumor cells is important on two accounts. First, molecular cloning of genes in the vicinity of chromosomal breakpoints or deletions has been extremely useful in identification of oncogenes (e.g., *BCL2*, *ABL*) and tumor suppressor genes (e.g., *APC*, *RB*). Second, certain karyotypic abnormalities are specific enough to be of diagnostic value, and in some cases they are predictive of clinical course. The translocations associated with the *ABL* oncogene in CML and with c-*MYC* in Burkitt lymphoma have been mentioned earlier, in the context of molecular defects in cancer cells (see Fig. 7-27). Several other karyotype alterations in cancer cells are presented in the discussion of specific tumors in later chapters.

Two types of chromosomal rearrangements can activate proto-oncogenes—translocations and inversions. Chromosomal translocations are much more common (Table 7-9) and are discussed here. Translocations can activate proto-oncogenes in two ways:

- In lymphoid tumors specific translocations result in overexpression of proto-oncogenes by swapping their

regulatory elements with those of another gene.

- In many hematopoietic tumors, sarcomas, and certain carcinomas, the translocations allow normally unrelated sequences from two different chromosomes to recombine and form hybrid fusion genes that encode chimeric proteins that variously promote growth and survival, or enhance self-renewal and block differentiation.

TABLE 7-9 -- Selected Examples of Oncogenes Activated by Translocation

Malignancy	Translocation	Affected Genes[*]
Chronic myeloid leukemia	(9;22)(q34;q11)	
Acute leukemias (AML and ALL)	(8;21)(q22;q22)	*AML* 8q22
	(15;17)(q22;q21)	
Burkitt lymphoma	(8;14)(q24;q32)	
Malignancy	Translocation	Affected Genes[*]
Mantle cell lymphoma	(11;14)(q13;q32)	
Follicular lymphoma	(14;18)(q32;q21)	T-cell ALL	(10;14)(q24;q11)	
Ewing sarcoma	(11;22)(q24;q12)	Prostatic adenocarcinoma	(21;21)(q22;q22)	*TMPRSS2* (21q22.3)
	(7:21)(p22;q22)	*ERG* (21q22.2)
	(17:21)(p21;q22)	*ETV1* (7p21.2)
		ETV4 (17q21)

AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia.

* Genes in boldface are involved in multiple translocations.

Overexpression of a proto-oncogene caused by translocation is best exemplified by Burkitt lymphoma. All such tumors carry one of three translocations, each involving chromosome 8q24, where the *MYC* gene has been mapped, as well as one of the three immunoglobulin gene–carrying chromosomes. At its normal locus, *MYC* is tightly controlled, and is most highly expressed in actively dividing cells. In Burkitt lymphoma the most common form of translocation results in the movement of the *MYC*-containing segment of chromosome 8 to chromosome 14q32 (see Fig. 7-27), placing it close to the *IGH* gene. The genetic notation for the translocation is t(8:14)(q24;q32). The molecular mechanisms of the translocation-associated activation of *MYC* are variable, as are the precise breakpoints within the gene. In most cases the translocation causes mutation or loss of the regulatory sequences of the *MYC* gene, replacing them with the control regions of the *IGH* locus, which is highly expressed in B-cell precursors. As the coding sequences remain intact, the gene is constitutively expressed at high levels. The invariable presence of the translocated *MYC* gene in Burkitt lymphomas attests to the importance of *MYC* overactivity in the pathogenesis of this tumor.

There are other examples of oncogenes translocated to antigen receptor loci in lymphoid tumors. As mentioned earlier, in mantle cell lymphoma the cyclin D1 gene (*CCND1*) on chromosome 11q13 is overexpressed by juxtaposition to the *IGH* locus on 14q32. In follicular lymphomas, a t(14;18)(q32;q21) translocation, the most common translocation in lymphoid malignancies, causes activation of the *BCL2* gene. Not unexpectedly, all these tumors in which the immunoglobulin gene is involved are of B-cell origin. In an analogous situation, overexpression of several proto-oncogenes in T-cell tumors results from translocations of oncogenes into the T-cell antigen receptor locus. The affected oncogenes are diverse, but in most cases, as with *MYC*, they encode nuclear transcription factors.

The Philadelphia chromosome, characteristic of CML and a subset of acute lymphoblastic leukemias, provides the prototypic example of an oncogene formed by *fusion of two separate genes*. In these cases, a reciprocal translocation between chromosomes 9 and 22 relocates a truncated portion of the proto-oncogene c-*ABL* (from chromosome 9) to the *BCR (b*reakpoint *c*luster *r*egion) on chromosome 22 (see Fig. 7-27). The hybrid fusion gene *BCR-ABL* encodes a chimeric protein that has constitutive tyrosine kinase activity. As mentioned, BCR-ABL tyrosine kinase has served as a target for leukemia therapy, with remarkable success so far. Although the translocations are cytogenetically identical in CML and acute lymphoblastic leukemias, they usually differ at the molecular level. In most cases of CML the chimeric protein has a molecular weight of 210 kD, whereas in the more aggressive acute leukemias a 190-kD BCR-ABL fusion protein is typically formed.[48,][49]

Transcription factors are often the partners in gene fusions occurring in cancer cells. For instance, the *MLL* (myeloid, lymphoid leukemia) gene on 11q23, which itself is a component of a chromatin-remodeling complex, is known to be involved in 50 different translocations with several different partner genes, some of which encode transcription factors (see Table 7-9). Ewing sarcoma/primitive neuroectodermal tumor (PNET) is defined by translocation of the Ewing sarcoma (*EWSR1*) gene at 22q12, which is involved in numerous translocations, and all of its partner genes analyzed so far also encode a transcription factor. In Ewing sarcoma/PNET, for example, the *EWSR1* gene fuses with the *FLI1* gene, also a member of the ETS transcription factor family; the resultant chimeric EWS-FLI1 protein has transforming ability. One might ask, why are particular translocations so strongly associated with specific tumors? This is incompletely understood, but one recurrent theme is that at least one of the affected genes often encodes a transcription factor that is required for the development and differentiation of normal cells of the same lineage as the tumor. For example, in acute leukemias many genes involved by recurrent translocations (such as *MLL*) play essential roles in regulating the self-renewal of hematopoietic stem cells and the normal differentiation of lymphoid and myeloid cells. The

fusion proteins resulting from translocations most often inhibit, but occasionally increase, transcriptional function. Until recently, most known translocations were discovered in leukemias/lymphomas and sarcomas; few common translocations had been identified in carcinomas, even though carcinomas are more common. The complex karyotypes of most carcinomas have made identifying translocations difficult. Recently, however, a translocation involving an androgen-regulated gene, *TMPRSS2* (21q22), and one of three ETS family transcription factors (*ERG* [21q22], *ETV1* [7p22.2], or *ETV4* [17q21]) was found to be present in 50% or more prostate adenocarcinomas.[137,][138] Development of this translocation seems to occur early in carcinogenesis, in that it is also present in high-grade prostatic intraepithelial neoplasia, a precursor lesion. Although the mechanism by which this translocation causes cancer is not completely understood, it removes the ETS family gene from its normal control region and fuses it to the androgen-regulated *TMPRSS2*. Thus, the ETS family transcription factor is inappropriately expressed in prostate cells, and as noted above with Ewing sarcoma, when ETS proteins are inappropriately expressed they have transforming ability. There is significant interest in identifying additional fusion genes in other carcinomas. Many fusion genes are thought to be initiators in carcinogenesis, and it is postulated that many cancers may be "addicted" to their properties, similar to the oncogene addiction seen in CML with the BCR-ABL fusion. Thus, inhibition of these genes may provide an avenue for targeted therapy.

Deletions.

Chromosomal deletions are the second most prevalent structural abnormality in tumor cells. *Compared with translocations, deletions are more common in nonhematopoietic solid tumors*. Deletion of specific regions of chromosomes is associated with the loss of particular tumor suppressor genes. As discussed, deletions involving chromosome 13q14, the site of the *RB* gene, are associated with retinoblastoma. Deletions of 17p, 5q, and 18q have all been noted in colorectal cancers; these regions harbor three tumor suppressor genes. Deletion of 3p, noted in several tumors, is extremely common in small-cell lung carcinomas, and the hunt is on for one or more cancer suppressor genes at this locale.

Gene Amplification

Activation of proto-oncogenes associated with overexpression of their products may result from reduplication and *amplification* of their DNA sequences.[139] Such amplification may produce several hundred copies of the proto-oncogene in the tumor cell. The amplified genes can be readily detected by molecular hybridization with appropriate DNA probes. In some cases the amplified genes produce chromosomal changes that can be identified microscopically. Two mutually exclusive patterns are seen: multiple small, centric structures called *double minutes* and *homogeneous staining regions*. The latter derive from the insertion of the amplified genes into new chromosomal locations, which may be distant from the normal location of the involved genes; because regions containing amplified genes lack a normal banding pattern, they appear homogeneous in a G-banded karyotype (see Fig. 7-28). The most interesting cases of amplification involve N-*MYC* in neuroblastoma and *ERBB2* in breast cancers. N-*MYC* is amplified in 25% to 30% of neuroblastomas, and the amplification is associated with poor prognosis. In neuroblastomas with N-*MYC* amplification, the gene is present both in double minutes and homogeneous staining regions. *ERBB2* amplification occurs in about 20% of breast cancers, and antibody therapy directed against this receptor has proven effective in this subset of tumors. Amplification of C-*MYC*, L-*MYC*, or N-*MYC* correlates with disease progression in small-cell cancer of the lung.

Epigenetic Changes

Epigenetics refers to reversible, heritable changes in gene expression that occur without mutation. Such changes involve post-translational modifications of histones and DNA methylation, both of which affect gene expression. In normal, differentiated cells, the majority of the genome is not expressed. Some

portions of the genome are silenced by DNA methylation and histone modifications that lead to the compaction of DNA into heterochromatin. On the other hand, cancer cells are characterized by a global DNA hypomethylation and selective promoter-localized hypermethylation.[140] Indeed, it has become evident during the past few years that tumor suppressor genes are sometimes silenced by hypermethylation of promoter sequences rather than mutation. One example is CDKN2A, a complex locus that encodes two tumor suppressors, p14/ARF and p16/INK4a from two different reading frames; p14/ARF is epigenetically silenced in colon and gastric cancers, while p16/INK4a is silenced in a wide variety of cancers. Since this locus produces two tumor suppressors which affect the p53 and Rb pathways, silencing this locus has the pleasing effect (from the cancer's point of view) of removing two checkpoints with a single alteration. Other tumor suppressor genes subject to silencing by methylation include *BRCA1* in breast cancer, *VHL* in renal cell carcinomas, and the *MLH1* mismatch-repair gene in colorectal cancer.[140] You will recall from Chapter 5 that methylation also participates in the phenomenon called *genomic imprinting*, in which the maternal or paternal allele of a gene or chromosome is modified by methylation and is inactivated. The reverse phenomenon—that is, demethylation of an imprinted gene leading to its biallelic expression (loss of imprinting)—can also occur in tumor cells.[141] There has been great interest in developing potential therapeutic agents that act to demethylate DNA sequences in tumor suppressor genes. Recent data demonstrating that genomic hypomethylation causes chromosomal instability and induces tumors in mice greatly strengthen the notion that epigenetic changes may directly contribute to tumor development.[141]

The chromatin changes that contribute to carcinogenesis are less well understood. The current paradigm is that there is a histone code in which various modifications to the tails of histones, such as acetylation and methylation, lead to activation or repression of transcription. Several chromatin-modifying enzymes, such as EZH2, have been shown to be overexpressed in breast and prostate carcinomas.[141] EZH2 is the enzymatic component of the multiprotein polycomb repressive complex 2, which places repressive chromatin marks at the promoter of genes. Although its targets in cancer in vivo have not yet been defined, in cell lines overexpression of EZH2 leads to the repression of tumor suppressors, such as p21. Interestingly, in flies and mammals the polycomb repressive complexes are required for the maintenance of stem cells, as well as to silence lineage-specific transcription factors until the proper cues signal differentiation. Inappropriate repression or expression of such genes could give cancer cells a stem cell–like, undifferentiated quality. There is, of course, significant cross-talk between the chromatin-remodeling enzymes and the DNA-methylation machinery. For example, the placement of repressive chromatin marks by enzymes like EZH2 in cancer cells results in the recruitment of DNA methylases, methylation of promoters, and durable repression of gene expression.

miRNAs and Cancer

As discussed in Chapter 5 , miRNAs are small noncoding, single-stranded RNAs, approximately 22 nucleotides in length, that are incorporated into the RNA-induced silencing complex. The miRNAs mediate sequence-specific recognition of mRNAs and, through the action of the RNA-induced silencing complex, mediate post-transcriptional gene silencing. Given that miRNAs control cell growth, differentiation, and cell survival, it is not surprising that they play a role in carcinogenesis.[142] miRNAs have been shown to undergo changes in expression in cancer cells, and frequent amplifications and deletions of miRNA loci have been identified in many cancers. As illustrated in Figure 7-39 , miRNAs can participate in neoplastic transformation either by increasing the expression of oncogenes or by reducing the expression of tumor suppressor genes. If a miRNA inhibits the translation of an oncogene, a reduction in the quantity or function of that miRNA will lead to overproduction of the oncogene product; thus, the miRNA acts as a tumor suppressor. Conversely, if the target of a miRNA is a tumor suppressor gene, then overactivity of the miRNA can reduce the tumor suppressor protein; thus, the miRNA acts as an oncogene. Such relationships have already been established by miRNA profiling of several human tumors. For example, down-regulation or deletion of certain miRNAs in some leukemias

and lymphomas results in increased expression of BCL2, the anti-apoptotic protein. Thus, by negatively regulating BCL2, such miRNAs behave as tumor suppressor genes. Similar miRNA-mediated upregulation of *RAS* and *MYC* oncogenes has also been detected in lung tumors and in certain B-cell leukemias, respectively. In some brain and breast tumors there is 5- to 100-fold greater expression of certain miRNAs. Although the targets of these miRNAs have not been identified, presumably they are tumor suppressor genes, whose activities are reduced by the overexpressed miRNA.

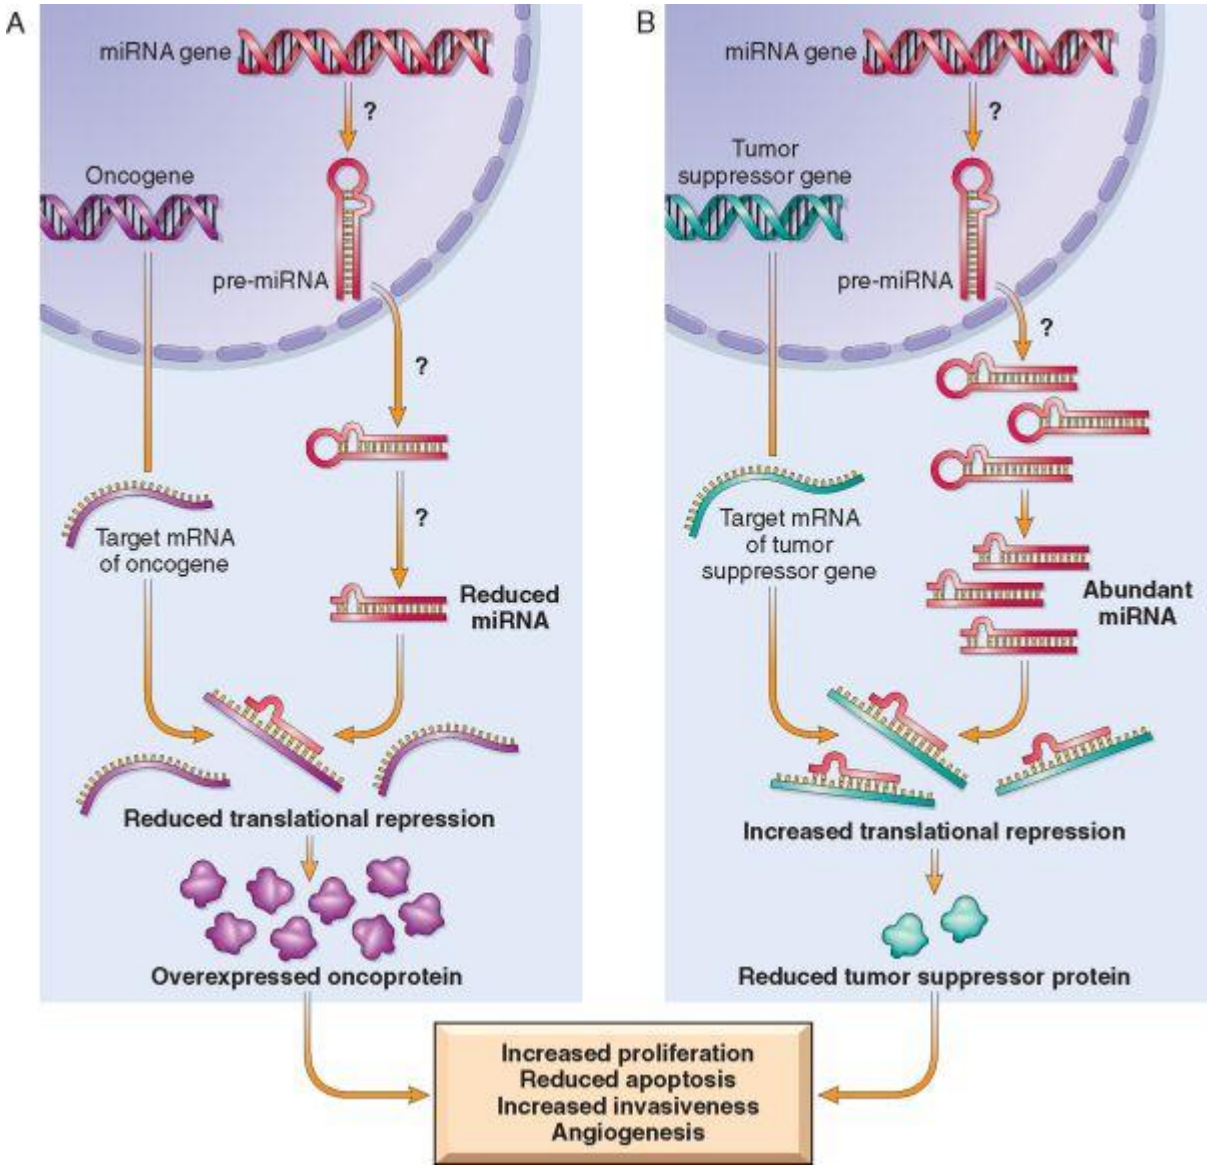

FIGURE 7-39 Role of miRNAs in tumorigenesis. **A**, Reduced activity of a miRNA that inhibits translation of an oncogene gives rise to an excess of oncoproteins. **B**, Overactivity of a miRNA that targets a tumor suppression gene reduces the production of the tumor suppressor protein. Question marks in **A** and **B** indicate that the mechanisms by which changes in the level or activity of miRNA are not entirely known.

These findings not only provide novel insights into carcinogenesis, they also have practical implications. For instance, drugs that inhibit or augment the functions of miRNAs could be useful in chemotherapy. Since miRNAs regulate normal cellular differentiation, the patterns of miRNA expression ("miRNA

profiling") can provide clues to the cell of origin and classification of tumors. Much remains to be learned about these oncogenic miRNAs, or so called "oncomirs."

2.7.5 Molecular Basis of Multistep Carcinogenesis

The notion that malignant tumors arise from a protracted sequence of events is supported by epidemiologic, experimental, and molecular studies. The study of oncogenes and tumor suppressor genes has provided a firm molecular footing for the concept of multistep carcinogenesis.[143]

Given that malignant tumors must acquire several fundamental abnormalities, discussed above, it follows that *each cancer must result from the accumulation of multiple mutations*. Indeed, recently completed genome-wide sequencing analysis of breast and colon cancers has revealed that individual tumors accumulate an average of 90 mutant genes. A much smaller subset of these (11/tumor) were mutated at significant frequency.[144] Included among the mutated genes are some known oncogenes and tumor suppressor genes, and others that were not previously known to be tumor-associated. It is not yet established which of these mutations establish the transformed state, contribute to tumor progression, or are "passengers" (neutral mutations) occurring in genomically unstable cells that are merely "along for the ride". More directly, however, no single oncogene can fully transform nonimmortalized cells in vitro, but *cells can generally be transformed by combinations of oncogenes*. Such cooperation is required because each oncogene is specialized to induce part of the phenotype necessary for full transformation. For instance, the *RAS* oncogene induces cells to secrete growth factors and permits them to grow without anchorage to a normal substrate (anchorage independence), whereas the *MYC* oncogene renders cells more sensitive to growth factors and immortalizes cells. These two genes, acting in conjunction, can cause neoplastic transformation of mouse fibroblasts in culture.

Furthermore, it seems that evolution has installed a variety of "intrinsic tumor-suppressive mechanisms" such as apoptosis and senescence that thwart the actions of growth-promoting mutations. Indeed, in cells with competent checkpoints, oncogenic signaling through proteins like RAS leads not to transformation but to senescence or apoptosis.[33] Thus, emergence of malignant tumors requires mutational loss of many genes, including those that regulate apoptosis and senescence.[145] A classic example of incremental acquisition of the malignant phenotype is documented by the study of colon carcinoma. Many of these cancers are believed to evolve through a series of morphologically identifiable stages: colon epithelial hyperplasia followed by formation of adenomas that progressively enlarge and ultimately undergo malignant transformation (Chapter 17). The proposed molecular correlates of this adenoma-carcinoma sequence are illustrated in Figure 7-40 . According to this scheme, inactivation of the *APC* tumor suppressor gene occurs first, followed by activation of *RAS* and, ultimately, loss of a tumor suppressor gene on 18q and loss of *p53*. Also depicted is the senescence pathway if *p53* loss does not occur. Indeed, it has been shown that most cells in most adenomas are senescent. It is thought that mutation of a proto-oncogene such as *RAS* drives a cell into senescence instead of proliferation[33] by activating the DNA-damage checkpoint, as discussed previously. The loss of p53 in adenomas prevents oncogene-induced senescence, allowing the adenomatous cells to continue to proliferate, generating a carcinoma. While multiple mutations, including gain of oncogenes and loss of tumor suppressors, are required for carcinogenesis, the precise temporal sequence of mutations may be different in each organ and tumor type.

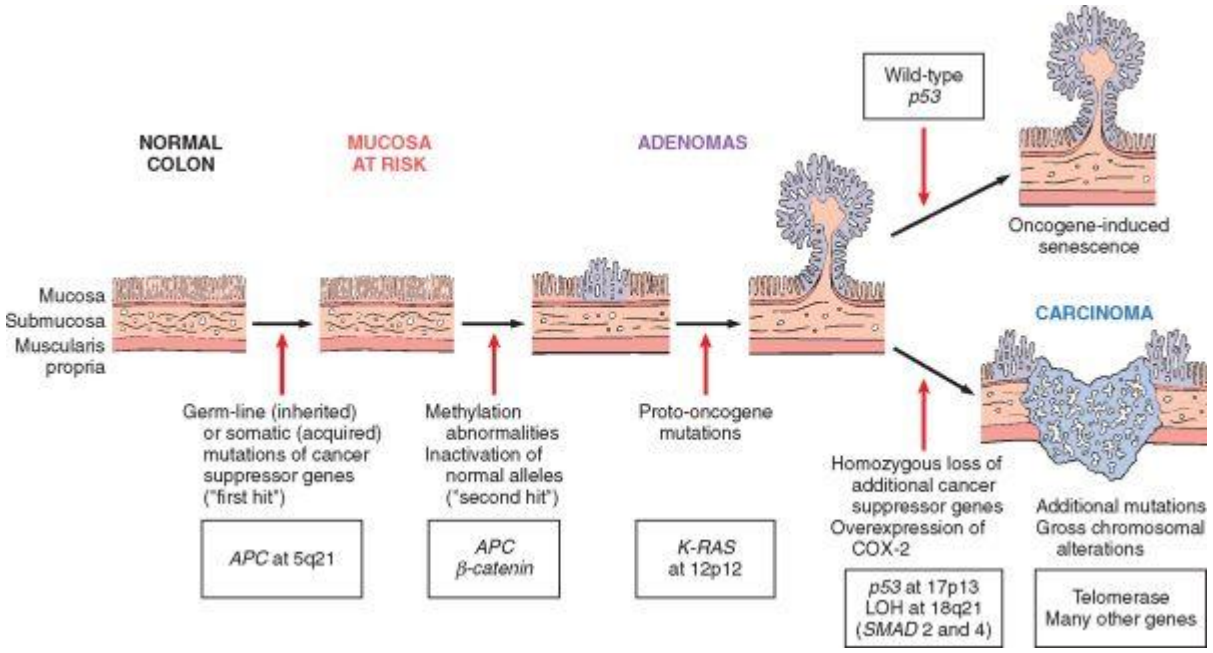

FIGURE 7-40 Molecular model for the evolution of colorectal cancers through the adenoma-carcinoma sequence. Although *APC* mutation is an early event and loss of *p53* occurs late in the process of tumorigenesis, the timing for the other changes may be variable. Note also that individual tumors may not have all of the changes listed. *Top right*, cells that gain oncogene signaling without loss of p53 eventually enter oncogene-induced senescence.

2.7.6 Carcinogenic Agents & Their Cellular Interactions

More than 200 years ago the London surgeon Sir Percival Pott correctly attributed scrotal skin cancer in chimney sweeps to chronic exposure to soot. Based on this observation, the Danish Chimney Sweeps Guild ruled that its members must bathe daily. No public health measure since that time has achieved so much in the control of a form of cancer. Subsequently, hundreds of chemicals have been shown to be carcinogenic in animals.

Some of the major agents are presented in Table 7-10 . A few comments are offered on a handful of these.

TABLE 7-10 -- Major Chemical Carcinogens

DIRECT-ACTING CARCINOGENS
Alkylating Agents
β-Propiolactone Dimethyl sulfate Diepoxybutane Anticancer drugs (cyclophosphamide, chlorambucil, nitrosoureas, and others)
Acylating Agents
1-Acetyl-imidazole Dimethylcarbamyl chloride
PROCARCINOGENS THAT REQUIRE METABOLIC ACTIVATION

Polycyclic and Heterocyclic Aromatic Hydrocarbons
Benz[*a*]anthracene
Benzo[*a*]pyrene
Dibenz[*a,h*]anthracene
3-Methylcholanthrene
7,12-Dimethylbenz[*a*]anthracene
Aromatic Amines, Amides, Azo Dyes
2-Naphthylamine (β-naphthylamine)
Benzidine
2-Acetylaminofluorene
Dimethylaminoazobenzene (butter yellow)
Natural Plant and Microbial Products
Aflatoxin B_1
Griseofulvin
Cycasin
Safrole
Betel nuts
Others
Nitrosamine and amides
Vinyl chloride, nickel, chromium
Insecticides, fungicides
Polychlorinated biphenyls

Steps Involved in Chemical Carcinogenesis

As discussed earlier, carcinogenesis is a multistep process. This is most readily demonstrated in experimental models of chemical carcinogenesis, in which the stages of initiation and progression during cancer development were first described.[146] The classic experiments that allowed the distinction between initiation and promotion were performed on mouse skin and are outlined in Figure 7-41 . The following concepts relating to the initiation-promotion sequence have emerged from these experiments:

- *Initiation* results from exposure of cells to a sufficient dose of a carcinogenic agent (initiator); an initiated cell is altered, making it potentially capable of giving rise to a tumor (groups 2 and 3). *Initiation alone, however, is not sufficient for tumor formation* (group 1).
- *Initiation causes permanent DNA damage (mutations). It is therefore rapid and irreversible and has "memory."* This is illustrated by group 3, in which tumors were produced even if the application of the promoting agent was delayed for several months after a single application of the initiator.
- *Promoters can induce tumors in initiated cells, but they are nontumorigenic by themselves* (group 5). Furthermore, tumors do not result when the promoting agent is applied before, rather than after, the initiating agent (group 4). This indicates that, *in contrast to the effects of initiators, the cellular changes resulting from the application of promoters do not affect DNA directly and are reversible*. As discussed later, promoters enhance the proliferation of initiated cells, an effect that may contribute to the development of additional mutations in these cells. That the effects of promoters are reversible is further documented in group 6, in

which tumors failed to develop in initiated cells if the time between multiple applications of the promoter was sufficiently extended.

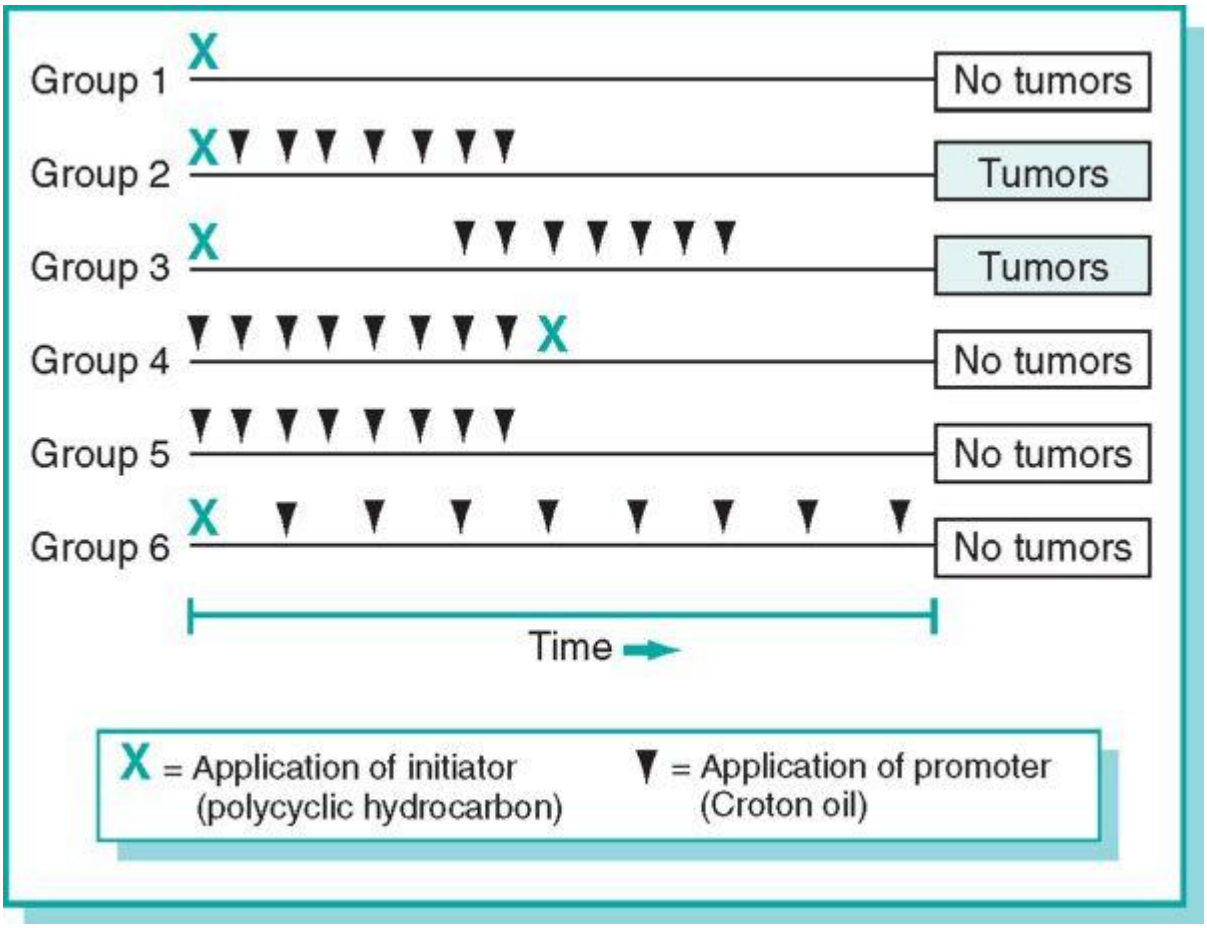

FIGURE 7-41 Experiments demonstrating the initiation and promotion phases of carcinogenesis in mice. Group 2: application of promoter repeated at twice-weekly intervals for several months. Group 3: application of promoter delayed for several months and then applied twice weekly. Group 6: promoter applied at monthly intervals.

Although the concepts of initiation and promotion have been derived largely from experiments involving induction of skin cancer in mice, these stages are also discernible in the development of cancers of the liver, urinary bladder, breast, colon, and respiratory tract. With this brief overview of two major steps in carcinogenesis, we can examine initiation and promotion in more detail (Fig. 7-42). All initiating chemical carcinogens are highly reactive electrophiles (have electron-deficient atoms) that can react with nucleophilic (electron-rich) sites in the cell. Their targets are DNA, RNA, and proteins, and in some cases these interactions cause cell death. Initiation, obviously, inflicts nonlethal damage on the DNA that cannot be repaired. The mutated cell then passes on the DNA lesions to its daughter cells. Chemicals that can cause initiation of carcinogenesis can be classified into two categories: direct acting and indirect acting.

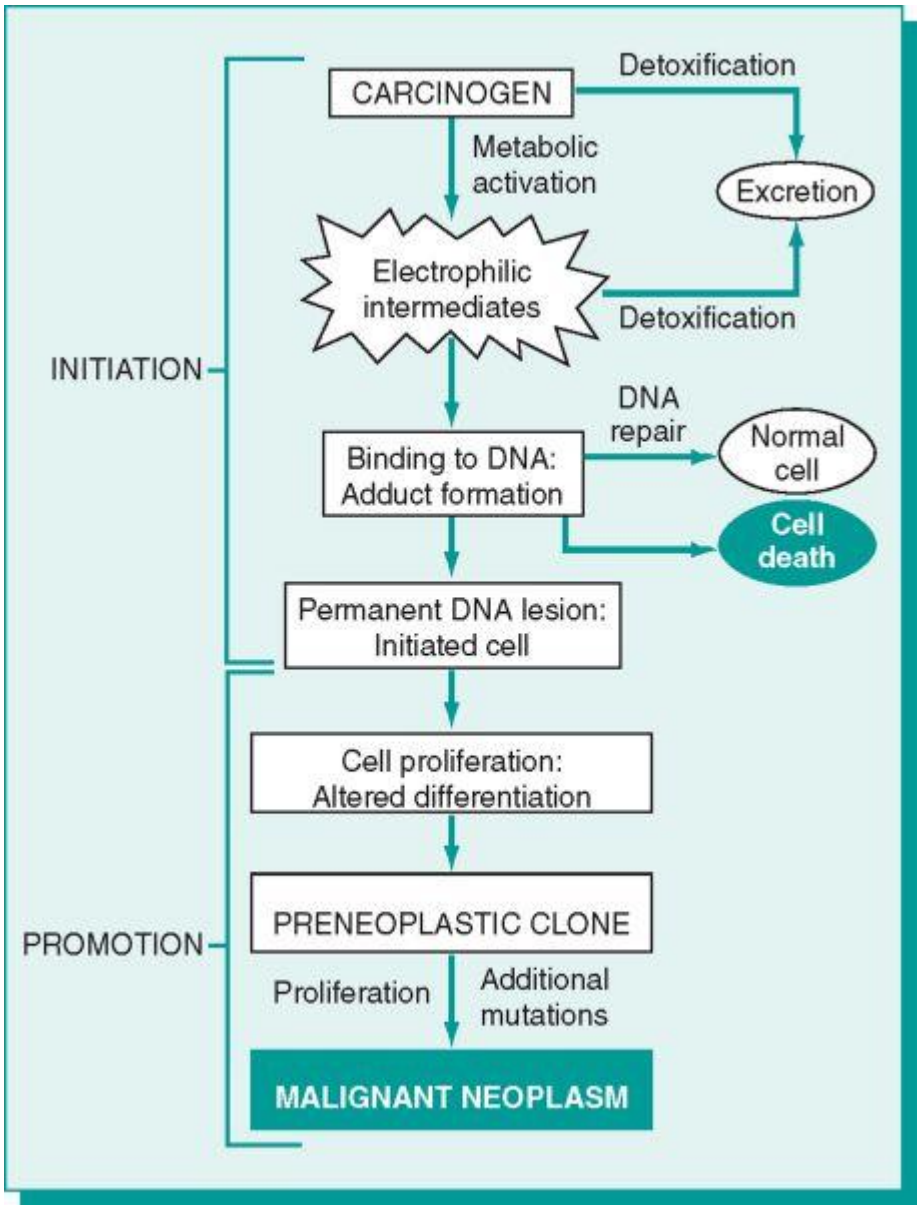

FIGURE 7-42 General schema of events in chemical carcinogenesis. Note that promoters cause clonal expansion of the initiated cell, thus producing a preneoplastic clone. Further proliferation induced by the promoter or other factors causes accumulation of additional mutations and emergence of a malignant tumor.

Direct-Acting Agents

Direct-acting agents require no metabolic conversion to become carcinogenic. Most of them are weak carcinogens but are important because some are cancer chemotherapeutic drugs (e.g., alkylating agents) that have successfully cured, controlled, or delayed recurrence of certain types of cancer (e.g., leukemia, lymphoma, and ovarian carcinoma), only to evoke later a second form of cancer, usually acute myeloid leukemia. The risk of induced cancer is low, but its existence dictates judicious use of such agents.

Indirect-Acting Agents

The designation *indirect-acting agent* refers to chemicals that require metabolic conversion to an *ultimate carcinogen* before they become active. Some of the most potent indirect chemical

carcinogens—the polycyclic hydrocarbons—are present in fossil fuels. Others, for example, benzo[*a*]pyrene and other carcinogens, are formed in the high-temperature combustion of tobacco in cigarette smoking. *These products are implicated in the causation of lung cancer in cigarette smokers*. Polycyclic hydrocarbons may also be produced from animal fats during the process of broiling meats and are present in smoked meats and fish. The principal active products in many hydrocarbons are epoxides, which form covalent adducts (addition products) with molecules in the cell, principally DNA, but also with RNA and proteins.

The aromatic amines and azo dyes are another class of indirect-acting carcinogens that were widely used in the past in the aniline dye and rubber industries.[147] Many other occupational carcinogens are listed in Table 7-3 .

Most chemical carcinogens require metabolic activation for conversion into ultimate carcinogens (see Fig. 7-42). Other metabolic pathways may lead to the inactivation (detoxification) of the procarcinogen or its derivatives. Thus, *the carcinogenic potency of a chemical is determined not only by the inherent reactivity of its electrophilic derivative but also by the balance between metabolic activation and inactivation reactions*.

Most of the known carcinogens are metabolized by cytochrome P-450–dependent mono-oxygenases. The genes that encode these enzymes are quite polymorphic, and the activity and inducibility of these enzymes have been shown to vary among different individuals. Because these enzymes are essential for the activation of procarcinogens, the susceptibility to carcinogenesis is regulated in part by polymorphisms in the genes that encode these enzymes. Thus, it may be possible to assess cancer risk in a given individual by genetic analysis of such enzyme polymorphisms.[147]

The metabolism of polycyclic aromatic hydrocarbons, such as benzo[*a*]pyrene by the product of the P-450 gene, *CYP1A1*, provides an instructive example. Approximately 10% of the white population has a highly inducible form of this enzyme that is associated with an increased risk of lung cancer in smokers.[148,][149] Light smokers with the susceptible genotype *CYP1A1* have a sevenfold higher risk of developing lung cancer, compared with smokers without the permissive genotype. Not all variations in the activation or detoxification of carcinogens are genetically determined. Age, sex, and nutritional status also determine the internal dose of toxicants produced and hence influence the risk of cancer development in a particular individual.[150]

Molecular Targets of Chemical Carcinogens.

Because malignant transformation results from mutations, it comes as no surprise that the majority of initiating chemicals are mutagenic. Thus, DNA is the primary target for chemical carcinogens, but there is no single or unique alteration associated with initiation of chemical carcinogenesis. Although any gene may be the target of chemical carcinogens, the commonly mutated oncogenes and tumor suppressors, such as *RAS* and *p53*, are particularly important targets. An illustrative example of a chemical carcinogenesis is aflatoxin B_1, a naturally occurring agent produced by some strains of *Aspergillus*, a mold that grows on improperly stored grains and nuts. There is a *strong correlation between the dietary level of this food contaminant and the incidence of hepatocellular carcinoma in parts of Africa and the Far East*. Interestingly, aflatoxin B_1 produces mutations in the *p53* gene; 90% or more of these mutations are a characteristic G : C→T : A transversion in codon 249 (called *249(ser) p53* mutation).[151] By contrast, *p53* mutations are much less frequent in liver tumors from areas where aflatoxin contamination of food is not a risk factor, and the *249(ser)* mutation is uncommon. Thus, the detection of the "*signature mutation*" within the *p53* gene establishes aflatoxin as the causative agent. These associations are proving to be useful tools in epidemiologic studies of chemical carcinogenesis.

Additionally, vinyl chloride, arsenic, nickel, chromium, insecticides, fungicides, and polychlorinated biphenyls are potential carcinogens in the workplace and at home. Finally, nitrites used as food preservatives have caused concern, since they cause nitrosylation of amines contained in the food. The nitrosoamines so formed are suspected to be carcinogenic.

Initiation and Promotion of Chemical Carcinogenesis

Unrepaired alterations in the DNA are essential first steps in the process of initiation. *For the change to be heritable, the damaged DNA template must be replicated. Thus, for initiation to occur, carcinogen-altered cells must undergo at least one cycle of proliferation so that the change in DNA becomes fixed*. In the liver, many chemicals are activated to reactive electrophiles, yet most of them do not produce cancers unless the liver cells proliferate within a few days of the formation of DNA adducts. In tissues that are normally quiescent, the mitogenic stimulus may be provided by the carcinogen itself, because many cells die as a result of toxic effects of the carcinogenic chemical, thereby stimulating regeneration in the surviving cells. Alternatively, cell proliferation may be induced by concurrent exposure to biologic agents such as viruses and parasites, dietary factors, or hormonal influences. Agents that do not cause mutation but instead stimulate the division of mutated cells are known as *promoters*.

The carcinogenicity of some initiators is augmented by subsequent administration of *promoters* (such as phorbol esters, hormones, phenols, and drugs) that by themselves are nontumorigenic. Application of promoters leads to proliferation and clonal expansion of initiated (mutated) cells. Such cells have reduced growth factor requirements and may also be less responsive to growth-inhibitory signals in their extracellular milieu. Driven to proliferate, the initiated clone of cells suffers additional mutations, developing eventually into a malignant tumor. Thus, the process of tumor promotion includes multiple steps: proliferation of preneoplastic cells, malignant conversion, and eventually tumor progression, which depends on changes in tumor cells and the tumor stroma—the process of multistep carcinogenesis highlighted above.

RADIATION CARCINOGENESIS

Radiant energy, whether in the form of the UV rays of sunlight or as ionizing electromagnetic and particulate radiation, is a well-established carcinogen. UV light is clearly implicated in the causation of skin cancers, and ionizing radiation exposure from medical or occupational exposure, nuclear plant accidents, and atomic bomb detonations has produced a variety of cancers. Although the contribution of radiation to the total human burden of cancer is probably small, the well-known latency of damage caused by radiant energy and its cumulative effect require extremely long periods of observation and make it difficult to ascertain its full significance. An increased incidence of breast cancer has become apparent decades later among women exposed during childhood to atomic bomb tests. The incidence peaked during 1988–1992 and then declined.[152] Moreover, radiation's possible additive or synergistic effects with other potential carcinogenic influences add another dimension to the picture.

Ultraviolet Rays

There is ample evidence from epidemiologic studies that *UV rays* derived from the sun cause an increased incidence of squamous cell carcinoma, basal cell carcinoma, and possibly melanoma of the skin.[153] The degree of risk depends on the type of UV rays, the intensity of exposure, and the quantity of the light-absorbing “protective mantle” of melanin in the skin. Persons of European origin who have fair skin that repeatedly becomes sunburned but stalwartly refuses to tan and who live in locales receiving a great deal of sunlight (e.g., Queensland, Australia, close to the equator) have among the highest incidence of skin cancers (melanomas, squamous cell carcinomas, and basal cell carcinomas) in the world. Nonmelanoma skin cancers are associated with total cumulative exposure to UV radiation, whereas melanomas are associated with intense intermittent exposure—as occurs with sunbathing. The

UV portion of the solar spectrum can be divided into three wavelength ranges: UVA (320–400 nm), UVB (280–320 nm), and UVC (200–280 nm). Of these, UVB is believed to be responsible for the induction of cutaneous cancers. UVC, although a potent mutagen, is not considered significant because it is filtered out by the ozone shield around the earth (hence the concern about ozone depletion).

The carcinogenicity of UVB light is attributed to its formation of pyrimidine dimers in DNA. This type of DNA damage is repaired by the nucleotide excision repair pathway. There are five steps in nucleotide excision repair, and in mammalian cells the process may involve 30 or more proteins. It is postulated that with excessive sun exposure, the capacity of the nucleotide excision repair pathway is overwhelmed, and error-prone nontemplated DNA-repair mechanisms become operative that provide for the survival of the cell at the cost of genomic mutations that in some instances, lead to cancer. The importance of the nucleotide excision repair pathway of DNA repair is most graphically illustrated by the high frequency of cancers in individuals with the hereditary disorder *xeroderma pigmentosum* (discussed previously).[126]

Ionizing Radiation

Electromagnetic (x-rays, γ rays) and particulate (α particles, β particles, protons, neutrons) radiations are all carcinogenic. The evidence is so voluminous that a few examples suffice.[152,][154] Many individuals pioneering the use of x-rays developed skin cancers. Miners of radioactive elements in central Europe and the Rocky Mountain region of the United States have a tenfold increased incidence of lung cancers compared to the rest of the population. Most telling is the follow-up of survivors of the atomic bombs dropped on Hiroshima and Nagasaki. Initially there was a marked increase in the incidence of leukemias—principally acute and chronic myelogenous leukemia—after an average latent period of about 7 years. Subsequently the incidence of many solid tumors with longer latent periods (e.g., breast, colon, thyroid, and lung) increased.

In humans there is a hierarchy of vulnerability of different tissues to radiation-induced cancers. Most frequent are the acute and chronic myeloid leukemia. Cancer of the thyroid follows closely but only in the young. In the intermediate category are cancers of the breast, lungs, and salivary glands. In contrast, skin, bone, and the gastrointestinal tract are relatively resistant to radiation-induced neoplasia, even though the gastrointestinal epithelial cells are vulnerable to the acute cell-killing effects of radiation, and the skin is in the pathway of all external radiation. Nonetheless, the physician dare not forget: practically *any* cell can be transformed into a cancer cell by sufficient exposure to radiant energy.

MICROBIAL CARCINOGENESIS

Many RNA and DNA viruses have proved to be oncogenic in animals as disparate as frogs and primates. Despite intense scrutiny, however, only a few viruses have been linked with human cancer. Our discussion focuses on human oncogenic viruses as well as the emerging role of the bacterium *Helicobacter pylori* in gastric cancer.

Oncogenic RNA Viruses

Human T-Cell Leukemia Virus Type 1.

Although the study of animal retroviruses has provided spectacular insights into the molecular basis of cancer, only one human retrovirus, human T-cell leukemia virus type 1 (HTLV-1), is firmly implicated in the causation of cancer in humans.

HTLV-1 causes a form of T-cell leukemia/lymphoma that is endemic in certain parts of Japan and the Caribbean basin but is found sporadically elsewhere, including the United States.[155] Similar to the human immunodeficiency virus, which causes acquired immunodeficiency syndrome (AIDS), HTLV-1

has tropism for CD4+ T cells, and hence this subset of T cells is the major target for neoplastic transformation. Human infection requires transmission of infected T cells via sexual intercourse, blood products, or breastfeeding. Leukemia develops in only 3% to 5% of the infected individuals after a long latent period of 40 to 60 years.

There is little doubt that HTLV-1 infection of T lymphocytes is necessary for leukemogenesis, but the molecular mechanisms of transformation are not entirely clear. In contrast to several murine retroviruses, HTLV-1 does not contain an oncogene, and no consistent integration next to a proto-oncogene has been discovered. In leukemic cells, however, viral integration shows a clonal pattern. In other words, although the site of viral integration in host chromosomes is random (the viral DNA is found at different locations in different cancers), the site of integration is identical within all cells of a given cancer. This would not occur if HTLV-1 were merely a passenger that infects cells after transformation. The HTLV-1 genome contains the *gag*, *pol*, *env*, and long-terminal-repeat regions typical of other retroviruses, but, in contrast to other leukemia viruses, it contains another region, referred to as *tax*. It seems that the secrets of its transforming activity are locked in the *tax* gene.[156] The product of this gene is essential for viral replication, because it stimulates transcription of viral mRNA by acting on the 5′ long terminal repeat. It is now established that the Tax protein can also activate the transcription of several host cell genes involved in proliferation and differentiation of T cells. These include the immediate early gene *FOS*, genes encoding interleukin-2 (IL-2) and its receptor, and the gene for the myeloid growth factor granulocyte-macrophage colony-stimulating factor. In addition, Tax protein inactivates the cell cycle inhibitor p16/INK4a and enhances cyclin D activation, thus dysregulating the cell cycle. Tax also activates NF-κb, a transcription factor that regulates a host of genes, including pro-survival/anti-apoptotic genes. Another mechanism by which Tax may contribute to malignant transformation is through genomic instability. Recent data show that Tax interferes with DNA-repair functions and inhibits ATM-mediated cell cycle checkpoints activated by DNA damage.[156]

The main steps that lead to the development of adult T-cell leukemia/lymphoma may be summarized as follows. Infection by HTLV-1 causes the expansion of a nonmalignant polyclonal cell population through stimulatory effects of Tax on cell proliferation. The proliferating T cells are at increased risk of mutations and genomic instability induced by Tax. This instability allows the accumulation of mutations and chromosomal abnormalities, and eventually a monoclonal neoplastic T-cell population emerges. The malignant cells replicate independently of IL-2 and contain molecular and chromosomal abnormalities.

Oncogenic DNA Viruses

As with RNA viruses, several oncogenic DNA viruses that cause tumors in animals have been identified. Of the various human DNA viruses, four—HPV, Epstein-Barr virus (EBV), hepatitis B virus (HBV), and Kaposi sarcoma herpesvirus, also called human herpesvirus 8—have been implicated in the causation of human cancer. A fifth virus, Merkel cell polyomavirus, has been identified in Merkel cell carcinomas and may soon join the rogue's gallery; it is described in Chapter 25 . Kaposi sarcoma herpesvirus is discussed in Chapters 6 and 11 . Though not a DNA virus, HCV is also associated with cancer and is discussed briefly here.[157]

Human Papillomavirus.

At least 70 genetically distinct types of HPV have been identified. Some types (e.g., 1, 2, 4, and 7) cause benign squamous papillomas (warts) in humans (Chapters 19 and 22 . By contrast, high-risk HPVs (e.g., types 16 and 18) have been implicated in the genesis of several cancers, particularly squamous cell carcinoma of the cervix and anogenital region.[158,][159] Thus, cervical cancer is a sexually transmitted disease, caused by transmission of HPV. In addition, at least 20% of oropharyngeal cancers are associated with HPV. In contrast to cervical cancers, genital warts have low malignant potential and

are associated with low-risk HPVs, predominantly HPV-6 and HPV-11. Interestingly, in benign warts the HPV genome is maintained in a nonintegrated episomal form, while in cancers the HPV genome is integrated into the host genome, suggesting that integration of viral DNA is important for malignant transformation. As with HTLV-1, the site of viral integration in host chromosomes is random, but the pattern of integration is clonal. Cells in which the viral genome has integrated show significantly more genomic instability. Furthermore, since the integration site is random there is no consistent association with a host proto-oncogene. Rather, integration interrupts the viral DNA within the E1/E2 open reading frame, leading to loss of the E2 viral repressor and overexpression of the oncoproteins E6 and E7.

Indeed, the oncogenic potential of HPV can be related to the products of two viral genes, E6 and E7. Together, they interact with a variety of growth-regulating proteins encoded by proto-oncogenes and tumor suppressor genes (Fig. 7-43). The E7 protein binds to the RB protein and displaces the E2F transcription factors that are normally sequestered by RB, promoting progression through the cell cycle. Of note, E7 protein from high-risk HPV types has a higher affinity for RB than does E7 from low-risk HPV types. E7 also inactivates the CDKIs p21 and p27. E7 proteins from high-risk HPV types (types 16, 18, and 31) also bind and presumably activate cyclins E and A. The E6 protein has complementary effects. It binds to and mediates the degradation of p53 and BAX, a pro-apoptotic member of the BCL2 family, and it activates telomerase. Like E7, E6 from high-risk HPV types has a higher affinity for p53 than E6 from low-risk HPV types. Interestingly the E6-p53 interaction may offer some clues regarding polymorphisms and risk factors for development of cervical cancer. Human *p53* is polymorphic at amino acid 72, encoding either a proline or arginine residue at that position. The p53 Arg72 variant is much more susceptible to degradation by E6. Not surprisingly, infected individuals with the Arg72 polymorphism are more likely to develop cervical carcinomas.[160]

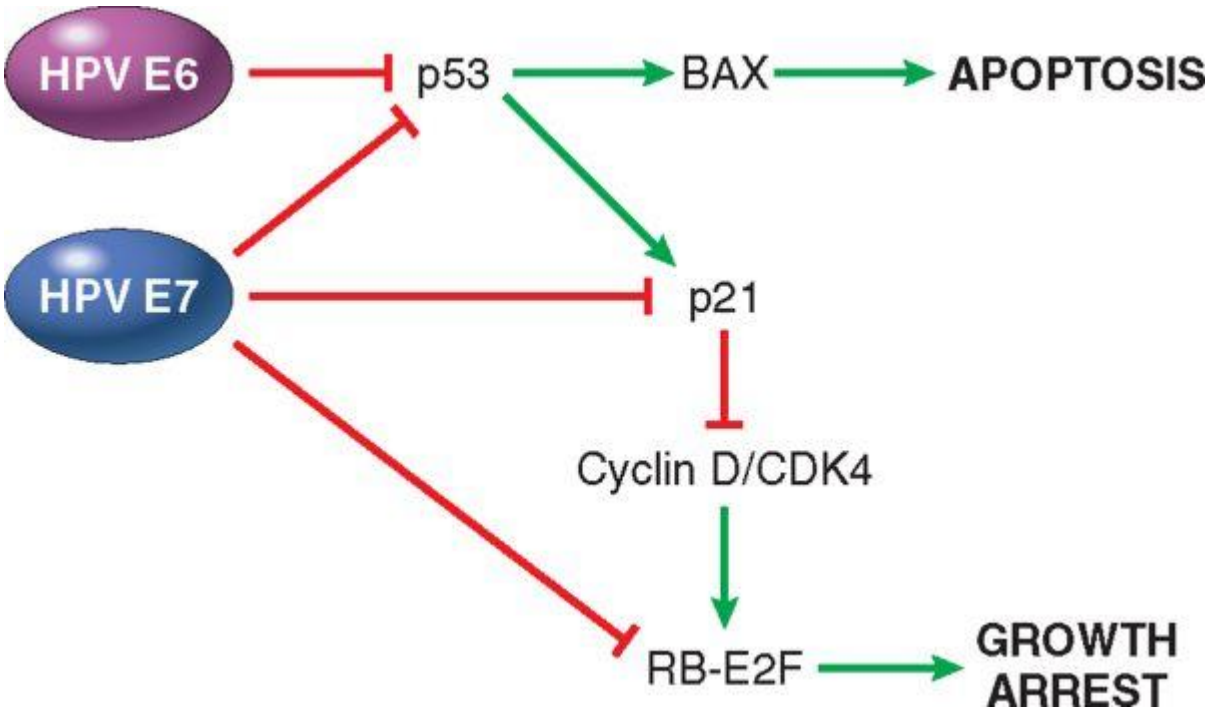

FIGURE 7-43 Effect of HPV proteins E6 and E7 on the cell cycle. E6 and E7 enhance p53 degradation, causing a block in apoptosis and decreased activity of the p21 cell cycle inhibitor. E7 associates with p21 and prevents its inhibition of the cyclin-CDK4 complex; E7 can bind to RB, removing cell cycle restriction. The net effect of HPV E6 and E7 proteins is to block apoptosis and remove the restraints to cell proliferation (see Fig. 7-29). *(Modified from Münger K, Howley PM: Human papillomavirus immortalization and transformation functions. Virus Res 89:213–228, 2002.)*

To summarize, *high-risk HPV types express oncogenic proteins that inactivate tumor suppressors, activate cyclins, inhibit apoptosis, and combat cellular senescence*. Thus, it is evident that many of the hallmarks of cancer discussed earlier are driven by HPV proteins. The primacy of HPV infection in the causation of cervical cancer is confirmed by the effectiveness of anti-HPV vaccines in preventing cervical cancer. However, infection with HPV itself is not sufficient for carcinogenesis. For example, when human keratinocytes are transfected with DNA from HPV types 16, 18, or 31 in vitro, they are immortalized but do not form tumors in experimental animals. Co-transfection with a mutated *RAS* gene results in full malignant transformation. In addition to such genetic co-factors, HPV in all likelihood also acts in concert with environmental factors (Chapter 22). These include cigarette smoking, coexisting microbial infections, dietary deficiencies, and hormonal changes, all of which have been implicated in the pathogenesis of cervical cancers. A high proportion of women infected with HPV clear the infection by immunological mechanisms, but some do not for unknown reasons.

Epstein-Barr Virus.

EBV, a member of the herpes family, has been implicated in the pathogenesis of several human tumors: the African form of Burkitt lymphoma; B-cell lymphomas in immunosuppressed individuals (particularly in those with HIV infection or undergoing immunosuppressive therapy after organ transplantation); a subset of Hodgkin lymphoma; nasopharyngeal and some gastric carcinomas and rare forms of T cell lymphomas and natural killer (NK) cell lymphomas.[161] Except for nasopharyngeal carcinoma, all others are B-cell tumors. These neoplasms are reviewed elsewhere in this book; therefore, only their association with EBV is discussed here.

EBV infects B lymphocytes and possibly epithelial cells of the oropharynx. EBV uses the complement receptor CD21 to attach to and infect B cells. The infection of B cells is latent; that is, there is no viral replication and the cells are not killed, but the B cells latently infected with EBV are immortalized and acquire the ability to propagate indefinitely in vitro. The molecular basis of B-cell proliferations induced by EBV is complex, but as with other viruses it involves the "hijacking" of several normal signaling pathways.[162] One EBV gene, latent membrane protein-1 (*LMP-1),* acts as an oncogene, in that its expression in transgenic mice induces B-cell lymphomas. LMP-1 behaves like a constitutively active CD40 receptor, a key recipient of helper T-cell signals that stimulate B-cell growth (Chapter 6). LMP-1 activates the NF-κB and JAK/STAT signaling pathways and promotes B-cell survival and proliferation, all of which occur autonomously (i.e., without T cells or other outside signals) in EBV-infected B cells. Concurrently, LMP-1 prevents apoptosis by activating BCL2. Thus, the virus "borrows" a normal B-cell activation pathway to expand the pool of latently infected cells. Another EBV gene, *EBNA-2*, encodes a nuclear protein that mimics a constitutively active Notch receptor. EBNA-2 transactivates several host genes, including cyclin D and the *src* family of proto-oncogenes. In addition, the EBV genome contains a viral cytokine, vIL-10, that was hijacked from the host genome. This viral cytokine can prevent macrophages and monocytes from activating T cells and is required for EBV-dependent transformation of B cells. In immunologically normal individuals EBV-driven polyclonal B-cell proliferation in vivo is readily controlled, and the individual either remains asymptomatic or develops a self-limited episode of infectious mononucleosis (Chapter 8). Evasion of the immune system seems to be a key step in EBV-related oncogenesis.

Burkitt lymphoma is a neoplasm of B lymphocytes that is the most common childhood tumor in central Africa and New Guinea. A morphologically identical lymphoma occurs sporadically throughout the world. The association between endemic Burkitt lymphoma and EBV is quite strong (Fig. 7-44):

- More than 90% of African tumors carry the EBV genome.

- One hundred percent of the patients have elevated antibody titers against viral capsid antigens.
- Serum antibody titers against viral capsid antigens are correlated with the risk of developing the tumor.

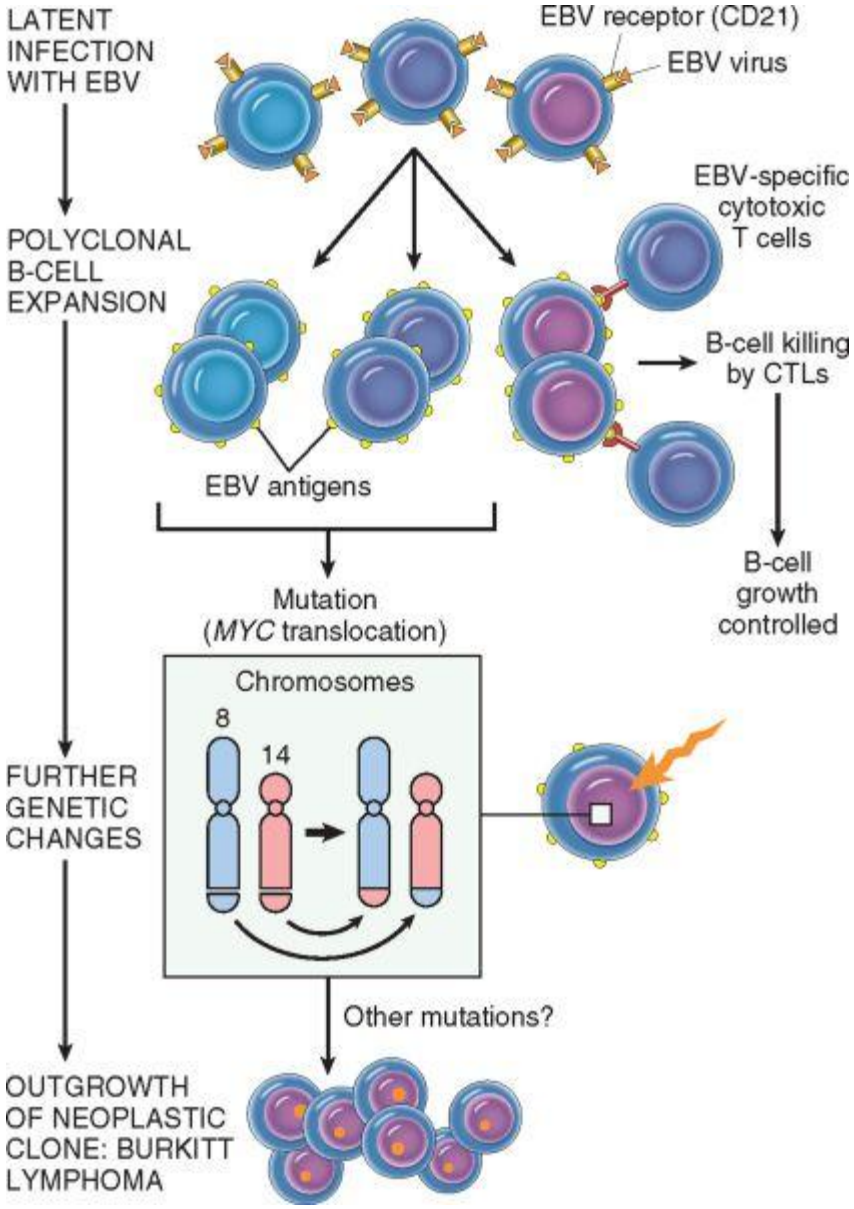

FIGURE 7-44 Possible evolution of EBV-induced Burkitt lymphoma.

Although EBV is intimately involved in the causation of Burkitt lymphoma, several observations suggest that additional factors must also be involved.[163,][164] (1) EBV infection is not limited to the geographic locales where Burkitt lymphoma is found, but it is a ubiquitous virus that asymptomatically infects almost all humans worldwide. (2) The EBV genome is found in only 15% to 20% of sufferers of Burkitt lymphoma outside Africa. (3) There are significant differences in the patterns of viral gene expression in EBV-transformed (but not tumorigenic) B-cell lines and Burkitt lymphoma cells. Most notably, Burkitt lymphoma cells do not express LMP-1, EBNA2, and other EBV proteins that drive B-cell growth and immortalization.

Given these observations, how then does EBV contribute to the genesis of endemic Burkitt lymphoma? A plausible scenario is shown in Figure 7-44 . In regions of the world where Burkitt lymphoma is endemic, concomitant infections such as malaria impair immune competence, allowing sustained B-cell proliferation. Eventually, however, T-cell immunity directed against EBV antigens such as EBNA2 and LMP-1 eliminates most of the EBV-infected B cells, but a small number of cells downregulate expression of these immunogenic antigens. These cells persist indefinitely, even in the face of normal immunity. Lymphoma cells may emerge from this population only with the acquisition of specific mutations, most notably translocations that activate the c-*MYC* oncogene. It should be noted that in nonendemic areas 80% of tumors do not harbor the EBV genome, but all tumors possess the t(8;14) or other translocations that dysregulate c-*MYC*. This observation suggests that, although non-African Burkitt lymphomas are triggered by mechanisms other than EBV, they develop through very similar oncogenic pathways.

In summary, in the case of Burkitt lymphoma, it seems that EBV is not directly oncogenic, but by acting as a polyclonal B-cell mitogen, it sets the stage for the acquisition of the t(8;14) translocation and other mutations, which ultimately release the cells from normal growth regulation. In normal individuals, EBV infection is readily controlled by effective immune responses directed against viral antigens expressed on the cell membranes. Hence, the vast majority of infected individuals remain asymptomatic or develop self-limited infectious mononucleosis. In regions of Africa where Burkitt lymphoma is endemic, poorly understood cofactors (e.g., chronic malaria) may favor the acquisition of genetic events (e.g., the t(8;14) translocation) that lead to transformation.

The role played by EBV is more direct in B-cell lymphomas in immunosuppressed patients. Some persons with AIDS and those who receive long-term immunosuppressive therapy for preventing allograft rejection present with multifocal B-cell tumors within lymphoid tissue or in the central nervous system. These tumors are polyclonal at the outset but can develop into monoclonal neoplasms. In contrast to Burkitt lymphoma, the tumors in immunosuppressed patients uniformly express LMP-1 and EBNA2, that are recognized by cytotoxic T cells. These potentially lethal proliferations can be subdued if the immunological status of the host improves, as may occur with withdrawal of immunosuppressive drugs in transplant recipients.

Nasopharyngeal carcinoma is also associated with EBV infection. This tumor is endemic in southern China, in some parts of Africa, and in the Inuit population of the Arctic. In contrast to Burkitt lymphoma, 100% of nasopharyngeal carcinomas obtained from all parts of the world contain EBV DNA.[165] The viral integration in the host cells is clonal, thus ruling out the possibility that EBV infection occurred after tumor development. Antibody titers to viral capsid antigens are greatly elevated, and in endemic areas patients develop IgA antibodies before the appearance of the tumor. The 100% correlation between EBV and nasopharyngeal carcinoma suggests that EBV[110] plays a role in the genesis of this tumor, but (as with Burkitt tumor) the restricted geographic distribution indicates that genetic or environmental cofactors, or both, also contribute to tumor development. LMP-1 is expressed in epithelial cells as well. In these cells, as in B cells, *LMP-1* activates the NF-κB pathway. Furthermore, *LMP-1* induces the expression of pro-angiogenic factors such as VEGF, FGF-2, MMP9, and COX2, which may contribute to oncogenesis. The relationship of EBV to the pathogenesis of Hodgkin lymphoma is discussed in Chapter 13 .

Hepatitis B and C Viruses.

Epidemiologic studies strongly suggest a close association between HBV infection and the occurrence of liver cancer (Chapter 18). It is estimated that 70% to 85% of hepatocellular carcinomas worldwide are due to infection with HBV or HCV.[111,] [166] [167] [168] HBV is endemic in countries of the Far East and Africa; correspondingly, these areas have the highest incidence of hepatocellular carcinoma.

Despite compelling epidemiologic and experimental evidence, the mode of action of these viruses in liver tumorigenesis is not fully elucidated. The HBV and HCV genomes do not encode any viral oncoproteins, and although the HBV DNA is integrated within the human genome, there is no consistent pattern of integration in liver cells. Indeed, the oncogenic effects of HBV and HCV are multifactorial, but the dominant effect seems to be immunologically mediated chronic inflammation with hepatocyte death leading to regeneration and genomic damage. Although the immune system is generally thought to be protective, recent work has demonstrated that in the setting of unresolved chronic inflammation, as occurs in viral hepatitis or chronic gastritis caused by *H. pylori* (see below), the immune response may become maladaptive, promoting tumorigenesis.

As with any cause of hepatocellular injury, chronic viral infection leads to the compensatory proliferation of hepatocytes. This regenerative process is aided and abetted by a plethora of growth factors, cytokines, chemokines, and other bioactive substances that are produced by activated immune cells and promote cell survival, tissue remodeling, and angiogenesis (Chapter 3). The activated immune cells also produce other mediators, such as reactive oxygen species, that are genotoxic and mutagenic. One key molecular step seems to be activation of the NF-κB pathway in hepatocytes in response to mediators derived from the activated immune cells. Activation of the NF-κB pathway within hepatocytes blocks apoptosis, allowing the dividing hepatocytes to incur genotoxic stress and to accumulate mutations. Although this seems to be the dominant mechanism in the pathogenesis of viral-induced hepatocellular carcinoma, both HBV and HCV also contain proteins within their genomes that may more directly promote the development of cancer. The HBV genome contains a gene known as *HBx* that can directly or indirectly activate a variety of transcription factors and several signal transduction pathways. In addition, viral integration can cause secondary rearrangements of chromosomes, including multiple deletions that may harbor unknown tumor suppressor genes.

Though not a DNA virus, HCV is also strongly linked to the pathogenesis of liver cancer. The molecular mechanisms used by HCV are less well defined than are those of HBV. In addition to chronic liver cell injury and compensatory regeneration, components of the HCV genome, such as the HCV core protein, may have a direct effect on tumorigenesis, possibly by activating a variety of growth-promoting signal transduction pathways.

Helicobacter pylori

First incriminated as a cause of peptic ulcers, *H. pylori* now has acquired the dubious distinction of being the first bacterium classified as a carcinogen. Indeed, *H. pylori* infection is implicated in the genesis of both gastric adenocarcinomas and gastric lymphomas.[169]

The scenario for the development of gastric adenocarcinoma is similar to that of HBV- and HCV-induced liver cancer. It involves increased epithelial cell proliferation in a background of chronic inflammation. As in viral hepatitis, the inflammatory milieu contains numerous genotoxic agents, such as reactive oxygen species. There is an initial development of chronic gastritis, followed by gastric atrophy, intestinal metaplasia of the lining cells, dysplasia, and cancer. This sequence takes decades to complete and occurs in only 3% of infected patients. Like HBV and HCV, the *H. pylori* genome also contains genes directly implicated in oncogenesis. Strains associated with gastric adenocarcinoma have been shown to contain a “pathogenicity island” that contains cytotoxin-associated A (*CagA*) gene. Although *H. pylori* is noninvasive, *CagA* penetrates into gastric epithelial cells, where it has a variety of effects, including the initiation of a signaling cascade that mimics unregulated growth factor stimulation.

As mentioned above, *H. pylori* is associated with an increased risk for the development of gastric lymphomas as well. The gastric lymphomas are of B-cell origin, and because the tumors recapitulate some of the features of normal Peyer's patches, they are often called lymphomas of mucosa-associated lymphoid tissue, or MALTomas (also discussed in Chapters 13 and 17 . Their molecular pathogenesis is

incompletely understood but seems to involve strain-specific *H. pylori* factors, as well as host genetic factors, such as polymorphisms in the promoters of inflammatory cytokines such as IL-1β and tumor necrosis factor (TNF). It is thought that *H. pylori* infection leads to the appearance of *H. pylori*–reactive T cells, which in turn stimulate a polyclonal B-cell proliferation. In chronic infections, currently unknown mutations may be acquired that give individual cells a growth advantage. These cells grow out into a monoclonal "MALToma" that nevertheless remains dependent on T-cell stimulation of B-cell pathways that activate the transcription factor NF-κB. At this stage, eradication of *H. pylori* by antibiotic therapy "cures" the lymphoma by removing the antigenic stimulus for T cells. At later stages, however, additional mutations may be acquired, such as an (11;18) translocation, that cause NF-κB to be activated constitutively. At this point, the MALToma no longer requires the antigenic stimulus of the bacterium for growth and survival and develops the capacity to spread beyond the stomach to other tissues.

2.7.7 Host Defense against Tumors: Tumor Immunity

The idea that tumors are not entirely self and may be recognized by the immune system was conceived by Paul Ehrlich, who proposed that immune recognition of autologous tumor cells may be capable of eliminating tumors. Subsequently, Lewis Thomas and Macfarlane Burnet formalized this concept by coining the term *immune surveillance*, which implies that a normal function of the immune system is to survey the body for emerging malignant cells and destroy them.[170,][171] This idea has been supported by many observations—the occurrence of lymphocytic infiltrates around tumors and in lymph nodes draining sites of cancer; experimental results, mostly with transplanted tumors; the increased incidence of some cancers in immunodeficient individuals; and the direct demonstration of tumor-specific T cells and antibodies in patients. The fact that cancers occur in immunocompetent individuals suggests that immune surveillance is imperfect; however, that some tumors escape such policing does not preclude the possibility that others may have been aborted.[172] The concept of tumor immune surveillance has recently been expanded to encompass not only the protective role of the immune system in tumor development but also the effect of the immune system in selecting for tumor variants.[173,][174] These variants have reduced immunogenicity and can more easily escape immunological detection and rejection. The term *cancer immunoediting* is now being used to describe the effects of the immune system in preventing tumor formation and also in "sculpting" the immunogenic properties of tumors to select tumor cells that escape immune elimination.[175]

In the following section we explore some of the important questions about tumor immunity: What is the nature of tumor antigens? What host effector systems may recognize tumor cells? Is antitumor immunity effective against spontaneous neoplasms? Can immune reactions against tumors be exploited for immunotherapy?

TUMOR ANTIGENS

Antigens that elicit an immune response have been demonstrated in many experimentally induced tumors and in some human cancers.[176] Initially, they were broadly classified into two categories based on their patterns of expression: *tumor-specific antigens*, which are present only on tumor cells and not on any normal cells, and *tumor-associated antigens*, which are present on tumor cells and also on some normal cells. This classification, however, is imperfect because many antigens thought to be tumor-specific turned out to be expressed by some normal cells as well. The modern classification of tumor antigens is based on their molecular structure and source.

The early attempts to purify and characterize tumor antigens relied on producing monoclonal antibodies specific for tumor cells and defining the antigens that these antibodies recognized. An important advance in the field was the development of techniques for identifying tumor antigens that were recognized by cytotoxic T lymphocytes (CTLs), because CTLs are the major immune defense

mechanism against tumors. Recall that CTLs recognize peptides derived from cytoplasmic proteins that are displayed bound to class I major histocompatibility complex (MHC) molecules (Chapter 6). Below we describe the main classes of tumor antigens (Fig. 7-45).

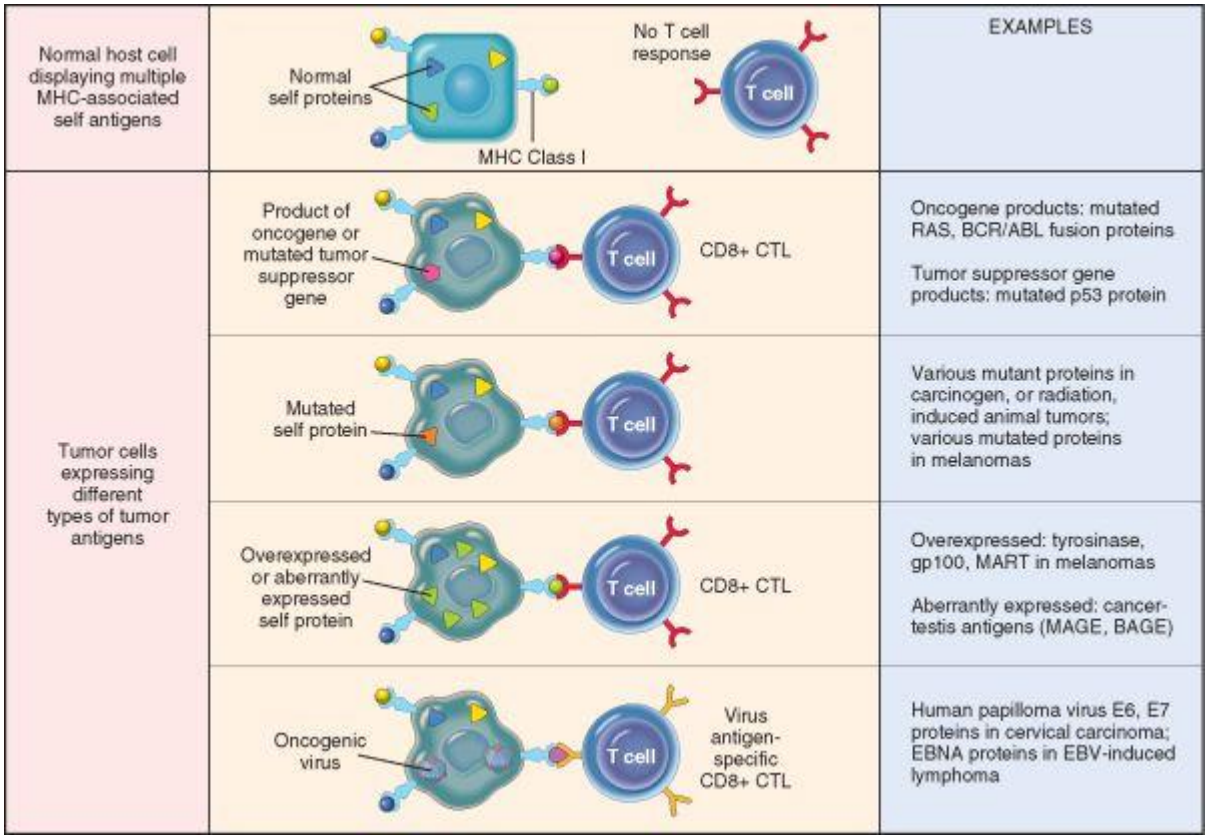

FIGURE 7-45 Tumor antigens recognized by CD8+ T cells. *(Modified from Abbas AK, Lichtman AH: Cellular and Molecular Immunology, 5th ed. Philadelphia, WB Saunders, 2003.)*

Products of Mutated Genes.

Neoplastic transformation, as we have discussed, results from genetic alterations in proto-oncogenes and tumor suppressor genes; these mutated proteins represent antigens that have never been seen by the immune system and thus can be recognized as non-self.[177,][178] Additionally, because of the genetic instability of tumor cells, many different genes may be mutated in these cells, including genes whose products are not related to the transformed phenotype and have no known function. Products of these mutated genes can also be potential tumor antigens. The products of altered proto-oncogenes, tumor suppressor genes, or other mutated genes not associated with transformation are synthesized in the cytoplasm of tumor cells, and like any cytoplasmic protein, they may enter the class I MHC antigenprocessing pathway and be recognized by CD8+ T cells. In addition, these proteins may enter the class II antigen-processing pathway in antigen-presenting cells that have phagocytosed dead tumor cells, and thus be recognized by CD4+ T cells also. Because these altered proteins are not present in normal cells, they do not induce self-tolerance. Some cancer patients have circulating CD4+ and CD8+ T cells that can respond to the products of mutated oncogenes such as RAS, p53, and BCR-ABL proteins. In animals, immunization with mutated RAS or p53 proteins induces CTLs and rejection

responses against tumors expressing these mutants. However, these oncoproteins do not seem to be major targets of tumorspecific CTLs in most patients.

Overexpressed or Aberrantly Expressed Cellular Proteins.

Tumor antigens may be normal cellular proteins that are abnormally expressed in tumor cells and elicit immune responses. In a subset of human melanomas some tumor antigens are structurally normal proteins that are produced at low levels in normal cells and overexpressed in tumor cells. One such antigen is tyrosinase, an enzyme involved in melanin biosynthesis that is expressed only in normal melanocytes and melanomas.[179] T cells from melanoma patients recognize peptides derived from tyrosinase, raising the possibility that tyrosinase vaccines may stimulate such responses to melanomas; clinical trials with these vaccines are ongoing. It may be surprising that these patients are able to respond to a normal self-antigen. The probable explanation is that tyrosinase is normally produced in such small amounts and in so few cells that it is not recognized by the immune system and fails to induce tolerance.

Another group, the "cancer-testis" antigens, are encoded by genes that are silent in all adult tissues except the testis—hence their name. Although the protein is present in the testis it is not expressed on the cell surface in an antigenic form, because sperm do not express MHC class I antigens. Thus, for all practical purposes these antigens are tumor specific. Prototypic of this group is the melanoma antigen gene (MAGE) family. Although originally described in melanomas, MAGE antigens are expressed by a variety of tumor types. For example, MAGE-1 is expressed on 37% of melanomas and a variable number of lung, liver, stomach, and esophageal carcinomas.[180] Similar antigens called GAGE, BAGE, and RAGE have been detected in other tumors.

Tumor Antigens Produced by Oncogenic Viruses.

As we have discussed, several viruses are associated with cancers. Not surprisingly, these viruses produce proteins that are recognized as foreign by the immune system. The most potent of these antigens are proteins produced by latent DNA viruses; examples in humans include HPV and EBV. There is abundant evidence that CTLs recognize antigens of these viruses and that a competent immune system plays a role in surveillance against virus-induced tumors because of its ability to recognize and kill virus-infected cells. In fact, the concept of immune surveillance against tumors is best established for DNA virus–induced tumors. Indeed, vaccines against HPV antigens are effective in preventing cervical cancers in young females.

Oncofetal Antigens.

Oncofetal antigens are proteins that are expressed at high levels on cancer cells and in normal developing (fetal) but not adult tissues. It is believed that the genes encoding these proteins are silenced during development and are derepressed upon malignant transformation. Oncofetal antigens were identified with antibodies raised in other species, and their main importance is that they provide markers that aid in tumor diagnosis. As techniques for detecting these antigens have improved, it has become clear that their expression in adults is not limited to tumors. Amounts of these proteins are increased in tissues and in the circulation in various inflammatory conditions, and they are found in small quantities even in normal tissues. There is no evidence that oncofetal antigens are important inducers or targets of antitumor immunity. The two most thoroughly characterized oncofetal antigens are carcinoembryonic antigen (CEA) and α-fetoprotein (AFP). These are discussed in the section on "Tumor Markers".

Altered Cell Surface Glycolipids and Glycoproteins.

Most human and experimental tumors express higher than normal levels and/or abnormal forms of surface glycoproteins and glycolipids, which may be diagnostic markers and targets for therapy. These

altered molecules include gangliosides, blood group antigens, and mucins. Many antibodies have been raised in animals that recognize the carbohydrate groups or peptide cores of these molecules. Although most of the epitopes recognized by these antibodies are not specifically expressed on tumors, they are present at higher levels on cancer cells than on normal cells. This class of antigens is a target for cancer therapy with specific antibodies.

Among the glycolipids expressed at high levels in melanomas are the gangliosides GM_2, GD_2, and GD_3. Clinical trials of anti-GM_2 and anti-GD_3 antibodies and immunization with vaccines containing GM_2 are underway in melanoma patients. Mucins are high-molecular-weight glycoproteins containing numerous O-linked carbohydrate side chains on a core polypeptide. Tumors often have dysregulated expression of the enzymes that synthesize these carbohydrate side chains, which leads to the appearance of tumor-specific epitopes on the carbohydrate side chains or on the abnormally exposed polypeptide core. Several mucins have been the focus of diagnostic and therapeutic studies, including CA-125 and CA-19-9, expressed on ovarian carcinomas, and MUC-1, expressed on breast carcinomas. Unlike many mucins, MUC-1 is an integral membrane protein that is normally expressed only on the apical surface of breast ductal epithelium, a site that is relatively sequestered from the immune system. In ductal carcinomas of the breast, however, the molecule is expressed in an unpolarized fashion and contains new, tumor-specific carbohydrate and peptide epitopes detectable by mouse monoclonal antibodies. The peptide epitopes induce both antibody and T-cell responses in cancer patients and are therefore being considered as candidates for tumor vaccines.

Cell Type–Specific Differentiation Antigens.

Tumors express molecules that are normally present on the cells of origin. These antigens are called *differentiation antigens* because they are specific for particular lineages or differentiation stages of various cell types. Such differentiation antigens are typically normal self-antigens, and therefore they do not induce immune response in tumor-bearing hosts. Their importance is as potential targets for immunotherapy and for identifying the tissue of origin of tumors. For example, lymphomas may be diagnosed as B cell–derived tumors by the detection of surface markers characteristic of this lineage, such as CD20. Antibodies against CD20 are also used for tumor immunotherapy. These kill normal B cells as well but because hemopoeitic stem cells are spared, new B cells emerge eventually. The idiotypic determinants of the surface immunoglobulin of a clonal B-cell population are markers for that B-cell clone, because all other B cells express different idiotypes. Therefore, the immunoglobulin idiotype is a highly specific tumor antigen for B-cell lymphomas and leukemias.

ANTITUMOR EFFECTOR MECHANISMS

Cell-mediated immunity is the dominant antitumor mechanism in vivo. Although antibodies can be made against tumors, there is no evidence that they play a protective role under physiologic conditions. The cellular effectors that mediate immunity were described in Chapter 6 , so it is necessary here only to characterize them briefly.

- *Cytotoxic T lymphocytes:* The antitumor effect of cytotoxic T cells reacting against tumor antigens is well established in experimentally induced tumors. In humans, CD8+ CTLs play a protective role against virus-associated neoplasms (e.g., EBV- and HPV-induced tumors) and have been demonstrated in the blood and tumor infiltrates of cancer patients. In some cases, such CD8+ T cells do not develop spontaneously in vivo but can be generated by immunization with tumor antigen–pulsed dendritic cells.
- *Natural killer cells:* NK cells are lymphocytes that are capable of destroying tumor cells without prior sensitization and thus may provide the first line of defense against tumor cells.[181] After activation with IL-2 and IL-15, NK cells can lyse a wide range of human tumors, including many that seem to be nonimmunogenic for T cells. T cells and NK cells seem to provide complementary antitumor mechanisms. Tumors that fail to express MHC class I antigens cannot be recognized by T cells, but these tumors may trigger NK cells because the latter are inhibited by recognition of normal autologous class I molecules

(Chapter 6). The triggering receptors on NK cells are extremely diverse and belong to several gene families. NKG2D proteins expressed on NK cells and some T cells are important activating receptors. They recognize stress-induced antigens that are expressed on tumor cells and cells that have incurred DNA damage and are at risk for neoplastic transformation.

- *Macrophages:* Activated macrophages exhibit cytotoxicity against tumor cells in vitro. T cells, NK cells, and macrophages may collaborate in antitumor reactivity, because interferon-γ, a cytokine secreted by T cells and NK cells, is a potent activator of macrophages. Activated macrophages may kill tumors by mechanisms similar to those used to kill microbes (e.g., production of reactive oxygen metabolites; Chapter 2) or by secretion of TNF.
- *Antibodies:* Although there is no evidence for the protective effects of antitumor antibodies against spontaneous tumors, administration of monoclonal antibodies against tumor cells can be therapeutically effective. A monoclonal antibody against CD20, a B-cell surface antigen, is widely used for treatment of lymphomas.

IMMUNE SURVEILLANCE AND ESCAPE

Given the many potential antitumor mechanisms, is there any evidence that they operate in vivo to prevent emergence of neoplasms? The strongest argument for the existence of immune surveillance is the increased frequency of cancers in immunodeficient hosts. About 5% of persons with congenital immunodeficiencies develop cancers, about 200 times the rate in immunocompetent individuals. Immunosuppressed transplant recipients and persons with AIDS also have an increased incidence of malignancies. Most (but not all) of these neoplasms are lymphomas, often diffuse large B-cell lymphomas. Particularly illustrative is the rare X-linked recessive immunodeficiency disorder termed *XLP (X-linked lymphoproliferative syndrome),* caused by mutations in the gene encoding an adapter protein *(SAP),* which participates in lymphocyte signaling pathways.[182] When affected boys develop an EBV infection, such infection does not take the usual self-limited form of infectious mononucleosis but instead evolves into a chronic or sometimes fatal form of infectious mononucleosis or, even worse, B-cell lymphoma.

Most cancers occur in persons who do not suffer from any overt immunodeficiency. It is evident, then, that *tumor cells must develop mechanisms to escape or evade the immune system* in immunocompetent hosts. Several such mechanisms may be operative (Fig. 7-46).

- *Selective outgrowth of antigen-negative variants:* During tumor progression, strongly immunogenic subclones may be eliminated.
- *Loss or reduced expression of MHC molecules:* Tumor cells may fail to express normal levels of HLA class I molecules, thereby escaping attack by cytotoxic T cells. Such cells, however, may trigger NK cells.
- *Lack of costimulation:* It may be recalled that sensitization of T cells requires two signals, one by a foreign peptide presented by MHC molecules and the other by costimulatory molecules (Chapter 6); although tumor cells may express peptide antigens with class I molecules, they often do not express costimulatory molecules. This not only prevents sensitization but also may render T cells anergic or, worse, cause them to undergo apoptosis. To bypass this problem, attempts are being made to immunize patients with autologous tumor cells that have been transfected with the gene for the costimulatory molecule B7-1 (CD 80). In another approach, autologous dendritic cells expanded in vitro and pulsed with tumor antigens (e.g., MAGE1) are infused into cancer patients. Because dendritic cells express high levels of costimulatory molecules, it is expected that such immunization will stimulate antitumor T cells.
- *Immunosuppression:* Many oncogenic agents (e.g., chemicals and ionizing radiation) suppress host immune responses. Tumors or tumor products also may be immunosuppressive. For example, TGF-β, secreted in large quantities by many tumors, is a potent immunosuppressant. In some cases the immune response induced by the tumor may inhibit tumor immunity. Several mechanisms of such inhibition have been described. For instance, recognition of tumor cells may lead to engagement of the T-cell inhibitory receptor, CTLA4, or activation of regulatory T cells that suppress immune responses.
- *Antigen masking:* The cell surface antigens of tumors may be hidden, or masked, from the immune system by glycocalyx molecules, such as sialic acid–containing mucopolysaccharides. This may be a consequence

of the fact that tumor cells often express more of these glycocalyx molecules than normal cells do.

- *Apoptosis of cytotoxic T cells:* Some melanomas and hepatocellular carcinomas express FasL. It has been postulated that these tumors kill Fas-expressing T lymphocytes that come in contact with them, thus eliminating tumor-specific T cells.[183]

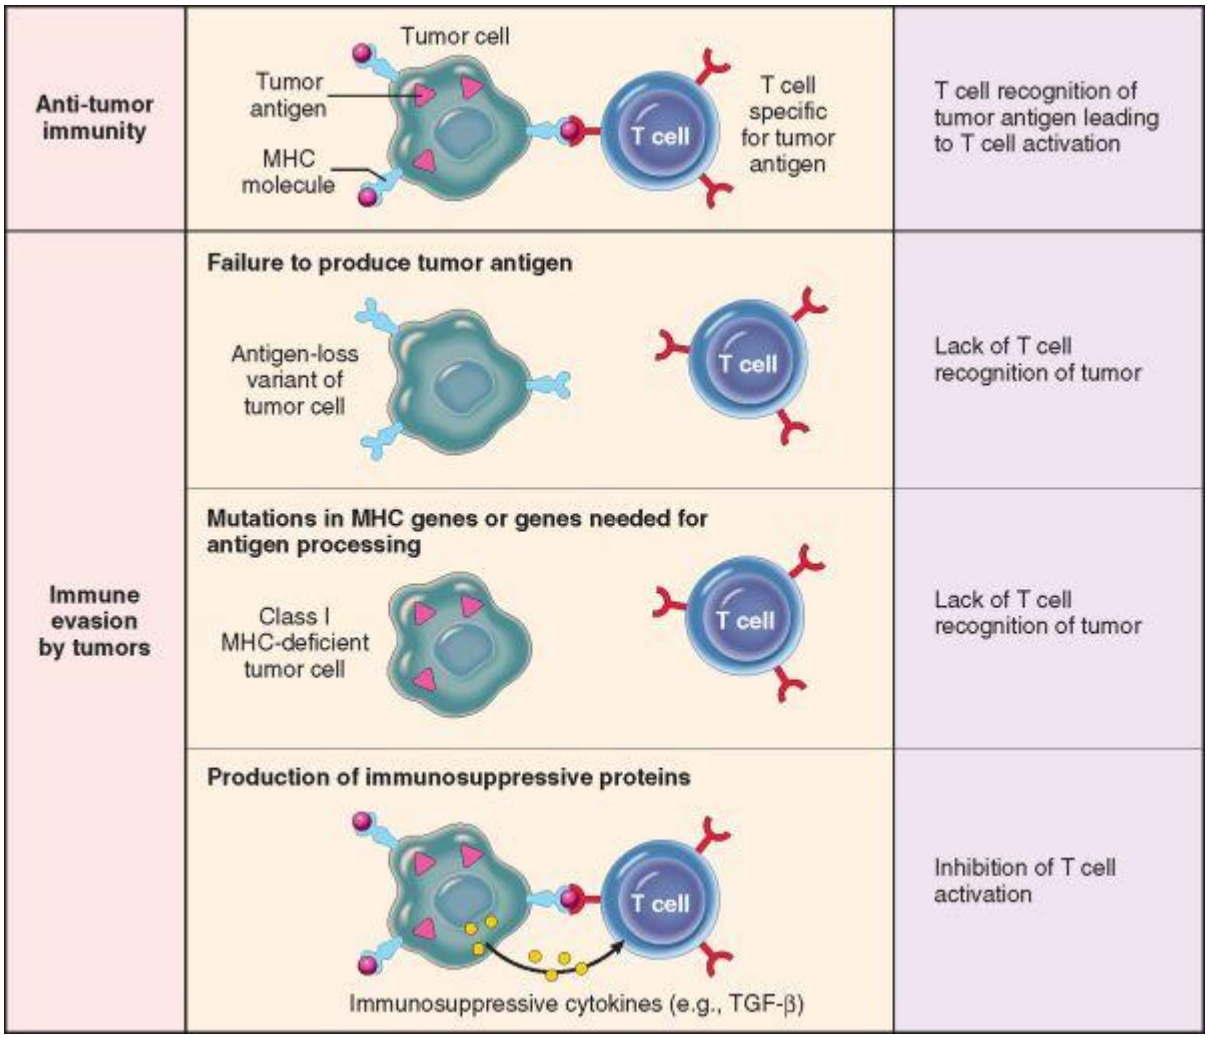

FIGURE 7-46 Mechanisms by which tumors evade the immune system. *(Reprinted from Abbas AK, Lichtman AH: Cellular and Molecular Immunology, 5th ed. Philadelphia, WB Saunders, 2003)*

Thus, it seems that there is no dearth of mechanisms by which tumor cells can outwit the host and thrive despite an intact immune system.

It is worth mentioning that although much of the focus in the field of tumor immunity has been on the mechanisms by which the host immune system defends against tumors, there is some recent evidence that, paradoxically, the immune system may promote the growth of tumors.[184] It is possible that activated lymphocytes and macrophages produce growth factors for tumor cells, and regulatory T-cells and certain subtypes of macrophages may suppress the host response to tumors. Enzymes, such as MMPs, that enhance tumor invasion, may also be produced. Harnessing the protective actions of the

immune system and abolishing its ability to increase tumor growth are obviously important goals of immunologists and oncologists.

2.7.8 Clinical Aspects of Neoplasia

Ultimately the importance of neoplasms lies in their effects on patients. Although malignant tumors are of course more threatening than benign tumors, any tumor, even a benign one, may cause morbidity and mortality. Indeed, both malignant and benign tumors may cause problems because of (1) location and impingement on adjacent structures, (2) functional activity such as hormone synthesis or the development of paraneoplastic syndromes, (3) bleeding and infections when the tumor ulcerates through adjacent surfaces, (4) symptoms that result from rupture or infarction, and (5) cachexia or wasting.

Local and Hormonal Effects

Location is crucial in both benign and malignant tumors. A small (1-cm) pituitary adenoma, though benign and possibly nonfunctional, can compress and destroy the surrounding normal gland and thus lead to serious hypopituatarism. Cancers arising within or metastatic to an endocrine gland may cause an endocrine insufficiency by destroying the gland. Neoplasms in the gut, both benign and malignant, may cause obstruction as they enlarge. Infrequently, peristaltic movement telescopes the neoplasm and its affected segment into the downstream segment, producing an obstructing intussusception (Chapter 17).

Hormone production is seen with benign and malignant neoplasms arising in endocrine glands. Such functional activity is more typical of benign than of malignant tumors, which may be sufficiently undifferentiated to have lost such capability. A benign beta-cell adenoma of the pancreatic islets less than 1 cm in diameter may produce sufficient insulin to cause fatal hypoglycemia. In addition, nonendocrine tumors may elaborate hormones or hormone-like products and give rise to paraneoplastic syndromes (discussed later). The erosive and destructive growth of cancers or the expansile pressure of a benign tumor on any natural surface, such as the skin or mucosa of the gut, may cause ulcerations, secondary infections, and bleeding. Melena (blood in the stool) and hematuria, for example, are characteristic of neoplasms of the gut and urinary tract. Neoplasms, benign as well as malignant, may cause problems in varied ways, but all are far less common than the cachexia of malignancy.

Cancer Cachexia

Individuals with cancer commonly suffer progressive loss of body fat and lean body mass accompanied by profound weakness, anorexia, and anemia, referred to as *cachexia*. Unlike starvation, the weight loss seen in cachexia results equally from loss of fat and lean muscle. There is some correlation between the tumor burden and the severity of the cachexia. However, cachexia is not caused by the nutritional demands of the tumor. In persons with cancer, the basal metabolic rate is increased, despite reduced food intake. This is in contrast to the lower metabolic rate that occurs as an adaptational response in starvation. Although patients with cancer are often anorexic, cachexia probably results from the action of soluble factors such as cytokines produced by the tumor and the host rather than reduced food intake. The basis of these metabolic abnormalities is not fully understood. It is suspected that TNF produced by macrophages in response to tumor cells or by the tumor cells themselves mediates cachexia. TNF at high concentrations may mobilize fats from tissue stores and suppress appetite; both activities would contribute to cachexia. Other cytokines, such as IL-1, interferon-γ, and leukemia inhibitory factor, synergize with TNF. Additionally, other soluble factors produced by tumors, such as proteolysis-inducing factor and a lipid-mobilizing factor, increase the catabolism of muscle and adipose tissue.[185] These factors reduce protein synthesis by decreasing m-RNA translation and by stimulating protein catabolism through the activation of the ATP-dependent ubiquitin-proteasome pathway. It is now thought that there is a balance between factors that regulate muscle hypertrophy, such as IGF, and

factors that regulate muscle catabolism. In cachexia these homeostatic mechanisms are disrupted, tilting the scales toward cachectic factors. There is currently no satisfactory treatment for cancer cachexia other than removal of the underlying cause, the tumor. However, cachexia clearly hampers effective chemotherapy, by reducing the dosages that can be given. Furthermore, it has been estimated that a third of deaths of cancer are attributable to cachexia, rather than directly due to the tumor burden itself. Identification of the molecular mechanisms involved in cancer cachexia may allow treatment of cachexia itself.

Paraneoplastic Syndromes

Symptom complexes in cancer-bearing individuals that cannot readily be explained, either by the local or distant spread of the tumor or by the elaboration of hormones indigenous to the tissue from which the tumor arose, are known as *paraneoplastic syndromes*.[186] These occur in about 10% of persons with malignant disease. Despite their relative infrequency, paraneoplastic syndromes are important to recognize, for several reasons:

- They may represent the earliest manifestation of an occult neoplasm.
- In affected patients they may represent significant clinical problems and may even be lethal.
- They may mimic metastatic disease and therefore confound treatment.

A classification of paraneoplastic syndromes and their presumed origins is presented in Table 7-11 . A few comments on some of the more common and interesting syndromes follow.

TABLE 7-11 -- Paraneoplastic Syndromes

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
ENDOCRINOPATHIES		
Cushing syndrome	Small-cell carcinoma of lung	ACTH or ACTH-like substance
	Pancreatic carcinoma	
	Neural tumors	
Syndrome of inappropriate antidiuretic hormone secretion	Small-cell carcinoma of lung; intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung	Parathyroid hormone–related protein (PTHRP), TGF-α, TNF, IL-1
	Breast carcinoma	
	Renal carcinoma	
	Adult T-cell leukemia/lymphoma	
Hypoglycemia	Ovarian carcinoma	
	Fibrosarcoma	Insulin or insulin-like substance
	Other mesenchymal sarcomas	
Carcinoid syndrome	Hepatocellular carcinoma	
	Bronchial adenoma (carcinoid)	Serotonin, bradykinin
	Pancreatic carcinoma	
Polycythemia	Gastric carcinoma	
	Renal carcinoma	Erythropoietin
	Cerebellar hemangioma	

Clinical Syndromes	Major Forms of Underlying Cancer	Causal Mechanism
	Hepatocellular carcinoma	
NERVE AND MUSCLE SYNDROMES		
Myasthenia	Bronchogenic carcinoma	Immunological
Disorders of the central and peripheral nervous system	Breast carcinoma	
DERMATOLOGIC DISORDERS		
Acanthosis nigricans	Gastric carcinoma	Immunological; secretion of epidermal growth factor
	Lung carcinoma	
	Uterine carcinoma	
Dermatomyositis	Bronchogenic, breast carcinoma	Immunological
OSSEOUS, ARTICULAR, AND SOFT-TISSUE CHANGES		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma	Unknown
VASCULAR AND HEMATOLOGIC CHANGES		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma	Tumor products (mucins that activate clotting)
	Bronchogenic carcinoma	
	Other cancers	
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Red cell aplasia	Thymic neoplasms	Unknown
OTHERS		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

ACTH, adrenocorticotropic hormone; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.

The *endocrinopathies* are frequently encountered paraneoplastic syndromes.[187] Because the cancer cells are not of endocrine origin, the functional activity is referred to as *ectopic hormone production*. Cushing syndrome is the most common endocrinopathy. Approximately 50% of individuals with this endocrinopathy have carcinoma of the lung, chiefly the small-cell type. It is caused by excessive production of corticotropin or corticotropin-like peptides. The precursor of corticotropin is a large molecule known as pro-opiomelanocortin. Lung cancer patients with Cushing syndrome have elevated serum levels of pro-opiomelanocortin and of corticotropin. The former is not found in serum of patients with excess corticotropin produced by the pituitary.

Hypercalcemia is probably the most common paraneoplastic syndrome; overtly symptomatic hypercalcemia is most often related to some form of cancer rather than to hyperparathyroidism. Two general processes are involved in cancer-associated hypercalcemia: (1) osteolysis induced by cancer, whether primary in bone, such as multiple myeloma, or metastatic to bone from any primary lesion, and (2) the production of calcemic humoral substances by extraosseous neoplasms. *Hypercalcemia due to skeletal metastases is not a paraneoplastic syndrome*.

Several humoral factors have been associated with paraneoplastic hypercalcemia of malignancy. The most important, parathyroid hormone–related protein (PTHRP), is a molecule related to, but distinct from, parathyroid hormone (PTH). PTHRP resembles the native hormone only in its N terminus.[188] It has some biologic actions similar to those of PTH, and both hormones share a G protein–coupled receptor, known as PTH/PTHRP receptor (often referred to as PTH-R or PTHRP-R). In contrast to PTH, PTHRP is produced in small amounts by many normal tissues, including keratinocytes, muscles, bone, and ovary. It regulates calcium transport in the lactating breast and across the placenta, and seems to regulate development and remodeling in the lung. Tumors most often associated with paraneoplastic hypercalcemia are carcinomas of the breast, lung, kidney, and ovary. In breast cancers, PTHRP production is associated with osteolytic bone disease, bone metastasis, and humoral hypercalcemia. The most common lung neoplasm associated with hypercalcemia is squamous cell bronchogenic carcinoma. In addition to PTHRP, several other factors, such as IL-1, TGF-α, TNF, and dihydroxyvitamin D, have also been implicated in causing the hypercalcemia of malignancy.

The *neuromyopathic paraneoplastic syndromes* take diverse forms, such as peripheral neuropathies, cortical cerebellar degeneration, a polymyopathy resembling polymyositis, and a myasthenic syndrome similar to *myasthenia gravis* (Chapter 27). The cause of these syndromes is poorly understood. In some cases, antibodies, presumably induced against tumor cell antigens (Chapter 28) that cross-react with neuronal cell antigens, have been detected. It is postulated that some neural antigens are ectopically expressed by visceral cancers. For some unknown reason, the immune system recognizes these antigens as foreign and mounts an immune response.

Acanthosis nigricans is characterized by gray-black patches of verrucous hyperkeratosis on the skin. This disorder occurs rarely as a genetically determined disease in juveniles or adults (Chapter 25). In addition, in about 50% of the cases, particularly in those over age 40, the appearance of such lesions is associated with some form of cancer. Sometimes the skin changes appear before discovery of the cancer.

Hypertrophic osteoarthropathy is encountered in 1% to 10% of patients with bronchogenic carcinomas. Rarely, other forms of cancer are involved. This disorder is characterized by (1) periosteal new bone formation, primarily at the distal ends of long bones, metatarsals, metacarpals, and proximal phalanges; (2) arthritis of the adjacent joints; and (3) clubbing of the digits. Although the osteoarthropathy is seldom seen in noncancer patients, clubbing of the fingertips may be encountered in liver diseases, diffuse lung disease, congenital cyanotic heart disease, ulcerative colitis, and other disorders. The cause of hypertrophic osteoarthropathy is unknown.

Several *vascular and hematologic manifestations* may appear in association with a variety of forms of cancer. As mentioned in the discussion of thrombosis (Chapter 4), *migratory thrombophlebitis* (Trousseau syndrome) may be encountered in association with deep-seated cancers, most often carcinomas of the pancreas or lung. Disseminated intravascular coagulation may complicate a diversity of clinical disorders (Chapter 14). Acute disseminated intravascular coagulation is most commonly associated with acute promyelocytic leukemia and prostatic adenocarcinoma. Bland, small, nonbacterial fibrinous vegetations sometimes form on the cardiac valve leaflets (more often on left-sided valves), particularly in individuals with advanced mucin-secreting adenocarcinomas. These lesions, called *nonbacterial thrombotic endocarditis*, are described further in Chapter 12 . The vegetations are potential sources of emboli that can further complicate the course of cancer.

GRADING AND STAGING OF TUMORS

Methods to quantify the probable clinical aggressiveness of a given neoplasm and its apparent extent and spread in the individual patient are necessary for making an accurate prognosis and for comparing end results of various treatment protocols. For instance, the results of treating well-differentiated thyroid adenocarcinoma that is localized to the thyroid gland will be different from those obtained from treating

highly anaplastic thyroid cancers that have invaded the neck organs. Systems have been developed to express, at least in semiquantitative terms, the level of differentiation, or *grade*, and extent of spread of a cancer within the patient, or *stage*, as parameters of the clinical gravity of the disease.

Grading of a cancer is based on the degree of differentiation of the tumor cells and, in some cancers, the number of mitoses or architectural features. Grading schemes have evolved for each type of malignancy, and generally range from two categories (low grade and high grade) to four categories. Criteria for the individual grades vary with each form of neoplasia and so are not detailed here, but all attempt, in essence, to judge the extent to which the tumor cells resemble or fail to resemble their normal counterparts. Although histologic grading is useful, the correlation between histologic appearance and biologic behavior is less than perfect. In recognition of this problem and to avoid spurious quantification, it is common practice to characterize a particular neoplasm in descriptive terms, for example, well-differentiated, mucin-secreting adenocarcinoma of the stomach, or poorly differentiated pancreatic adenocarcinoma. In general, with a few exceptions, such as soft-tissue sarcomas, grading of cancers has proved of less clinical value than has staging.

The staging of cancers is based on the size of the primary lesion, its extent of spread to regional lymph nodes, and the presence or absence of blood-borne metastases. The major staging system currently in use is the American Joint Committee on Cancer Staging. This system uses a classification called the *TNM system—T* for primary tumor, *N* for regional lymph node involvement, and *M* for metastases. The TNM staging varies for each specific form of cancer, but there are general principles. With increasing size the primary lesion is characterized as T1 to T4. T0 is used to indicate an in situ lesion. N0 would mean no nodal involvement, whereas N1 to N3 would denote involvement of an increasing number and range of nodes. M0 signifies no distant metastases, whereas M1 or sometimes M2 indicates the presence of metastases and some judgment as to their number.

LABORATORY DIAGNOSIS OF CANCER

Every year the approach to laboratory diagnosis of cancer becomes more complex, more sophisticated, and more specialized. For virtually every neoplasm mentioned in this text, the experts have characterized several subcategories; we must walk, however, before we can run. Each of the following sections attempts to present the state of the art, avoiding details of method.

Histologic and Cytologic Methods.

The laboratory diagnosis of cancer is, in most instances, not difficult. The two ends of the benign-malignant spectrum pose no problems; however, in the middle lies a gray zone that the novices dread and where experts tread cautiously. The focus here is on the roles of the clinician (often a surgeon) and the pathologist in facilitating the correct diagnosis.

Clinical data are invaluable for optimal pathologic diagnosis, but often clinicians underestimate its value. Radiation changes in the skin or mucosa can be similar to those associated with cancer. Sections taken from a healing fracture can mimic an osteosarcoma. Moreover, the laboratory evaluation of a lesion can be only as good as the specimen made available for examination. It must be adequate, representative, and properly preserved. Several sampling approaches are available: (1) excision or biopsy, (2) needle aspiration, and (3) cytologic smears. When excision of a small lesion is not possible, selection of an appropriate site for biopsy of a large mass requires awareness that the periphery may not be representative and the center largely necrotic. Appropriate preservation of the specimen is obvious, yet it involves such actions as prompt immersion in a usual fixative (commonly formalin solution, but other fluids can be used), preservation of a portion in a special fixative (e.g., glutaraldehyde) for electron microscopy, or prompt refrigeration to permit optimal hormone, receptor, or other types of molecular analysis. Requesting “quick-frozen section” diagnosis is sometimes desirable, for example, in

determining the nature of a mass lesion or in evaluating the margins of an excised cancer to ascertain that the entire neoplasm has been removed. This method permits histologic evaluation within minutes. In experienced, competent hands, frozen-section diagnosis is highly accurate, but there are particular instances in which the better histologic detail provided by the more time-consuming routine methods is needed—for example, when extremely radical surgery, such as the amputation of an extremity, may be indicated. Better to wait a day or two despite the drawbacks, than to perform inadequate or unnecessary surgery.

Fine-needle aspiration of tumors is another approach that is widely used. The procedure involves aspirating cells and attendant fluid with a small-bore needle, followed by cytologic examination of the stained smear. This method is used most commonly for the assessment of readily palpable lesions in sites such as the breast, thyroid, and lymph nodes. Modern imaging techniques permit extension of the method to lesions in deep-seated structures, such as pelvic lymph nodes and pancreas. Fine-needle aspiration is less invasive and more rapidly performed than are needle biopsies. It obviates surgery and its attendant risks. Although it entails some difficulties, such as small sample size and sampling errors, in experienced hands it is extremely reliable, rapid, and useful.

Cytologic (Pap) smears provide yet another method for the detection of cancer (Chapter 22). This approach is widely used to screen for carcinoma of the cervix, often at an in situ stage, but it is also used with many other forms of suspected malignancy, such as endometrial carcinoma, bronchogenic carcinoma, bladder and prostatic tumors, and gastric carcinomas; for the identification of tumor cells in abdominal, pleural, joint, and cerebrospinal fluids; and, less commonly, with other forms of neoplasia.

As pointed out earlier, cancer cells have lowered cohesiveness and exhibit a range of morphologic changes encompassed by the term *anaplasia*. Thus, shed cells can be evaluated for the features of anaplasia indicative of their origin from a tumor (Figs. 7-47 and 7-48). In contrast to the histologist's task, judgment here must be rendered based on the features of individual cells or, at most, a clump of cells, without the supporting evidence of loss of orientation of one cell to another, and (most importantly) evidence of invasion. This method permits differentiation among normal, dysplastic, and malignant cells and, in addition, permits the recognition of cellular changes characteristic of carcinoma in situ. The gratifying control of cervical cancer is the best testament to the value of the cytologic method.

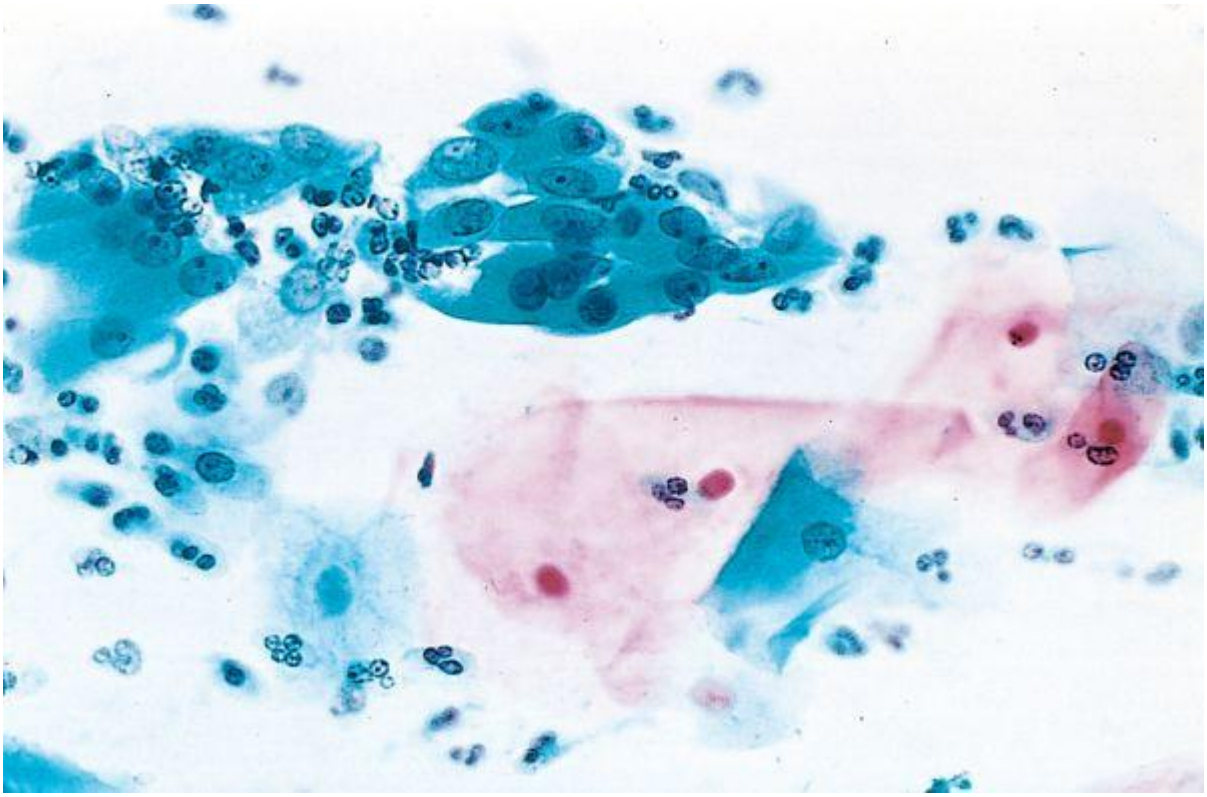

FIGURE 7-47 A normal cervicovaginal smear shows large, flattened squamous cells and groups of metaplastic cells; interspersed are some neutrophils. There are no malignant cells. *(Courtesy of Dr. P.K. Gupta, University of Pennsylvania, Philadelphia, PA.)*

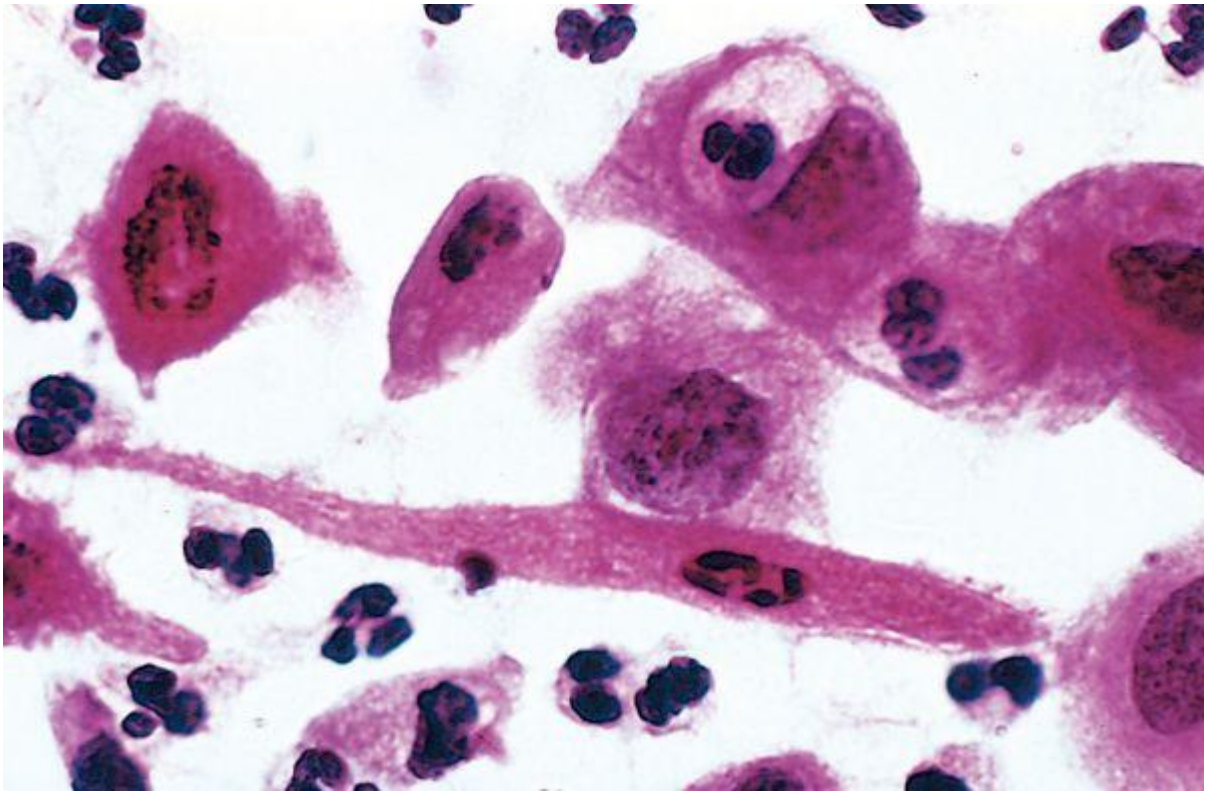

FIGURE 7-48 An abnormal cervicovaginal smear shows numerous malignant cells that have pleomorphic, hyperchromatic nuclei; interspersed are some normal polymorphonuclear leukocytes. *(Courtesy of Dr. P.K. Gupta, University of Pennsylvania, Philadelphia, PA.)*

Although histology and exfoliative cytology remain the most commonly used methods in the diagnosis of cancer, new techniques are being constantly added to the tools of the surgical pathologist. Some, such as immunohistochemistry, are already well established and widely used; others, including molecular methods, are rapidly finding their way into the "routine" category. Only some highlights of these diagnostic modalities are presented.

Immunohistochemistry.

The availability of specific antibodies has greatly facilitated the identification of cell products or surface markers. Some examples of the utility of immunohistochemistry in the diagnosis or management of malignant neoplasms follow.

- *Categorization of undifferentiated malignant tumors:* In many cases malignant tumors of diverse origin resemble each other because of limited differentiation. These tumors are often quite difficult to distinguish on the basis of routine hematoxylin and eosin (H&E)–stained tissue sections. For example, certain anaplastic carcinomas, lymphomas, melanomas, and sarcomas may look quite similar, but they must be accurately identified because their treatment and prognosis are different. Antibodies specific to intermediate filaments have proved to be of particular value in such cases, because solid tumor cells often contain intermediate filaments characteristic of their cell of origin. For example, the presence of cytokeratins, detected by immunohistochemistry, points to an epithelial origin (carcinoma) (Fig. 7-49), whereas desmin is specific for neoplasms of muscle cell origin.
- *Determination of site of origin of metastatic tumors:* Many cancer patients present with metastases. In some the primary site is obvious or readily detected on the basis of clinical or radiologic features. In cases in which the origin of the tumor is obscure, immunohistochemical detection of tissue-specific or organ-specific antigens in a biopsy specimen of the metastatic deposit can lead to the identification of the tumor source. For example, prostate-specific antigen (PSA) and thyroglobulin are markers of carcinomas of the prostate and thyroid, respectively.
- *Detection of molecules that have prognostic or therapeutic significance:* Immunohistochemical detection of hormone (estrogen/progesterone) receptors in breast cancer cells is of prognostic and therapeutic value because these cancers are susceptible to anti-estrogen therapy (Chapter 23). In general, receptor-positive breast cancers have a better prognosis. Protein products of oncogenes such as *ERBB2* in breast cancers can also be detected by immunostaining. Breast cancers with overexpression of ERBB2 protein generally have a poor prognosis. In general practice, the overexpression of ERBB2 is confirmed by fluorescent in situ hybridization (FISH) to confirm amplification of the genomic region containing the *ERBB2* gene.

Flow Cytometry.

Flow cytometry can rapidly and quantitatively measure several individual cell characteristics, such as membrane antigens and the DNA content of tumor cells. *Flow cytometry* has also proved useful in the identification and classification of tumors arising from T and B lymphocytes and from mononuclear-phagocytic cells. Monoclonal antibodies directed against various lymphohematopoietic cells are listed in Chapter 13 .

Molecular Diagnosis.

Several molecular techniques—some established, others emerging—have been used for diagnosis and, in some cases, for predicting behavior of tumors.

- *Diagnosis of malignant neoplasms:* Although molecular methods are not the primary modality of cancer diagnosis, they are of considerable value in selected cases. Molecular techniques are useful in differentiating benign (polyclonal) proliferations of T or B cells from malignant (monoclonal) proliferations. Because each T and B cell has unique rearrangements of its antigen receptor genes (Chapter 6), PCR–based detection of T-cell receptor or immunoglobulin genes allows distinction between monoclonal (neoplastic) and polyclonal (reactive) proliferations. Many hematopoietic neoplasms (leukemias and lymphomas) are associated with specific translocations that activate oncogenes. Detection of such translocations, usually by routine cytogenetic analysis or by FISH technique (Chapter 5), is often extremely helpful in diagnosis.[189] In some cases, molecular techniques, such as PCR, can detect residual disease in cases that appear negative by conventional analysis. Diagnosis of sarcomas (Chapter 26) with characteristic translocations is also aided by molecular techniques, because chromosome preparations are

often difficult to obtain from solid tumors. For example, many sarcomas of childhood, so-called round blue cell tumors (Chapter 10), can be difficult to distinguish from each other on the basis of morphology. However, the presence of the characteristic [t(11;22)(q24;q12)] translocation, established by PCR, in one of these tumors confirms the diagnosis of Ewing sarcoma.[190] A molecular cytogenetic technique called *spectral karyotyping* has great sensitivity and allows the examination of all chromosomes in a single experiment.[191] This technique, which is based on 24-color chromosomal painting with a mixture of fluorochromes, can detect all types of chromosomal rearrangements in tumor cells, even small, cryptic translocations and insertions (Chapter 5 ; see Fig. 5-35). It can also detect the origin of unidentified chromosomes, called *marker chromosomes*, seen in many hematopoietic malignancies. Another available technique is *comparative genomic hybridization, now more conveniently converted to microarray format*, which allows the analysis of chromosomal gains and losses in tumor cells. The use of DNA microarrays (discussed later), either tiling arrays, which cover the entire human genome, or single-nucleotide polymorphism arrays (SNP chips), also allows analysis of genomic amplifications and deletions at very high resolution.

- *Prognosis of malignant neoplasms:* Certain genetic alterations are associated with poor prognosis, and hence their detection allows stratification of patients for therapy. For example, amplification of the N-*MYC* gene and deletions of 1p bode poorly for patients with neuroblastoma, while amplification of *HER-2/NEU* in breast cancer is an indication that therapy with antibodies against the ERBB2 receptor may be effective. These can be detected by routine cytogenetics and also by FISH or PCR assays. Oligodendrogliomas in which the only genomic abnormality is the loss of chromosomes 1p and 19q respond well to therapy and are associated with long-term survival when compared to tumors with intact 1p and 19q but with EGF receptor amplification.[192]
- *Detection of minimal residual disease:* After treatment of patients with leukemia or lymphoma, the presence of minimal disease or the onset of relapse can be monitored by PCR-based amplification of nucleic acid sequences unique to the malignant clone. For example, detection of *BCR-ABL* transcripts by PCR gives a measure of the residual leukemia cells in treated patients with CML. Similarly, detection of specific *KRAS* mutations in stool samples of persons previously treated for colon cancer can alert the clinician to the possible recurrence of the tumor. The prognostic importance of minimal disease has been established in acute lymphoblastic leukemia, and is being evaluated in other neoplasms.
- *Diagnosis of hereditary predisposition to cancer:* As was discussed earlier, germ-line mutations in several tumor suppressor genes, including *BRCA1*, *BRCA2*, and the *RET* proto-oncogene, are associated with a high risk of developing specific cancers. Thus, detection of these mutated alleles may allow the patient and physician to devise an aggressive screening program, consider the option of prophylactic surgery, and counseling of relatives at risk. Such analysis usually requires detection of a specific mutation (e.g., *RET* gene) or sequencing of the entire gene. The latter is necessitated when several different cancer-associated mutations are known to exist. Although the detection of mutations in such cases is relatively straightforward, the ethical issues surrounding such presymptomatic diagnosis are complex.

Molecular Profiles of Tumors

Until recently, studies of gene expression in tumors involved the analysis of individual genes. These studies have been revolutionized by the introduction of methods that can measure the expression of essentially all the genes in the genome simultaneously.[193,][194] The most common method for large-scale analysis of gene expression in use today is based on DNA microarray technology. There are essentially two methods for expression analysis. Either PCR products from cloned genes or oligonucleotides homologous to genes of interest are spotted onto a glass slide. Each method has its advantages and disadvantages. Chips can be purchased from commercial suppliers or produced on the premises, and high-density oligonucleotide arrays can contain more than 2 million elements. The gene chip is then hybridized to “probes” prepared from tumor and control samples (the probes are usually complementary DNA copies of RNAs extracted from tumor and uninvolved tissues) that have been labeled with a fluorochrome. After hybridization the chip is read using a laser scanner (Fig. 7-50); sophisticated software has been developed to measure the intensity of the fluorescence for each spot. A variety of analyses can then be performed with these data; one of the most useful for cancer research has been hierarchical clustering, which can be used in many ways to understand the molecular heterogeneity and biologic behavior of cancer. One can determine the expression profiles of many different individual tumors that have different outcomes, for example, breast cancers that relapsed and those that did not.

Using a hierarchical clustering, a (hopefully) short list of genes that are differentially expressed in these two groups can be generated. This “signature” may then be used to predict the behavior of tumors. In this way it is hoped that gene expression profiles will improve our ability to stratify patients' risk and guide treatment beyond the limits of histology and pathologic staging. Indeed, analysis of phenotypically identical large B-cell lymphomas (Chapter 13) from different individuals shows that these tumors are heterogeneous with respect to their gene expression profiles. Importantly, gene expression signatures have been identified that allow segregation of morphologically similar lymphomas into distinct subcategories with markedly different survival rates.[195]

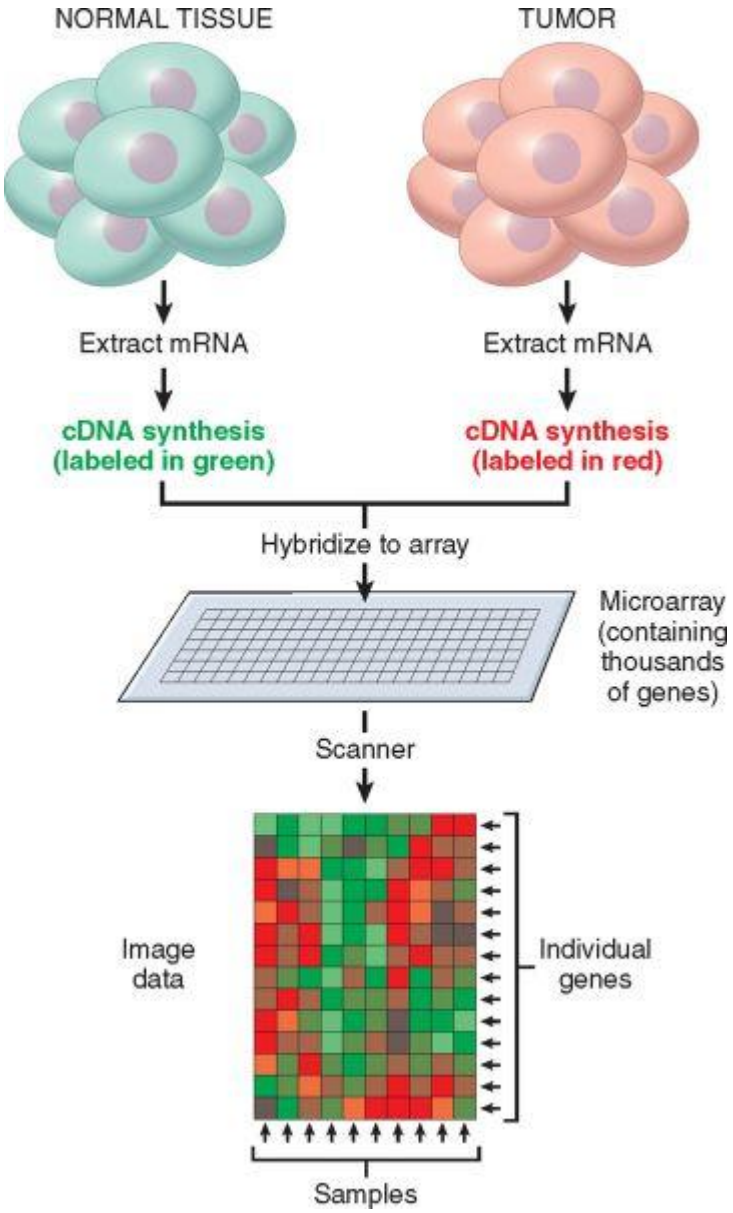

FIGURE 7-50 Steps required for the analysis of global gene expression by DNA microarray. RNA is extracted from tumor and normal tissue. Complementary DNA (cDNA) synthesized from each preparation is labeled with fluorescent dyes (in the example shown, normal tissue cDNA is labeled with a green dye; tumor cDNA is labeled with a red dye). The array consists of a solid support in which DNA fragments from many thousands of genes are spotted. The labeled cDNAs from tumor and normal tissue are combined and hybridized to the genes contained in the array. Hybridization signals are detected using a confocal laser scanner and downloaded to a computer for analysis (*red squares*, expression of the gene is higher in tumor; *green squares*, expression of the gene is higher in normal tissue; *black squares*, no difference in the expression of the gene between tumor and normal tissue). In the display the horizontal rows correspond to each gene contained in the array; each vertical row corresponds to single samples.

A major problem in the analysis of gene expression in tumors is the heterogeneity of the tissue. In addition to the heterogeneity of the tumor cells, samples may contain variable amounts of stromal connective tissue, inflammatory infiltrates, and normal tissue cells. One way to overcome this problem is to obtain nearly pure tumor cells or small tumors free from associated stroma using *laser capture microdissection*. In this technique, the dissection of tumor cells is made under a microscope through a focused laser. The dissected material is then captured or "catapulted" into a small cap and processed for RNA and DNA isolation.

The applications of molecular profiling technology keep expanding and being refined, but much has already been accomplished. The work that has received the most publicity involves gene expression profiling of breast cancers. In addition to identifying new subtypes of breast cancers, a 70-gene prognosis signature has been established.[196] It has been reported that the signature is a powerful predictor of disease prognosis for young patients and is particularly accurate for predicting metastasis during the first 5 years after diagnosis. Prognosis determined by gene expression profile correlates highly with histologic grade and estrogen receptor status but not with lymphatic spread of the tumor. A smaller panel of 21 genes is currently being used to assess the risk or recurrence and likely benefit of chemotherapy in a subset of breast cancer patients.[197]

The development of new microarray platforms and new technologies, such as high-throughput sequencing, make the methodical categorization of all the genomic changes present in a cancer cell a realistic possibility. Array-based comparative genomic hybridization can be used to look for alterations in genomic structure, such as amplifications and deletions. These changes can then be correlated to changes in gene expression. So-called single nucleotide polymorphism (SNP) chips, which include SNPs that span the entire genome, have been used in genome-wide linkage analysis (Chapter 5) and association studies to identify genes associated with increased risk of cancer. [198] [199] [200] Arrays tiled across the entire genome can be used to look for novel transcripts, novel promoters, and novel splice variants. These tiling arrays can also be used to identify epigenetic events, such as DNA methylation, and, when combined with a technique called chromatin immunoprecipitation, can map the genomic site of chromatin marks, as well as genomic binding sites of transcription factors. High-throughput resequencing methods, which can generate hundreds of millions to billions of base pairs in a single run, may allow identification of unknown fusion gene products, as well as efficient resequencing of entire cancer genomes.[201]

Next on the horizon of molecular techniques for the global analysis of cancers is *proteomics*, a technique used to obtain profiles of proteins contained in tissues, serum, or other body fluids. Indeed, with the realization that mRNA levels are regulated post-transcriptionally, it is not clear how closely the levels of proteins, the molecules that execute cellular processes, actually correlate with mRNA levels. Technologies to achieve global protein measurements, such as mass spectroscopy and antibody arrays, are currently being developed.

The excitement created by the development of new techniques for the global molecular analysis of tumors has led some scientists to predict that the end of histopathology is in sight, and to consider existing approaches to tumor diagnosis as the equivalent of magical methods of divination. Indeed, it is hard to escape the excitement generated by the development of entirely new and powerful methods of molecular analysis. However, what lies ahead is not the replacement of one set of techniques by another. On the contrary, the most accurate diagnosis and prognosis of cancer will be arrived at by a combination of morphologic and molecular techniques.

Biochemical assays for tumor-associated enzymes, hormones, and other tumor markers in the blood cannot be used for definitive diagnosis of cancer; however, they contribute to the detection of cancer and in some instances are useful in determining the effectiveness of therapy or the appearance of a recurrence.

A host of tumor markers have been described, and new ones are identified every year. Only a few have stood the test of time and proved to have clinical usefulness.

The application of several markers, listed in Table 7-12 , is considered in the discussion of specific forms of neoplasia in other chapters, so only a few widely used examples suffice here. PSA, used to screen for prostatic adenocarcinoma, may be one of the most used, and most successful, tumor markers in clinical practice.[202] Prostatic carcinoma can be suspected when elevated levels of PSA are found in the blood. However, PSA screening also highlights problems encountered with virtually every tumor marker. Although PSA levels are often elevated in cancer, PSA levels also may be elevated in benign prostatic hyperplasia (Chapter 18). Furthermore, there is no PSA level that ensures that a person does not have prostate cancer. *Thus, the PSA test suffers from both low sensitivity and low specificity*. Other tumor markers occasionally used in clinical practice include CEA, which is elaborated by carcinomas of the colon, pancreas, stomach, and breast, and AFP, which is produced by hepatocellular carcinomas, yolk sac remnants in the gonads, and occasionally teratocarcinomas and embryonal cell carcinomas. Unfortunately, like PSA, both of these markers can be produced by a variety of non-neoplastic conditions as well. Thus, as with PSA levels, CEA and AFP assays lack both specificity and sensitivity required for the early detection of cancers. They are still useful in the detection of recurrences after excision. With successful resection of the tumor, these markers disappear from the serum; their reappearance almost always signifies the beginning of the end.

TABLE 7-12 -- Selected Tumor Markers

HORMONES	
Human chorionic gonadotropin	Trophoblastic tumors, nonseminomatous testicular tumors
Calcitonin	Medullary carcinoma of thyroid
Catecholamine and metabolites	Pheochromocytoma and related tumors
Ectopic hormones	See “Paraneoplastic Syndromes” (Table 7-11)
ONCOFETAL ANTIGENS	
α-Fetoprotein	Liver cell cancer, nonseminomatous germ cell tumors of testis
Carcinoembryonic antigen	Carcinomas of the colon, pancreas, lung, stomach, and heart
ISOENZYMES	
Prostatic acid phosphatase	Prostate cancer
Neuron-specific enolase	Small-cell cancer of lung, neuroblastoma
SPECIFIC PROTEINS	
Immunoglobulins	Multiple myeloma and other gammopathies
Prostate-specific antigen and prostate-specific membrane antigen	Prostate cancer
MUCINS AND OTHER GLYCOPROTEINS	
CA-125	Ovarian cancer

CA-19-9	Colon cancer, pancreatic cancer
CA-15-3	Breast cancer
NEW MOLECULAR MARKERS	
p53, APC, RAS mutants in stool and serum	Colon cancer
p53 and RAS mutants in stool and serum	Pancreatic cancer
p53 and RAS mutants in sputum and serum	Lung cancer
p53 mutants in urine	Bladder cancer

Other widely used markers include human chorionic gonadotropin for testicular tumors, CA-125 for ovarian tumors, and immunoglobulins in multiple myeloma and other secretory plasma cell tumors. The development of tests to detect cancer markers in blood and body fluids is an active area of research. Some of the markers being evaluated include the detection of mutated *APC*, *p53*, and *RAS* in the stool of individuals with colorectal carcinomas; the presence of mutated *p53* and of hypermethylated genes in the sputum of persons with lung cancer and in the saliva of persons with head and neck cancers; and the detection of mutated *p53* in the urine of patients with bladder cancer.

2.8 8. Infectious Diseases

2.8.1 General Principles of Microbial Pathogenesis

Alexander J. McADam,
Arlene H. Sharpe

General Principles of Microbial Pathogenesis

Despite the availability and use of effective vaccines and antibiotics, infectious diseases remain an important health problem in the United States and worldwide. In the United States, 2 of the top 10 leading causes of death are infectious diseases (pneumonia and influenza, and septicemia).[1] Infectious diseases are particularly important causes of death among the elderly, people with acquired immunodeficiency syndrome (AIDS), those with chronic diseases, and those receiving immunosuppressive drugs. In developing countries, unsanitary living conditions and malnutrition contribute to a massive burden of infectious diseases that kills more than 10 million people each year. Most of these deaths are among children, especially from respiratory and diarrheal infections.[2]

CATEGORIES OF INFECTIOUS AGENTS

Infectious agents belong to a wide range of classes and vary in size from the approximately 27-kD nucleic acid–free prion to 20-nm poliovirus to 10-m tapeworms (Table 8-1).

TABLE 8-1 -- Classes of Human Pathogens and Their Lifestyles

Taxonomic	Size	Site of Propagation	Examples	Disease
Prions	30–50 kD	Intracellular	Prion protein	Creutzfeld-Jacob disease
Viruses	20–300 nm	Obligate intracellular	Poliovirus	Poliomyelitis
Bacteria	0.2–15 μm	Obligate intracellular	*Chlamydia trachomatis*	Trachoma, urethritis
		Extracellular	*Streptococcus pneumoniae*	Pneumonia
		Facultative intracellular	*Mycobacterium tuberculosis*	Tuberculosis
Fungi	2–200 μm	Extracellular	*Candida albicans*	Thrush
		Facultative intracellular	*Histoplasma capsulatum*	Histoplasmosis
Protozoa	1–50 μm	Extracellular	*Trypanosoma gambiense*	Sleeping sickness
		Facultative intracellular	*Trypanosoma cruzi*	Chagas disease
		Obligate intracellular	*Leishmania donovani*	Kala-azar
Helminths	3 mm–10 m	Extracellular	*Wuchereria bancrofti*	Filariasis

Taxonomic	Size	Site of Propagation	Examples	Disease
		Intracellular	*Trichinella spiralis*	Trichinosis

Prions

Prions are composed of abnormal forms of a host protein, termed *prion protein* (PrP).[3] These agents cause transmissible spongiform encephalopathies, including kuru (associated with human cannibalism), Creutzfeldt-Jakob disease (CJD), bovine spongiform encephalopathy (BSE; better known as mad cow disease), and variant Creutzfeldt-Jakob disease (vCJD; probably transmitted to humans from BSE-infected cattle).[4] PrP is normally found in neurons. Diseases occur when the PrP undergoes a conformational change that confers resistance to proteases. The protease-resistant PrP promotes conversion of the normal protease-sensitive PrP to the abnormal form, explaining the infectious nature of these diseases. Accumulation of abnormal PrP leads to neuronal damage and distinctive spongiform pathologic changes in the brain. Spontaneous or inherited mutations in PrP, which make PrP resistant to proteases, have been observed in the sporadic and familial forms of CJD, respectively. CJD can be transmitted from person to person iatrogenically, by surgery, organ transplant, or blood transfusion. These diseases are discussed in detail in Chapter 28 .

Viruses

Viruses are obligate intracellular parasites that depend on the host cell's metabolic machinery for their replication. They consist of a nucleic acid genome surrounded by a protein coat (called a capsid) that is sometimes encased in a lipid membrane. Viruses are classified by their nucleic acid genome (DNA or RNA but not both), the shape of the capsid (icosahedral or helical), the presence or absence of a lipid envelope, their mode of replication, the preferred cell type for replication (called tropism), or the type of pathology. Because viruses are only 20 to 300 nm in size, they are best visualized with the electron microscope (Fig. 8-1). However, some viral particles aggregate within the cells they infect and form characteristic inclusion bodies, which may be seen with the light microscope and are useful for diagnosis. For example, cytomegalovirus (CMV)-infected cells are enlarged and show a large eosinophilic nuclear inclusion and smaller basophilic cytoplasmic inclusions; herpesviruses form a large nuclear inclusion surrounded by a clear halo; and both smallpox and rabies viruses form characteristic cytoplasmic inclusions. Many viruses do not produce inclusions (e.g., Epstein-Barr virus [EBV]).

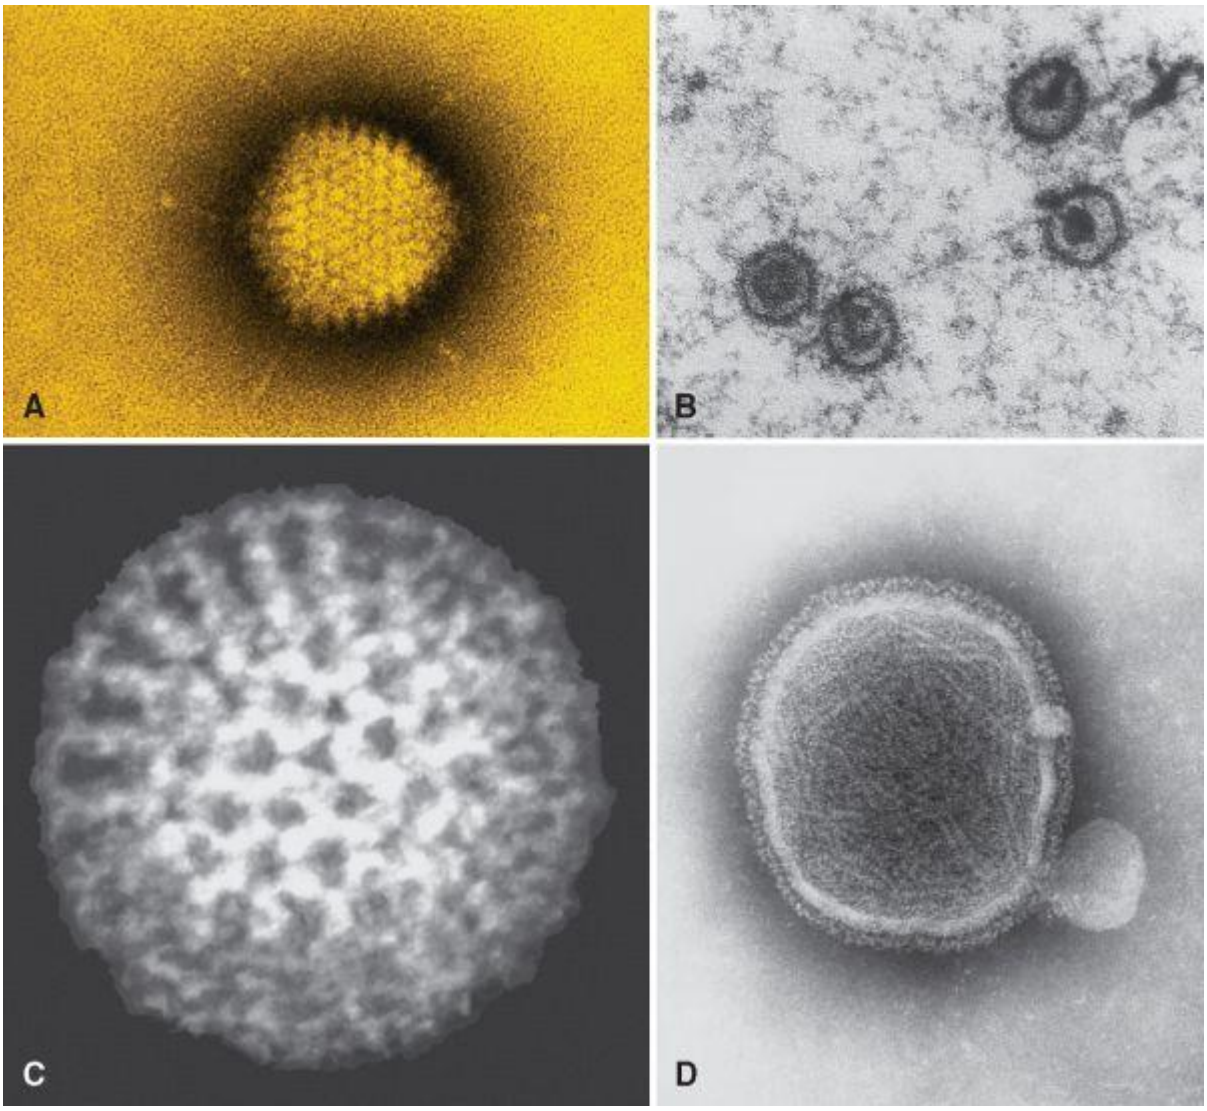

FIGURE 8-1 The variety of viral structures, as seen by electron microscopy. **A**, Adenovirus, an icosahedral nonenveloped DNA virus with fibers. **B**, Epstein-Barr virus, an icosahedral enveloped DNA virus. **C**, Rotavirus, a nonenveloped, wheel-like, RNA virus. **D**, Paramyxovirus, a spherical enveloped RNA virus. RNA is seen spilling out of the disrupted virus. *(Photos courtesy of Science Source; © Photo Researchers, Inc., New York, NY.)*

Viruses account for a large share of human infections. Many viruses cause transient illnesses (e.g., colds, influenza). Other viruses are not eliminated from the body and persist within cells of the host for years, either continuing to multiply (e.g., chronic infection with hepatitis B virus [HBV]) or surviving in some nonreplicating form (termed *latent infection*) with the potential to be reactivated later. For example, herpes zoster virus, the cause of chickenpox, can enter dorsal root ganglia and establish latency there and later be periodically activated to cause shingles, a painful skin condition. Some viruses are involved in transformation of a host cell into a benign or malignant tumor (e.g., human papillomavirus [HPV]-induced benign warts and cervical carcinoma). Different species of viruses can produce the same clinical picture (e.g., upper respiratory infection); conversely, a single virus can cause different clinical manifestations depending on host age or immune status (e.g., CMV).

Bacteria

Bacteria are prokaryotes, meaning that they have a cell membrane but lack membrane-bound nuclei and other membrane-enclosed organelles. Most bacteria are bound by a cell wall consisting of peptidoglycan, a polymer of long sugar chains linked by peptide bridges. There are two forms of cell wall structures: a thick wall surrounding the cell membrane that retains crystal-violet stain (gram-positive bacteria) or a thin cell wall sandwiched between two phospholipid bilayer membranes (gram-negative bacteria) (Fig. 8-2). Bacteria are classified by Gram staining (positive or negative), shape (spherical ones are cocci; rod-shaped ones are bacilli) (Fig. 8-3), and need for oxygen (aerobic or anaerobic). Many bacteria have flagella, long helical filaments extending from the cell surface that enable bacteria to move. Some bacteria possess pili, another kind of surface projection that can attach bacteria to host cells or extracellular matrix. Most bacteria synthesize their own DNA, RNA, and proteins, but they depend on the host for favorable growth conditions.

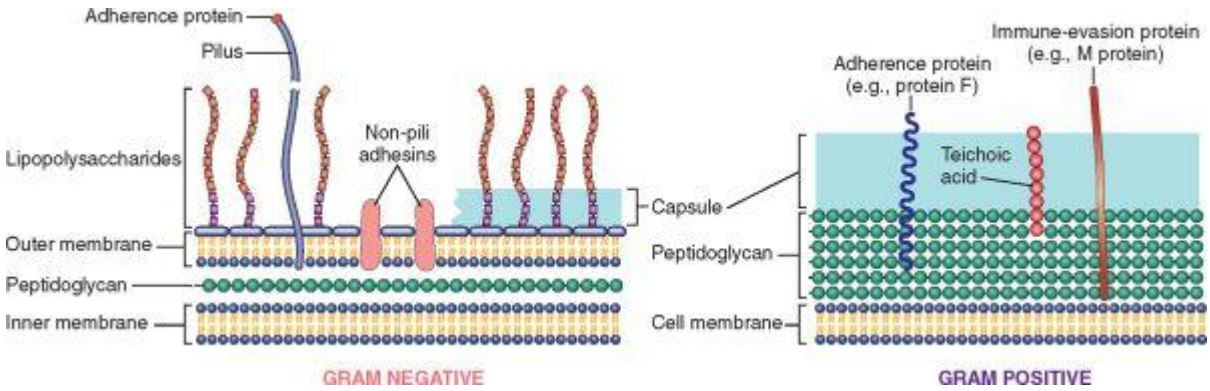

FIGURE 8-2 Molecules on the surface of gram-negative and gram-positive bacteria involved in pathogenesis. Not shown is the type 3 secretory apparatus of gram-negative bacteria (see text).

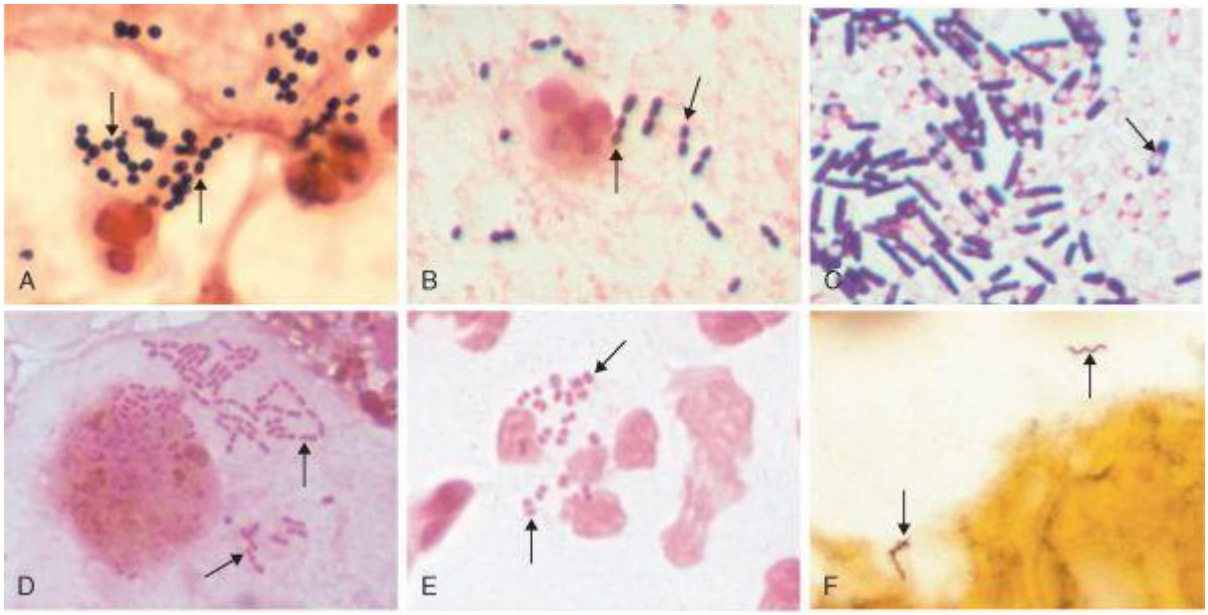

FIGURE 8-3 The variety of bacterial morphology. The bacteria are indicated by arrows in each panel. **A**, Gram stain of sputum from a patient with pneumonia. There are gram-positive cocci in clusters *(Staphylococcus aureus)* with degenerating neutrophils. **B**, Gram stain of sputum

from a patient with pneumonia. Gram-positive, elongated cocci in pairs and short chains *(Streptococcus pneumoniae)* and a neutrophil are seen. **C**, Gram stain of *Clostridium sordellii* grown in culture. A mixture of gram-positive and gram-negative rods, many of which have subterminal spores (clear areas), are present. *Clostridia* species often stain as both gram-positive and gram-negative, although they are true gram-positive bacteria. **D**, Gram stain of a bronchoalveolar lavage specimen showing gram-negative intracellular rods typical of Enterobacteriaceae such as *Klebsiella pneumoniae* or *Escherichia coli*. **E**, Gram stain of urethral discharge from a patient with gonorrhea. Many gram-negative diplococci *(Neisseria gonorrhoeae)* are present within a neutrophil. **F**, Silver stain of brain tissue from a patient with Lyme disease meningoencephalitis. Two helical spirochetes *(Borrelia burgdorferi)* are indicated by arrows. The panels are at different magnifications. *(**D**, Courtesy of Dr. Karen Krisher, Clinical Microbiology Institute, Wilsonville, OR. Other panels courtesy of Dr. Kenneth Van Horn, Focus Diagnostics.)*

Normal healthy people can be colonized by as many as 10^{12} bacteria on the skin, 10^{10} bacteria in the mouth, and 10^{14} bacteria in the gastrointestinal tract. Bacteria colonizing the skin include *Staphylococcus epidermidis* and *Propionibacterium acnes*, the cause of acne. Aerobic and anaerobic bacteria in the mouth, particularly *Streptococcus mutans*, contribute to dental plaque, a major cause of tooth decay. High-throughput sequencing methods have recently allowed detailed analysis of the diversity of intestinal bacterial flora. There are at least 395 species of bacteria in the normal intestinal flora, but only a small subset, mainly anaerobes, account for the great majority. In-depth analysis of the collective genome (called the "microbiome") of the intestinal flora may yield insights into the evolutionary pressures that have selected the organisms that have succeeded in making humans their home, as well as disturbances in this symbiotic relationship, as in inflammatory bowel diseases.[5] Many bacteria remain extracellular when they invade the body, while others can survive and replicate either outside or inside of host cells (*facultative intracellular* bacteria) and some grow only inside host cells (*obligate intracellular* bacteria).

Obligate intracellular bacteria include *Chlamydia* and *Rickettsia*, which replicate inside membrane-bound vacuoles in epithelial and endothelial cells, respectively. These bacteria get most or all of their energy source, ATP, from the host cell. *Chlamydia trachomatis* is the most frequent infectious cause of female sterility (by scarring and narrowing of the fallopian tubes) and blindness (by chronic inflammation of the conjunctiva that eventually causes scarring and opacification of the cornea). Rickettsiae injure the endothelial cells in which they grow, and so cause a hemorrhagic vasculitis, often visible as a rash, but they may also injure the central nervous system (CNS) and cause death (Rocky Mountain spotted fever [RMSF] and epidemic typhus). Rickettsiae are transmitted by arthropod vectors, including lice (epidemic typhus), ticks (RMSF and ehrlichiosis), and mites (scrub typhus).[6]

Mycoplasma organisms and those belonging to the related genus *Ureaplasma* are unique among extracellular bacterial pathogens, because they do not have a cell wall. These are the tiniest free-living organisms known (125–300 nm).

Fungi

Fungi are eukaryotes that possess thick chitin-containing cell walls and ergosterol-containing cell membranes. Fungi can grow either as rounded yeast cells or as slender filamentous hyphae. Hyphae may be septate (with cell walls separating individual cells) or aseptate, which is an important distinguishing characteristic in clinical material. Some of the most important pathogenic fungi exhibit thermal dimorphism; that is, they grow as hyphal forms at room temperature but as yeast forms at body temperature. Fungi may produce sexual spores or, more commonly, asexual spores referred to as *conidia*. The latter are produced on specialized structures or fruiting bodies arising along the hyphal filament. Fungi may cause superficial or deep infections. Superficial infections involve the skin, hair, and nails. Fungal species that are confined to superficial layers of the human skin are known as dermatophytes. These infections are commonly referred to by the term "tinea" followed by the area of the body affected (e.g., tinea pedis, "athlete's foot"; tinea capitis, "ringworm of the scalp"). Certain

fungal species invade the subcutaneous tissue, causing abscesses or granulomas (e.g., sporotrichosis and tropical mycoses).

Deep fungal infections can spread systemically and invade tissues, destroying vital organs in immunocompromised hosts, but usually heal or remain latent in otherwise normal hosts. Some deep fungal species are limited to a particular geographic region (e.g., *Coccidioides* in the southwestern United States and *Histoplasma* in the Ohio River Valley). Opportunistic fungi (e.g., *Candida, Aspergillus, Mucor*, and *Cryptococcus*), by contrast, are ubiquitous organisms that either colonize individuals or are encountered from environmental sources. In immunodeficient individuals, opportunistic fungi give rise to life-threatening infections characterized by tissue necrosis, hemorrhage, and vascular occlusion, with little or no inflammatory response. AIDS patients are often infected by the opportunistic fungus *Pneumocystis jiroveci* (previously called *Pneumocystis carinii*).

Protozoa

Parasitic protozoa are single-celled eukaryotes that are major causes of disease and death in developing countries. Protozoa can replicate intracellularly within a variety of cells (e.g., *Plasmodium* in red blood cells, *Leishmania* in macrophages) or extracellularly in the urogenital system, intestine, or blood. *Trichomonas vaginalis* are flagellated protozoal parasites that are sexually transmitted and can colonize the vagina and male urethra. The most prevalent intestinal protozoans, *Entamoeba histolytica* and *Giardia lamblia*, have two forms: (1) motile trophozoites that attach to the intestinal epithelial wall and may invade, and (2) immobile cysts that are resistant to stomach acids and are infectious when ingested. Blood-borne protozoa (e.g., *Plasmodium, Trypanosoma*, and *Leishmania*) are transmitted by insect vectors, in which they replicate before being passed to new human hosts. Intestinal protozoa are acquired by ingestion of cysts from contaminated food or water. *Toxoplasma gondii* is acquired either by contact with oocyst-shedding kittens or by eating cyst-ridden, undercooked meat.

Helminths

Parasitic worms are highly differentiated multicellular organisms. Their life cycles are complex; most alternate between sexual reproduction in the definitive host and asexual multiplication in an intermediary host or vector. Thus, depending on parasite species, humans could harbor adult worms (e.g., *Ascaris lumbricoides*) or immature stages (e.g., *Toxocara canis*) or asexual larval forms (e.g., *Echinococcus* species). Once adult worms take up residence in humans, they do not multiply but they produce eggs or larvae that are usually passed out in stool. Often, the severity of disease is in proportion to the number of organisms that have infected the individual (e.g., 10 hookworms cause little disease, whereas 1000 hookworms cause severe anemia by consuming 100 mL of blood per day). In some helminthic infections, disease is caused by inflammatory responses to the eggs or larvae rather than to the adults (e.g., schistosomiasis).

Ectoparasites

Ectoparasites are insects (lice, bedbugs, fleas) or arachnids (mites, ticks, spiders) that attach to and live on or in the skin. Arthropods may produce disease directly by damaging the human host or indirectly by serving as the vectors for transmission of an infectious agent into a human host. Some arthropods cause itching and excoriations (e.g., pediculosis caused by lice attached to hair shafts, or scabies caused by mites burrowing into the stratum corneum). At the site of the bite, mouth parts may be found associated with a mixed infiltrate of lymphocytes, macrophages, and eosinophils. In addition, attached arthropods can be vectors for other pathogens. For example, deer ticks transmit the Lyme disease spirochete *Borrelia burgdorferi*.

SPECIAL TECHNIQUES FOR DIAGNOSING INFECTIOUS AGENTS

Some infectious agents or their products can be directly observed in hematoxylin and eosin–stained sections (e.g., the inclusion bodies formed by CMV and herpes simplex virus (HSV); bacterial clumps, which usually stain blue; *Candida* and *Mucor* among the fungi; most protozoans; and all helminths). Many infectious agents, however, are best visualized by special stains that identify organisms on the basis of particular characteristics of their cell wall or coat—Gram, acid-fast, silver, mucicarmine, and Giemsa stains—or after labeling with specific antibody probes (Table 8-2). Regardless of the staining technique, organisms are usually best visualized at the advancing edge of a lesion rather than at its center, particularly if there is necrosis.

TABLE 8-2 -- Special Techniques for Diagnosing Infectious Agents

Techniques	Infectious Agents
Gram stain	Most bacteria
Acid-fast stain	Mycobacteria, nocardiae (modified)
Silver stains	Fungi, legionellae, pneumocystis
Periodic acid–Schiff	Fungi, amebae
Mucicarmine	Cryptococci
Giemsa	Campylobacteria, leishmaniae, malaria parasites
Antibody probes	All classes
Culture	All classes
DNA probes	All classes

Acute infections can be diagnosed serologically by detecting pathogen-specific antibodies in the serum. The presence of specific IgM antibody shortly after the onset of symptoms is often diagnostic. Alternatively, specific antibody titers can be measured early (“acute”) and 4–6 weeks (“convalescent”) after infection; a four-fold rise in titer is usually considered diagnostic.

Nucleic acid–based tests, collectively called *molecular diagnostics*, have become routine methods for detecting and quantifying several pathogens. For instance, in people infected with the human immunodeficiency virus (HIV), quantification of HIV RNA is an important guide to antiretroviral therapy.[7] The management of HBV and HCV infections is similarly guided by nucleic acid–based viral quantification or typing to predict resistance to antiviral drugs.

Nucleic acid amplification tests, such as polymerase chain reaction (PCR) and transcription-mediated amplification, have become routine for diagnosis of gonorrhea, chlamydial infection, tuberculosis, and herpes encephalitis. In some cases, molecular assays are much more sensitive than conventional testing.[8,][9] PCR testing of cerebrospinal fluid (CSF) for herpes simplex virus (HSV) encephalitis has a sensitivity of about 80%, while viral culture of CSF has a sensitivity of less than 10%. Similarly, nucleic acid tests for genital chlamydia detect 10% to 30% more infections than does conventional chlamydia culture. In other cases, such as gonorrhea, the sensitivity of nucleic acid testing is similar to that of culture.

NEW AND EMERGING INFECTIOUS DISEASES

Although infectious diseases such as leprosy have been known since biblical times, and parasitic schistosomes and mycobacteria have been demonstrated in Egyptian mummies, a surprising number of new infectious agents continue to be discovered (Table 8-3). The infectious causes of some diseases with significant morbidity and mortality were previously unrecognized, because some of the infectious

agents are difficult to culture; examples include *Helicobacter pylori* gastritis, HBV and HCV, and Legionnaires pneumonia. Some infectious agents are genuinely new to humans, e.g., HIV, which causes AIDS, and *B. burgdorferi*, which causes Lyme disease. Other infections have become much more common because of immunosuppression caused by AIDS or therapy for transplant rejection and some cancers (e.g., CMV, Kaposi sarcoma herpesvirus, *Mycobacterium avium-intracellulare, P. jiroveci*, and *Cryptosporidium parvum*).[10,][11] Finally, infectious diseases that are common in one area may be introduced into a new area. For example, West Nile virus has been common in Europe, Asia, and Africa for years but was first described in the United States in 1999.

TABLE 8-3 -- Some Recently Recognized Infectious Agents and Manifestations

Date Recognized	Infectious Agent	Manifestations
1977	Ebola virus	Epidemic Ebola hemorrhagic fever
	Hantaan virus	Hemorrhagic fever with renal syndrome
	Legionella pneumophila	Legionnaires disease
	Campylobacter jejuni	Enteritis
1980	HTLV-I	T-cell lymphoma or leukemia, HTLV-associated myelopathy
1981	*Staphylococcus aureus*	Toxic shock syndrome
1982	*Escherichia coli* O157:H7	Hemorrhagic colitis, hemolytic-uremic syndrome
	Borrelia burgdorferi	Lyme disease
1983	HIV	AIDS
	Helicobacter pylori	Gastric ulcers
1988	Hepatitis E	Enterically transmitted hepatitis
1989	Hepatitis C	Hepatitis C
1992	*Vibrio cholerae* O139	New epidemic cholera strain
	Bartonella henselae	Cat-scratch disease
1995	KSHV (HHV-8)	Kaposi sarcoma in AIDS
1999	West Nile virus	West Nile fever, neuroinvasive disease
2003	SARS coronavirus	Severe acute respiratory syndrome

Human demographics and behavior are among the many variables that contribute to the emergence of infectious diseases. AIDS was first recognized in the United States as predominantly a disease of homosexuals and drug abusers, but heterosexual transmission is now common. In sub-Saharan Africa, the area of the world with the highest number of AIDS cases, it is predominantly a heterosexual disease.[12] Changes in the environment occasionally drive rates of infectious diseases. Reforestation of the eastern United States has led to massive increases in the populations of deer and mice, which carry the ticks that transmit Lyme disease, babesiosis, and ehrlichiosis.[13] Failure of DDT to control the mosquitoes that transmit malaria and the development of drug-resistant parasites have dramatically increased the morbidity and mortality of *Plasmodium falciparum* in Asia, Africa, and Latin America. Microbial adaptation to widespread antibiotic use contributed to the emergence of drug resistance in many species of bacteria, including *Mycobacterium tuberculosis, Neisseria gonorrhoeae, Staphylococcus aureus*, and *Enterococcus faecium*. Infections with antibiotic-resistant bacteria are becoming a serious problem, such as methicillin-resistant staphylococcus (discussed later).

AGENTS OF BIOTERRORISM

Sadly, the anthrax attacks in the United States in 2001 transformed the theoretical threat of bioterrorism into reality. The Centers for Disease Control and Prevention (CDC) have evaluated the microorganisms that pose the greatest danger as weapons on the basis of the efficiency with which disease can be transmitted, how difficult the microorganisms are to produce and distribute, what can be done to defend against them, and the extent to which they are likely to alarm the public and produce widespread fear. The CDC has ranked bioweapons into three categories, A, B, and C, based on these criteria (Table 8-4).[14]

TABLE 8-4 -- Potential Agents of Bioterrorism

Category A Diseases/Agents
Anthrax *(Bacillus anthracis)*
Botulism *(Clostridium botulinum* toxin)
Plague *(Yersinia pestis)*
Smallpox *(Variola major virus)*
Tularemia *(Francisella tularensis)*
Viral hemorrhagic fevers (filoviruses [e.g., Ebola, Marburg] and arenaviruses [e.g., Lassa, Machupo])
Category B Diseases/Agents
Brucellosis *(Brucella* sp.)
Epsilon toxin of *Clostridium perfringens*
Food safety threats (e.g., *Salmonella* sp., *Escherichia coli* O157:H7, *Shigella*)
Glanders *(Burkholderia mallei)*
Melioidosis *(Burkholderia pseudomallei)*
Psittacosis *(Chlamydia psittaci)*
Q fever *(Coxiella burnetti)*
Ricin toxin from *Ricinus communis* (castor beans)
Staphylococcal enterotoxin B
Typhus fever *(Rickettsia prowazekii)*
Viral encephalitis (alphaviruses [e.g., Venezuelan equine encephalitis, eastern equine encephalitis, western equine encephalitis])
Water safety threats (e.g., *Vibrio cholerae*, *Cryptosporidium parvum*)
Category C Diseases/Agents
Emerging infectious disease threats such as Nipah virus and Hantavirus

Adapted from Centers for Disease Control Information.

Category A agents pose the highest risk and can be readily disseminated or transmitted from person to person, can cause high mortality with potential for major public health impact, might cause public panic and social disruption, and might require special action for public health preparedness. For example, smallpox is a category A agent because of its high transmissibility in any climate or season, case mortality rate of 30% or greater, and lack of effective antiviral therapy. This agent can be easily disseminated because of the stability of the virus in aerosol form and the very small dose needed for infection. Smallpox naturally spreads from person to person mainly by direct contact with virus in skin lesions or contaminated clothing or bedding. Symptoms appear after 7 to 17 days. Initially there is high

fever, headache, and backache, followed by the appearance of the rash, which first appears on the mucosa of the mouth and pharynx, face, and forearms and later spreads to the trunk and legs and becomes vesicular and later pustular. Because people can be contagious during the incubation period, this virus has the potential to continue to spread throughout an unprotected population. Since vaccination ended in the United States in 1972 and vaccination immunity has waned, the population is highly susceptible to smallpox. Recent concern that smallpox could be used for bioterrorism has led to a return of vaccination for selected groups in the United States and Israel.

Category B agents are moderately easy to disseminate, produce moderate morbidity but low mortality, and require specific diagnostic and disease surveillance. Many of these agents are food-borne or water-borne. Category C agents include emerging pathogens that could be engineered for mass dissemination because of availability, ease of production and dissemination, potential for high morbidity and mortality, and great impact on health.

TRANSMISSION AND DISSEMINATION OF MICROBES

Routes of Entry of Microbes

Microbes can enter the host by inhalation, ingestion, sexual transmission, insect or animal bites, or injection. The first defenses against infection are intact skin and mucosal surfaces, which provide physical barriers and produce antimicrobial substances. In general, respiratory, gastrointestinal, or genitourinary tract infections that occur in healthy persons are caused by relatively virulent microorganisms that are capable of damaging or penetrating intact epithelial barriers. In contrast, most skin infections in healthy persons are caused by less virulent organisms entering the skin through damaged sites (cuts and burns).

Skin.

The dense, keratinized outer layer of skin is a natural barrier to infection, and the low pH of the skin (~5.5) and the presence of fatty acids inhibit growth of microorganisms other than residents of the normal flora. Human skin is normally inhabited by a variety of bacterial and fungal species, including some potential opportunists, such as *S. epidermidis* and *Candida albicans*. Although skin is usually an effective barrier, certain types of fungi (dermatophytes) can infect the stratum corneum, hair, and nails, and a few microorganisms are able to traverse the unbroken skin. For example, *Schistosoma* larvae released from freshwater snails penetrate swimmers' skin by releasing collagenase, elastase, and other enzymes that dissolve the extracellular matrix. *Most microorganisms, however, penetrate through breaks in the skin*, including superficial pricks (fungal infections), wounds (staphylococci), burns *(Pseudomonas aeruginosa)*, and diabetic and pressure-related foot sores (multibacterial infections). Intravenous catheters in hospitalized patients can produce local or systemic infection (bacteremia). Needle sticks can expose the recipient to potentially infected blood and may transmit HBV, hepatitis C virus (HCV), or HIV. Some pathogens penetrate the skin via an insect or animal bite. For instance, bites by fleas, ticks, mosquitoes, mites, and lice break the skin and transmit arboviruses (causes of yellow fever and encephalitis), rickettsiae (Rocky Mountain spotted fever [RMSF]), bacteria (plague, Lyme disease), protozoa (malaria, leishmaniasis), and helminths (filariasis). Animal bites can lead to infections with bacteria or certain viruses such as rabies.

Gastrointestinal Tract.

Most gastrointestinal pathogens are transmitted by food or drink contaminated with fecal material. Where hygiene fails, diarrheal disease becomes rampant.

Acidic gastric secretions are important defenses within the gastrointestinal tract and are lethal for many gastrointestinal pathogens.[14] Healthy volunteers do not become infected by *Vibrio cholerae* unless they

are fed 10^{11} organisms, whereas volunteers given *V. cholerae* and sodium bicarbonate have a 10,000-fold increase in susceptibility to cholera. In contrast, some ingested agents, such as *Shigella* and *Giardia* cysts, are relatively resistant to gastric acid; hence, as few as 100 organisms of each are sufficient to cause illness.

Other normal defenses within the gastrointestinal tract include (1) the layer of viscous mucus covering the intestinal epithelium, (2) lytic pancreatic enzymes and bile detergents, (3) mucosal antimicrobial peptides called defensins, (4) normal flora, and (5) secreted IgA antibodies. IgA antibodies are made by plasma cells located in mucosa-associated lymphoid tissues (MALT). These lymphoid aggregates are covered by a single layer of specialized epithelial cells called M cells. M cells are important for transport of antigens to mucosa-associated lymphoid tissues and for binding and uptake of numerous gut pathogens, including poliovirus, enteropathic *Escherichia coli, V. cholerae, Salmonella typhi,* and *Shigella flexneri*.[15]

Infections via the gastrointestinal tract occur when local defenses are weakened or the organisms develop strategies to overcome these defenses. Host defenses are weakened by low gastric acidity, by antibiotics that alter the normal bacterial flora (e.g., in pseudomembranous colitis), or when there is stalled peristalsis or mechanical obstruction (e.g., in blind-loop syndrome). Most enveloped viruses are inactivated by bile and digestive enzymes, but nonenveloped viruses may be resistant (e.g., the hepatitis A virus, rotaviruses, reoviruses, and norovirus).

Enteropathogenic bacteria elicit gastrointestinal disease by a variety of mechanisms:

- While growing on contaminated food, certain staphylococcal strains release powerful enterotoxins that cause food poisoning without any bacterial multiplication in the gut.
- *V. cholerae* and toxigenic *E. coli* multiply inside the mucous layer overlying the gut epithelium and release exotoxins that cause the gut epithelium to secrete large volumes of fluid, resulting in watery diarrhea.
- *Shigella*, *Salmonella*, and *Campylobacter* invade and damage the intestinal mucosa and lamina propria and so cause ulceration, inflammation, and hemorrhage that is clinically manifested as dysentery.
- *Salmonella typhi* passes from the damaged mucosa through Peyer patches and mesenteric lymph nodes and into the bloodstream, resulting in a systemic infection.

Fungal infection of the gastrointestinal tract occurs mainly in immunologically compromised people. *Candida*, part of the normal gastrointestinal flora, shows a predilection for stratified squamous epithelium, causing oral thrush or membranous esophagitis, but may also spread to the stomach, lower gastrointestinal tract, and systemic organs.

The cyst forms of *intestinal protozoa* are essential for their transmission, because cysts resist stomach acid. In the gut, cysts convert to motile trophozoites and attach to sugars on the intestinal epithelia through surface lectins. What happens next differs among pathogens. *Giardia lamblia* attaches to the epithelial brush border, whereas cryptosporidia are taken up by enterocytes, in which they form gametes and spores. *E. histolytica* causes contact-mediated cytolysis through a channel-forming pore protein and thereby ulcerates and invades the colonic mucosa. Intestinal helminths, as a rule, cause disease only when they are present in large numbers or in ectopic sites, for example, by obstructing the gut or invading and damaging the bile ducts *(Ascaris lumbricoides)*. Hookworms may cause iron deficiency anemia by chronic loss of blood sucked from intestinal villi; the fish tapeworm *Diphyllobothrium latum* can deplete its host of vitamin B_{12}, giving rise to an illness resembling pernicious anemia. Finally, the larvae of several helminths pass through the gut briefly on their way to another organ; for example, *Trichinella spiralis* larvae preferentially encyst in muscle, *Echinococcus* species larvae in the liver or lung.

Respiratory Tract.

A large number of microorganisms, including viruses, bacteria, and fungi, are inhaled daily by every city inhabitant. In many cases, the microbes are inhaled in dust or aerosol particles. The distance these particles travel into the respiratory system is inversely proportional to their size. Large particles are trapped in the mucociliary blanket that lines the nose and the upper respiratory tract. Inhaled microorganisms are trapped in the mucus secreted by goblet cells and are then transported by ciliary action to the back of the throat, where they are swallowed and cleared. Particles smaller than 5 μm travel directly to the alveoli, where they are phagocytosed by alveolar macrophages or by neutrophils recruited to the lung by cytokines.

Microorganisms that invade the normal healthy respiratory tract have developed specific mechanisms to overcome the mucociliary defenses or to avoid destruction by alveolar macrophages. Some successful respiratory pathogens evade these defenses by attaching to epithelial cells in the lower respiratory tract and pharynx. For example, influenza viruses possess hemagglutinin proteins that project from the surface of the virus and bind to sialic acid on the surface of epithelial cells. This attachment induces the host cell to engulf the virus, leading to viral entry and replication within the host cell. However, sialic acid also interferes with shedding of newly synthesized viruses from the host cell. Influenza viruses have another cell surface protein, neuraminidase, which cleaves sialic acid and allows virus to release from the host cell. Neuraminidase also lowers the viscosity of mucus and facilitates viral transit within the respiratory tract. Interestingly, some anti-influenza drugs are sialic acid analogues that inhibit neuraminidase and prevent viral release from host cells.

Certain bacterial respiratory pathogens can impair ciliary activity. For instance, *Haemophilus influenzae* and *Bordetella pertussis* elaborate toxins that paralyze mucosal cilia; *P. aeruginosa*, a cause of severe respiratory infection in persons with cystic fibrosis, and *M. pneumoniae* produce ciliostatic substances. Some bacteria such as *Streptococcus pneumoniae* or *Staphylococcus* species lack specific adherence factors and often gain access after viral infection causes loss of ciliated epithelium, making individuals with a viral respiratory infection more susceptible to these secondary bacterial superinfections. Chronic damage to mucociliary defense mechanisms occurs in smokers and people with cystic fibrosis, while acute injury occurs in intubated patients and in those who aspirate gastric acid.

Some respiratory pathogens avoid phagocytosis or destruction after phagocytosis. M. tuberculosis, for example, gains its foothold in normal alveoli because it is able to escape killing within the phagolysosomes of macrophages. Opportunistic fungi infect the lungs when cellular immunity is depressed or when leukocytes are reduced in number (e.g., *P. jiroveci* in AIDS patients and *Aspergillus* species following chemotherapy).

Urogenital Tract.

The urinary tract is almost always invaded from the exterior via the urethra. The regular flushing of the urinary tract with urine serves as a defense against invading microorganisms. Urine in the bladder is normally sterile, and successful pathogens (e.g., *N. gonorrhoeae*, *E. coli*) adhere to the urinary epithelium. Anatomy plays an important role in infection. Women have more than 10 times as many urinary tract infections as men, because the distance between the urinary bladder and skin (i.e., the length of the urethra) is 5 cm in women, in contrast to 20 cm in men. Obstruction of urinary flow and/or reflux can compromise normal defenses and increase susceptibility to urinary tract infections. Urinary tract infections can spread retrogradely from the bladder to the kidney and cause acute and chronic pyelonephritis, which is the major preventable cause of renal failure.

From puberty until menopause the vagina is protected from pathogens by a low pH resulting from catabolism of glycogen in the normal epithelium by lactobacilli. Antibiotics can kill the lactobacilli and

make the vagina susceptible to infection. Sexually transmitted pathogens have developed specific mechanisms for attaching to the vaginal or cervical mucosa, or they enter via local breaks in the mucosa during sexual intercourse (HIV, HPV, *Treponema pallidum*).

Spread and Dissemination of Microbes

Some microorganisms proliferate locally, at the site of infection, whereas others penetrate the epithelial barrier and spread to distant sites via the lymphatics, the blood, or nerves (Fig. 8-4). Pathogens that cause superficial infections stay confined to the lumen of hollow viscera (e.g., *Vibrio cholera*), or adhere to or proliferate exclusively in or on epithelial cells (e.g., papillomaviruses, dermatophytes). A variety of pathogenic bacteria, fungi, and helminths are invasive by virtue of their motility or ability to secrete lytic enzymes (e.g., streptococci and staphylococci secrete hyaluronidase, which degrades the extracellular matrix between host cells). Microbial spread initially follows tissue planes of least resistance and to sites drained by regional lymphatics. For example, staphylococcal infections may progress from a localized abscess or furuncle to regional lymph nodes. This can sometimes leads to bacteremia and colonization of distant organs (heart, liver, brain, kidney, bone). Within the blood, microorganisms may be transported free or within host cells. Some viruses (e.g., poliovirus and HBV), most bacteria and fungi, some protozoa (e.g., African trypanosomes), and all helminths are transported free in the plasma. Leukocytes can carry herpesviruses, HIV, mycobacteria, and *Leishmania* and *Toxoplasma* organisms. Certain viruses (e.g., Colorado tick fever virus) and parasites (*Plasmodium* and *Babesia*) are carried by red blood cells. Most viruses spread from cell to cell by replication and release of infectious virions, but others may propagate from cell to cell by fusion or transport within nerves (e.g., rabies virus). Infectious foci seeded by blood are called secondary foci. They can be single and large (a solitary abscess or tuberculoma) or multiple and tiny (e.g., miliary tuberculosis or *Candida* microabscesses in many tissues). Sporadic bloodstream invasion by low-virulence or nonvirulent microbes (e.g., during brushing of teeth) is common but is quickly controlled by normal host defenses. By contrast, disseminated viremia, bacteremia, fungemia, or parasitemia by virulent pathogens is a serious insult and manifests itself by fever, low blood pressure, and multiple other systemic signs and symptoms of sepsis. Massive bloodstream invasion by bacteria or their endotoxins can rapidly become fatal, even for previously healthy individuals.

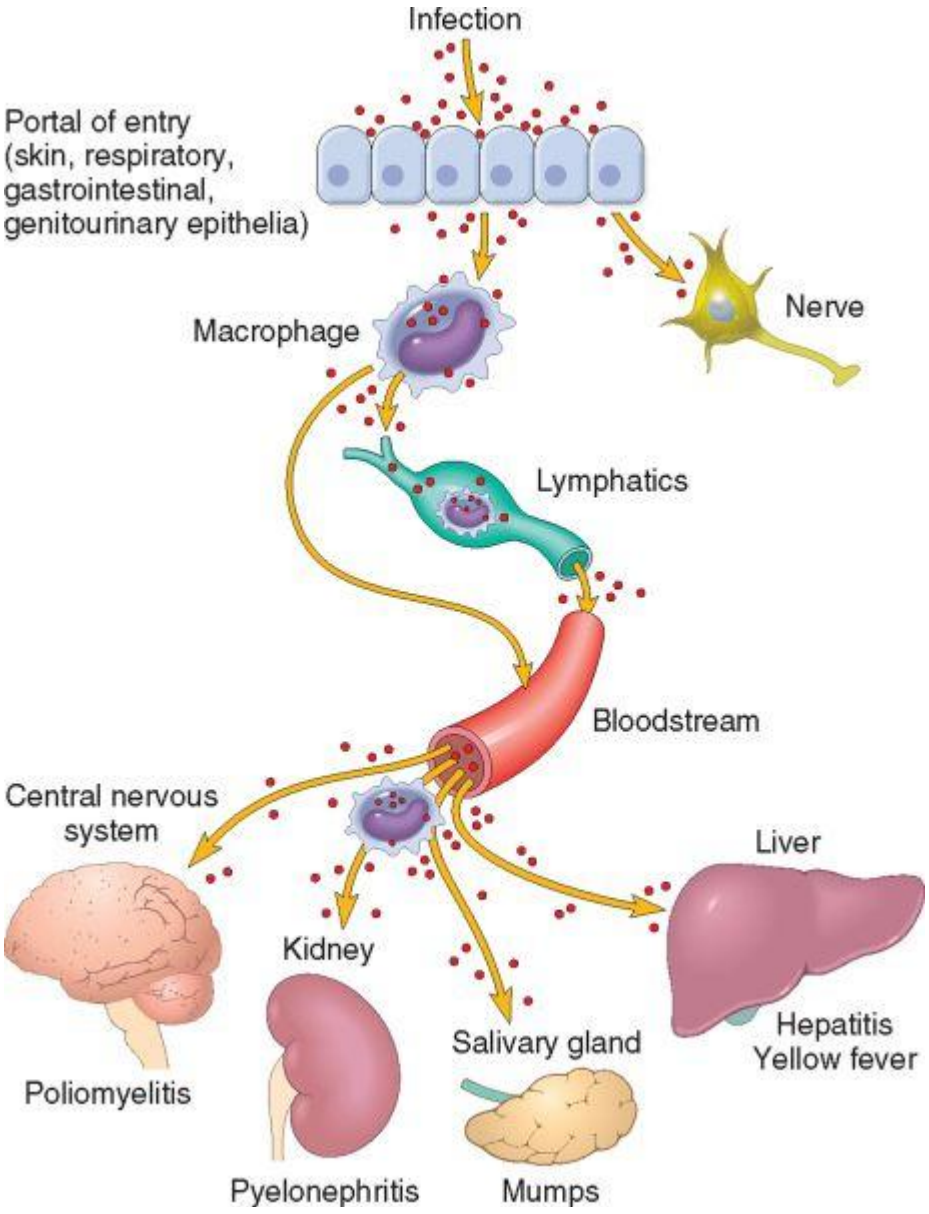

FIGURE 8-4 Routes of entry and dissemination of microbes. To enter the body microbes penetrate the epithelial or mucosal barriers. Infection may remain localized at the site of entry or spread to other sites in the body. Most common microbes (selected examples are shown) spread through the lymphatics or bloodstream (either freely or within inflammatory cells). However, certain viruses and bacterial toxins may also travel through nerves. *(Adapted from Mims CA: The Pathogenesis of Infectious Disease, 4th ed. San Diego, Academic Press, 1996.)*

The major manifestations of infectious disease may appear at sites distant from the point of microbe entry. For example, chickenpox and measles viruses enter through the airways but cause rashes in the skin; poliovirus enters through the intestine but kills motor neurons. *Schistosoma mansoni* parasites penetrate the skin but eventually localize in blood vessels of the portal system and mesentery, damaging the liver and intestine. *Schistosoma hematobium*, on the other hand, localizes to the urinary bladder and causes cystitis. The rabies virus travels to the brain in a retrograde fashion within nerves, while the varicella zoster virus (VZV) hides in dorsal root ganglia, and on reactivation, travels along nerves to cause shingles.

The placental-fetal route is an important mode of transmission (Chapter 10). When infectious organisms reach the pregnant uterus through the cervical orifice or the bloodstream and are able to traverse the placenta, severe damage to the fetus can result. Bacterial or mycoplasmal placentitis can cause premature delivery or stillbirth. Viral infections can cause maldevelopment of the fetus, with infection early in pregnancy resulting in the most severe disease. Rubella infection during the first trimester can cause congenital heart disease, mental retardation, cataracts, or deafness in the infant, while little damage is caused by rubella infection during the third trimester. Transmission of treponemes leads to congenital syphilis only when *T. pallidum* infects the mother late in the second trimester but then causes severe fetal osteochondritis and periostitis that leads to multiple bony lesions. Infection also can occur during passage through the birth canal (e.g., gonococcal or chlamydial conjunctivitis) or through maternal milk (e.g., CMV, HBV, human T-cell leukemia virus-1 [HTLV-1]). Maternal transmission of HIV is the major cause of AIDS in children. Maternal transmission of HBV can later cause chronic hepatitis or liver cancer.

Release of Microbes from the Body

For transmission of disease, the mode of exit of a microorganism from the host's body is as important as entry into it. Depending on the location of infection, release may be accomplished by skin shedding, coughing, sneezing, voiding of urine or feces, during sexual contact, or through insect vectors. Some microbes are hardy and can survive for extended periods in dust, food, or water. Bacterial spores, protozoan cysts, and thick-shelled helminth eggs can survive in a cool and dry environment. Some enteric pathogens are shed for long periods by asymptomatic carrier hosts (e.g., *S. typhi*). Less hardy microorganisms must be quickly passed from person to person, often by direct contact.

Transmission from person to person can occur by respiratory, fecal-oral, or sexual routes (discussed below). Viruses and bacteria transmitted by the respiratory route (e.g., *M. tuberculosis*) are infectious only when lesions are open to the airways. Many pathogens, ranging from viruses to helminths, can be transmitted by the fecal-oral route, that is, by ingestion of stool-contaminated food or water. Water-borne viruses involved in epidemic outbreaks include hepatitis A and E viruses, poliovirus, and rotavirus. Some parasitic helminths (e.g., hookworms, schistosomes) shed eggs in stool that gain access to new hosts by larval penetration of the skin rather than by oral intake. Protozoa and helminths have evolved complex transmission cycles involving a chain of intermediate and vector hosts bearing successive developmental stages of the parasites. Viruses infecting the oropharynx (e.g., EBV, CMV, mumps viruses) are transmitted principally through saliva. Other pathogens are spread mainly by prolonged intimate or mucosal contact (as occurs during sexual transmission) including viruses (HPV, HSV, HBV, HIV), bacteria *(T. pallidum, N. gonorrhoeae, Chlamydia trachomatis)*, fungi (*Candida* species), protozoa (*Trichomonas* species), and arthropods (*Phthirus pubis*, or crab lice). Transmission of HBV, HCV, and HIV infections through blood and blood products may be caused by human behavior, e.g., needle sharing by drug abusers, cuts, and needle sticks.

Microbes can be transmitted from animal to human (termed *zoonotic infections*), either by direct contact or consumption of animal products or indirectly via an invertebrate vector. Invertebrate vectors (insects, ticks, mites) can spread infection passively in some cases or serve as necessary hosts for replication and development of the pathogen.

Sexually Transmitted Infections

A number of organisms can be transmitted through sexual contact (Table 8-5). Some, such as *C. trachomatis* and *N. gonorrhoeae*, are usually spread by sexual intercourse, while others, such as *Shigella* species and *E. histolytica*, are typically spread by other means but are also occasionally spread by oral-anal sex. Groups that are at greater risk for some sexually transmitted infections (STIs) include adolescents, men who have sex with men, and people who use illegal drugs. While the increased risk

among these groups is partially due to unsafe sexual practices, limited access to health care is also often a contributing factor. The presence of an STI in young children, unless acquired during birth, strongly suggests sexual abuse.

TABLE 8-5 -- Classification of Important Sexually Transmitted Diseases

Pathogens	Disease or Syndrome and Population Principally Affected		
	Males	***Females***	***Both***
VIRUSES			
Herpes simplex virus			Primary and recurrent herpes, neonatal herpes
Hepatitis B virus			Hepatitis
Human papillomavirus	Cancer of penis (some cases)	Cervical dysplasia and cancer, vulvar cancer	Condyloma acuminatum
Human immunodeficiency virus			Acquired immunodeficiency syndrome
CHLAMYDIAE			
Chlamydia trachomatis	Urethritis, epididymitis, proctitis	Urethral syndrome, cervicitis, bartholinitis, salpingitis and sequelae	Lymphogranuloma venereum
MYCOPLASMAS			
Ureaplasma urealyticum	Urethritis		
BACTERIA			
Neisseria gonorrhoeae	Epididymitis, prostatitis, urethral stricture	Cervicitis, endometritis, bartholinitis, salpingitis, and sequelae (infertility, ectopic pregnancy, recurrent salpingitis)	Urethritis, proctitis, pharyngitis, disseminated gonococcal infection
Treponema pallidum			Syphilis
Haemophilus ducreyi			Chancroid
Klebsiella granulomatis			Granuloma inguinale (donovanosis)
PROTOZOA			
Trichomonas vaginalis	Urethritis, balanitis	Vaginitis	

The initial site of an STI may be the urethra, vagina, cervix, rectum, or oral pharynx. The organisms that cause these infections tend to be short-lived outside of the host, so they usually depend on direct person-to-person spread. Most of these agents can be infectious in the absence of symptoms, so transmission often occurs from people who do not realize that they have an infection. To reduce the spread of STIs, these infections are often reported to public health authorities so that people who have had intimate contact with the person may be tested and treated.

Although the various pathogens that cause STIs differ in many ways, some general features should be noted.

- *Infection with one STI-associated organism increases the risk for additional STIs*. This is mainly because the risk factors are the same for all STIs, which probably explains the association between two common STIs in

the United States: chlamydia and gonorrhea. Infection with both of these bacteria is so common that the diagnosis of either should lead to treatment for both. In addition, the epithelial injury caused by *N. gonorrhoeae* or *C. trachomatis* can increase the chance of co-infection with the other, as well as the risk of HIV infection with concomitant exposure.

- *The microbes that cause STIs can be spread from a pregnant woman to the fetus and cause severe damage to the fetus or child*. Perinatally acquired *C. trachomatis* causes conjunctivitis, and neonatal HSV infection is much more likely to cause visceral and CNS disease than is infection acquired later in life. Syphilis frequently causes miscarriage. HIV infection may be fatal to children infected with the virus prenatally or perinatally. Diagnosis of STIs in pregnant women is critical, because intrauterine or neonatal STI transmission can often be prevented by treatment of the mother or newborn. Bacterial infections such as gonorrhea, syphilis, and chlamydia can be easily cured with antibiotics. Antiretroviral treatment of pregnant women with HIV infection and treatment of the newborn can reduce transmission of HIV to children from 25% to less than 2%.

Syphilis is discussed later in this chapter, and other STIs are described in Chapters 21 and 22 .

Healthcare-Associated Infections

An increasingly important source of infections is the healthcare setting. “Nosocomial” infections are those acquired in the hospital. It is estimated that about 1.7 million patients each year get nosocomial infections in the United States.[15] These infections can be transmitted in many ways (e.g. blood transfusion or organ transplant), but perhaps the most common, and readily preventable, means of transmission include spread from the hands of healthcare workers or from contaminated surfaces such as bedrails. Proper attention to hygiene and cleansing (e.g., hand washing) can greatly reduce the transmission of important pathogens such as methicillin-resistant *S. aureus* and vancomycin-resistant enterococci.

Host Defenses Against Infections

The outcome of infection is determined by the ability of the microbe to infect, colonize, and damage host tissues and the ability of host defense mechanisms to eradicate the infection. *Host barriers to infection prevent microbes from entering the body and consist of innate and adaptive immune defenses*. Innate immune defense mechanisms exist before infection and respond rapidly to microbes. These mechanisms include physical barriers to infection, phagocytic cells, natural killer (NK) cells, and plasma proteins, including the complement system proteins and other mediators of inflammatory responses (cytokines, collectins, acute-phase reactants). Adaptive immune responses are stimulated by exposure to microbes and increase in magnitude, speed, and effectiveness with successive exposures to microbes. Adaptive immunity is mediated by T and B lymphocytes and their products (Chapter 6).

Microbes and the immune system have been engaged in an evolutionary battle, in which each tries to outwit the other. The immune system is capable of effectively combating many infections, but different microbes have developed ways of evading host defenses (discussed later). In some infections, a balance is reached between the microbe and the host such that the infection persists in a state of latency but does not cause significant pathology. In such situations, decline of immune responses can result in rapid reactivation of the infection and severe pathologic manifestations. Such reactivation is seen in latent viral infections (e.g., EBV) and some bacterial infections (e.g., tuberculosis).

HOW MICROORGANISMS CAUSE DISEASE

Infectious agents establish infection and damage tissues by three mechanisms:

- They can contact or enter host cells and directly cause cell death.
- They may release toxins that kill cells at a distance, release enzymes that degrade tissue components, or

damage blood vessels and cause ischemic necrosis.

- They can induce host immune responses that, though directed against the invader, cause additional tissue damage. Thus, as we discussed in Chapters 2 and 6 , the defensive responses of the host constitute a double-edged sword: They are necessary to overcome the infection but at the same time may directly contribute to tissue damage.

Here we describe some of the mechanisms whereby viruses and bacteria damage host tissues.

Mechanisms of Viral Injury

Viruses can directly damage host cells by entering them and replicating at the host's expense. The predilection for viruses to infect certain cells and not others is called *tropism* and is determined by several factors, including (1) expression of host cell receptors for the virus, (2) presence of cellular transcription factors that recognize viral enhancer and promoter sequences, (3) anatomic barriers, and (4) local temperature, pH, and host defenses.[17] Each of these is described briefly.

A major determinant of tissue tropism is the presence of viral receptors on host cells. Viruses possess specific cell-surface proteins that bind to particular host cell-surface proteins. Many viruses use normal cellular receptors of the host to enter cells. For example, HIV glycoprotein gp120 binds to CD4 on T cells and to the chemokine receptors CXCR4 (mainly on T cells) and CCR5 (mainly on macrophages) (Chapter 6). EBV envelope glycoprotein gp350 binds to complement receptor 2 (CR2/CD21) on B cells. In some cases, host proteases are needed to enable binding of virus to host cells; for instance, a host protease cleaves and activates the influenza virus hemagglutinin. Another determinant of viral tropism is the ability of the virus to replicate inside some cells but not in others, and this is related to the presence of cell type–specific transcription factors. For example, the JC virus, which causes leukoencephalopathy (Chapter 28), is restricted to oligodendroglia in the CNS, because the promoter and enhancer DNA sequences upstream from the viral genes are active in glial cells but not in neurons or endothelial cells. Physical barriers also can contribute to tissue tropism. For example, enteroviruses replicate in the intestine in part because they can resist inactivation by acids, bile, and digestive enzymes. Rhinoviruses infect only within the upper respiratory tract because they replicate optimally at the lower temperature of the upper respiratory tract.

Once viruses are inside host cells, they can damage or kill the cells by a number of mechanisms (Fig. 8-5):

- *Direct cytopathic effects*. Some viruses kill cells by preventing synthesis of host macromolecules (e.g., host cell DNA, RNA, or proteins), by producing degradative enzymes and toxic proteins, or by inducing apoptosis. For example, poliovirus inactivates cap-binding protein, which is essential for translation of host cell mRNAs but leaves translation of poliovirus mRNAs unaffected. HSV produces proteins that inhibit synthesis of cellular DNA and mRNA and other proteins that degrade host DNA. Some viruses can stimulate apoptosis by production of proteins that are pro-apoptotic (e.g., HIV vpr protein). Viral replication also can trigger apoptosis of host cells by cell-intrinsic mechanisms, such as perturbations of the endoplasmic reticulum during virus assembly, which can activate proteases that mediate apoptosis (caspases).
- *Antiviral immune responses*. Viral proteins on the surface of the host cells may be recognized by the immune system, and the host lymphocytes may attack virus-infected cells. Cytotoxic T lymphocytes (CTLs) are important for defense against viral infections, but CTLs also can be responsible for tissue injury. Lymphocytic choriomeningitis virus infection in mice is an experimental model in which disease is caused by the host immune response. Acute liver failure during hepatitis B infection may be accelerated by CTL-mediated destruction of infected hepatocytes (a normal response to clear the infection).
- *Transformation of infected cells* into benign or malignant tumor cells. Different oncogenic viruses can stimulate cell growth and survival by a variety of mechanisms, including expression of virus-encoded oncogenes, anti-apoptotic strategies, or insertional mutagenesis (in which the function of host genes is altered by viral genes inserted into the host genome). The mechanisms of viral transformation are numerous

and are discussed in Chapter 7 .

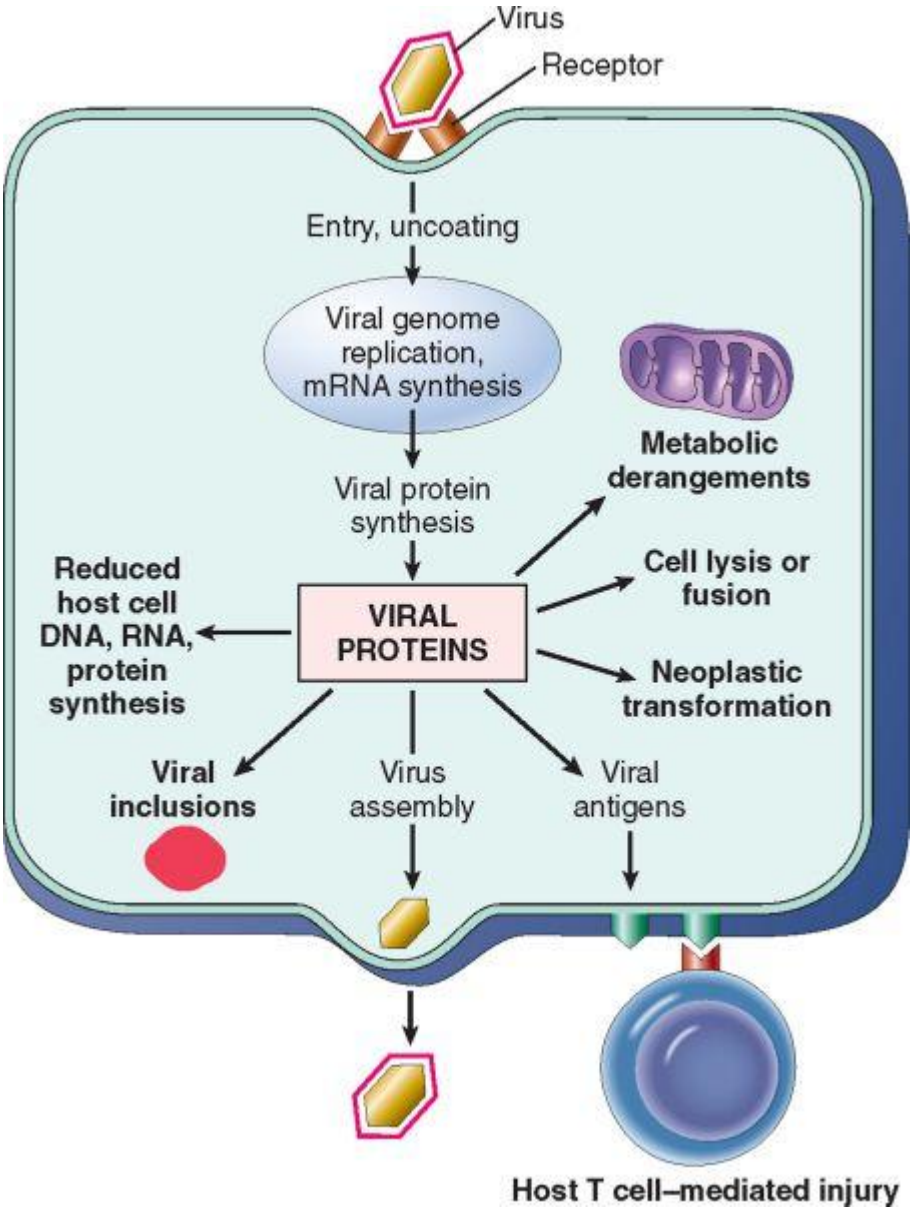

FIGURE 8-5 Mechanisms by which viruses cause injury to cells.

Mechanisms of Bacterial Injury

Bacterial Virulence.

Bacterial damage to host tissues depends on the ability of the bacteria to adhere to host cells, invade cells and tissues, or deliver toxins. Pathogenic bacteria have virulence genes that encode proteins that confer these properties. Virulence genes are frequently found grouped together in clusters called *pathogenicity islands*. All of the *Salmonella* strains that infect humans are closely related enough to form a single species, meaning that they share many "housekeeping" genes.[16] Differences in a relatively small number of pathogenicity genes determine whether an isolate of *Salmonella* can cause life-threatening typhoid fever or self-limited enteritis.

Plasmids and bacteriophages (viruses) are mobile genetic elements that spread between bacteria and can encode virulence factors (e.g., toxins, or enzymes that confer antibiotic resistance). Bacteriophages or plasmids can convert otherwise nonpathogenic bacteria into virulent ones. Exchange of these elements between bacteria can endow the recipient with a survival advantage, with the capacity to cause disease, or both. Plasmids or transposons encoding antibiotic resistance can convert an antibiotic-susceptible bacterium into a resistant one, making therapy difficult (e.g., vancomycin-resistant enterococci and methicillin-resistant staphylococci are endemic in many hospitals).

Many bacteria coordinately regulate gene expression within a large population of organisms by *quorum sensing*. For example, bacteria can induce expression of virulence factors as their concentration in the tissues increases. This may allow bacteria growing in discrete host sites, such as an abscess or consolidated pneumonia, to overcome host defenses. *S. aureus* coordinately regulates virulence factors by secreting *autoinducer peptides*.[17] As the bacteria grow to increasing concentrations, the level of the autoinducer peptide increases, stimulating toxin production. Within the population, some bacteria produce the autoinducer peptide and others respond to it by secreting toxins. Thus, because of quorum sensing, unicellular bacteria acquire some of the more complex properties of multicellular organisms, in which different cells perform different functions.

Communities of bacteria can form *biofilms* in which the organisms live within a viscous layer of extracellular polysaccharides that adhere to host tissues or devices such as intravascular catheters and artificial joints. In addition to enhancing adherence to host tissues, biofilms increase the virulence of bacteria by making them inaccessible to immune effector mechanisms and increasing their resistance to antimicrobial drugs. Biofilm formation seems to be important in the persistence and relapse of infections such as bacterial endocarditis, artificial joint infections, and respiratory infections in people with cystic fibrosis.

Bacterial Adherence to Host Cells.

Adhesins are bacterial surface molecules that bind to host cells or extracellular matrix. Bacterial adhesins that bind bacteria to host cells are limited in structural type but have a broad range of host cell specificity. *Streptococcus pyogenes* is a gram-positive bacterium that adheres to host tissues by virtue of protein F and teichoic acid projecting from the bacterial cell wall and binding to fibronectin on the surface of host cells and in the extracellular matrix.

Pili are filamentous proteins on the surface of bacteria. The stalks of pili are composed of conserved repeating subunits, while the variable amino acids on the tips of the pili determine the binding specificity of the bacteria. Strains of *E. coli* that cause urinary tract infections uniquely express a specific P pilus, which binds to a gal(α1–4)gal moiety expressed on uroepithelial cells.[18] Pili on *N. gonorrhoeae* bacteria mediate adherence of the bacteria to host cells and also are targets of the antibody response against *N. gonorrhoeae*. Variation in the type of pili expressed is an important mechanism by which *N. gonorrhoeae* escapes the immune response.[19]

Virulence of Intracellular Bacteria.

Facultative intracellular bacteria infect either epithelial cells (*Shigella* and enteroinvasive *E. coli*), macrophages (*M. tuberculosis, M. leprae*), or both (*S. typhi*). The growth of bacteria in cells may allow the bacteria to escape from certain effector mechanisms of the immune response (e.g., antibodies), or it may facilitate spread of the bacteria, as migration of macrophages carries *M. tuberculosis* bacteria from the lung to other sites.

Bacteria have a number of mechanisms for entering host cells. Some bacteria use the host immune response to gain entry into macrophages. Coating of bacteria with antibodies or the complement protein

C3b (opsonization) normally results in phagocytosis of bacteria by macrophages. Like many bacteria, *M. tuberculosis* activates the alternative complement pathway, resulting in opsonization with C3b. Once coated with C3b, *M. tuberculosis* binds to the CR3 complement receptor on macrophages and is endocytosed into the cell.[20] Gram-negative bacteria use a complex secretion system to enter epithelial cells.[21] This system consists of needle-like structures projecting from the bacterial surface that bind to host cells, form pores in the host cell membrane, and then inject proteins that mediate rearrangement of the cell cytoskeleton, facilitating bacterial entry. Bacteria such as *Listeria monocytogenes* can manipulate the cell cytoskeleton to spread directly from cell to cell, perhaps allowing the bacteria to evade immune effector mechanisms.[22]

Once in the cytoplasm, bacteria have different strategies for interacting with the host cell. *Shigella* and *E. coli* inhibit host protein synthesis, replicate rapidly, and lyse the host cell within 6 hours. Within macrophages, most bacteria are killed when the phagosome fuses with an acidic lysosome to form a phagolysosome, but certain bacteria elude this host defense. For example, *M. tuberculosis* blocks fusion of the lysosome with the phagosome,[23] allowing it to proliferate unchecked within the macrophage. Other bacteria avoid destruction in macrophages by escaping from the phagosome. *L. monocytogenes* produces a pore-forming protein called listeriolysin O and two phospholipases that degrade the phagosome membrane, allowing the bacteria to escape into the cytoplasm.[22]

Bacterial Toxins.

Any bacterial substance that contributes to illness can be considered a toxin. Toxins are classified as endotoxins, which are components of the bacterial cell, and exotoxins, which are proteins that are secreted by the bacterium.

Bacterial endotoxin is a lipopolysaccharide (LPS) that is a large component of the outer membrane of gram-negative bacteria. LPS is composed of a long-chain fatty acid anchor (lipid A) connected to a core sugar chain, both of which are very similar in all gram-negative bacteria. Attached to the core sugar is a variable carbohydrate chain (O antigen), which is used diagnostically to serotype and discriminate between different strains of bacteria. The response to bacterial LPS can be both beneficial and harmful to the host. The response is beneficial in that LPS activates protective immunity in several ways, including induction of important cytokines and chemoattractants (chemokines) of the immune system as well as increased expression of costimulatory molecules, which enhance T-lymphocyte activation. However, high levels of LPS are thought to play an important role in septic shock, disseminated intravascular coagulation (DIC), and adult respiratory distress syndrome, mainly through induction of excessive levels of cytokines such as TNF, IL-1, and IL-12 (Chapter 4). LPS binds to the cell-surface receptor CD14, and the complex then binds to Toll-like receptor 4 (TLR4), which is a pattern recognition receptor of the innate immune system and transmits signals that lead to the cellular response.[24]

Exotoxins are secreted proteins that cause cellular injury and disease. They can be classified into broad categories by their site and mechanism of action. These are briefly described next and discussed in more detail in the specific sections about each type of bacteria.

- *Enzymes*. Bacteria secrete a variety of enzymes (proteases, hyaluronidases, coagulases, fibrinolysins) that act on their respective substrates in vitro, but the role of only a few of these in disease is understood. For example, certain proteases produced by *S. aureus* degrade proteins that hold keratinocytes together, causing the epidermis to detach from the deeper skin.[25]
- *Toxins that alter intracellular signaling or regulatory pathways*. Most of these toxins have an active (A) subunit with enzymatic activity and a binding (B) subunit that binds receptors on the cell surface and delivers the A subunit into the cell cytoplasm. The effect of these toxins depends on the binding specificity of the B domain and the cellular pathways affected by the A domain. A-B toxins are made by many bacteria including

Bacillus anthracis, V. cholerae, and some strains of *E. coli*.

- *Neurotoxins* produced by *Clostridium botulinum* and *Clostridium tetani* inhibit release of neurotransmitters, resulting in paralysis.[26] These toxins do not kill neurons; instead, the A domains interact specifically with proteins involved in secretion of neurotransmitters at the synaptic junction. Both tetanus and botulism can result in death from respiratory failure due to paralysis of the chest and diaphragm muscles.
- *Superantigens* are bacterial toxins that stimulate very large number of T lymphocytes by binding to conserved portions of the T-cell receptor, leading to massive Tlymphocyte proliferation and cytokine release. The high levels of cytokines can lead to capillary leak and shock.[27] Superantigens made by *S. aureus* and *S. pyogenes* cause toxic shock syndrome (TSS).

Injurious Effects of Host Immunity

As was mentioned earlier, the host immune response to microbes can sometimes be the cause of tissue injury. The granulomatous inflammatory reaction to *M. tuberculosis* is a delayed hypersensitivity response that sequesters the bacilli and prevents spread but also can produce tissue damage and fibrosis. Similarly, the liver damage following HBV and HCV infection of hepatocytes is mainly due to the immune response to the infected liver cells and not to cytopathic effects of the virus. The humoral immune response to microbes also can have pathologic consequences. For example, following infection with *S. pyogenes*, antibodies produced against the streptococcal M protein can cross-react with cardiac proteins and damage the heart, leading to rheumatic heart disease. Poststreptococcal glomerulonephritis, which also can develop following infection with *S. pyogenes*, is caused by antistreptococcal antibodies that bind to streptococcal antigens and form immune complexes, which deposit in renal glomeruli and produce nephritis. Thus, antimicrobial immune responses can have beneficial and pathologic consequences.

The examples provided above are relatively infrequent situations in which specific immune responses to microbes have been identified as causative agents of various diseases. Recent clinical, epidemiologic, and experimental studies suggest that infections may be associated with a wide variety of chronic inflammatory disorders as well as cancer.[28] In some chronic inflammatory diseases, such as inflammatory bowel disease (Chapter 17), an important early event may be compromise of the intestinal epithelial barrier, which enables the entry of both pathogenic and commensal microbes and their interactions with local immune cells, resulting in inflammation. The cycle of inflammation and epithelial injury may be the basis of the disease, with microbes playing the central role. Viruses (HBV, HCV) and bacteria (*H. pylori*) that are not known to carry or activate oncogenes are associated with cancers, presumably because these microbes trigger chronic inflammation, which provides fertile ground for the development of cancer (Chapter 7).

IMMUNE EVASION BY MICROBES

Humoral and cellular immune responses that protect the host from most infections were discussed in Chapter 6 . Not surprisingly, microorganisms have developed many means to resist and evade the immune system (Fig. 8-6).[29] These mechanisms are important determinants of microbial virulence and pathogenicity. They include (1) growth in niches that are inaccessible to the host immune system, (2) antigenic variation, (3) resistance to innate immune defenses, and (4) impairment of effective T-cell antimicrobial responses by specific or nonspecific immunosuppression.

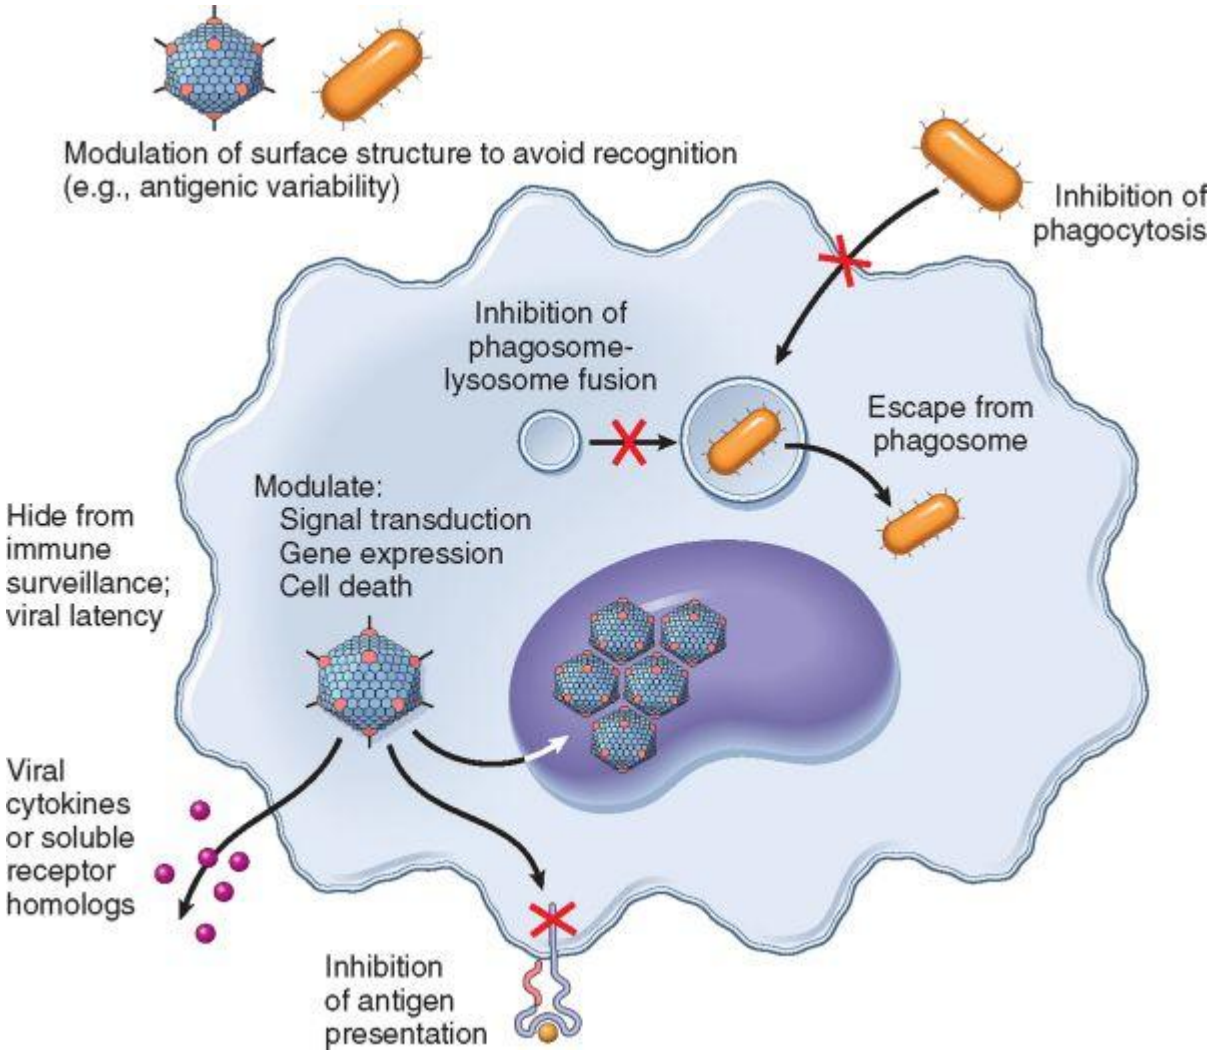

FIGURE 8-6 An overview of mechanisms used by viral and bacterial pathogens to evade innate and adaptive immunity. *(Modified with permission from Finlay B, McFadden G: Anti-immunology: evasion of the host immune system by bacterial and viral pathogens. Cell 124:767–782, 2006.)*

Some microorganisms replicate in sites that are inaccessible to the host immune response. Microbes that propagate in the lumen of the intestine (e.g., toxin-producing *Clostridium difficile*) or gallbladder (e.g., *S. typhi*) are concealed from cell-mediated immune defenses. Some organisms establish infections by rapidly invading host cells before the host humoral response becomes effective (e.g., malaria sporozoites entering liver cells, *Trichinella* and *Trypanosoma cruzi* entering skeletal or cardiac muscle cells). Some larger parasites (e.g., the larvae of tapeworms) form cysts in host tissues that are covered by a dense capsule and are thus inaccessible to host immune cells and antibodies. Viral latency is the ultimate strategy for hiding antigens from the immune system. During the latent state, many viral genes are not expressed.

Some microbes can evade immune responses by varying the antigens they express. Neutralizing antibodies block the ability of microbes to infect cells and recruit effector mechanisms to kill pathogens. To escape recognition, microbes use many strategies that involve genetic mechanisms for generating antigenic variation. The low fidelity of viral RNA polymerases (in HIV and many respiratory viruses

including influenza virus) and reassortment of viral genomes (influenza viruses) create viral antigenic variation (Table 8-6). The spirochete *Borrelia recurrentis* repeatedly switches its surface antigens, and the Lyme disease *Borrelia* organisms use similar mechanisms to vary their outer membrane proteins.[30] *Trypanosoma* species have many genes for their major surface antigen, VSG, and can vary the expression of this surface protein. There are at least 80 different serotypes of *S. pneumoniae*, each with different capsular polysaccharides.

TABLE 8-6 -- Mechanisms of Antigenic Variation

Type	Example	Disease
High mutation rate	HIV	AIDS
	Influenza virus	Influenza
Genetic reassortment	Influenza virus	Influenza
	Rotavirus	Diarrhea
Genetic rearrangement (e.g., gene recombination, gene conversion, site-specific inversion)	*Borrelia burgdorferi*	Lyme disease
	Neisseria gonorrhoeae	Gonorrhea
	Trypanosoma sp.	African sleeping sickness
	Plasmodium sp.	Malaria
Large diversity of serotypes	Rhinoviruses	Colds
	Streptococcus pneumoniae	Pneumonia
		Meningitis

Some microbes have devised methods for evading innate immune defenses, such as escaping killing by phagocytic cells and complement.[31] Cationic antimicrobial peptides, including defensins, cathelicidins, and thrombocidins, provide important initial defense against invading microbes. Resistance to these antimicrobial peptides is key to the virulence of a number of bacterial pathogens, enabling them to avoid killing by neutrophils and macrophages.[32] The carbohydrate capsule on the surface of all the major bacteria that cause pneumonia or meningitis (pneumococcus, meningococcus, *H. influenzae*) makes them more virulent by shielding bacterial antigens and by preventing phagocytosis of the organisms by neutrophils. For example, *E. coli* with the sialic acid–containing K1 capsule causes meningitis in newborns. Sialic acid will not bind C3b, which is critical for activation of the alternative complement pathway, so the bacteria escape from complement-mediated lysis and opsonization-directed phagocytosis. Many bacteria make toxic proteins that kill phagocytes, prevent their migration, or diminish their oxidative burst. Bacteria also can circumvent immune defenses by covering themselves with host proteins. Some bacterial pathogens including *Salmonella* can modify the lipid moiety of LPS to reduce Toll-like receptor (TLR) activation. *S. aureus* are covered by protein A molecules that bind the Fc portion of antibodies and so inhibit phagocytosis. *Neisseria, Haemophilus*, and *Streptococcus* all secrete proteases that degrade antibodies. As already mentioned, another successful strategy for circumventing defense mechanisms is to replicate within phagocytic cells. A number of viruses, some intracellular bacteria (including mycobacteria, *Listeria*, and *Legionella*), fungi (e.g., *Cryptococcus neoformans*), and protozoa (e.g., leishmania, trypanosomes, toxoplasmas) can multiply within phagocytes.

Viruses can produce molecules that inhibit innate immunity.[29,][33] Some viruses (e.g., herpesviruses and poxviruses) produce proteins that block complement activation. Viruses have developed a large number of strategies to combat interferons (IFNs), an early host defense against viruses. Some viruses produce

soluble homologues of IFN-α/β or IFN-γ receptors that bind to and inhibit actions of secreted IFNs, or produce proteins that inhibit intracellular JAK/STAT signaling downstream of IFN receptors. They may also inactivate or inhibit double-stranded RNA–dependent protein kinase (PKR), a key mediator of the antiviral effects of IFN. Some viruses encode within their genomes homologues of other cytokines and chemokines, or their receptors, which act in various ways to inhibit immune responses. Many viruses have developed strategies to block apoptosis in the host cell, which may give the viruses time to complete replication, assembly, and exit, promote viral persistence, and contribute to cell transformation.

Some microbes produce factors that decrease recognition of infected cells by CD4+ helper T cells and CD8+ cytotoxic T cells. For example, several DNA viruses (e.g., herpesviruses, including HSV, CMV, and EBV) can bind to or alter localization of major histocompatibility complex (MHC) class I proteins, impairing peptide presentation to CD8+ T cells.[34,][35] Downregulation of MHC class I molecules might make it likely that virus-infected cells would be targets for NK cells. However, herpesviruses also express MHC class I homologues that act as effective inhibitors of NK cells by engaging killer inhibitory receptors (Chapter 6). Herpesviruses can target MHC class II molecules for degradation, impairing antigen presentation to CD4+ T helper cells. Viruses also can infect leukocytes and directly compromise their function. HIV infects CD4+ T cells, macrophages, and dendritic cells, and EBV infects B lymphocytes.

INFECTIONS IN IMMUNOSUPPRESSED HOSTS

Inherited or acquired defects in immunity (Chapter 6) often impair only part of the immune system, rendering the affected individual susceptible to specific types of infections. Patients with antibody deficiency, as in X-linked agammaglobulinemia, contract severe bacterial infections by organisms including *S. pneumoniae, H. influenzae*, and *S. aureus*, as well as a few viral infections (rotavirus and enteroviruses). Patients with T-cell defects are especially susceptible to infections with intracellular pathogens, notably viruses and some parasites. Patients with deficiencies in complement proteins are particularly susceptible to infections by *S. pneumoniae, H. influenzae*, and *N. meningitidis*. Some children have deficiencies in neutrophil function, leading to increased infections with *S. aureus* as well as some gram-negative bacteria and fungi.

Acquired immunodeficiencies have a variety of causes, the most important being infection with HIV, which causes AIDS. HIV infects and eventually kills CD4+ helper T lymphocytes. As discussed in Chapter 6 , this leads to profound immunosuppression and a multitude of infections. While most organisms that infect people with AIDS were common pathogens before the era of HIV, others were uncommon (cryptococcus, pneumocystis), and one, Kaposi sarcoma herpesvirus (KSHV), also called human herpesvirus-8 (HHV-8), was discovered as a result of research in AIDS patients.[36]

Diseases that impair production of leukocytes, such as leukemia, which fills the bone marrow with cancerous cells, make patients vulnerable to opportunistic infections. Iatrogenic causes of immunosuppression include immunosuppressive drugs used to treat patients with autoimmune diseases and organ transplant recipients, as well as drugs used to treat cancer. Therapy to prevent rejection of organ transplants leads to severe immunosuppression, making transplant recipients very susceptible to infectious diseases. Patients receiving bone marrow transplants have profound defects in innate and adaptive immunity during the long time that it takes for the donated bone marrow to engraft, and become susceptible to infection with almost any organism, including opportunistic organisms that seldom cause disease in healthy people (e.g., *Aspergillus* species and *Pseudomonas* species).

Diseases of organ systems other than the immune system can also make patients susceptible to specific microorganisms. People with cystic fibrosis commonly get respiratory infections with *P. aeruginosa, S. aureus*, and *Burkholdaria cepacia*.[37] The lack of splenic function in individuals with sickle cell disease makes them susceptible to infection with encapsulated bacteria such as *S. pneumoniae*, which are

normally opsonized and phagocytosed by splenic macrophages. Burns destroy skin, removing this barrier to microbes, allowing infection with pathogens such as *P. aeruginosa*. Finally, malnutrition may impair the host defenses.

SPECTRUM OF INFLAMMATORY RESPONSES TO INFECTION

In contrast to the vast molecular diversity of microbes, the morphologic patterns of tissue responses to microbes are limited, as are the mechanisms directing these responses. Therefore, many pathogens produce similar reaction patterns, and few features are unique or pathognomonic for a particular microorganism. Moreover, it is the interaction between the microorganism and the host that determines the histologic features of the inflammatory response. Thus, pyogenic bacteria, which normally evoke vigorous leukocyte responses, may cause rapid tissue necrosis with little leukocyte exudation in a profoundly neutropenic host. Similarly, in a normal patient, *M. tuberculosis* causes well-formed granulomas with few mycobacteria present, whereas in an AIDS patient the same mycobacteria multiply profusely in macrophages, which fail to coalesce into granulomas.

There are five major histologic patterns of tissue reaction in infections.

Suppurative (Purulent) Inflammation

This pattern is the reaction to acute tissue damage, described in Chapter 2 , characterized by increased vascular permeability and leukocytic infiltration, predominantly of neutrophils (Fig. 8-7). The neutrophils are attracted to the site of infection by release of chemoattractants from the “pyogenic” (pus-forming) bacteria that evoke this response, mostly extracellular gram-positive cocci and gram-negative rods. Massing of neutrophils and liquefactive necrosis of the tissue form pus. The sizes of exudative lesions range from tiny microabscesses formed in multiple organs during bacterial sepsis secondary to a colonized heart valve to diffuse involvement of entire lobes of the lung in pneumonia. How destructive the lesions are depends on their location and the organism involved. For example, pneumococci usually spare alveolar walls and cause lobar pneumonia that resolves completely, whereas staphylococci and *Klebsiella* species destroy alveolar walls and form abscesses that heal with scar formation. Bacterial pharyngitis resolves without sequelae, whereas untreated acute bacterial inflammation of a joint can destroy it in a few days.

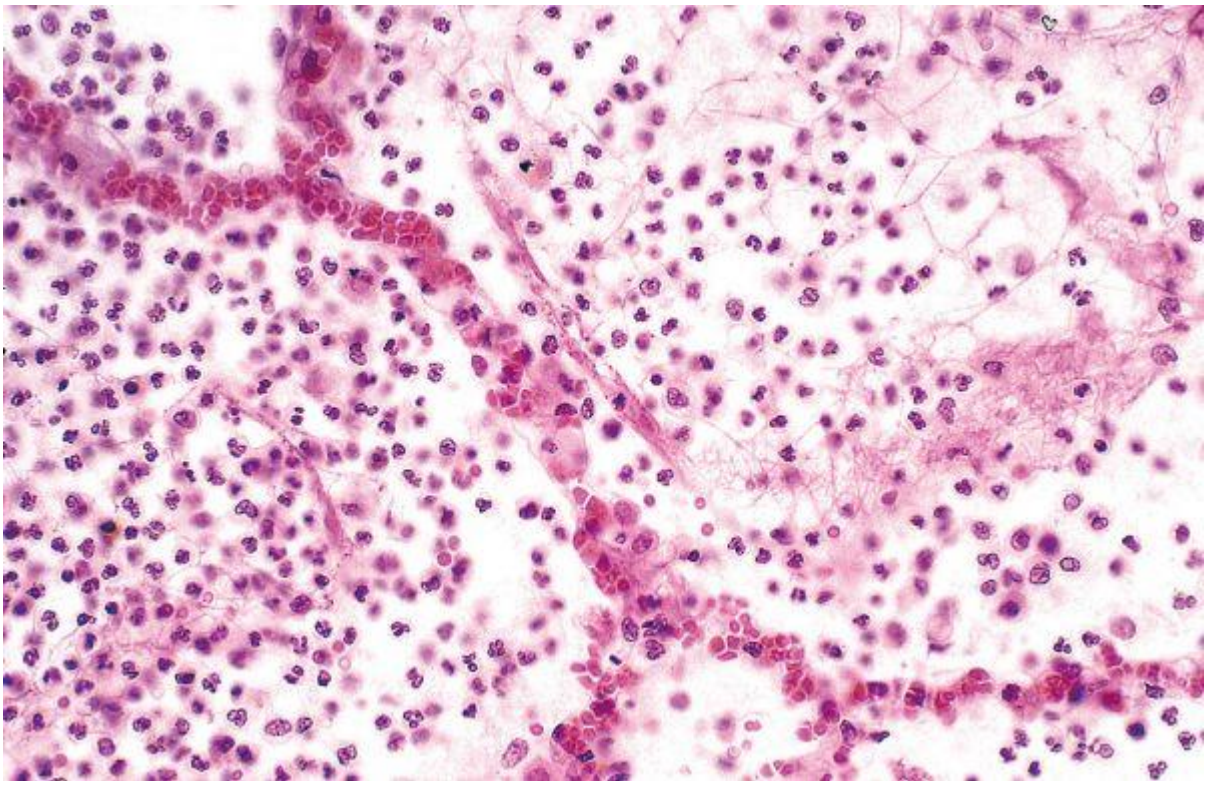

FIGURE 8-7 Pneumococcal pneumonia. Note the intra-alveolar polymorphonuclear exudate and intact alveolar septa.

Mononuclear and Granulomatous Inflammation

Diffuse, predominantly mononuclear, interstitial infiltrates are a common feature of all chronic inflammatory processes, but when they develop acutely, they often are a response to viruses, intracellular bacteria, or intracellular parasites. In addition, spirochetes and helminths provoke chronic inflammatory responses. Which mononuclear cell predominates within the inflammatory lesion depends on the host immune response to the organism. For example, plasma cells are abundant in the primary and secondary lesions of syphilis (Fig. 8-8), whereas lymphocytes predominate in HBV infection or viral infections of the brain. The presence of these lymphocytes reflects cell-mediated immune responses against the pathogen or pathogen-infected cells. At the other extreme, macrophages may become filled with organisms, as occurs in *M. avium-intracellulare* infections in AIDS patients, who cannot mount an effective immune response to the organisms. *Granulomatous inflammation* is a distinctive form of mononuclear inflammation usually evoked by infectious agents that resist eradication and are capable of stimulating strong T cell–mediated immunity (e.g., *M. tuberculosis, Histoplasma capsulatum*, schistosome eggs). Granulomatous inflammation is characterized by accumulation of activated macrophages called “epithelioid” cells, which may fuse to form giant cells. In some cases there is a central area of caseous necrosis (see Chapter 2 and “Tuberculosis” in this chapter).

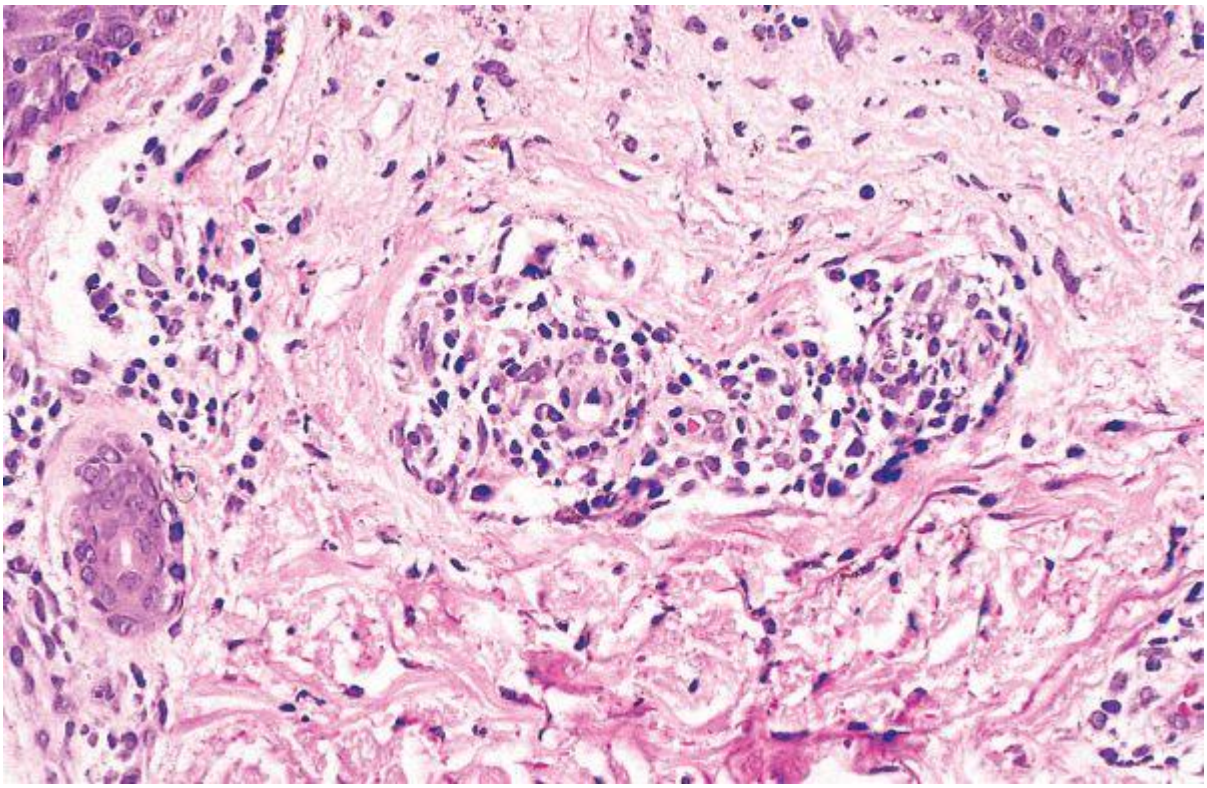

FIGURE 8-8 Secondary syphilis in the dermis with perivascular lymphoplasmacytic infiltrate and endothelial proliferation.

Cytopathic-Cytoproliferative Reaction

These reactions are usually produced by viruses. The lesions are characterized by cell necrosis or cellular proliferation, usually with sparse inflammatory cells. Some viruses replicate within cells and make viral aggregates that are visible as inclusion bodies (e.g., herpesviruses or adenovirus) or induce cells to fuse and form multinucleated cells called polykaryons (e.g., measles virus or herpesviruses). Focal cell damage in the skin may cause epithelial cells to become detached, forming blisters (Fig. 8-9). Some viruses can cause epithelial cells to proliferate (e.g., venereal warts caused by HPV or the umbilicated papules of molluscum contagiosum caused by poxviruses). Finally, viruses can contribute to the development of malignant neoplasms (Chapter 7).

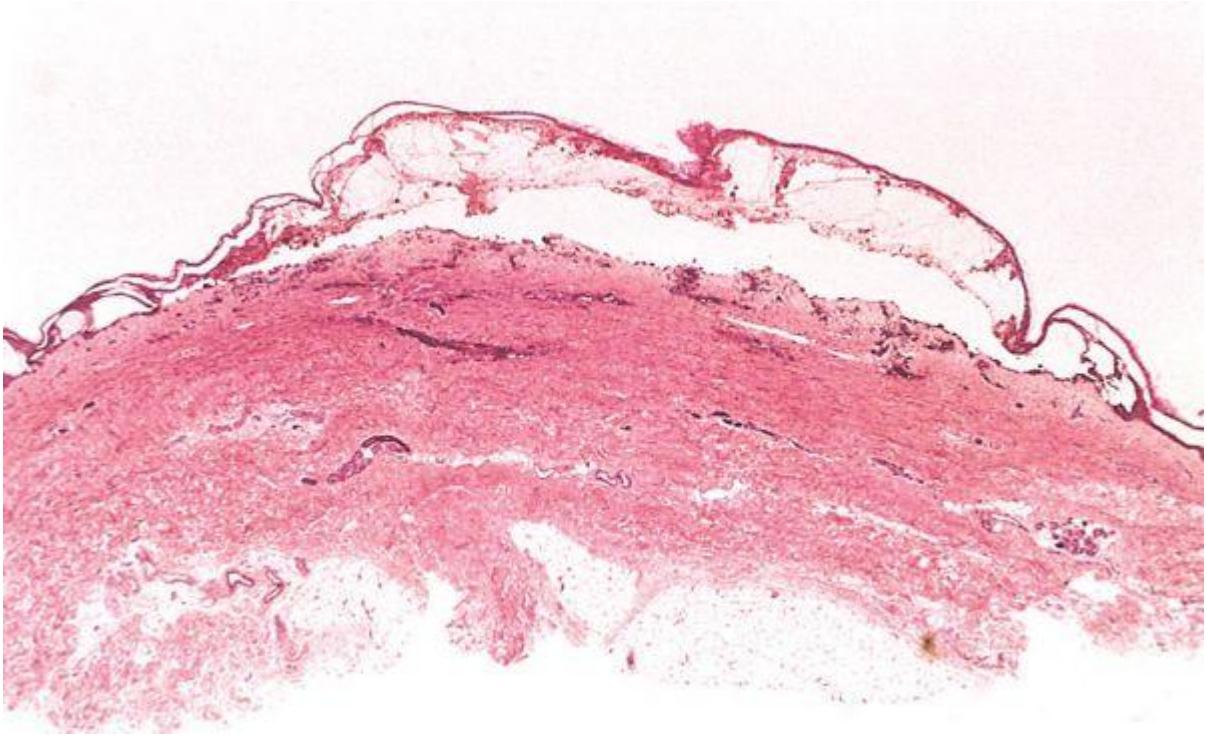

FIGURE 8-9 Herpesvirus blister in mucosa. See Figure 8-12 for viral inclusions.

Tissue Necrosis

Clostridium perfringens and other organisms that secrete powerful toxins can cause such rapid and severe necrosis (gangrenous necrosis) that tissue damage is the dominant feature. Because few inflammatory cells are present, these lesions resemble infarcts with disruption or loss of basophilic nuclear staining and preservation of cellular outlines. Clostridia are often opportunistic pathogens that are introduced into muscle tissue by penetrating trauma or infection of the bowel in a neutropenic host. Similarly, the parasite *E. histolytica* causes colonic ulcers and liver abscesses characterized by extensive tissue destruction with liquefactive necrosis and without a prominent inflammatory infiltrate. By entirely different mechanisms, viruses can cause widespread and severe necrosis of host cells associated with inflammation, as exemplified by total destruction of the temporal lobes of the brain by herpesvirus or the liver by HBV.

Chronic Inflammation and Scarring

Many infections elicit chronic inflammation, which can lead either to complete healing or to extensive scarring. For example, chronic HBV infection may cause cirrhosis of the liver, in which dense fibrous septae surround nodules of regenerating hepatocytes. Sometimes the exuberant scarring response is the major cause of dysfunction (e.g., the “pipe-stem” fibrosis of the liver or fibrosis of the bladder wall caused by schistosomal eggs [Fig. 8-10] or the constrictive fibrous pericarditis in tuberculosis).

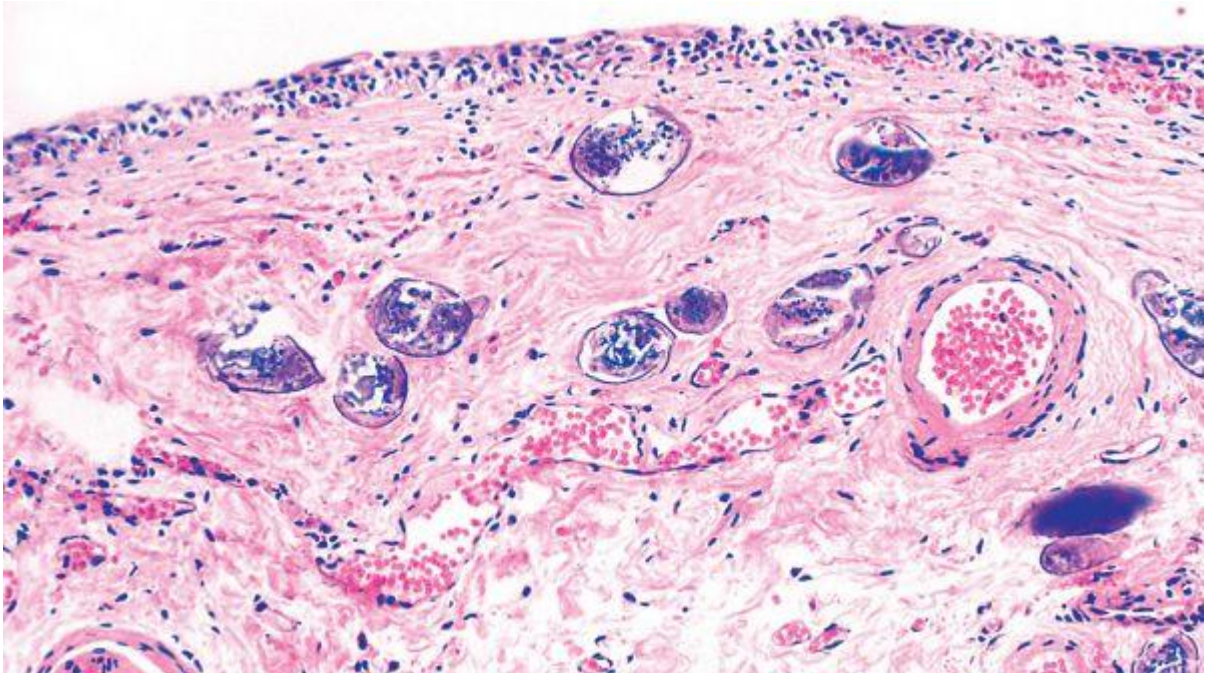

FIGURE 8-10 *Schistosoma haematobium* infection of the bladder with numerous calcified eggs and extensive scarring.

These patterns of tissue reaction are useful guidelines for analyzing microscopic features of infectious processes, but they rarely appear in pure form because different types of host reactions often occur at the same time. For example, the lung of an AIDS patient may be infected with CMV, which causes cytolytic changes, and at the same time by *Pneumocystis*, which causes interstitial inflammation. Similar patterns of inflammation also can be seen in tissue responses to physical or chemical agents and in inflammatory diseases of unknown cause (Chapter 2).

This concludes our discussion of the general principles of the pathogenesis and pathology of infectious disease. We now turn to descriptions of specific infections caused by viruses, bacteria, fungi, and parasites. In this discussion we emphasize *pathogenic mechanisms* and *pathologic changes*, rather than details of clinical features, which are available in clinical textbooks. Infections that typically involve a specific organ are discussed in other chapters.

2.8.2 Viral Infections

Viruses are the cause of many clinically important acute and chronic infections affecting virtually every organ system (Table 8-7).

TABLE 8-7 -- Selected Human Viruses and Viral Diseases

Organ System	Species	Disease
Respiratory	Adenovirus	Upper and lower respiratory tract infections, conjunctivitis, diarrhea
	Rhinovirus	Upper respiratory tract infection
	Influenza viruses A, B	Influenza
	Respiratory syncytial	Bronchiolitis, pneumonia

Organ System	Species	Disease
	virus	
Digestive	Mumps virus	Mumps, pancreatitis, orchitis
	Rotavirus	Childhood gastroenteritis
	Norovirus	Gastroenteritis
	Hepatitis A virus	Acute viral hepatitis
	Hepatitis B virus	Acute or chronic hepatitis
	Hepatitis D virus	With HBV, acute or chronic hepatitis
	Hepatitis C virus	Acute or chronic hepatitis
	Hepatitis E virus	Enterically transmitted hepatitis
Systemic with Skin Eruptions	Measles virus	Measles (rubeola)
	Rubella virus	German measles (rubella)
	Varicella-zoster virus	Chickenpox, shingles
	Herpes simplex virus 1	Oral herpes (“cold sore”)
	Herpes simplex virus 2	Genital herpes
Systemic with Hematopoietic Disorders	Cytomegalovirus	Cytomegalic inclusion disease
	Epstein-Barr virus	Infectious mononucleosis
	HIV-1 and HIV-2	AIDS
Arboviral and Hemorrhagic Fevers	Dengue virus 1–4	Dengue hemorrhagic fever
	Yellow fever virus	Yellow fever
Skin/Genital Warts	Papillomavirus	Condyloma; cervical carcinoma
Central Nervous System	Poliovirus	Poliomyelitis
	JC virus	Progressive multifocal leukoencephalopathy (opportunistic)

ACUTE (TRANSIENT) INFECTIONS

The viruses that cause transient infections are structurally heterogeneous, but each elicits an effective immune response that eliminates the organism and may or may not confer lifelong protection. The mumps virus, for example, has only one serotype and infects people only once, whereas other transient viruses, such as influenza viruses, can repeatedly infect the same individual because of antigenic variation. The immune response to some transient viruses wanes with time, allowing even the same serotype of virus to infect repeatedly (e.g., respiratory syncytial virus).

Measles

Measles (rubeola) virus is a leading cause of vaccine-preventable death and illness worldwide. More than 20 million people are affected by measles each year. In 2005, there were an estimated 345,000 deaths globally, the majority of them in children in developing countries. Because of poor nutrition, children in developing countries are 10 to 1000 times more likely to die of measles pneumonia than are children in developed countries.[38] Epidemics of measles occur among unvaccinated individuals. Measles can produce severe disease in people with defects in cellular immunity (such as HIV-infected people or people with hematologic malignancy). In the United States the incidence of measles has decreased dramatically since 1963, when a measles vaccine was licensed. The diagnosis is usually made clinically, or by serology or detection of viral antigen in nasal exudate or urinary sediment.

Pathogenesis.

Measles virus is a single-stranded RNA virus of the paramyxovirus family that includes mumps, respiratory syncytial virus (the major cause of lower respiratory infections in infants), parainfluenza virus (a cause of croup), and human metapneumovirus. There is only one serotype of measles virus. Two cell-surface receptors have been identified for the virus: CD46, a complement-regulatory protein that inactivates C3 convertases, and signaling lymphocytic activation molecule (SLAM), a molecule involved in T-cell activation.[39] CD46 is expressed on all nucleated cells, while SLAM is expressed on cells of the immune system. Both these receptors bind the viral hemagglutinin protein. Measles virus is transmitted by respiratory droplets. The virus initially multiplies within upper respiratory epithelial cells and then spreads to local lymphoid tissue. Measles can replicate in epithelial cells, endothelial cells, monocytes, macrophages, dendritic cells, and lymphocytes. Replication of the virus in lymphatic tissue is followed by viremia and systemic dissemination of the virus to many tissues, including the conjunctiva, respiratory tract, urinary tract, small blood vessels, lymphatic system, and CNS. Measles may cause croup, pneumonia, diarrhea with protein-losing enteropathy, keratitis with scarring and blindness, encephalitis, and hemorrhagic rashes ("black measles") in malnourished children with poor medical care. Most children develop T cell–mediated immunity to measles virus that controls the viral infection and produces the measles rash, a hypersensitivity reaction to measles-infected cells in the skin. The rash is less frequent in people with deficiencies in cell-mediated immunity but does occur in agammaglobulinemic people. Antibody-mediated immunity to measles virus protects against reinfection. Measles also can cause transient but profound immunosuppression, resulting in secondary bacterial and viral infection, which are responsible for much of measles-related morbidity and mortality. Alterations of both innate and adaptive immune responses occur following measles infection, including defects in dendritic cell and lymphocyte function.[40] Subacute sclerosing panencephalitis (described in Chapter 28) and measles inclusion body encephalitis (in immunocompromised individuals) are rare late complications of measles. The pathogenesis of subacute sclerosing panencephalitis is not well understood, but a replication-defective variant of measles may be involved in this persistent viral infection.[41]

Morphology. The blotchy, reddish brown rash of measles virus infection on the face, trunk, and proximal extremities is produced by dilated skin vessels, edema, and a moderate, nonspecific, mononuclear perivascular infiltrate. Ulcerated mucosal lesions in the oral cavity near the opening of Stensen ducts (the pathognomonic Koplik spots) are marked by necrosis, neutrophilic exudate, and neovascularization. The lymphoid organs typically have marked follicular hyperplasia, large germinal centers, and randomly distributed multinucleate giant cells, called Warthin-Finkeldey cells, which have eosinophilic nuclear and cytoplasmic inclusion bodies. These are pathognomonic of measles and are also found in the lung and sputum (Fig. 8-11). The milder forms of measles pneumonia show the same peribronchial and interstitial mononuclear cell infiltration that is seen in other nonlethal viral infections. In severe or neglected cases, bacterial superinfection may be a cause of death.

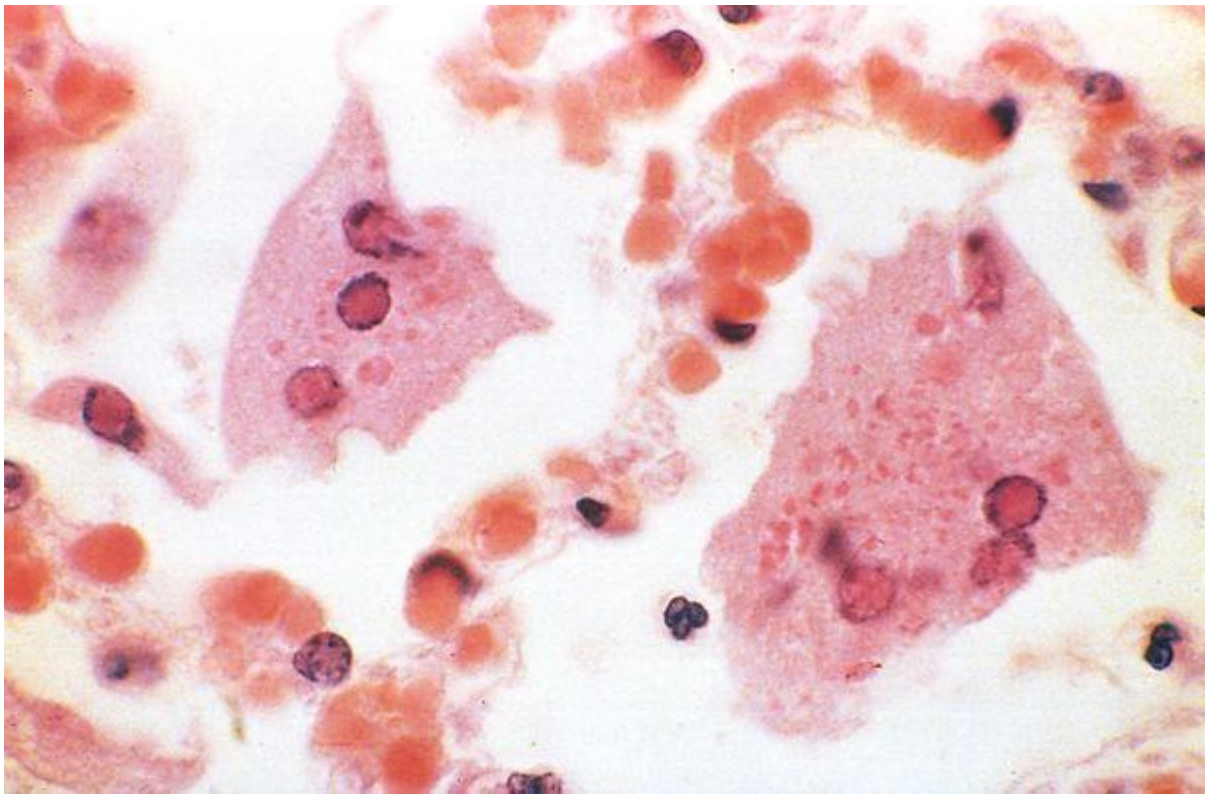

FIGURE 8-11 Measles giant cells in the lung. Note the glassy eosinophilic intranuclear inclusions.

Mumps

Like measles virus, mumps virus is a member of the paramyxovirus family. Mumps virus has two types of surface glycoproteins, one with hemagglutinin and neuraminidase activities and the other with cell fusion and cytolytic activities. Mumps viruses enter the upper respiratory tract through inhalation of respiratory droplets, spread to draining lymph nodes where they replicate in lymphocytes (preferentially in activated T cells), and then spread through the blood to the salivary and other glands. Mumps virus infects salivary gland ductal epithelial cells, resulting in desquamation of involved cells, edema, and inflammation that leads to the classic salivary gland pain and swelling of mumps. Mumps virus also can spread to other sites, including the CNS, testis and ovary, and pancreas. Aseptic meningitis is the most common extrasalivary gland complication of mumps infection, occurring in about 10% of cases. The mumps vaccine has reduced the incidence of mumps by 99% in the United States. The diagnosis is usually made clinically, but serology or viral culture can be used for definitive diagnosis.

Morphology. In **mumps parotitis**, which is bilateral in 70% of cases, affected glands are enlarged, have a doughy consistency, and are moist, glistening, and reddish brown on cross-section. On microscopic examination the gland interstitium is edematous and diffusely infiltrated by macrophages, lymphocytes, and plasma cells, which compress acini and ducts. Neutrophils and necrotic debris may fill the ductal lumen and cause focal damage to the ductal epithelium.

In **mumps orchitis** testicular swelling may be marked, caused by edema, mononuclear cell infiltration, and focal hemorrhages. Because the testis is tightly contained within the tunica albuginea,

parenchymal swelling may compromise the blood supply and cause areas of infarction. Sterility, when it occurs, is caused by scars and atrophy of the testis after resolution of viral infection.

In the enzyme-rich **pancreas**, lesions may be destructive, causing parenchymal and fat necrosis and neutrophil-rich inflammation. **Mumps encephalitis** causes perivenous demyelination and perivascular mononuclear cuffing.

Poliovirus Infection

Poliovirus is a spherical, unencapsulated RNA virus of the enterovirus genus. Other enteroviruses cause childhood diarrhea as well as rashes (coxsackievirus A), conjunctivitis (enterovirus 70), viral meningitis (coxsackieviruses and echovirus), and myopericarditis (coxsackievirus B). There are three major strains of poliovirus, each of which is included in the Salk formalin-fixed (killed) vaccine and the Sabin oral, attenuated (live) vaccine.[42] These vaccines have nearly eliminated poliovirus from the Western hemisphere, because the poliovirus, like smallpox virus, infects people but not other animals, is only briefly shed, does not undergo antigenic variation, and is effectively prevented by immunization.[43] Poliovirus still persists in parts of Africa.

Poliovirus, like other enteroviruses, is transmitted by the fecal-oral route. It first infects tissues in the oropharynx, then is secreted into the saliva and swallowed, and subsequently multiplies in the intestinal mucosa and lymph nodes, causing a transient viremia and fever. The virus infects only humans because it uses human CD155 to gain entry into cells but does not bind to cells in other species.[44] Although most polio infections are asymptomatic, in about 1 of 100 infected persons poliovirus invades the CNS and replicates in motor neurons of the spinal cord (spinal poliomyelitis) or brain stem (bulbar poliomyelitis). Antiviral antibodies control the disease in most cases, and it is not known why they fail to contain the virus in some individuals. Viral spread to the nervous system may be secondary to viremia or occur by retrograde transport of the virus along axons of motor neurons.[45] Rare cases of poliomyelitis that occur after vaccination are caused by mutations of the attenuated viruses to wild-type forms. The diagnosis can be made by viral culture of throat secretions or stool, or by serology. The neurologic features and neuropathology of poliovirus infection are described in Chapter 28 .

West Nile Virus

West Nile virus is an arthropod-borne virus (arbovirus) of the flavivirus group, which also includes viruses that cause dengue fever and yellow fever. West Nile virus has a broad geographic distribution in the Old World, with outbreaks in Africa, the Middle East, Europe, Southeast Asia, and Australia. This virus was first detected in the United States in 1999 during an outbreak in New York City.[46] West Nile virus is transmitted by mosquitoes to birds and to mammals. Wild birds develop prolonged viremia and are the major reservoir for the virus. Humans are usually incidental hosts. However, West Nile virus has been transmitted by blood transfusion, transplanted organs, breast milk, and transplacentally.[47]

After inoculation by a mosquito, West Nile virus replicates in skin dendritic cells, which then migrate to lymph nodes, where virus replicates further, enters the bloodstream, and, in some individuals, crosses the blood-brain barrier. In the CNS the virus infects neurons. Chemokines have essential roles in directing leukocytes to the CNS for viral clearance. In humans and in mice, the chemokine receptor CCR5 functions as an essential host factor to resist neuroinvasive infection. The CCR5Δ32 allele, which contains a 32–base pair deletion in the coding sequence and results in a complete loss of function in a homozygous individual, is associated with symptomatic and lethal West Nile virus infection. Thus, the loss of CCR5 receptor increases the risk of fatal West Nile virus infection but is protective against HIV-1 infection because HIV uses the receptor to infect host cells (Chapter 6).[48]

West Nile virus infection is usually asymptomatic, but in 20% of infected individuals it gives rise to a mild, short-lived febrile illness associated with headache and myalgia. A maculopapular rash is seen in approximately half the cases. CNS complications (meningitis, encephalitis, meningoencephalitis) are not frequent, occurring in about 1 in 150 clinically apparent infections. There is a mortality of about 10% in people with meningoencephalitis and long-term cognitive and neurologic impairment in many survivors. Perivascular and leptomeningeal chronic inflammation, microglial nodules (Chapter 28), and neuronophagia predominantly involving the temporal lobes and brain stem have been observed in the brains of patients who died of West Nile virus infection. Immunosuppressed persons and the elderly appear to be at the greatest risk for severe disease. Rare complications include hepatitis, myocarditis, and pancreatitis. The diagnosis is usually made by serology, but viral culture and PCR-based tests are also used.

Viral Hemorrhagic Fevers

Viral hemorrhagic fevers (VHFs) are systemic infections. They are caused by enveloped RNA viruses in four different families: arenaviruses, filoviruses, bunyaviruses, and flaviviruses. Although structurally distinct, these viruses all depend on an animal or insect host for survival and transmission. VHF viruses are restricted geographically to areas in which their hosts reside. Humans are infected when they come into contact with infected hosts or insect vectors, but humans are not the natural reservoir for any of these viruses. Some viruses that cause hemorrhagic fever (Ebola, Marburg, Lassa) also can spread from person to person. VHF viruses produce a spectrum of illnesses, ranging from relatively mild acute disease characterized by fever, headache, myalgia, rash, neutropenia, and thrombocytopenia to severe, life-threatening disease in which there is sudden hemodynamic deterioration and shock. These viruses are potential biologic weapons because of their infectious properties, morbidity and mortality, and the absence of therapy and vaccines.

The pathogenesis of viral hemorrhagic fevers is not well understood. The hemorrhagic manifestations are due to thrombocytopenia or severe platelet or endothelial dysfunction. Typically there is increased vascular permeability. There may be necrosis and hemorrhage in many organs, particularly the liver. Although the viruses that cause hemorrhagic fever can replicate in endothelial cells and direct cytopathic effects may contribute to disease, most disease manifestations are related to activation of innate immune responses.[49] Viral infection of macrophages and dendritic cells leads to release of mediators that modify vascular function and have procoagulant activity.

CHRONIC LATENT INFECTIONS (HERPESVIRUS INFECTIONS)

Herpesviruses are large encapsulated viruses that have a double-stranded DNA genome that encodes approximately 70 proteins. Herpesviruses cause acute infection followed by latent infection in which the viruses persist in a noninfectious form with periodic reactivation and shedding of infectious virus. Latency is operationally defined as the inability to recover infectious particles from cells that harbor the virus. There are eight types of human herpesviruses, belonging to three subgroups defined by the type of cell most frequently infected and the site of latency: α-*group viruses*, including HSV-1, HSV-2, and VZV, which infect epithelial cells and produce latent infection in neurons; *lymphotropic* β-*group viruses*, including CMV, human herpesvirus-6 (which causes exanthem subitum, also known as roseola infantum and sixth disease, a benign rash of infants), and human herpesvirus-7 (a virus without a known disease association), which infect and produce latent infection in a variety of cell types; and the γ-*group viruses* EBV and KSHV/HHV-8, the cause of Kaposi sarcoma,[58] which produce latent infection mainly in lymphoid cells. In addition, herpesvirus simiae is an Old World monkey virus that resembles HSV-1 and can cause fatal neurologic disease in animal handlers, usually resulting from an animal bite.

Herpes Simplex Virus (HSV)

HSV-1 and HSV-2 differ serologically but are genetically similar and cause a similar set of primary and recurrent infections.[50] These viruses produce acute and latent infections. Both viruses replicate in the skin and the mucous membranes at the site of entrance of the virus (usually oropharynx or genitals), where they produce infectious virions and cause vesicular lesions of the epidermis. The viruses spread to sensory neurons that innervate these primary sites of replication. Viral nucleocapsids are transported along axons to the neuronal cell bodies, where the viruses establish latent infection. In immunocompetent hosts, primary HSV infection resolves in a few weeks, although the virus remains latent in nerve cells. During latency the viral DNA remains within the nucleus of the neuron, and only latency-associated viral RNA transcripts (LATs) are synthesized.[51] In this state, no viral proteins appear to be produced. Recent data suggest that some LATs may be microRNAs that confer resistance to apoptosis and thus contribute to virus persistence in sensory neurons.[52] Reactivation of HSV-1 and HSV-2 may occur repeatedly with or without symptoms, and results in the spread of virus from the neurons to the skin or to mucous membranes. Reactivation occurs in the presence of host immunity, because herpesviruses have developed ways to avoid immune recognition. For example, HSVs can evade antiviral CTLs by inhibiting the MHC class I recognition pathway, and elude humoral immune defenses by producing receptors for the Fc domain of immunoglobulin and inhibitors of complement.[34,][35]

In addition to causing cutaneous lesions, HSV-1 is the major infectious cause of corneal blindness in the United States; corneal epithelial disease is thought to be due to direct viral damage, while corneal stromal disease appears to be immune mediated. HSV-1 is also the major cause of fatal sporadic encephalitis in the United States, when the virus spreads to the brain, particularly the temporal lobes and orbital gyri of the frontal lobes. In addition, neonates and individuals with compromised cellular immunity (e.g., secondary to HIV infection or chemotherapy) may suffer disseminated herpesvirus infections.

Morphology. HSV-infected cells contain large, pink to purple intranuclear inclusions (Cowdry type A) that consist of intact and disrupted virions with the stained host cell chromatin pushed to the edges of the nucleus (Fig. 8-12). Due to cell fusion, HSV also produces inclusion-bearing multinucleated syncytia.

HSV-1 and HSV-2 cause lesions ranging from self-limited cold sores and gingivostomatitis to life-threatening disseminated visceral infections and encephalitis. **Fever blisters or cold sores** favor the facial skin around mucosal orifices (lips, nose), where their distribution is frequently bilateral and independent of skin dermatomes. Intraepithelial vesicles (blisters), which are formed by intracellular edema and ballooning degeneration of epidermal cells, frequently burst and crust over, but some may result in superficial ulcerations.

Gingivostomatitis, which is usually encountered in children, is caused by HSV-1. It is a vesicular eruption extending from the tongue to the retropharynx and causing cervical lymphadenopathy. Swollen, erythematous HSV lesions of the fingers or palm (herpetic whitlow) occur in infants and, occasionally, in health care workers.

Genital herpes is more often caused by HSV-2 than by HSV-1. It is characterized by vesicles on the genital mucous membranes as well as on the external genitalia that are rapidly converted into superficial ulcerations, rimmed by an inflammatory infiltrate (Chapter 22). Herpesvirus (usually HSV-2) can be transmitted to neonates during passage through the birth canal of infected mothers. Although HSV-2 infection in the neonate may be mild, more commonly it is fulminating with generalized lymphadenopathy, splenomegaly, and necrotic foci throughout the lungs, liver, adrenals,

and CNS.

Two forms of **corneal lesions** are caused by HSV (Chapter 29). **Herpes epithelial keratitis** shows typical virus-induced cytolysis of the superficial epithelium. In contrast, **herpes stromal keratitis** is characterized by infiltrates of mononuclear cells around keratinocytes and endothelial cells, leading to neovascularization, scarring, opacification of the cornea, and eventual blindness. This is an immunological reaction to the HSV infection.

Herpes simplex encephalitis is described in Chapter 28 .

Disseminated skin and visceral herpes infections are usually encountered in hospitalized patients with some form of underlying cancer or immunosuppression. **Kaposi varicelliform eruption** is a generalized vesiculating involvement of the skin, whereas **eczema herpeticum** is characterized by confluent, pustular, or hemorrhagic blisters, often with bacterial superinfection and viral dissemination to internal viscera. **Herpes esophagitis** is frequently complicated by superinfection with bacteria or fungi. **Herpes bronchopneumonia**, which may be introduced by intubation of a patient with active oral lesions, is often necrotizing, and **herpes hepatitis** may cause liver failure.

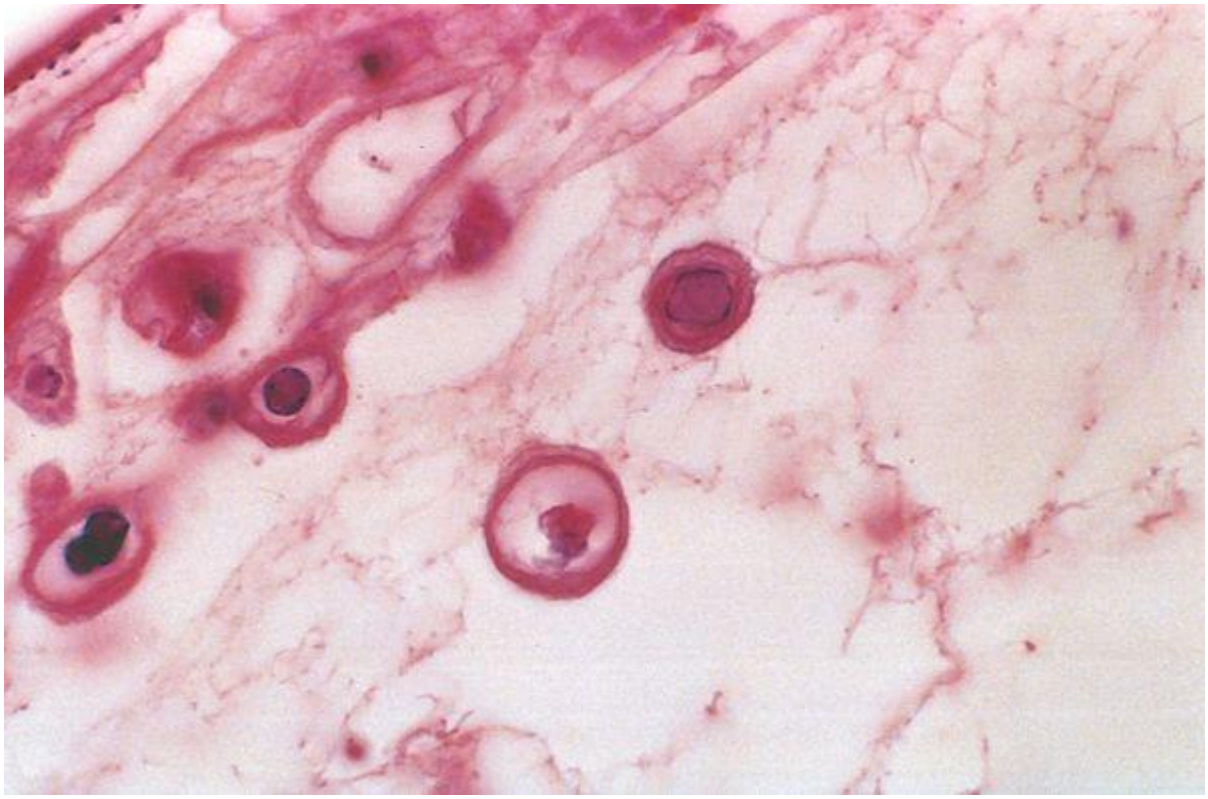

FIGURE 8-12 High-power view of cells from the blister in Figure 8-9 showing glassy intranuclear herpes simplex inclusion bodies.

Varicella-Zoster Virus (VZV)

Two conditions—*chickenpox* and *shingles*—are caused by VZV. Acute infection with VZV causes chickenpox; reactivation of latent VZV causes shingles (also called herpes zoster). Chickenpox is mild in children but more severe in adults and in immunocompromised people. Shingles is a source of morbidity in elderly and immunosuppressed persons.[53] Like HSV, VZV infects mucous membranes,

skin, and neurons and causes a self-limited primary infection in immunocompetent individuals. Also like HSV, VZV evades immune responses and establishes a latent infection in sensory ganglia.[51] In contrast to HSV, VZV is transmitted in epidemic fashion by aerosols, disseminates hematogenously, and causes widespread vesicular skin lesions. VZV infects neurons and/or satellite cells around neurons in the dorsal root ganglia and may recur many years after the primary infection, causing shingles. Localized recurrence of VZV is most frequent and painful in dermatomes innervated by the trigeminal ganglia, where it is most likely to exist in a state of latency. In contrast to numerous recurrences of HSV, most people do not have a recurrence of VZV. VZV usually recurs only once in immunocompetent individuals, but immunosuppressed or elderly persons can have multiple recurrences of VZV. VZV infection is diagnosed by viral culture or detection of viral antigens in cells scraped from superficial lesions.

Morphology. The **chickenpox** rash occurs approximately 2 weeks after respiratory infection. Lesions appear in multiple waves centrifugally from the torso to the head and extremities. Each lesion progresses rapidly from a macule to a vesicle, which resembles a dewdrop on a rose petal. On histologic examination, chickenpox vesicles contain intranuclear inclusions in the epithelial cells like those of HSV-1 (Fig. 8-13). After a few days most chickenpox vesicles rupture, crust over, and heal by regeneration, leaving no scars. However, bacterial superinfection of vesicles that are ruptured by trauma may lead to destruction of the basal epidermal layer and residual scarring.

Shingles occurs when VZV that has long remained latent in the dorsal root ganglia after a previous chickenpox infection is reactivated and infects sensory nerves that carry it to one or more dermatomes. There, the virus infects keratinocytes and causes vesicular lesions, which, unlike chickenpox, are often associated with intense itching, burning, or sharp pain because of the simultaneous radiculoneuritis. This pain is especially severe when the trigeminal nerves are involved; rarely, the geniculate nucleus is involved, causing facial paralysis (Ramsay Hunt syndrome). The sensory ganglia contain a dense, predominantly mononuclear infiltrate, with herpetic intranuclear inclusions within neurons and their supporting cells (Fig. 8-14). VZV can also cause interstitial pneumonia, encephalitis, transverse myelitis, and necrotizing visceral lesions, particularly in immunosuppressed people.

inflammation. *(Courtesy of Dr. James Morris, Radcliffe Infirmary, Oxford, England.)*

Cytomegalovirus (CMV)

Cytomegalovirus (CMV), a β-group herpesvirus, can produce a variety of disease manifestations, depending on the age of the host, and, more important, on the host's immune status. CMV latently infects monocytes and their bone marrow progenitors and can be reactivated when cellular immunity is depressed. CMV causes an asymptomatic or mononucleosis-like infection in healthy individuals but devastating systemic infections in neonates and in immunocompromised people. As its name implies, CMV-infected cells exhibit gigantism of both the entire cell and its nucleus. Within the nucleus is a large inclusion surrounded by a clear halo (owl's eye).

Transmission of CMV can occur by several mechanisms, depending on the age group affected.[54,][55] These include the following:

- Transplacental transmission can occur from a newly acquired or primary infection in a mother who does not have protective antibodies (“congenital CMV”).
- Neonatal transmission can occur through cervical or vaginal secretions at birth or, later, through breast milk from a mother who has active infection (“perinatal CMV”).
- Transmission can occur through saliva during preschool years, especially in day care centers. Toddlers so infected readily transmit the virus to their parents.
- Transmission by the venereal route is the dominant mode after about 15 years of age, but spread may also occur via respiratory secretions and the fecal-oral route.
- Iatrogenic transmission can occur at any age through organ transplants or blood transfusions.

Acute CMV infection induces transient but severe immunosuppression. CMV can infect dendritic cells and impair their maturation and ability to stimulate T cells.[55] Similar to other herpesviruses, CMV can elude immune responses by downmodulating MHC class I and II molecules and producing homologues of TNF receptor, IL-10, and MHC class I molecules.[29,][34,][35] Interestingly, CMV can both activate and evade NK cells by inducing ligands for activating receptors and class I–like proteins that engage inhibitory receptors. Thus, CMV can both hide from immune defenses and actively suppress immune responses.

Morphology. The characteristic enlargement of infected cells can be appreciated histologically. Prominent **intranuclear basophilic inclusions** spanning half the nuclear diameter are usually set off from the nuclear membrane by a clear halo (Fig. 8-15). Within the cytoplasm of these cells, smaller basophilic inclusions can also be seen. In the glandular organs, the parenchymal epithelial cells are affected; in the brain, the neurons; in the lungs, the alveolar macrophages and epithelial and endothelial cells; and in the kidneys, the tubular epithelial and glomerular endothelial cells. Affected cells are strikingly enlarged, often to a diameter of 40 μm, and they show cellular and nuclear pleomorphism. Disseminated CMV causes focal necrosis with minimal inflammation in virtually any organ.

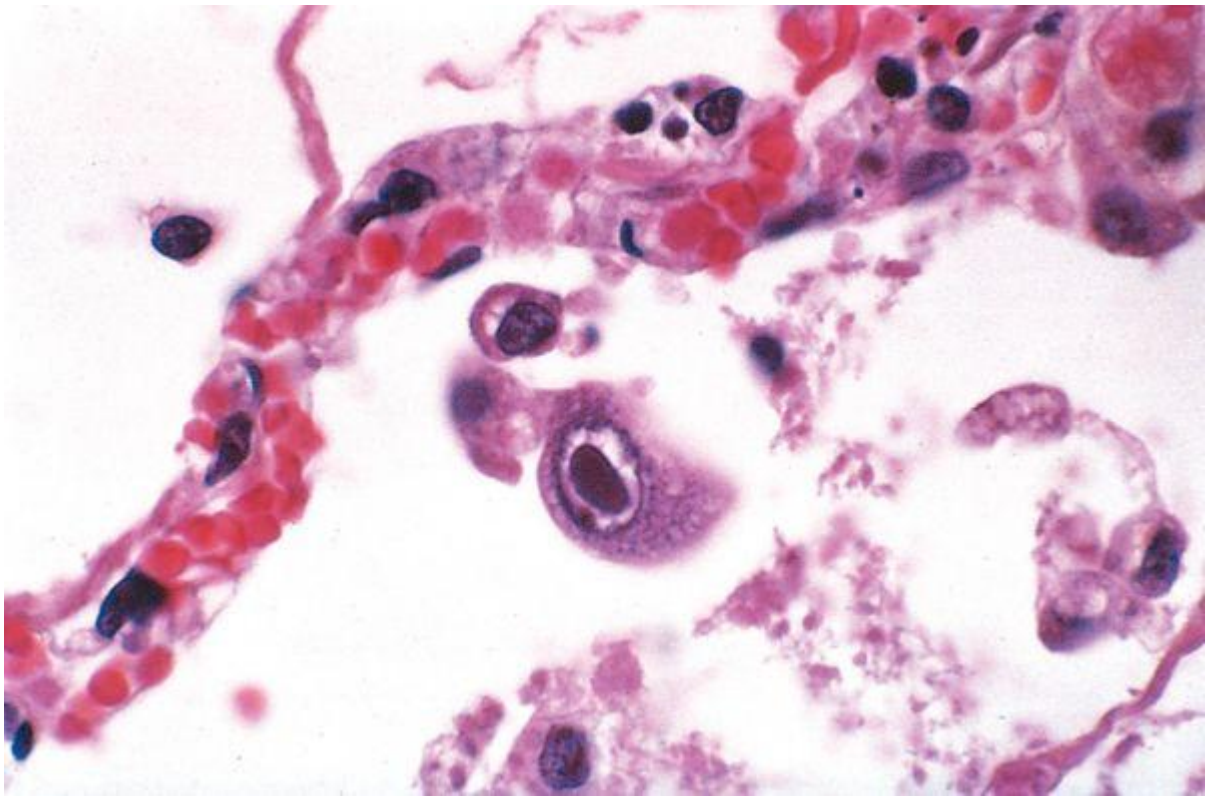

FIGURE 8-15 Cytomegalovirus: distinct nuclear and ill-defined cytoplasmic inclusions in the lung.

Congenital Infections.

Infection acquired in utero may take many forms. In approximately 95% of cases it is asymptomatic. However, sometimes when the virus is acquired from a mother with primary infection (who does not have protective antibodies), classic *cytomegalic inclusion disease* develops. Cytomegalic inclusion disease resembles erythroblastosis fetalis. Affected infants may suffer intrauterine growth retardation, be profoundly ill, and manifest jaundice, hepatosplenomegaly, anemia, bleeding due to thrombocytopenia, and encephalitis. In fatal cases the brain is often smaller than normal (microcephaly) and may show foci of calcification. Diagnosis of neonatal CMV is made by shell-virus culture of urine or oral secretions.

The infants who survive usually have permanent deficits, including mental retardation, hearing loss, and other neurologic impairments. The congenital infection is not always devastating, however, and may take the form of interstitial pneumonitis, hepatitis, or a hematologic disorder. Most infants with this milder form of cytomegalic inclusion disease recover, although a few develop mental retardation later. Uncommonly, a totally asymptomatic infection may be followed months to years later by neurologic sequelae, including delayed-onset mental retardation and deafneas.

Perinatal Infections.

Infection acquired during passage through the birth canal or from breast milk is asymptomatic in the vast majority of cases, although, uncommonly, infants may develop an interstitial pneumonitis, failure to thrive, skin rash, or hepatitis. These children have acquired maternal antibodies against CMV, which reduce the severity of disease. Despite the lack of symptoms, many of these people continue to excrete

CMV in their urine or saliva for months to years. Subtle effects on hearing and intelligence later in life have been reported in some studies.

Cytomegalovirus Mononucleosis.

In healthy young children and adults the disease is nearly always asymptomatic. In surveys around the world, 50% to 100% of adults demonstrate antibodies to CMV in the serum, indicating previous exposure. *The most common clinical manifestation of CMV infection in immunocompetent hosts beyond the neonatal period is an infectious mononucleosis–like illness, with fever, atypical lymphocytosis, lymphadenopathy, and hepatomegaly accompanied by abnormal liver function test results, suggesting mild hepatitis.* The diagnosis is made by serology. Most people recover without any sequelae, although excretion of the virus may occur in body fluids for months to years.

Irrespective of the presence or absence of symptoms, once infected a person becomes seropositive for life. The virus remains latent within leukocytes.

CMV in Immunosuppressed Individuals.

Immunocompromised individuals (e.g., transplant recipients, HIV-infected individuals) are susceptible to severe CMV infection. This can be either primary infection or reactivation of latent CMV. *CMV is the most common opportunistic viral pathogen in AIDS.* Recipients of solid-organ transplants (heart, liver, kidney) also may contract CMV from the donor organ.

In all these settings, serious, life-threatening disseminated CMV infections primarily affect the lungs (pneumonitis) and gastrointestinal tract (colitis). In the pulmonary infection an interstitial mononuclear infiltrate with foci of necrosis develops, accompanied by the typical enlarged cells with inclusions. The pneumonitis can progress to full-blown acute respiratory distress syndrome. Intestinal necrosis and ulceration can develop and be extensive, leading to the formation of pseudomembranes and debilitating diarrhea. Diagnosis of CMV infections is made by demonstration of characteristic morphologic alterations in tissue sections, viral culture, rising antiviral antibody titer, detection of CMV antigens, and PCR-based detection of CMV DNA. The antigen- and PCR-based methods have revolutionized the approach to monitoring CMV infection in people after transplantation.

CHRONIC PRODUCTIVE INFECTIONS

In some infections the immune system is unable to eliminate the virus, and continued viral replication leads to persistent viremia. The high mutation rate of viruses such as HIV and HBV may allow them to escape control by the immune system.

Hepatitis B Virus

HBV is a significant cause of acute and chronic liver disease worldwide. Here we will briefly discuss HBV as an example of a chronic productive viral infection; viral hepatitis is discussed in detail in Chapter 18 . HBV, a member of the hepadnavirus family, is a DNA virus that can be transmitted percutaneously (e.g., intravenous drug use or blood transfusion), perinatally, and sexually. HBV infects hepatocytes, and cellular injury occurs mainly from the immune response to infected liver cells and not to cytopathic effects of the virus.[56] The effectiveness of the cytotoxic T-lymphocyte (CTL) response is a major determinant of whether a person clears the virus or becomes a chronic carrier. When infected hepatocytes are destroyed by CTLs, replicating virus is also eliminated and the infection is cleared. However, if the rate of infection of hepatocytes outpaces the ability of CTLs to eliminate infected cells, a chronic infection is established. This may happen in about 5% of adults and up to 90% of children infected perinatally. In this setting the liver develops a chronic hepatitis, with lymphocytic inflammation, apoptotic hepatocytes resulting from CTL-mediated killing, and progressive destruction of the liver

parenchyma. Long-term viral replication and recurrent immune-mediated liver injury can lead to cirrhosis of the liver and an increased risk for hepatocellular carcinoma. The morphology and pathogenesis of hepatocellular carcinoma and the role of HBV are discussed in Chapter 18 . In some infected individuals, hepatocytes are infected but the CTL response is dormant, resulting in the establishment of a “carrier” state, without progressive liver damage.

TRANSFORMING INFECTIONS

This group includes several viruses that have been implicated in the causation of human cancer: EBV, HPV, HBV, and HTLV-1. EBV is discussed here; others are discussed in later chapters.

Epstein-Barr Virus (EBV)

EBV causes *infectious mononucleosis*, a benign, self-limited lymphoproliferative disorder, and is associated with the development of a number of neoplasms, most notably certain lymphomas and nasopharyngeal carcinoma.[57] Infectious mononucleosis is characterized by fever, generalized lymphadenopathy, splenomegaly, sore throat, and the appearance in the blood of atypical activated T lymphocytes (mononucleosis cells). Some people develop hepatitis, meningoencephalitis, and pneumonitis. Infectious mononucleosis occurs principally in late adolescents or young adults among upper socioeconomic classes in developed nations. In the rest of the world, primary infection with EBV occurs in childhood and is usually asymptomatic.

Pathogenesis.

EBV is transmitted by close human contact, frequently with the saliva during kissing. An EBV envelope glycoprotein binds to CD21 (CR2), the receptor for the C3d component of complement (Chapter 2), present on B cells.[58] The viral infection begins in nasopharyngeal and oropharyngeal lymphoid tissues, particularly the tonsils (Fig. 8-16). Either through transient infection of epithelium or transcytosis into the submucosa, EBV gains access to submucosal lymphoid tissues. Here, infection of B cells may take one of two forms. In a minority of B cells there is productive infection with lysis of infected cells and release of virions, which may infect other B cells. In most B cells, EBV establishes latent infection. Of note, people with X-linked agammaglobulinemia, who lack B cells, do not become latently infected with EBV or shed virus, suggesting B cells are the main reservoir of latent infection. During latent infection, a small number of EBV genes are expressed and they are involved in the establishment of latency. The gene products include EBNA1, which binds the EBV genome to chromosomes, mediating episomal persistence and maintenance, and EBNA2 and latent membrane protein 1 (LMP1), which drive B-cell activation and proliferation.[59] LMP1 appears to act by binding to TNF receptor–associated factors, and activates signaling pathways that mimic B-cell activation by CD40, which is involved in normal B-cell responses (Chapter 6). EBNA2 stimulates transcription of many host cell genes, including genes that drive cell cycle entry. The activated B cells then disseminate in the circulation and secrete antibodies with several specificities, including the heterophile anti–sheep red blood cell antibodies used for the diagnosis of infectious mononucleosis. Heterophile antibodies bind to antigens that differ from the antigens that induced them. Thus, people with mononucleosis make antibodies that agglutinate sheep or horse red blood cells in the laboratory, but these antibodies do not react with EBV.

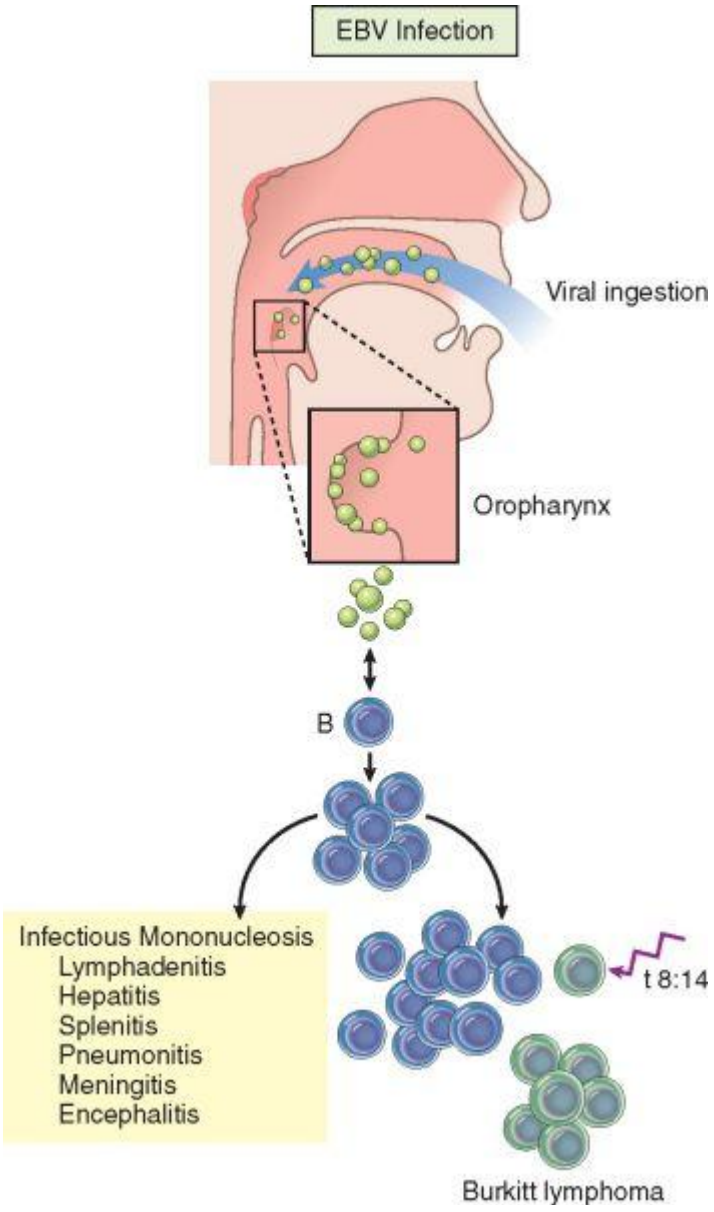

FIGURE 8-16 Outcome of Epstein-Barr virus (EBV) infection. In an individual with normal immune function, infection is usually either asymptomatic or leads to mononucleosis. In the setting of cellular immunodeficiency, the proliferation of infected B cells may be uncontrolled, leading to the development of B-cell neoplasms. In other instances, persons without overt evidence of immunodeficiency develop EBV-positive tumors, which are usually (but not always) also derived from B cells. One secondary genetic event that collaborates with EBV to cause B-cell transformation is a balanced 8;14 chromosomal translocation, which is seen in Burkitt lymphoma. EBV is also implicated in the pathogenesis of nasopharyngeal carcinoma, Hodgkin lymphoma, and certain other rare non-Hodgkin lymphomas.

The symptoms of infectious mononucleosis appear upon initiation of the host immune response. Cellular immunity mediated by CD8+ cytotoxic T cells and NK cells is the most important component of this response. The *atypical lymphocytes* seen in the blood, so characteristic of this disease, are mainly EBV-specific CD8+ cytotoxic T cells, but also include CD16+ NK cells. The reactive proliferation of T cells is largely centered in lymphoid tissues, which accounts for the lymphadenopathy and splenomegaly. Early in the course of the infection, IgM antibodies are formed against viral capsid antigens; later, IgG antibodies are formed that persist for life. In otherwise healthy persons, the fully developed humoral and cellular responses to EBV act as brakes on viral shedding, resulting in the

elimination of B cells expressing the full complement of EBV latency–associated genes. However, EBV persists throughout life in a small population of resting B cells in which expression of EBV genes is limited to *EBNA1* and *LMP2*. Cells within this pool are thought to occasionally reactivate expression of the other latency-associated genes, such as *EBNA2* and *LMP1*, causing them to proliferate. In hosts with acquired defects in cellular immunity (e.g., AIDS, organ transplantation), this proliferation can progress through a multi-step process to EBV-associated B-cell lymphomas. EBV also contributes to the development of some cases of Burkitt lymphoma (Chapter 13), in which a chromosomal translocation (most commonly an 8:14 translocation) involving the c-*myc* oncogene is the critical oncogenic event (see Fig. 8-16).

Morphology. The major alterations involve the blood, lymph nodes, spleen, liver, CNS, and, occasionally, other organs. The **peripheral blood** shows absolute lymphocytosis; more than 60% of white blood cells are lymphocytes. Between 5% and 80% of these are large, **atypical lymphocytes**, 12 to 16 μm in diameter, characterized by an abundant cytoplasm containing multiple clear vacuolations, an oval, indented, or folded nucleus, and scattered cytoplasmic azurophilic granules (Fig. 8-17). These atypical lymphocytes, most of which express CD8, are sufficiently distinctive to strongly suggest the diagnosis.

The **lymph nodes** are typically discrete and enlarged throughout the body, principally in the posterior cervical, axillary, and groin regions. On histologic examination the most striking feature is the expansion of paracortical areas by activated T cells (immunoblasts). A minor population of EBV-infected B cells expressing *EBNA2*, *LMP1*, and other latency-specific genes can also be detected in the paracortex using specific antibodies. Occasionally, EBV-infected B cells resembling Reed-Sternberg cells (the malignant cells of Hodgkin lymphoma, Chapter 13) may be found. B-cell areas (follicles) may also be hyperplastic, but this is usually mild. The T-cell proliferation is sometimes so exuberant that it is difficult to distinguish the nodal morphology from that seen in malignant lymphomas. Similar changes commonly occur in the tonsils and lymphoid tissue of the oropharynx.

The **spleen** is enlarged in most cases, weighing between 300 and 500 gm. It is usually soft and fleshy, with a hyperemic cut surface. The histologic changes are analogous to those of the lymph nodes, showing an expansion of white pulp follicles and red pulp sinusoids due to the presence of numerous activated T cells. These spleens are especially vulnerable to rupture, possibly in part because the rapid increase in size produces a tense, fragile splenic capsule.

The **liver** is usually involved to some degree, although hepatomegaly is at most moderate. On histologic examination, atypical lymphocytes are seen in the portal areas and sinusoids, and scattered, isolated cells or foci of parenchymal necrosis may be present. This histologic picture is similar to that of other forms of viral hepatitis.

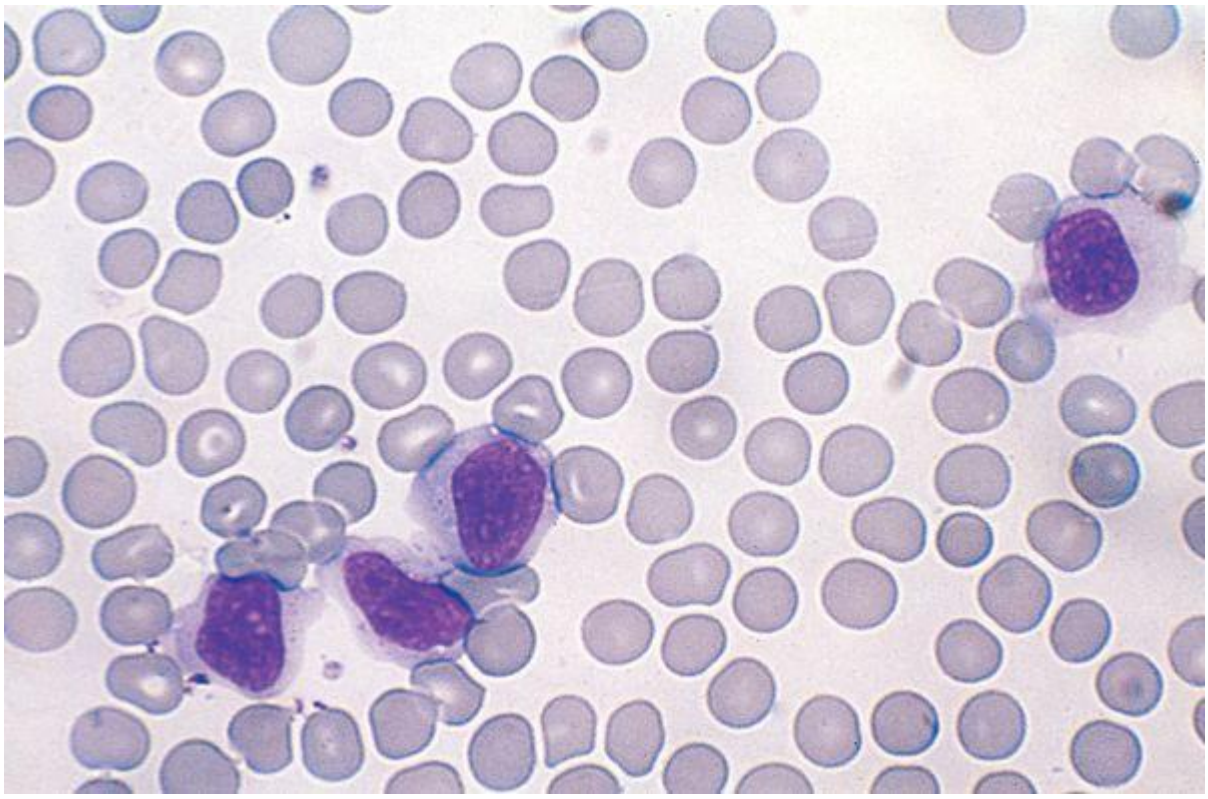

FIGURE 8-17 Atypical lymphocytes in infectious mononucleosis.

Clinical Features.

Infectious mononucleosis classically presents with fever, sore throat, lymphadenitis, and the other features mentioned earlier. However, atypical presentations are common, and include malaise, fatigue, and lymphadenopathy, raising the specter of leukemia or lymphoma; a fever of unknown origin without significant lymphadenopathy or other localized findings; hepatitis resembling one of the hepatotropic viral syndromes; or a febrile rash resembling rubella. *The diagnosis depends on the following findings (in increasing order of specificity): (1) lymphocytosis with the characteristic atypical lymphocytes in the peripheral blood, (2) a positive heterophile antibody reaction (monospot test), and (3) specific antibodies for EBV antigens (viral capsid antigens, early antigens, or Epstein-Barr nuclear antigen).* In most patients, infectious mononucleosis resolves within 4 to 6 weeks, but sometimes the fatigue lasts longer. One or more complications occasionally supervene. Perhaps most common is marked hepatic dysfunction with jaundice, elevated hepatic enzyme levels, disturbed appetite, and rarely even liver failure. Other complications involve the nervous system, kidneys, bone marrow, lungs, eyes, heart, and spleen. Splenic rupture can occur even with minor trauma, leading to hemorrhage that may be fatal. A more serious complication in those suffering from some form of immunodeficiency, such as AIDS, or receiving immunosuppressive therapy (e.g., bone marrow or solid-organ transplant recipients) is B-cell lymphomas. As detailed in Chapter 13 , EBV also causes another distinctive form of lymphoma, called *Burkitt lymphoma*, particularly in certain geographic locales.

Unfortunate consequences also occur in individuals suffering from the X-linked lymphoproliferation syndrome (also known as Duncan disease), a disorder caused by a defect in a gene, *SH2D1A*, that is expressed primarily in cytotoxic T cells and NK cells.[60] SH2D1A (also called SAP) participates in a

signaling pathway critical for an effective cellular response to EBV-infected B cells. Patients are often normal until they are acutely infected with EBV, often during adolescence. The failure to control EBV infection variously leads to chronic infectious mononucleosis, agammaglobulinemia, and B-cell lymphoma, each of which proves fatal in about a third of patients.

2.8.3 Bacterial Infections

Different classes of bacteria are responsible for diverse infections (Table 8-8).

TABLE 8-8 -- Selected Human Bacterial Diseases and Their Pathogens

Clinical or Microbiologic Category	Species	Frequent Disease Presentations
Infections by pyogenic cocci	*Staphylococcus aureus, S. epidermidis*	Abscess, cellulitis, pneumonia, sepsis
	Streptococcus pyogenes	Pharyngitis, erysipelas, scarlet fever
	Streptococcus pneumoniae (pneumococcus)	Lobar pneumonia, meningitis
	Neisseria meningitidis (meningococcus)	Meningitis
	Neisseria gonorrhoea (gonococcus)	Gonorrhea
Gram-negative infections	*Escherichia coli,*[*] *Klebsiella pneumoniae*[*]	Urinary tract infection, wound infection, abscess, pneumonia, sepsis, shock, endocarditis
	Enterobacter (Aerobacter) aerogenes[*]	
	Proteus spp. *(P. mirabilis, P. morgagni)*[*]	
	Serratia marcescens,[*] *Pseudomonas* spp. *(P. aeruginosa)*[*]	
	Bacteroides spp. *(B. fragilis)*	Anaerobic infection
	Legionella spp. *(L. pneumophila)*	Legionnaires disease
Contagious childhood bacterial diseases	*Haemophilus influenzae*	Meningitis, upper and lower respiratory tract infections
	Bordetella pertussis	Whooping cough
	Corynebacterium diphtheriae	Diphtheria
Enteric infections	Enteropathogenic *E. coli, Shigella* spp.	Invasive or noninvasive gastroenterocolitis
	Vibrio cholerae, Campylobacter jejuni, C. coli	
	Yersinia enterocolitica, Salmonella spp. (1000 strains)	
	Salmonella typhi	Typhoid fever
Clostridial infections	*Clostridium tetani*	Tetanus (lockjaw)
	Clostridium botulinum	Botulism (paralytic food poisoning)
	Clostridium perfringens, C. septicum	Gas gangrene, necrotizing cellulitis
	Clostridium difficile[*]	Pseudomembranous colitis

Clinical or Microbiologic Category	Species	Frequent Disease Presentations
Zoonotic bacterial infections	*Bacillus anthracis*	Anthrax
	Yersinia pestis	Bubonic plague
	Francisella tularensis	Tularemia
	Brucella melitensis, B. suis, B. abortus	Brucellosis (undulant fever)
	Borrelia recurrentis	Relapsing fever
	Borrelia burgdorferi	Lyme disease
Human treponemal infections	*Treponema pallidum*	Syphilis
Mycobacterial infections	*Mycobacterium tuberculosis,*[*] *M. bovis*	Tuberculosis
	M. leprae	Leprosy
	M. kansasii,[*] *M. avium, M. intracellulare*	Atypical mycobacterial infections
Actinomycetaceae	*Nocardia asteroides*[*]	Nocardiosis
	Actinomyces israelii	Actinomycosis

[*] Important opportunistic infections.

GRAM-POSITIVE BACTERIAL INFECTIONS

Common gram-positive pathogens include *Staphylococcus*, *Streptococcus*, and *Enterococcus*, each of which causes many types of infections. Four less common diseases caused by gram-positive rod-shaped organisms are also discussed here: diphtheria, listeriosis, anthrax, and nocardiosis. *Clostridia*, which are gram-positive, are discussed with the anaerobes. All these infections are diagnosed by culture and some special tests mentioned below.

Staphylococcal Infections

Staphylococcus aureus are pyogenic gram-positive cocci that form clusters like bunches of grapes. *These bacteria cause a myriad of skin lesions (boils, carbuncles, impetigo, and scalded-skin syndrome) as well as abscesses, sepsis, osteomyelitis, pneumonia, endocarditis, food poisoning, and toxic shock syndrome (TSS)* (Fig. 8-18). Here we review the general characteristics of *S. aureus* infection. Specific organ infections are described in other chapters. *S. epidermidis*, a species that is related to *S. aureus*, causes opportunistic infections in catheterized patients, patients with prosthetic cardiac valves, and drug addicts. *S. saprophyticus* is a common cause of urinary tract infections in young women.

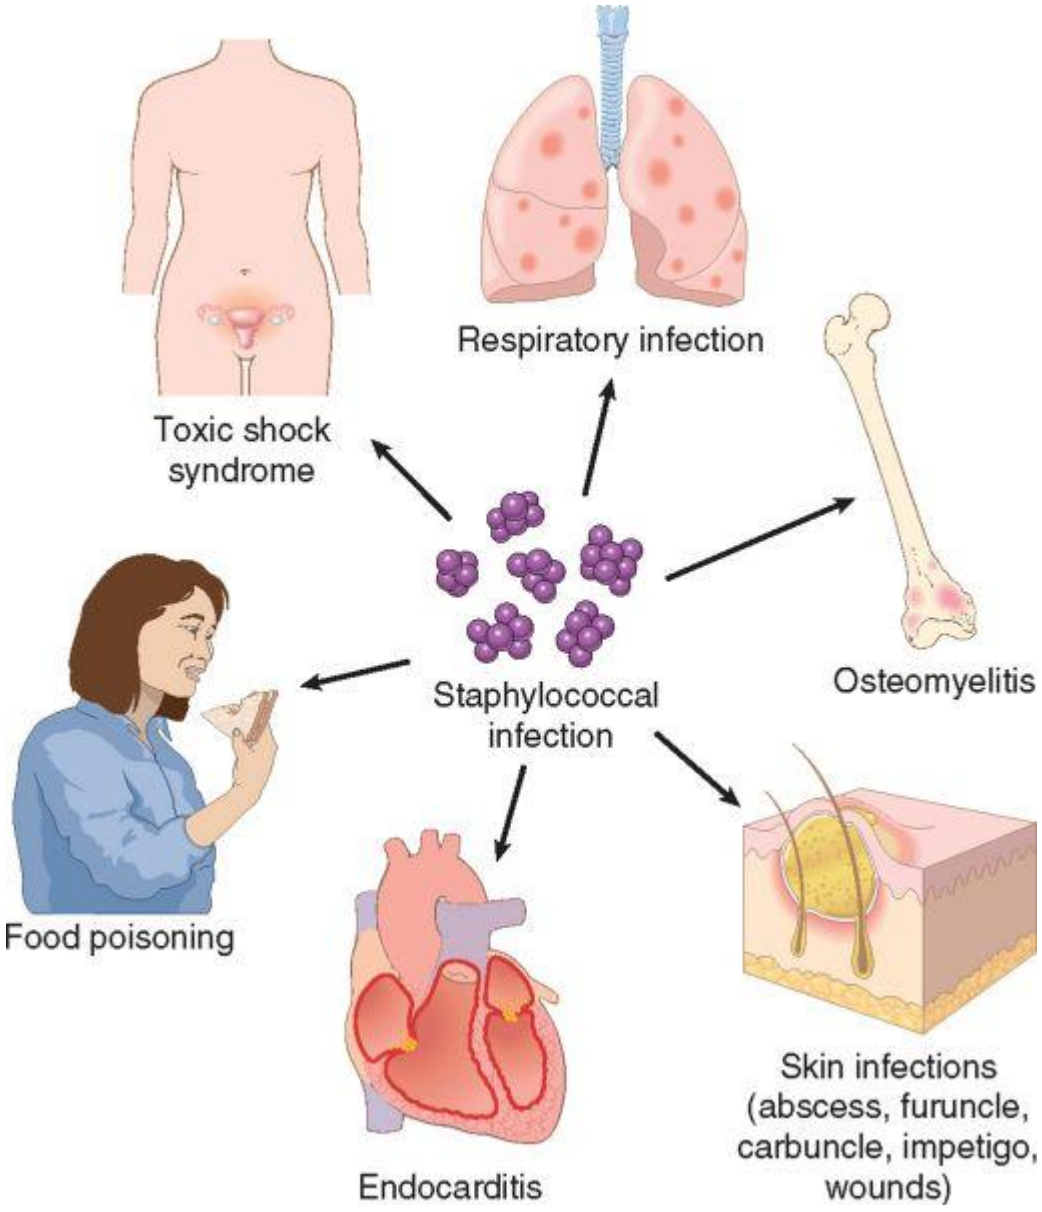

FIGURE 8-18 The many consequences of staphylococcal infection.

Pathogenesis.

S. aureus possess a multitude of virulence factors, which include surface proteins involved in adherence, secreted enzymes that degrade proteins, and secreted toxins that damage host cells.

S. aureus expresses surface receptors for fibrinogen (called clumping factor), fibronectin, and vitronectin, and uses these molecules as a bridge to bind to host endothelial cells.[61] Staphylococci infecting prosthetic valves and catheters have a polysaccharide capsule that allows them to attach to the artificial materials and to resist host cell phagocytosis. The lipase of *S. aureus* degrades lipids on the skin surface, and its expression is correlated with the ability of the bacteria to produce skin abscesses. Staphylococci also have protein A on their surface, which binds the Fc portion of immunoglobulins, allowing the organism to escape antibody-mediated killing.

S. aureus produces multiple membrane-damaging (hemolytic) toxins, including α-toxin, a pore-forming protein that intercalates into the plasma membrane of host cells and depolarizes them[62]; β-toxin, a sphingomyelinase; and δ-toxin, which is a detergent-like peptide. Staphylococcal γ-toxin and leukocidin lyse erythrocytes and phagocytic cells, respectively.

The exfoliative A and B toxins produced by *S. aureus* are serine proteases that cleave the protein desmoglein 1, which is part of the desmosomes that hold epidermal cells tightly together.[25] This causes keratinocytes to detach from one another and the underlying skin, resulting in a loss of barrier function that often leads to secondary skin infections. Exfoliation can occur locally at the site of infection (bullous impetigo) or can be widespread, when secreted toxin causes disseminated loss of the superficial epidermis (staphylococcal scalded-skin syndrome).

Superantigens produced by *S. aureus* cause food poisoning and TSS. TSS came to public attention because of its association with the use of hyperabsorbent tampons, which became colonized with *S. aureus* during use. It is now clear that TSS can be caused by growth of *S. aureus* at many sites, most commonly the vagina and infected surgical sites. TSS is characterized by hypotension (shock), renal failure, coagulopathy, liver disease, respiratory distress, a generalized erythematous rash, and soft tissue necrosis at the site of infection. If not promptly treated, TSS can be fatal. TSS can also be caused by *Streptococcus pyogenes*. As mentioned earlier, bacterial superantigens bind to conserved portions of MHC molecules and to relatively conserved portions of T-cell receptor β chains. In this manner superantigens may stimulate up to 20% of T lymphocytes, leading to release of large amounts of cytokines such as TNF and IL-1, which can produce a condition resembling septic shock (Chapter 4). Superantigens produced by *S. aureus* also cause vomiting, presumably by affecting the CNS or the enteric nervous system.[63]

Morphology. Whether the lesion is located in the skin, lungs, bones, or heart valves, *S. aureus* causes pyogenic inflammation that is distinctive for its local destructiveness.

Excluding impetigo, which is a staphylococcal or streptococcal infection restricted to the superficial epidermis, staphylococcal skin infections are centered around the hair follicles. A **furuncle**, or **boil**, is a focal suppurative inflammation of the skin and subcutaneous tissue, either solitary or multiple or recurrent in successive crops. Furuncles are most frequent in moist, hairy areas, such as the face, axillae, groin, legs, and submammary folds. Beginning in a single hair follicle, a boil develops into a growing and deepening abscess that eventually "comes to a head" by thinning and rupturing the overlying skin. A **carbuncle** is a deeper suppurative infection that spreads laterally beneath the deep subcutaneous fascia and then burrows superficially to erupt in multiple adjacent skin sinuses. Carbuncles typically appear beneath the skin of the upper back and posterior neck, where fascial planes favor their spread. **Hidradenitis** is a chronic suppurative infection of apocrine glands, most often in the axilla. Infections of the nail bed **(paronychia)** or on the palmar side of the fingertips **(felons)** are exquisitely painful. They may follow trauma or embedded splinters and, if deep enough, destroy the bone of the terminal phalanx or detach the fingernail.

Staphylococcal lung infections (Fig. 8-19) have a polymorphonuclear infiltrate similar to that of pneumococcus (Fig. 8-7) but cause much more tissue destruction. *S. aureus* lung infections usually occur in people with a hematogenous source, such as an infected thrombus, or a predisposing condition such as influenza.

Staphylococcal scalded-skin syndrome, also called **Ritter disease**, most frequently occurs in children with staphylococcal infections of the nasopharynx or skin. There is a sunburn-like rash that spreads over the entire body and evolves into fragile bullae that lead to partial or total skin loss. The

desquamation of the epidermis in staphylococcal scalded-skin syndrome occurs at the level of the granulosa layer, distinguishing it from toxic epidermal necrolysis, or Lyell's disease, which is secondary to drug hypersensitivity and causes desquamation at the level of the epidermal-dermal junction (Chapter 25).

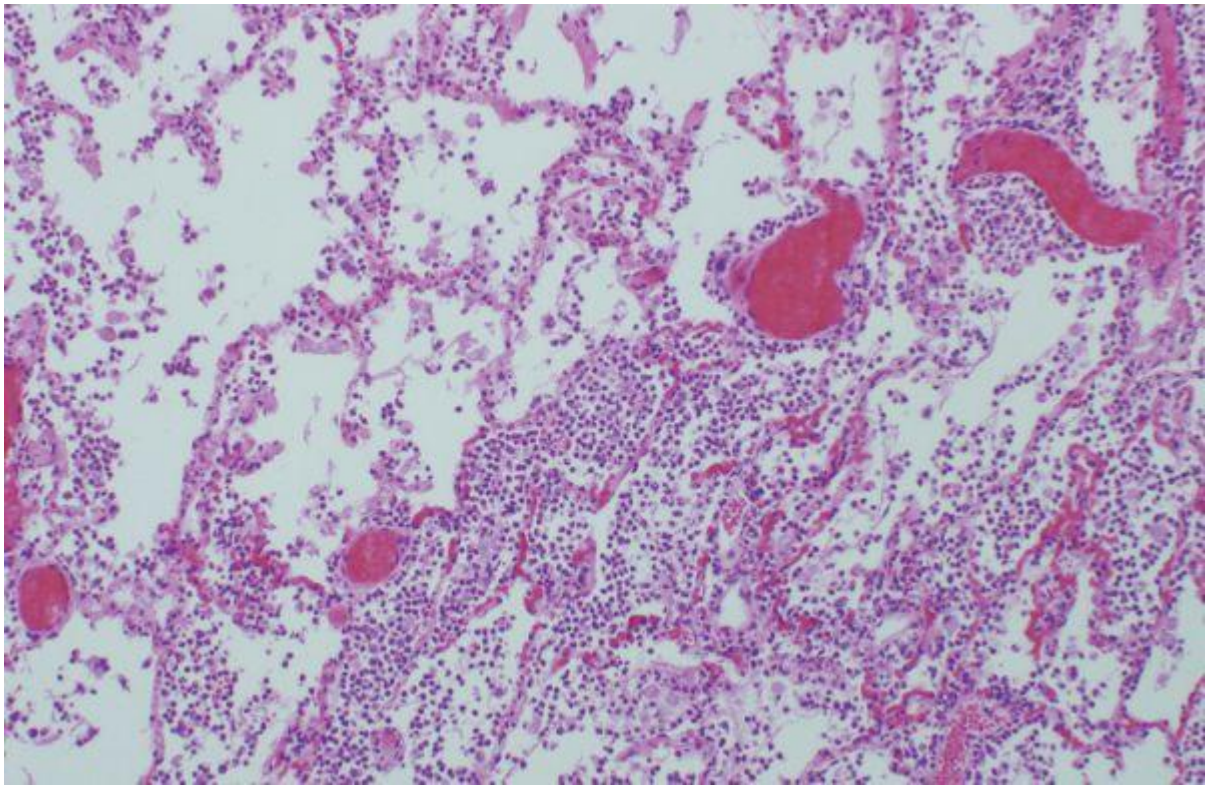

FIGURE 8-19 Staphylococcal abscess of the lung with extensive neutrophilic infiltrate and destruction of the alveoli (contrast with Fig. 8-7).

Antibiotic resistance is a growing problem in treatment of *S. aureus* infections. Methicillin-resistant *S. aureus* (MRSA) are resistant to all currently available beta-lactam cell-wall synthesis inhibitors (which include the penicillins and cephalosporins). Until recently, MRSA was mainly found in healthcare-associated infections, but community-acquired MRSA infections have now become common in many areas.[64] As a result, empiric treatment of staphylococcal infections with beta-lactam antibiotics has become less effective. Community-acquired MRSA commonly produce a potent membrane damaging toxin, which kills leukocytes and may make these strains of *S. aureus* particularly virulent.

Streptococcal and Enterococcal Infections

Streptococci are gram-positive cocci that grow in pairs or chains and cause a myriad of suppurative infections of the skin, oropharynx, lungs, and heart valves. They are also responsible for a number of post-infectious syndromes, including rheumatic fever (Chapter 12), immune complex glomerulonephritis (Chapter 20), and erythema nodosum (Chapter 25). β-hemolytic streptococci are typed according to their surface carbohydrate (Lancefield) antigens. *S. pyogenes* (group A) causes pharyngitis, scarlet fever, erysipelas, impetigo, rheumatic fever, TSS, and glomerulonephritis. *S. agalactiae* (group B) colonizes the female genital tract and causes sepsis and meningitis in neonates and

chorioamnionitis in pregnancy. *S. pneumoniae*, the most important α-hemolytic streptococcus, is a common cause of community-acquired pneumonia and meningitis in adults. The viridans group streptococci include several species of α-hemolytic and nonhemolytic streptococci that are normal oral flora and are also a common cause of endocarditis. Finally, *S. mutans* is the major cause of dental caries. Streptococcal infections are diagnosed by culture, and the rapid antigen test for pharyngitis.

Enterococci are also gram-positive cocci that grow in chains. Enterococci are often resistant to commonly used antibiotics and are a significant cause of endocarditis and urinary tract infections.

Pathogenesis.

The different species of streptococci produce many virulence factors and toxins. *S. pyogenes, S. agalactiae*, and *S. pneumoniae* have capsules that resist phagocytosis. *S. pyogenes* also expresses M protein, a surface protein that prevents bacteria from being phagocytosed, and a complement C5a peptidase, which degrades this chemotactic peptide.[64] *S. pyogenes* secrete a phage-encoded pyrogenic exotoxin that causes fever and rash in scarlet fever. Poststreptococcal acute rheumatic fever is probably caused by antistreptococcal M protein antibodies and T cells that cross-react with cardiac proteins.[66] Virulent *S. pyogenes* have been referred to as flesh-eating bacteria because they cause a rapidly progressive necrotizing fasciitis. Pneumolysin is a cytosolic bacterial protein released on disruption of *S. pneumoniae*.[67] Pneumolysin inserts into host cell membranes and lyses them, greatly increasing tissue damage. This toxin also activates the classical pathway of complement, reducing complement available for opsonization of bacteria. *S. mutans* produces caries by metabolizing sucrose to lactic acid (which causes demineralization of tooth enamel) and by secreting high-molecular-weight glucans that promote aggregation of bacteria and plaque formation.

Enterococci have an antiphagocytic capsule and produce enzymes that cleave host tissues, but they are relatively low-virulence bacteria. The emergence of enterococci as pathogens is primarily due to their resistance to antibiotics, including the broad-spectrum antibiotic vancomycin.

Morphology. Streptococcal infections are characterized by diffuse interstitial neutrophilic infiltrates with minimal destruction of host tissues. The skin lesions caused by streptococci (furuncles, carbuncles, and impetigo) resemble those of staphylococci, although streptococci are less likely to cause the formation of discrete abscesses.

Erysipelas is most common among middle-aged persons in warm climates and is caused by exotoxins from superficial infection with *S. pyogenes*. It is characterized by rapidly spreading erythematous cutaneous swelling that may begin on the face or, less frequently, on the body or an extremity. The rash has a sharp, well-demarcated, serpiginous border and may form a “butterfly” distribution on the face (Fig. 8-20). On histologic examination there is a diffuse, edematous, neutrophilic inflammatory reaction in the dermis and epidermis extending into the subcutaneous tissues. Microabscesses may be formed, but tissue necrosis is usually minor.

Streptococcal pharyngitis, which is the major antecedent of poststreptococcal glomerulonephritis (Chapter 20), is marked by edema, epiglottic swelling, and punctate abscesses of the tonsillar crypts, sometimes accompanied by cervical lymphadenopathy. Swelling associated with severe pharyngeal infection may encroach on the airways, especially if there is peritonsillar or retropharyngeal abscess formation.

Scarlet fever, associated with pharyngitis caused by *S. pyogenes*, is most common between the ages of 3 and 15 years. It is manifested by a punctate erythematous rash that is most prominent over the

trunk and inner aspects of the arms and legs. The face is also involved, but usually a small area about the mouth remains relatively unaffected to produce a circumoral pallor. The inflammation of the skin usually leads to hyperkeratosis and scaling during defervescence.

S. pneumoniae is an important cause of lobar pneumonia (described in Chapter 15 and pictured in Fig. 8-7).

FIGURE 8-20 Streptococcal erysipelas.

Diphtheria

Diphtheria is caused by *Corynebacterium diphtheriae*, a slender gram-positive rod with clubbed ends, that is passed from person to person through aerosols or skin exudate. *C. diphtheriae* may be carried asymptomatically or cause illnesses ranging from skin lesions in neglected wounds of combat troops in the tropics, and a life-threatening syndrome that includes formation of a tough pharyngeal membrane and toxin-mediated damage to the heart, nerves, and other organs. *C. diphtheriae* produces only one toxin, which is a phage-encoded A-B toxin that blocks host cell protein synthesis.[68] The A fragment does this by catalyzing the covalent transfer of adenosine diphosphate (ADP)-ribose to elongation factor-2 (EF-2). This inhibits EF-2 function, which is essential for the translation of mRNA into protein. A single molecule of diphtheria toxin can kill a cell by ADP-ribosylating, and thus inactivating, more than a million EF-2 molecules. Immunization with diphtheria toxoid (formalin-fixed toxin) does not

prevent colonization with *C. diphtheriae* but protects immunized people from the lethal effects of the toxin.

Morphology. Inhaled *C. diphtheriae* proliferate at the site of attachment on the mucosa of the nasopharynx, oropharynx, larynx, or trachea but also form satellite lesions in the esophagus or lower airways. Release of exotoxin causes necrosis of the epithelium, accompanied by an outpouring of a dense fibrinosuppurative exudate. The coagulation of this exudate on the ulcerated necrotic surface creates a tough, dirty gray to black, superficial membrane (Fig. 8-21). Neutrophilic infiltration in the underlying tissues is intense and is accompanied by marked vascular congestion, interstitial edema, and fibrin exudation. When the membrane sloughs off its inflamed and vascularized bed, bleeding and asphyxiation may occur. With control of the infection, the membrane is coughed up or removed by enzymatic digestion, and the inflammatory reaction subsides.

Although the bacterial invasion remains localized, generalized hyperplasia of the spleen and lymph nodes ensues as a result of the entry of soluble exotoxin into the blood. The exotoxin may cause fatty change in the myocardium with isolated myofiber necrosis, polyneuritis with degeneration of the myelin sheaths and axis cylinders, and (less commonly) fatty change and focal necroses of parenchymal cells in the liver, kidneys, and adrenals.

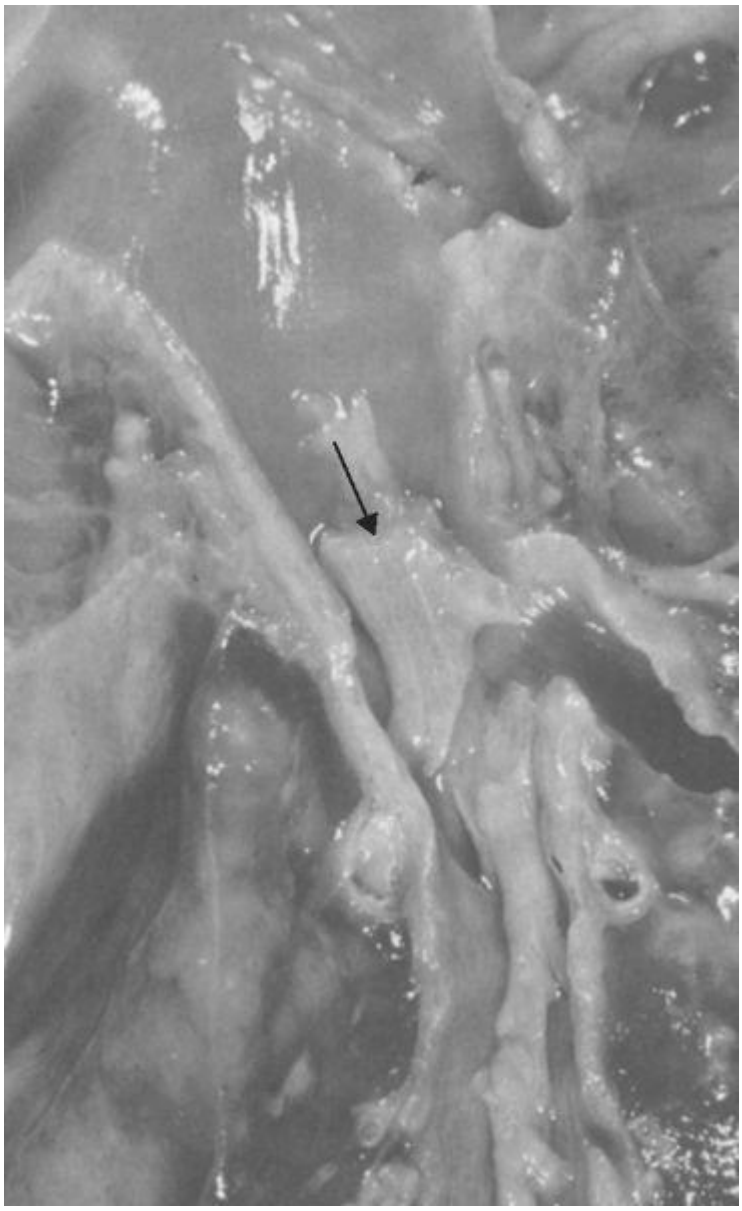

FIGURE 8-21 Membrane of diphtheria *(arrow)* lying within a transverse bronchus.

Listeriosis

Listeria monocytogenes is a gram-positive, facultative intracellular bacillus that causes severe food-borne infections. Mini-epidemics of *L. monocytogenes* infection have been linked to dairy products, chicken, and hot dogs. Pregnant women, their neonates, the elderly, and immunosuppressed persons (e.g., transplant recipients or AIDS patients) are particularly susceptible to severe *L. monocytogenes* infection. In pregnant women (and pregnant sheep and cattle), *L. monocytogenes* causes an amnionitis that may result in abortion, stillbirth, or neonatal sepsis. In neonates, *L. monocytogenes* may cause disseminated disease (granulomatosis infantiseptica) and an exudative meningitis, both of which are also seen in immunosuppressed adults.

Listeria monocytogenes has leucine-rich proteins on its surface called *internalins*, which bind to E-cadherin on host epithelial cells and induce internalization of the bacterium.[69] Inside the cell, the bacteria escape from the membrane-bound phagolysosome by the action of a pore-forming protein, listeriolysin O, and two phospholipases.[22] In the host cell cytoplasm, ACTA, a bacterial surface protein, binds to host cell cytoskeletal proteins and induces actin polymerization, which propels the bacteria into adjacent, uninfected host cells. Resting macrophages, which internalize *L. monocytogenes* through C3 activated on the bacterial surface, fail to kill the bacteria. In contrast, macrophages that are activated by IFN-γ phagocytose and kill the bacteria. Hence protection against *L. monocytogenes* is mediated largely by IFN-γ produced by NK cells and T cells.

Morphology. In acute human infections, *L. monocytogenes* evokes an exudative pattern of inflammation with numerous neutrophils. The meningitis it causes is macroscopically and microscopically indistinguishable from that caused by other pyogenic bacteria (Chapter 28). The finding of gram-positive, mostly intracellular, bacilli in the CSF is virtually diagnostic. More varied lesions may be encountered in neonates and immunosuppressed adults. Focal abscesses alternate with grayish or yellow nodules representing necrotic amorphous basophilic tissue debris. These can occur in any organ, including the lung, liver, spleen, and lymph nodes. In infections of longer duration, macrophages appear in large numbers, but granulomas are rare. Infants born with *L. monocytogenes* sepsis often have a papular red rash over the extremities, and listerial abscesses can be seen in the placenta. A smear of the meconium will disclose the gram-positive organisms.

Anthrax

Bacillus anthracis is a large, spore-forming gram-positive rod-shaped bacterium. These bacteria are common pathogens in farm and wild animals that have contact with soil contaminated with *B. anthracis* spores. Anthrax spores can be ground to a fine powder, making a potent biologic weapon. There are between 20,000 and 100,000 cases of anthrax each year, and recent use of the microbe as an agent of bioterrorism has heightened concern about this organism. In 1979, accidental release of *B. anthracis* spores at a military research institute in Russia killed 66 people. In 2001, 22 people in the United States were infected with *B. anthracis*, mostly through spores delivered in the mail.

B. anthracis is typically acquired through exposure to animals or animal products such as wool or hides.[70] There are three major anthrax syndromes.

- *Cutaneous anthrax*, which makes up 95% of naturally occurring infections, begins as a painless, pruritic papule that develops into a vesicle within 2 days. As the vesicle enlarges, striking edema may form around it, and regional lymphadenopathy develops. After the vesicle ruptures, the remaining ulcer becomes covered with a characteristic black eschar, which dries and falls off as the person recovers. Bacteremia is rare with cutaneous anthrax.
- *Inhalational anthrax* occurs when spores are inhaled. The organism is carried by phagocytes to lymph nodes where the spores germinate, and the release of toxins causes hemorrhagic mediastinitis. After a prodromal illness of 1 to 6 days characterized by fever, cough, and chest or abdominal pain, there is abrupt onset of increased fever, hypoxia, and sweating. Frequently, anthrax meningitis develops from bacteremia. Inhalational anthrax rapidly leads to shock and frequently death within 1 to 2 days.
- *Gastrointestinal anthrax* is an uncommon form of this infection that is usually contracted by eating undercooked meat contaminated with *B. anthracis*. Initially, the person has nausea, abdominal pain, and vomiting, followed by severe, bloody diarrhea. Mortality is over 50%.

Pathogenesis.

Bacillus anthracis produces potent toxins and a polyglutamyl capsule that is antiphagocytic. The mode of action of anthrax toxin is well understood[85] (Fig. 8-22). It has A and B subunits. The B subunit is

also referred to as the *protective antigen*, because antibodies against this protein protect animals against the toxin. The protective antigen binds to a cell-surface protein, and then a host protease clips off a 20-kD fragment of the B subunit. The remaining 63-kD fragment self-associates to form a heptamer. Anthrax toxin has two alternate A subunits: edema factor (EF) and lethal factor (LF), each named for the effect of the toxin in experimental animals. Three A subunits bind to the B heptamer, and this complex is endocytosed into the host cell. The low pH of the endosome causes a conformational change in the B heptamer, which then forms a selective channel in the endosome membrane through which EF and LF move into the cytoplasm. In the cytoplasm, EF binds to calcium and calmodulin to form an adenylate cyclase. The active EF converts ATP to cyclic adenosine monophosphate (cAMP), an important signaling molecule that stimulates efflux of water from the cell, leading to interstitial edema. LF has a different mechanism of action. LF is a protease that destroys mitogen-activated protein kinase kinases (MAPKKs). These kinases regulate the activity of MAPKs, which are important regulators of cell growth and differentiation (Chapter 3). The mechanism of cell death due to dysregulation of MAPKs is not understood.

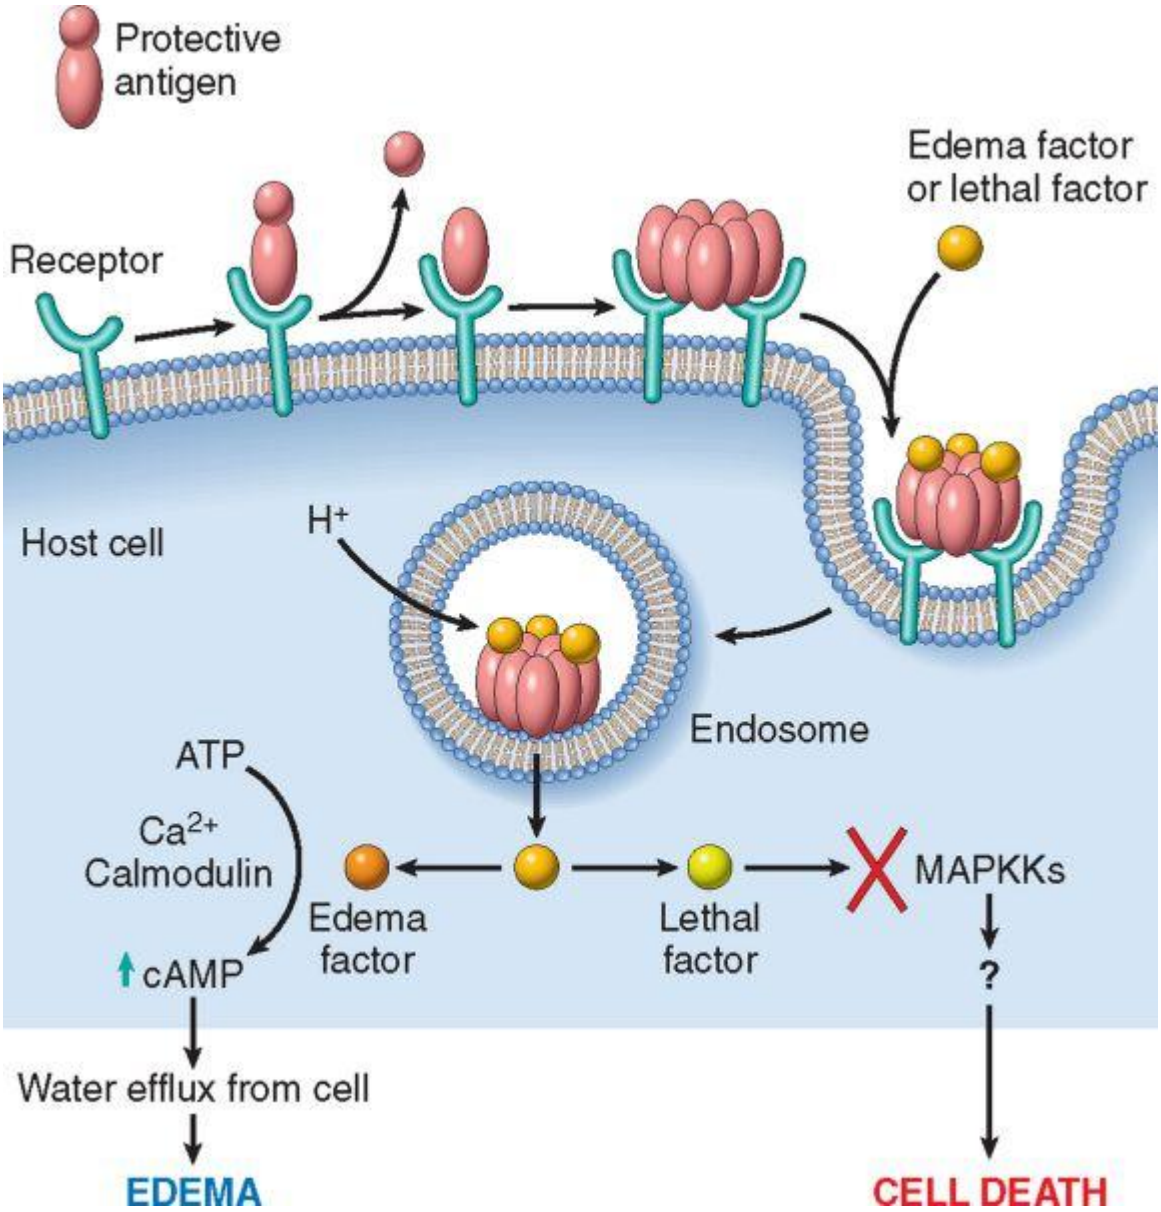

FIGURE 8-22 Mechanism of action of anthrax toxins. *(Adapted from Mourez M et al.: 2001: a year of major advances in anthrax toxin*

research. Trends Microbiol 10:287, 2002.)

Morphology. Anthrax lesions at any site are typified by necrosis and exudative inflammation with infiltration of neutrophils and macrophages. The presence of large, boxcar-shaped gram-positive extracellular bacteria in chains, seen histopathologically or recovered in culture, should suggest the diagnosis.

Inhalational anthrax causes numerous foci of hemorrhage in the mediastinum with hemorrhagic, enlarged hilar and peribronchial lymph nodes.[72] Microscopic examination of the lungs typically shows a perihilar interstitial pneumonia with infiltration of macrophages and neutrophils and pulmonary vasculitis. Hemorrhagic lesions associated with vasculitis are also present in about half of cases. Mediastinal lymph nodes show lymphocytosis, macrophages with phagocytosed apoptotic lymphocytes, and a fibrin-rich edema (Fig. 8-23). *B. anthracis* is present predominantly in the alveolar capillaries and venules and, to a lesser degree, within the alveolar space. In fatal cases, *B. anthracis* is evident in multiple organs (spleen, liver, intestines, kidneys, adrenal glands, and meninges).

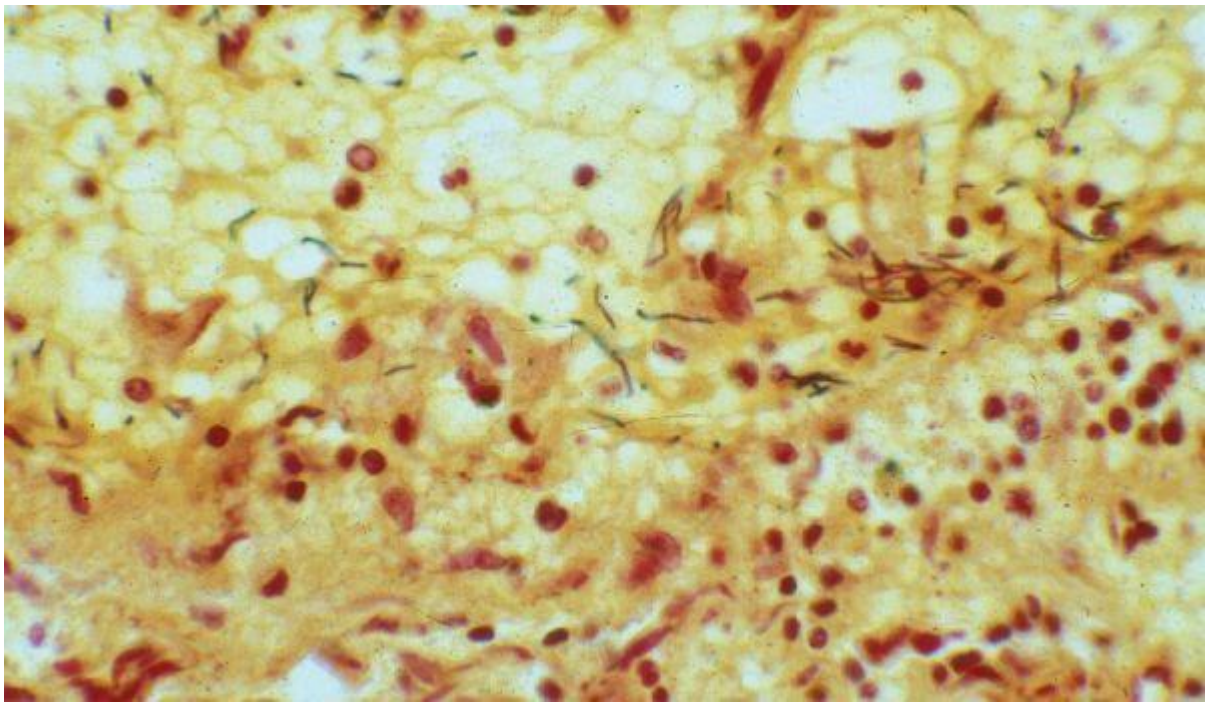

FIGURE 8-23 *Bacillus anthracis* in the subcapsular sinus of a hilar lymph node of a patient who died of inhalational anthrax. *(Courtesy of Dr. Lev Grinberg, Department of Pathology, Hospital 40, Ekaterinburg, Russia and Dr. David Walker, UTMB Center for Biodefense and Emerging Infectious Diseases, Galveston, TX.)*

Nocardia

Nocardia are aerobic gram-positive bacteria that grow in distinctive branched chains. In culture, *Nocardia* form thin aerial filaments resembling hyphae. Despite this morphologic similarity to molds, *Nocardia* are true bacteria.

Nocardia are found in soil and cause opportunistic infections in immunocompromised people.[73] *Nocardia asteroides* causes respiratory infections, while other species, mainly *Nocardia brasiliensis*, infect the skin. A fifth of *N. asteroides* infections involve the CNS, presumably after dissemination from the lungs. Most patients with *N. asteroides* have defects in T cell–mediated immunity, often due to prolonged steroid use or HIV infection, or diabetes mellitus. Respiratory infection with *N. asteroides* causes an indolent illness with fever, weight loss, and cough, which may be mistaken for tuberculosis or malignancy. CNS infections with *N. asteroides* are also indolent and cause varying neurologic deficits depending on the site of the infection. Skin infections have a range of manifestations, from rapidly progressive infections resembling those of *Staphylococcus* or *Streptococcus* to slowly progressive lesions.

Morphology. *Nocardia* appear in tissue as slender gram-positive organisms arranged in branching filaments (Fig. 8-24). Irregular staining gives the filaments a beaded appearance. *Nocardia* stain with modified acid-fast stains (Fite-Faraco stain), unlike *Actinomyces*, which may appear similar on Gram stain of tissue. At any site of infection, *Nocardia* elicit a suppurative response with central liquefaction and surrounding granulation and fibrosis. Granulomas do not form.

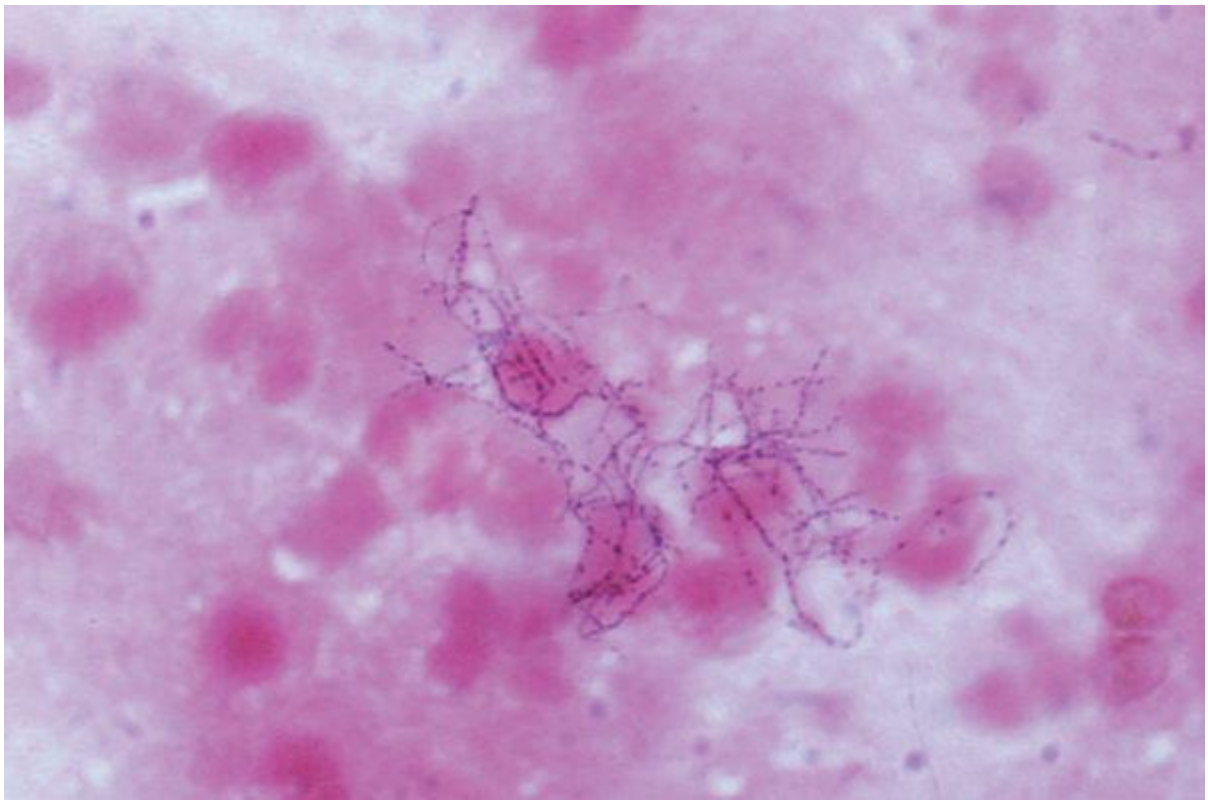

FIGURE 8-24 *Nocardia asteroides* in a Gram-stained sputum sample. Note the beaded, branched gram-positive organisms and leukocytes. *(Courtesy of Dr. Ellen Jo Baron, Stanford University Medical Center, Stanford, CA.)*

GRAM-NEGATIVE BACTERIAL INFECTIONS

Only a few gram-negative bacteria are considered in this section. A number of important gram-negative pathogens are discussed in the appropriate chapters of organ systems, including bacterial causes of gastrointestinal infections and urinary tract infections. Anaerobic gram-negative organisms are considered later in this chapter. Gram-negative bacterial infections are usually diagnosed by culture.

Neisserial Infections

Neisseria are gram-negative diplococci that are flattened on the adjoining sides, giving the pair the shape of a coffee bean (see Fig. 8-3E). These aerobic bacteria have stringent nutritional requirements and grow best on enriched media such as lysed sheep's blood agar (“chocolate” agar). The two clinically significant *Neisseria* are *N. meningitidis* and *N. gonorrhoeae*.

N. meningitidis is a significant cause of bacterial meningitis, particularly among children younger than 2 years of age. The organism is a common colonizer of the oropharynx and is spread by the respiratory route. Approximately 10% of the population is colonized at any one time, and each episode of colonization lasts, on average, for several months. An immune response leads to elimination of the organism in most people, and this response is protective against subsequent disease with the same serotype of bacteria. There are at least 13 serotypes of *N. meningitidis*. Invasive disease mainly occurs when people encounter new strains to which they are not immune, as may happen to young children or young adults living in crowded quarters such as military barracks or college dormitories. *N. meningitidis* disease is endemic in the United States, but epidemics occur periodically in sub-Saharan Africa and cause thousands of deaths.[74]

Even in the absence of pre-existing immunity, only a small fraction of people infected with *N. meningitidis* develop meningitis. The bacteria must invade respiratory epithelial cells and travel to the basolateral side of the cells to enter the blood.[75] In the blood, the capsule of the bacteria inhibits opsonization and destruction of the bacteria by complement proteins. Despite this, the importance of complement as a first-line defense against *N. meningitidis* is shown by the increased rates of serious infection among people who have inherited defects in the complement proteins (C5 to C9) that form the membrane attack complex. If *N. meningitidis* escapes the host response, the consequences can be severe. Although antibiotic treatment of meningitis has greatly reduced mortality of *N. meningitidis* infection, the death rate is still about 10%. The pathology of pyogenic meningitides is discussed in Chapter 28 .

N. gonorrhoeae is an important cause of sexually transmitted disease (STD), infecting about 700,000 people each year in the United States. It is second only to *C. trachomatis* as a bacterial causative agent of STDs. Infection in men causes urethritis. In women, *N. gonorrhoeae* infection is often asymptomatic and so may go unnoticed. Untreated infection can lead to pelvic inflammatory disease, which can cause infertility or ectopic pregnancy (Chapter 22). Infection is diagnosed by PCR tests, in addition to culture.

Although *N. gonorrhoeae* infection usually manifests locally in the genital or cervical mucosa, pharynx, or anorectum, disseminated infections may occur. Like *N. meningitidis*, *N. gonorrhoeae* is much more likely to become disseminated in people who lack the complement proteins that form the membrane attack complex. Disseminated infection of adults and adolescents usually causes septic arthritis accompanied by a rash of hemorrhagic papules and pustules. Neonatal *N. gonorrhoeae* infection causes blindness and, rarely, sepsis. The eye infection, which is preventable by instillation of silver nitrate or antibiotics in the newborn's eyes, remains an important cause of blindness in some developing nations.

Pathogenesis.

Neisseria use antigenic variation as a strategy to escape the immune response. The existence of multiple serotypes of *N. meningitidis* results in meningitis in some people on exposure to a new strain, as discussed above. In addition, *Neisseria* species also generate antigenic variation by special genetic mechanisms, which permit a single bacterial clone to change its expressed antigens (see below) and escape immune defenses.[19] *Neisseria* organisms adhere to and invade nonciliated epithelial cells at the site of entry (nasopharynx, urethra, or cervix). Two surface proteins of *Neisseria*, both of which bind the bacteria to host cells, undergo antigenic variation through different mechanisms. Although both *N. meningitidis* and *N. gonorrhoeae* use these mechanisms, they seem to be more important in *N. gonorrhoeae*.

- Pili proteins are altered by *genetic recombination*. Adherence of *N. gonorrhoeae* to epithelial cells is initially mediated by long pili, which bind to CD46, a complement-regulatory protein expressed on all human nucleated cells. The pili are composed of polypeptides encoded by the pili gene, which consists of a promoter and coding sequences for 10–15 pili protein variants. At any point in time, only one of these coding sequences is juxtaposed to the promoter, allowing it to be expressed. Periodically, homologous recombination shuttles one of the other coding sequences next to the promoter, resulting in expression of a different pili variant. Sometimes, only part of the second coding sequence is swapped, creating an entirely new chimeric variant.
- *N. gonorrhoeae* has three or four genes for OPA proteins, and *N. meningitidis* has up to 12. OPA proteins (so named because they make bacterial colonies opaque) are located in the outer membrane of the bacteria. They increase binding of *Neisseria* organisms to epithelial cells and promote entry of bacteria into cells. Each *OPA* gene has several repeats of a five-nucleotide sequence, which are frequently deleted or duplicated. These changes shift the reading frame of the gene so that it encodes new sequences. Stop codons are also introduced by the additions and deletions, which determine whether each *OPA* gene is expressed or silent. This allows *N. gonorrhoeae* to express none, one, or several *OPA* genes at a time.

Whooping Cough

Whooping cough, caused by the gram-negative coccobacillus *Bordetella pertussis*, is an acute, highly communicable illness characterized by paroxysms of violent coughing followed by a loud inspiratory "whoop." *B. pertussis* vaccination, whether with killed bacteria or the newer acellular vaccine, has been effective in preventing whooping cough. Since the 1980s, however, rates of pertussis have been increasing in the United States particularly in adolescents and adults, despite continued high rates of vaccination.[76] The cause of this increase is not known, but antigenic divergence of clinical strains from vaccine strains and waning immunity in young adults may play a role. In parts of the developing world, where vaccination is not widely practiced, pertussis kills hundreds of thousands of children each year. The diagnosis is best made by PCR, because culture is less sensitive.

Pathogenesis.

Bordetella pertussis colonizes the brush border of the bronchial epithelium and also invades macrophages. Coordinated expression of virulence factors is regulated by the *Bordetella* virulence gene locus *(bvg)*.[77] BVGS is a transmembrane protein that "senses" signals that induce expression of virulence factors. On activation, BVGS phosphorylates the protein BVGA, which regulates transcription of mRNA for adhesins and toxins. The filamentous hemagglutinin adhesin binds to carbohydrates on the surface of respiratory epithelial cells, as well as to CR3 (Mac-1) integrins on macrophages. Pertussis toxin is an exotoxin composed of five distinct proteins, including a catalytic peptide S1 that shows homology with the catalytic peptides of cholera toxin and *E. coli* heat-labile toxin.[78] Like cholera toxin, pertussis toxin ADP-ribosylates and inactivates guanine nucleotide–binding proteins, so these G proteins no longer transduce signals from host plasma membrane receptors. The toxin produced by *B. pertussis* paralyzes the cilia, thus impairing an important pulmonary defense.

Morphology. *Bordetella* bacteria cause a laryngotracheobronchitis that in severe cases features

bronchial mucosal erosion, hyperemia, and copious mucopurulent exudate (Fig. 8-25). Unless superinfected, the lung alveoli remain open and intact. In parallel with a striking peripheral lymphocytosis (up to 90%), there is hypercellularity and enlargement of the mucosal lymph follicles and peribronchial lymph nodes.

FIGURE 8-25 Whooping cough showing a haze of bacilli *(arrows)* entangled with the cilia of bronchial epithelial cells.

Pseudomonas Infection

Pseudomonas aeruginosa is an opportunistic aerobic gram-negative bacillus that is a frequent, deadly pathogen of people with cystic fibrosis, severe burns, or neutropenia.[93] Many people with cystic fibrosis die of pulmonary failure secondary to chronic infection with *P. aeruginosa*. *P. aeruginosa* can be very resistant to antibiotics, making these infections difficult to treat. *P. aeruginosa* often infects extensive skin burns, which can be a source of sepsis. *P. aeruginosa* is a common cause of hospital-acquired infections; it has been cultured from washbasins, respirator tubing, nursery cribs, and even antiseptic-containing bottles. *P. aeruginosa* also causes corneal keratitis in wearers of contact lenses, endocarditis and osteomyelitis in intravenous drug abusers, external otitis (swimmer's ear) in healthy individuals, and severe external otitis in diabetics.

Pathogenesis.

P. aeruginosa has pili and adherence proteins that bind to epithelial cells and lung mucin, and expresses an endotoxin that causes the symptoms and signs of gram-negative sepsis. *Pseudomonas* also has a number of distinctive virulence factors. In the lungs of people with cystic fibrosis, these bacteria secrete a mucoid exopolysaccharide called *alginate*, forming a slimy biofilm that protects bacteria from antibodies, complement, phagocytes, and antibiotics. The organisms also secrete an exotoxin and

several other virulence factors. Exotoxin A, like diphtheria toxin, inhibits protein synthesis by ADP-ribosylating the ribosomal protein EF-2.[80] *P. aeruginosa* also releases exoenzyme S, which ADPribosylates RAS and other G proteins that regulate cell growth and metabolism. The organisms also secrete a phospholipase C that lyses red cells and degrades pulmonary surfactant, and an elastase that degrades IgGs and extracellular matrix proteins. These enzymes may be important in tissue invasion and destruction of the cornea in keratitis. Finally, *P. aeruginosa* produces iron-containing compounds that are extremely toxic to endothelial cells and so may cause the vascular lesions that are characteristic of this infection.[81]

Morphology. *Pseudomonas* causes a **necrotizing pneumonia** that is distributed through the terminal airways in a fleur-de-lis pattern, with striking pale necrotic centers and red, hemorrhagic peripheral areas. On microscopic examination, masses of organisms cloud the tissue with a bluish haze, concentrating in the walls of blood vessels, where host cells undergo coagulative necrosis (Fig. 8-26). This picture of gram-negative vasculitis accompanied by thrombosis and hemorrhage, although not pathognomonic, is highly suggestive of *P. aeruginosa* infection.

Bronchial obstruction caused by mucus plugging and subsequent *P. aeruginosa* infection are frequent complications of cystic fibrosis. Despite antibiotic treatment and the host immune response, chronic *P. aeruginosa* infection may result in bronchiectasis and pulmonary fibrosis (Chapter 15).

In skin burns, *P. aeruginosa* proliferates widely, penetrating deeply into the veins and spreading hematogenously. Well-demarcated necrotic and hemorrhagic oval skin lesions, called **ecthyma gangrenosum**, often appear. Disseminated intravascular coagulation (DIC) is a frequent complication of bacteremia.

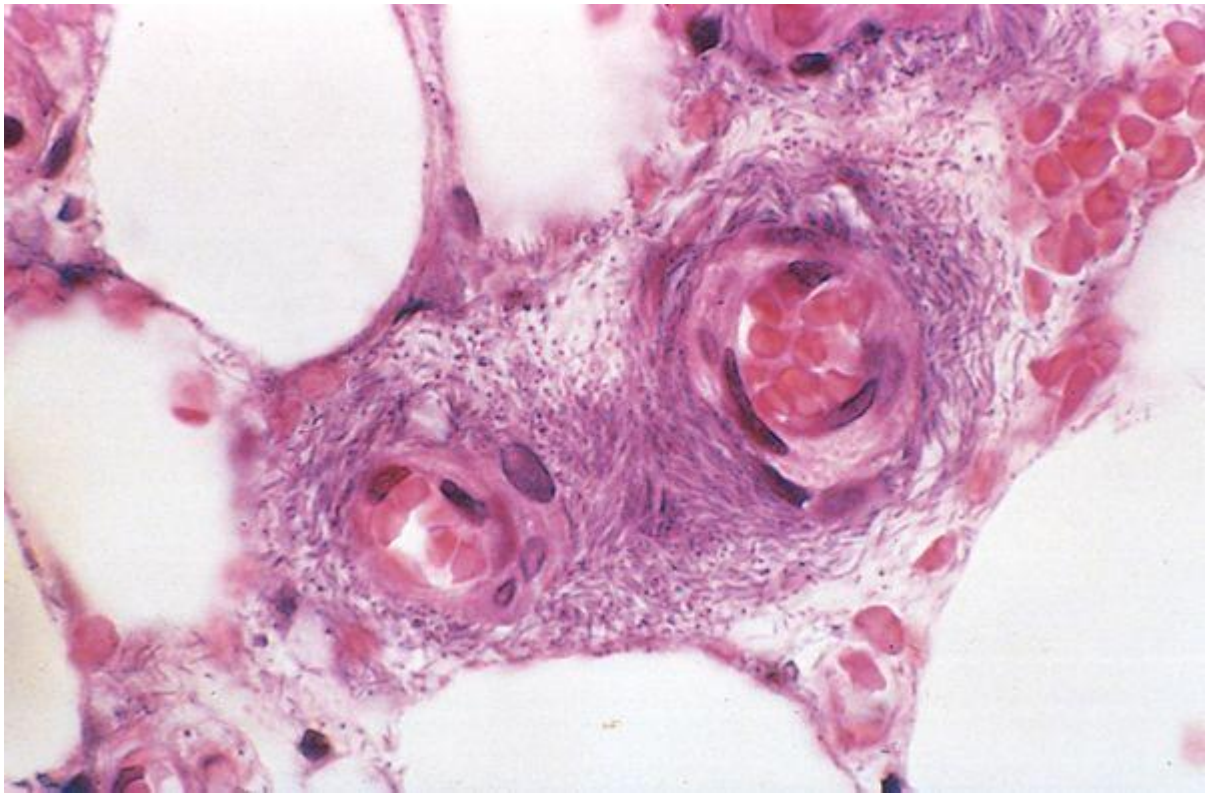

FIGURE 8-26 *Pseudomonas* vasculitis in which masses of organisms form a perivascular blue haze.

Plague

Yersinia pestis is a gram-negative facultative intracellular bacterium that is transmitted from rodents to humans by fleabites or, less often, from one human to another by aerosols. It causes an invasive, frequently fatal infection called *plague*. Plague, also named Black Death, caused three great pandemics that killed an estimated 100 million people in Egypt and Byzantium in the sixth century; one quarter of Europe's population in the fourteenth and fifteenth centuries; and tens of millions in India, Myanmar, and China at the beginning of the twentieth century. Currently, 1000 to 3000 cases of plague occur each year worldwide. Wild rodents in the rural western United States are infected with *Y. pestis*, and 10 to 15 human cases occur per year. *Y. enterocolitica* and *Y. pseudotuberculosis* are genetically similar to *Y. pestis*; these bacteria cause fecal-orally transmitted ileitis and mesenteric lymphadenitis.

Pathogenic *Yersinia* proliferate within lymphoid tissue. These organisms have a complex of genes, called the Yop virulon, which enable the bacteria to kill host phagocytes.[82] The Yop virulon encodes proteins that assemble into a type III secretion system, which is a hollow syringe-like structure that projects from the bacterial surface, binds to host cells, and injects bacterial toxins, called Yops (Yersinia outercoat proteins), into the cell. YopE, YopH, and YopT block phagocytosis by inactivating molecules that regulate actin polymerization. YopJ inhibits the signaling pathways that are activated by LPS, blocking the production of inflammatory cytokines. *Y. pestis* ensures its own spread by forming a biofilm that obstructs the gut of the infected flea. The flea must regurgitate before it feeds, and thus infects the rodent or human that it is biting.

Morphology. *Yersinia pestis* causes lymph node enlargement (buboes), pneumonia, or sepsis with a striking neutrophilia. The distinctive histologic features include (1) massive proliferation of the organisms, (2) early appearance of protein-rich and polysaccharide-rich effusions with few inflammatory cells but with marked tissue swelling, (3) necrosis of tissues and blood vessels with hemorrhage and thrombosis, and (4) neutrophilic infiltrates that accumulate adjacent to necrotic areas as healing begins.

In **bubonic plague** the infected fleabite is usually on the legs and is marked by a small pustule or ulcer. The draining lymph nodes enlarge dramatically within a few days and become soft, pulpy, and plum colored, and may infarct or rupture through the skin. In **pneumonic plague** there is a severe, confluent, hemorrhagic and necrotizing bronchopneumonia, often with fibrinous pleuritis. In **septicemic plague** lymph nodes throughout the body as well as organs rich in mononuclear phagocytes develop foci of necrosis. Fulminant bacteremias also induce DIC with widespread hemorrhages and thrombi.

Chancroid (Soft Chancre)

Chancroid is an acute, sexually transmitted, ulcerative infection caused by *Hemophilus ducreyi*.[83] The disease is most common in tropical and subtropical areas among lower socioeconomic groups and men who have regular contact with prostitutes. *Chancroid is one of the most common causes of genital ulcers in Africa and Southeast Asia*, where it probably serves as an important cofactor in the transmission of HIV infection. Chancroid is uncommon in the United States, with 20 to 50 cases per

year reported to the CDC in the past several years. The organism must be cultured in special conditions and PCR-based tests are not widely available, so chancroid may be underdiagnosed.

Morphology. Four to seven days after inoculation the person develops a tender, erythematous papule involving the external genitalia. In males the primary lesion is usually on the penis; in females most lesions occur in the vagina or the periurethral area. Over the course of several days the surface of the primary lesion erodes to produce an irregular ulcer, which is more apt to be painful in males than in females. In contrast to the primary chancre of syphilis, the ulcer of chancroid is not indurated, and multiple lesions may be present. The base of the ulcer is covered by shaggy, yellow-gray exudate. The regional lymph nodes, particularly in the inguinal region, become enlarged and tender in about 50% of cases within 1 to 2 weeks of the primary inoculation. In untreated cases the inflamed and enlarged nodes (buboes) may erode the overlying skin to produce chronic, draining ulcers.

Microscopically, the ulcer of chancroid contains a superficial zone of neutrophilic debris and fibrin, with an underlying zone of granulation tissue containing areas of necrosis and thrombosed vessels. A dense, lymphoplasmacytic inflammatory infiltrate is present beneath the layer of granulation tissue. Coccobacilli are sometimes demonstrable in Gram or silver stains, but they are often obscured by other bacteria that colonize the ulcer base.

Granuloma Inguinale

Granuloma inguinale, or donovanosis, is a chronic inflammatory disease caused by *Klebsiella granulomatis* (formerly called *Calymmatobacterium donovani*), a minute, encapsulated, coccobacillus. The organism is sexually transmitted. Granuloma inguinale is uncommon in the United States and western Europe but is endemic in rural areas in certain tropical and subtropical regions. Untreated cases are characterized by the development of extensive scarring, often associated with lymphatic obstruction and lymphedema (elephantiasis) of the external genitalia. Culture of the organism is difficult, and PCR assays are still in development, so the diagnosis is made by microscopic examination of smears or biopsy samples of the ulcer.

Morphology. Granuloma inguinale begins as a raised, papular lesion on the moist, stratified squamous epithelium of the genitalia or, rarely, the oral mucosa or pharynx. The lesion eventually ulcerates and develops abundant granulation tissue, which is manifested grossly as a protuberant, soft, painless mass. As the lesion enlarges, its borders become raised and indurated. Disfiguring scars may develop in untreated cases and are sometimes associated with urethral, vulvar, or anal strictures. Regional lymph nodes typically are spared or show only nonspecific reactive changes, in contrast to chancroid.

Microscopic examination of active lesions reveals marked epithelial hyperplasia at the borders of the ulcer, sometimes mimicking carcinoma **(pseudoepitheliomatous hyperplasia)**. A mixture of neutrophils and mononuclear inflammatory cells is present at the base of the ulcer and beneath the surrounding epithelium. The organisms are demonstrable in Giemsa-stained smears of the exudate as minute, encapsulated coccobacilli (Donovan bodies) in macrophages. Silver stains (e.g., the Warthin-Starry stain) may also be used to demonstrate the organism.

MYCOBACTERIA

Bacteria in the genus *Mycobacterium* are slender, aerobic rods that grow in straight or branching chains. Mycobacteria have a unique waxy cell wall composed of mycolic acid, which makes them *acid fast*,

meaning they will retain stains even on treatment with a mixture of acid and alcohol. Mycobacteria are weakly Gram positive.

Tuberculosis

Mycobacterium tuberculosis is responsible for most cases of tuberculosis; the reservoir of infection is humans with active tuberculosis. Oropharyngeal and intestinal tuberculosis contracted by drinking milk contaminated with *M. bovis* is rare in countries where milk is routinely pasteurized, but it is still seen in countries that have tuberculous dairy cows and unpasteurized milk.

Epidemiology.

Tuberculosis is estimated to affect 1.7 billion individuals worldwide, with 8 to 10 million new cases and 1.6 million deaths each year, a toll second only to HIV disease. Infection with HIV makes people susceptible to rapidly progressive tuberculosis; over 10 million people are infected with both HIV and *M. tuberculosis*. From 1985 to 1992, the number of tuberculosis cases in the United States rose by 20% because of increase in the disease in people with HIV, immigrants, and those in jail or homeless shelters. Because of public health efforts, the number of cases of tuberculosis has declined since 1993. Currently, there are about 14,000 new cases of active tuberculosis in the United States annually, about half of which occur in foreign-born people.

Tuberculosis flourishes wherever there is poverty, crowding, and chronic debilitating illness. In the United States tuberculosis is mainly a disease of the elderly, the urban poor, and people with AIDS. *Certain disease states also increase the risk*: diabetes mellitus, Hodgkin lymphoma, chronic lung disease (particularly silicosis), chronic renal failure, malnutrition, alcoholism, and immunosuppression.

It is important that *infection* with *M. tuberculosis* be differentiated from *disease*. Infection is the presence of organisms, which may or may not cause clinically significant disease. Most infections are acquired by person-to-person transmission of airborne organisms from an active case to a susceptible host. In most people primary tuberculosis is asymptomatic, although it may cause fever and pleural effusion. Generally, the only evidence of infection, if any remains, is a tiny, fibrocalcific nodule at the site of the infection. Viable organisms may remain dormant in such lesions for decades. If immune defenses are lowered, the infection may reactivate to produce communicable and potentially life-threatening disease.

Infection typically leads to the development of delayed hypersensitivity to *M. tuberculosis* antigens, which can be detected by the tuberculin (Mantoux) skin test. About 2 to 4 weeks after infection, intracutaneous injection of purified protein derivative of *M. tuberculosis* induces a visible and palpable induration that peaks in 48 to 72 hours. *A positive tuberculin test result signifies T cell–mediated immunity to mycobacterial antigens*. It does not differentiate between infection and disease. False-negative reactions may occur in the setting of certain viral infections, sarcoidosis, malnutrition, Hodgkin lymphoma, immunosuppression, and (notably) overwhelming active tuberculous disease. False-positive reactions may result from infection by atypical mycobacteria or prior vaccination with BCG (*Bacillus Calmette-Guerin*), an attenuated strain of *M. bovis* that is used as a vaccine in some countries.

Pathogenesis.

The pathogenesis of tuberculosis in a previously unexposed, immunocompetent person depends on the development of anti-mycobacterial cell-mediated immunity, which confers resistance to the bacteria and also results in development of hypersensitivity to mycobacterial antigens. The pathologic manifestations of tuberculosis, such as caseating granulomas and cavitation, are the result of the hypersensitivity that develops in concert with the protective host immune response. Because the effector cells that mediate

immune protection also mediate hypersensitivity and tissue destruction, the appearance of hypersensitivity also signals the acquisition of immunity to the organism. A summary of the pathogenesis of tuberculosis is shown in Figure 8-27 .

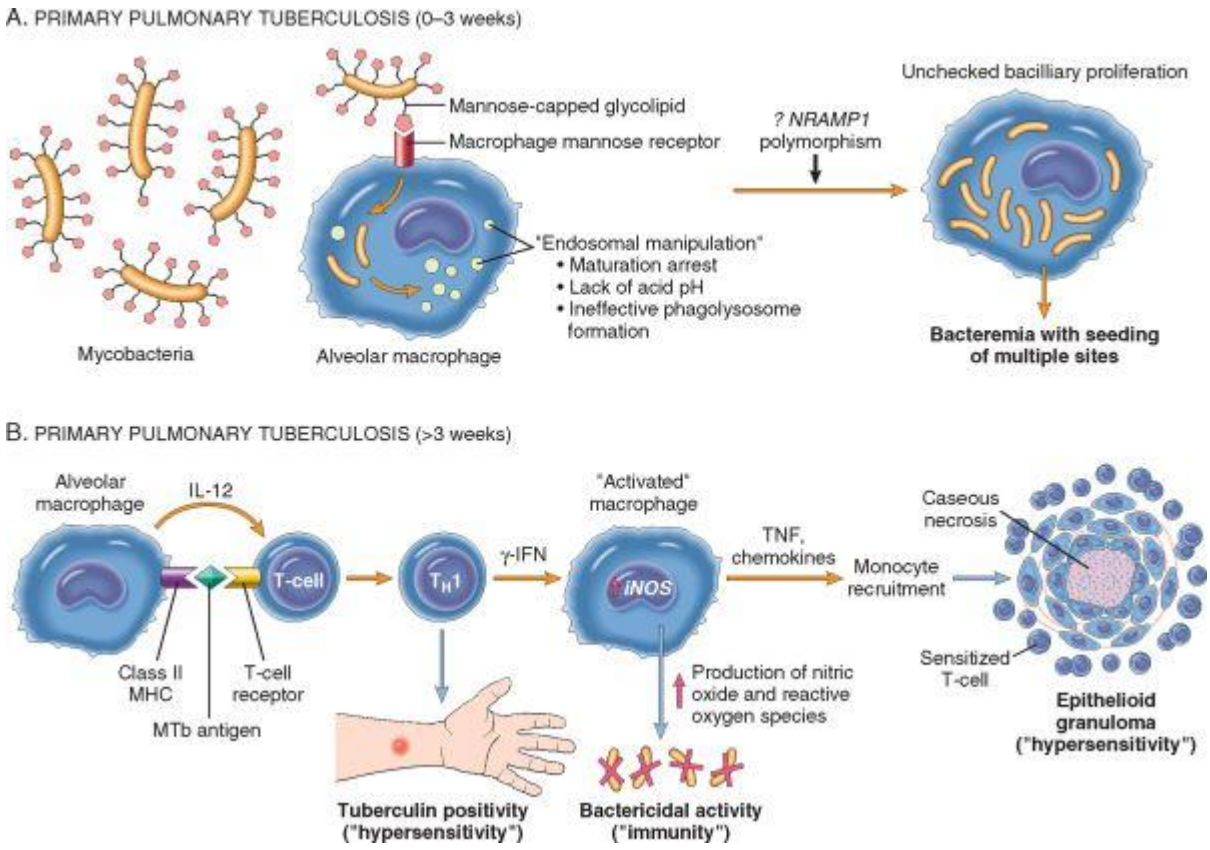

FIGURE 8-27 The sequence of events in primary pulmonary tuberculosis, commencing with inhalation of virulent *Mycobacterium tuberculosis* organisms and culminating with the development of cell-mediated immunity to the organism. **A**, Events occurring in the first 3 weeks after exposure. **B**, Events thereafter. The development of resistance to the organism is accompanied by the appearance of a positive tuberculin test. γ-IFN, interferon-γ; iNOS, inducible nitric oxide synthase; MHC, major histocompatibility complex; MTB, *M. tuberculosis*; NRAMP1, natural resistance–associated macrophage protein; TNF, tumor necrosis factor.

Macrophages are the primary cells infected by *M. tuberculosis*. Early in infection, tuberculosis bacilli replicate essentially unchecked, while later in infection, the cell response stimulates macrophages to contain the proliferation of the bacteria.

- *M. tuberculosis* enters macrophages by endocytosis mediated by several macrophage receptors: mannose receptors bind lipoarabinomannan, a glycolipid in the bacterial cell wall, and complement receptors (already discussed) bind opsonized mycobacteria.[23]
- Once inside the macrophage, *M. tuberculosis* organisms replicate within the phagosome by blocking fusion of the phagosome and lysosome. *M. tuberculosis* blocks phagolysosome formation by inhbiting Ca^{2+} signals and the recruitment and assembly of the proteins that mediate phagosome-lysosome fusion.[84] Thus, during the earliest stage of primary tuberculosis (<3 weeks) in the nonsensitized individual, bacteria proliferate in the pulmonary alveolar macrophages and airspaces, resulting in bacteremia and seeding of multiple sites. *Despite the bacteremia, most people at this stage are asymptomatic or have a mild flulike illness*.
- The genetic makeup of the host may influence the course of the disease. In some people with polymorphisms in the *NRAMP1* gene, the disease may progress due to the absence of an effective immune

response. NRAMP1 is a transmembrane protein found in endosomes and lysosomes that pumps divalent cations (e.g. Fe^{2+}) out of the lysosome. NRAMP1 may inhibit microbial growth by limiting availability of ions needed by the bacteria.[85]

- About 3 weeks after infection, a T-helper 1 (T_H1) response is mounted that activates macrophages to become bactericidal.[86] The response is initiated by mycobacterial antigens that enter draining lymph nodes and are displayed to T cells. Differentiation of T_H1 cells depends on IL-12, which is produced by antigen-presenting cells that have encountered the mycobacteria. *M. tuberculosis* makes several molecules that are ligands for TLR2, and stimulation of TLR2 by these ligands promotes production of IL-12 by dendritic cells.
- Mature T_H1 cells, both in lymph nodes and in the lung, produce IFN-γ. *INF-γ is the critical mediator that enables macrophages to contain the M. tuberculosis infection*. IFN-γ stimulates formation of the phagolysosome in infected macrophages, exposing the bacteria to an inhospitable acidic environment. IFN-γ also stimulates expression of inducible nitric oxide synthase, which produces nitric oxide, capable of destroying several mycobacterial constituents, from cell wall to DNA.
- In addition to stimulating macrophages to kill mycobacteria, the T_H1 response orchestrates the formation of granulomas and caseous necrosis. Macrophages activated by IFN-γ differentiate into the “epithelioid histiocytes” that characterize the granulomatous response, and may fuse to form giant cells. In many people this response halts the infection before significant tissue destruction or illness. In other people the infection progresses due to advanced age or immunosuppression, and the ongoing immune response results in tissue destruction due to caseation and cavitation. Activated macrophages also secrete TNF, which promotes recruitment of more monocytes. The importance of TNF is underscored by the fact that patients with rheumatoid arthritis who are treated with a TNF antagonist have an increased risk of tuberculosis reactivation.
- In addition to the T_H1 response, NK-T cells that recognize mycobacterial lipid antigens bound to CD1 on antigen-presenting cells, or T cells that express a γδ T-cell receptor, also make IFN-γ. However, it is clear that T_H1 cells have a central role in this process, since defects in any of the steps in generating a T_H1 response result in absence of resistance and disease progression.

In summary, immunity to *M. tuberculosis* is primarily mediated by T_H1 cells, which stimulate macrophages to kill the bacteria. This immune response, while largely effective, comes at the cost of hypersensitivity and accompanying tissue destruction. Reactivation of the infection or re-exposure to the bacilli in a previously sensitized host results in rapid mobilization of a defensive reaction but also increased tissue necrosis. Just as hypersensitivity and resistance are correlated, so, too, the loss of hypersensitivity (indicated by tuberculin negativity in a previously tuberculin-positive individual) may be an ominous sign that resistance to the organism has faded.

Clinical Features of Tuberculosis.

The many clinicalpathologic patterns of tuberculosis are shown in Figure 8-28 . *Primary tuberculosis is the form of disease that develops in a previously unexposed, and therefore unsensitized, person*. About 5% of newly infected people develop clinically significant disease. The elderly and profoundly immunosuppressed persons may lose their immunity to *M. tuberculosis* and so may develop primary tuberculosis more than once. With primary tuberculosis the source of the organism is exogenous.

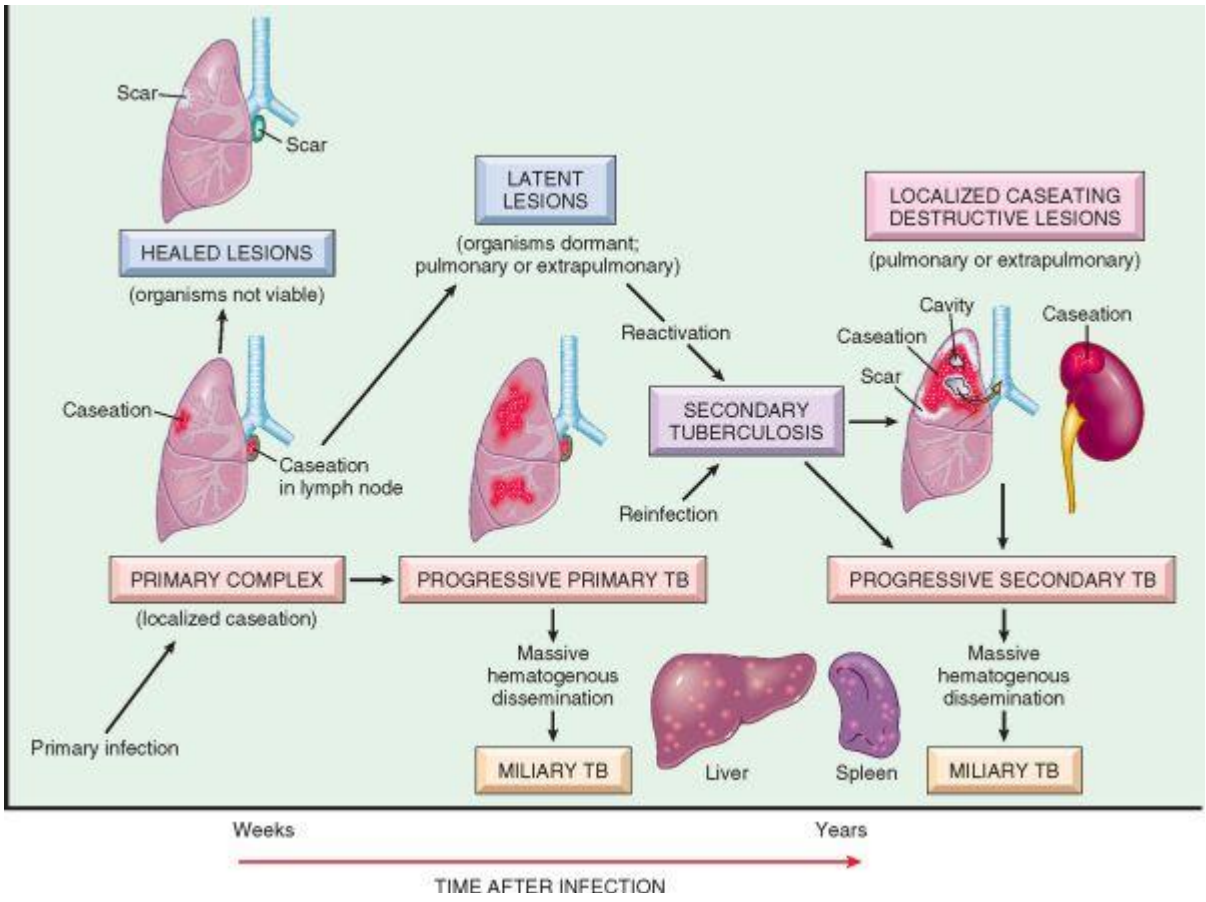

FIGURE 8-28 The natural history and spectrum of tuberculosis. *(Adapted from a sketch provided by Professor R.K. Kumar, The University of New South Wales, School of Pathology, Sydney, Australia.)*

In most people, the primary infection is contained, but in others, primary tuberculosis is progressive. The diagnosis of progressive primary tuberculosis in adults can be difficult. In contrast to secondary tuberculosis (apical disease with cavitation; see below), progressive primary tuberculosis more often resembles an acute bacterial pneumonia, with lower and middle lobe consolidation, hilar adenopathy, and pleural effusion; cavitation is rare, especially in people with severe immunosuppression. Lymphohematogenous dissemination may result in the development of *tuberculous meningitis* and *miliary tuberculosis* (discussed below).

Secondary tuberculosis is the pattern of disease that arises in a previously sensitized host. It may follow shortly after primary tuberculosis, but more commonly it appears many years after the initial infection, usually when host resistance is weakened. It most commonly stems from reactivation of a latent infection, but may also result from exogenous reinfection in the face of waning host immunity or when a large inoculum of virulent bacilli overwhelms the host immune system. Reactivation is more common in low-prevalence areas, while reinfection plays an important role in regions of high contagion.

Secondary pulmonary tuberculosis classically involves the apex of the upper lobes of one or both lungs. Because of the pre-existence of hypersensitivity, the bacilli elicit a prompt and marked tissue response that tends to wall off the focus of infection. As a result, the regional lymph nodes are less prominently involved early in secondary disease than they are in primary tuberculosis. On the other hand, cavitation

occurs readily in the secondary form. Indeed, cavitation is almost inevitable in neglected secondary tuberculosis, and erosion of the cavities into an airway is an important source of infection because the person now coughs sputum that contains bacteria.

Localized secondary tuberculosis may be asymptomatic. When manifestations appear, they are usually *insidious* in onset. Systemic symptoms, probably related to cytokines released by activated macrophages (e.g., TNF and IL-1), often appear early in the course and include malaise, anorexia, weight loss, and fever. Commonly, the *fever is low grade* and remittent (appearing late each afternoon and then subsiding), and *night sweats* occur. With progressive pulmonary involvement, increasing amounts of sputum, at first mucoid and later purulent, appear. Some degree of *hemoptysis* is present in about half of all cases of pulmonary tuberculosis. *Pleuritic pain* may result from extension of the infection to the pleural surfaces. Extrapulmonary manifestations of tuberculosis are legion and depend on the organ system involved.

The diagnosis of pulmonary disease is based in part on the history and on physical and radiographic findings of consolidation or cavitation in the apices of *the lungs*. Ultimately, however, *tubercle bacilli must be identified*. Acid-fast smears and cultures of the sputum of patients suspected of having tuberculosis should be performed. Conventional cultures require up to 10 weeks, but culture in liquid media can provide an answer within 2 weeks. PCR amplification of *M. tuberculosis* DNA allows for even more rapid diagnosis. PCR assays can detect as few as 10 organisms in clinical specimens, compared with more than 10,000 organisms required for smear positivity. However, culture remains the gold standard because it also allows testing of drug susceptibility. Multidrug resistance is now seen more commonly than it was in past years; hence, all newly diagnosed cases in the United States are assumed to be resistant and are treated with multiple drugs. The prognosis is generally good if infections are localized to the lungs, except when they are caused by drug-resistant strains or occur in aged, debilitated, or immunosuppressed individuals, who are at high risk for developing miliary tuberculosis (see below).

All stages of HIV infection are associated with an increased risk of tuberculosis. The use of highly active antiretroviral therapy (HAART) reduces the risk of tuberculosis in people with HIV infection, but even with HAART, people infected with HIV are more likely to get tuberculosis than the uninfected. A low CD4 count before starting HAART is an important risk factor for development of tuberculosis, which underscores the role of the immune response in keeping reactivation of *M. tuberculosis* in check. The manifestations of tuberculosis differ depending on the degree of immunosuppression. People with less severe immunosuppression (CD4+ T-cell counts >300 cells/mm^3) present with usual secondary tuberculosis (apical disease with cavitation). People with more advanced immunosuppression (CD4+ T-cell counts <200 cells/mm^3) present with a clinical picture that resembles progressive primary tuberculosis. The extent of immunodeficiency also determines the frequency of extrapulmonary involvement, rising from 10% to 15% in mildly immunosuppressed people to greater than 50% in those with severe immune deficiency. Other atypical features of tuberculosis in HIV-positive people include an increased frequency of false-negative sputum smears and tuberculin tests (the latter due to “anergy”), and the absence of characteristic granulomas in tissues, particularly in the late stages of HIV. The increased frequency of sputum smear-negativity is paradoxical because these immunosuppressed patients typically have higher bacterial loads. The likely explanation is that cavitation and bronchial damage are more in immunocompetent individuals, resulting in more bacilli in expelled sputum. In contrast, the absence of bronchial wall destruction due to reduced T-cell–mediated hypersensitivity results in the excretion of fewer bacilli in the sputum.

Morphology.

Primary Tuberculosis. In countries where infected milk has been eliminated, primary tuberculosis almost always begins in the lungs. Typically, the inhaled bacilli implant in the distal airspaces of the lower part of the upper lobe or the upper part of the lower lobe, usually close to the pleura. As sensitization develops, a 1- to 1.5-cm area of gray-white inflammation with consolidation emerges, known as the Ghon focus. In most cases, the center of this focus undergoes caseous necrosis. Tubercle bacilli, either free or within phagocytes, drain to the regional nodes, which also often caseate. This combination of parenchymal lung lesion and nodal involvement is referred to as the Ghon complex (Fig. 8-29). During the first few weeks there is also lymphatic and hematogenous dissemination to other parts of the body. In approximately 95% of cases, development of cell-mediated immunity controls the infection. Hence, the Ghon complex undergoes progressive fibrosis, often followed by radiologically detectable calcification (Ranke complex), and despite seeding of other organs, no lesions develop.

Histologically, sites of active involvement are marked by a characteristic granulomatous inflammatory reaction that forms both caseating and noncaseating tubercles (Fig. 8-30A to C). Individual tubercles are microscopic; it is only when multiple granulomas coalesce that they become macroscopically visible. The granulomas are usually enclosed within a fibroblastic rim punctuated by lymphocytes. Multinucleate giant cells are present in the granulomas. Immunocompromised people do not form the characteristic granulomas (Fig. 8-30D).

***Secondary Tuberculosis*. The initial lesion is usually a small focus of consolidation, less than 2 cm in diameter, within 1 to 2 cm of the apical pleura**. Such foci are sharply circumscribed, firm, gray-white to yellow areas that have a variable amount of central caseation and peripheral fibrosis (Fig. 8-31). In immunocomptetent individuals, the initial parenchymal focus undergoes progressive fibrous encapsulation, leaving only fibrocalcific scars. Histologically, the active lesions show characteristic coalescent tubercles with central caseation. Tubercle bacilli can often be identified with acid-fast stains in early exudative and caseous phases of granuloma formation but are usually too few to be found in the late, fibrocalcific stages. Localized, apical, secondary pulmonary tuberculosis may heal with fibrosis either spontaneously or after therapy, or the disease may progress and extend along several different pathways.

Progressive pulmonary tuberculosis may ensue in the elderly and immunosuppressed. The apical lesion expands into adjacent lung and eventually erodes into bronchi and vessels. This evacuates the caseous center, creating a ragged, irregular cavity that is poorly walled off by fibrous tissue. Erosion of blood vessels results in hemoptysis. With adequate treatment the process may be arrested, although healing by fibrosis often distorts the pulmonary architecture. The cavities, now free of inflammation, may persist or become fibrotic. If the treatment is inadequate or if host defenses are impaired, the infection may spread via airways, lymphatic channels, or the vascular system. **Miliary pulmonary disease** occurs when organisms draining through lymphatics enter the venous blood and circulate back to the lung. Individual lesions are either microscopic or small, visible (2-mm) foci of yellow-white consolidation scattered through the lung parenchyma (the adjective “miliary” is derived from the resemblance of these foci to millet seeds). Miliary lesions may expand and coalesce, resulting in consolidation of large regions or even whole lobes of the lung. With progressive pulmonary tuberculosis, the pleural cavity is invariably involved, and serous **pleural effusions**, **tuberculous empyema**, or **obliterative fibrous pleuritis** may develop.

Endobronchial, **endotracheal**, and **laryngeal tuberculosis** may develop by spread through lymphatic channels or from expectorated infectious material. The mucosal lining may be studded with minute granulomatous lesions that may only be apparent microscopically.

Systemic miliary tuberculosis occurs when bacteria disseminate through the systemic arterial

system. Miliary tuberculosis is most prominent in the liver, bone marrow, spleen, adrenals, meninges, kidneys, fallopian tubes, and epididymis, but could involve any organ (Fig. 8-32).

Isolated tuberculosis may appear in any of the organs or tissues seeded hematogenously and may be the presenting manifestation. Organs that are commonly involved include the meninges (tuberculous meningitis), kidneys (renal tuberculosis), adrenals (formerly an important cause of Addison disease), bones (osteomyelitis), and fallopian tubes (salpingitis). When the vertebrae are affected, the disease is referred to as **Pott disease**. Paraspinal "cold" abscesses in these patients may track along tissue planes and present as an abdominal or pelvic mass.

Lymphadenitis is the most frequent presentation of extrapulmonary tuberculosis, usually occurring in the cervical region ("scrofula"). In HIV-negative individuals, lymphadenitis tends to be unifocal and localized. HIV-positive people, on the other hand, almost always have multifocal disease, systemic symptoms, and either pulmonary or other organ involvement by active tuberculosis.

In years past, **intestinal tuberculosis** contracted by the drinking of contaminated milk was a fairly common primary focus of disease. In countries where milk is pasteurized, intestinal tuberculosis is more often caused by the swallowing of coughed-up infective material in patients with advanced pulmonary disease. Typically the organisms are seed to mucosal lymphoid aggregates of the small and large bowel, which then undergo granulomatous inflammation that can lead to ulceration of the overlying mucosa, particularly in the ileum.

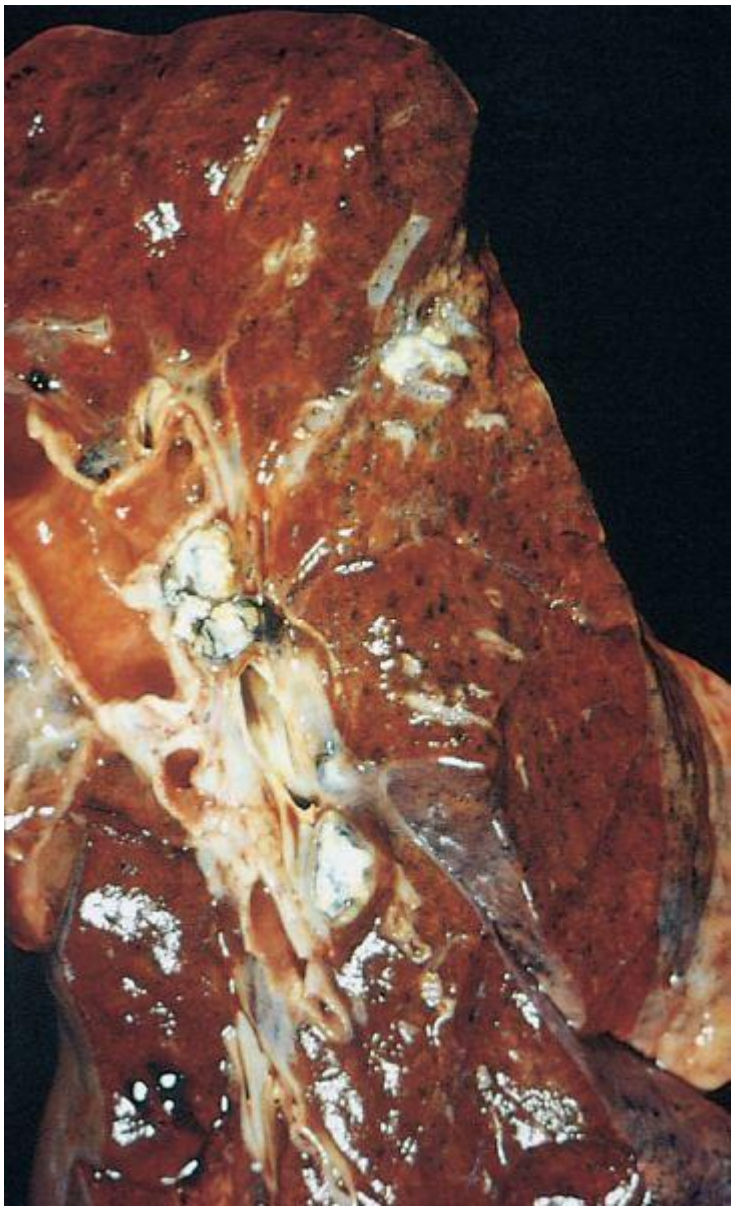

FIGURE 8-29 Primary pulmonary tuberculosis, Ghon complex. The gray-white parenchymal focus is under the pleura in the lower part of the upper lobe. Hilar lymph nodes with caseation are seen on the left.

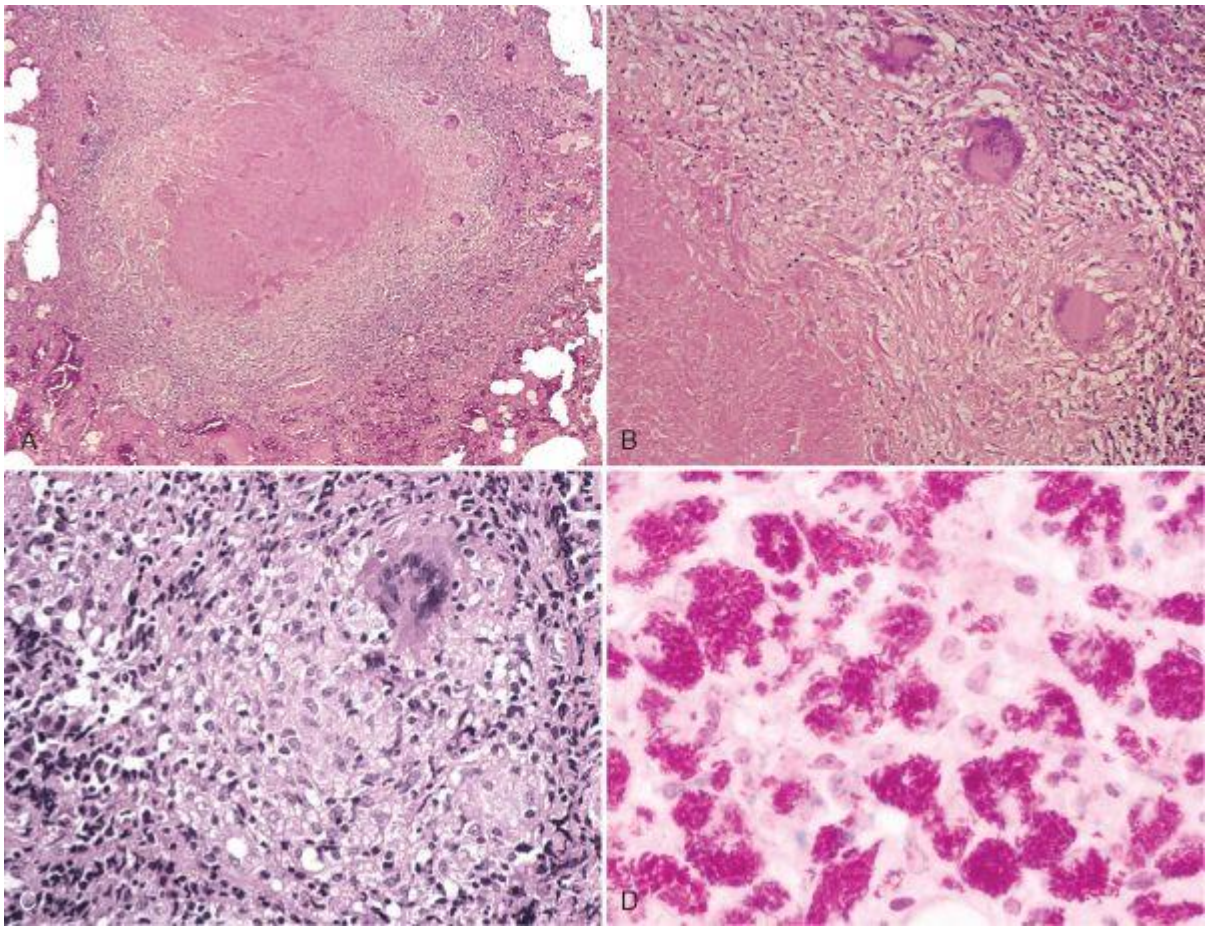

FIGURE 8-30 The morphologic spectrum of tuberculosis. A characteristic tubercle at low magnification (**A**) and in detail (**B**) illustrates central caseation surrounded by epithelioid and multinucleated giant cells. This is the usual response seen in patients who have cell-mediated immunity to the organism. Not all tubercular granulomas might show central caseation (**C**); hence, irrespective of the presence or absence of caseous necrosis, special stains for acid-fast organisms must be performed when granulomas are present. In immunosuppressed individuals without cellular immunity sheets of foamy macrophages are seen that are packed with mycobacteria (demonstrable with acid-fast stains) (**D**). *(**D**, Courtesy of Dr. Dominick Cavuoti, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

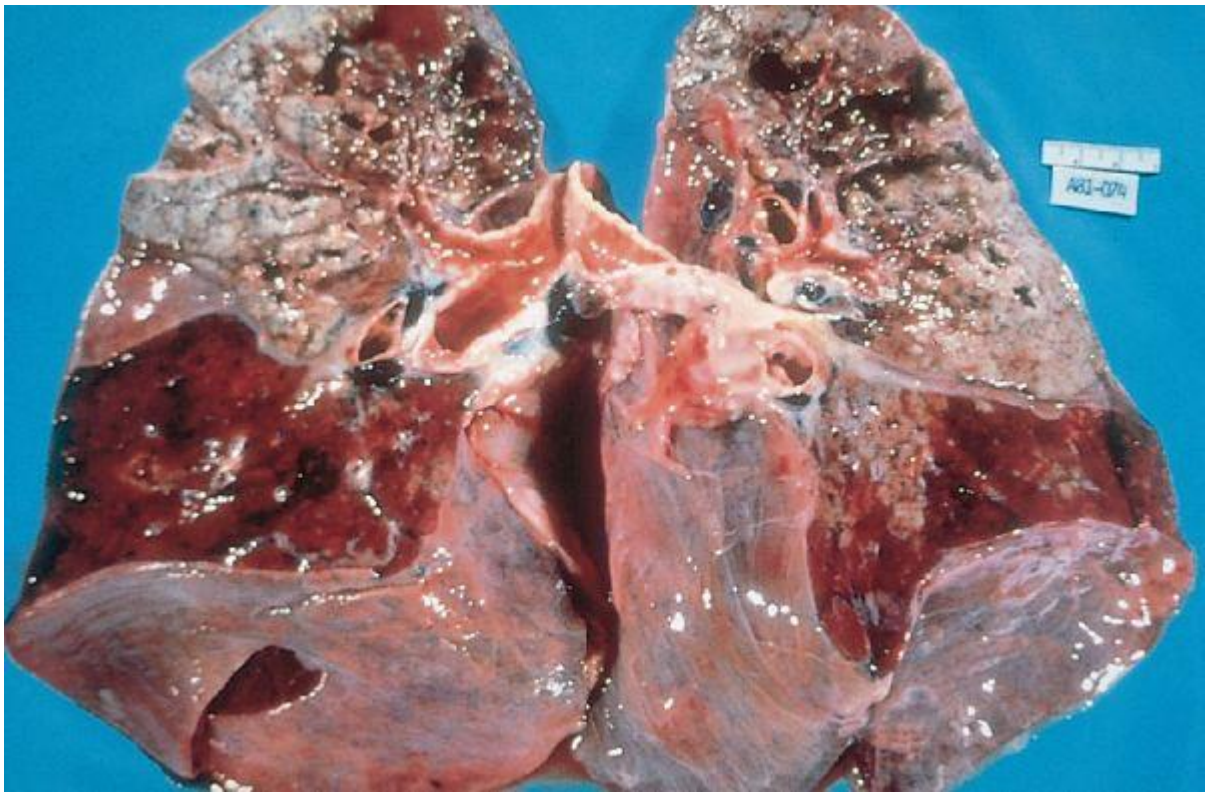

FIGURE 8-31 Secondary pulmonary tuberculosis. The upper parts of both lungs are riddled with gray-white areas of caseation and multiple areas of softening and cavitation.

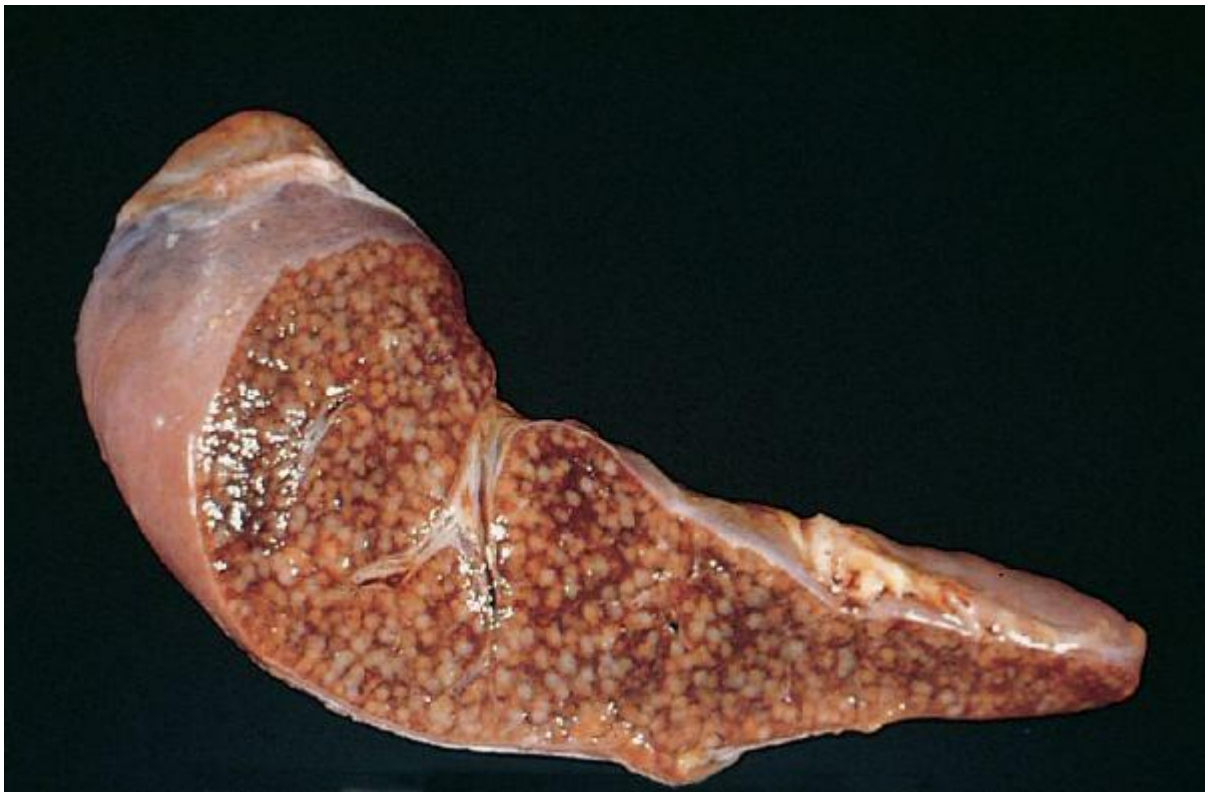

FIGURE 8-32 Miliary tuberculosis of the spleen. The cut surface shows numerous gray-white tubercles.

Mycobacterium avium-intracellulare Complex

Mycobacterium avium and *M. intracellulare* are separate species, but the infections they cause are so similar that they are simply referred to as *M. avium-intracellulare* complex, or MAC. MAC is common in soil, water, dust, and domestic animals. Clinically significant infection with MAC is uncommon except among people with AIDS and low numbers of CD4+ lymphocytes (<60 cells/mm^3).

In AIDS patients MAC causes widely disseminated infections, and organisms proliferate abundantly in many organs, including the lungs and gastrointestinal system. Unchecked by the immune response, the organisms reach very high levels: up to 10^4 organisms/mL of blood and 10^6 organisms/gm in tissue. Patients are feverish, with drenching night sweats and weight loss. In the rare case of MAC in a person without HIV, the organisms primarily infect the lung, causing a productive cough and sometimes fever and weight loss.

Morphology. The hallmark of MAC infections in patients with HIV is abundant acid-fast bacilli within macrophages (Fig. 8-33). Depending on the severity of immune deficiency, MAC infections can be widely disseminated throughout the mononuclear phagocyte system, causing enlargement of involved lymph nodes, liver, and spleen, or localized to the lungs. There may be a yellowish pigmentation to these organs secondary to the large number of organisms present in swollen macrophages. Granulomas, lymphocytes, and tissue destruction are rare.

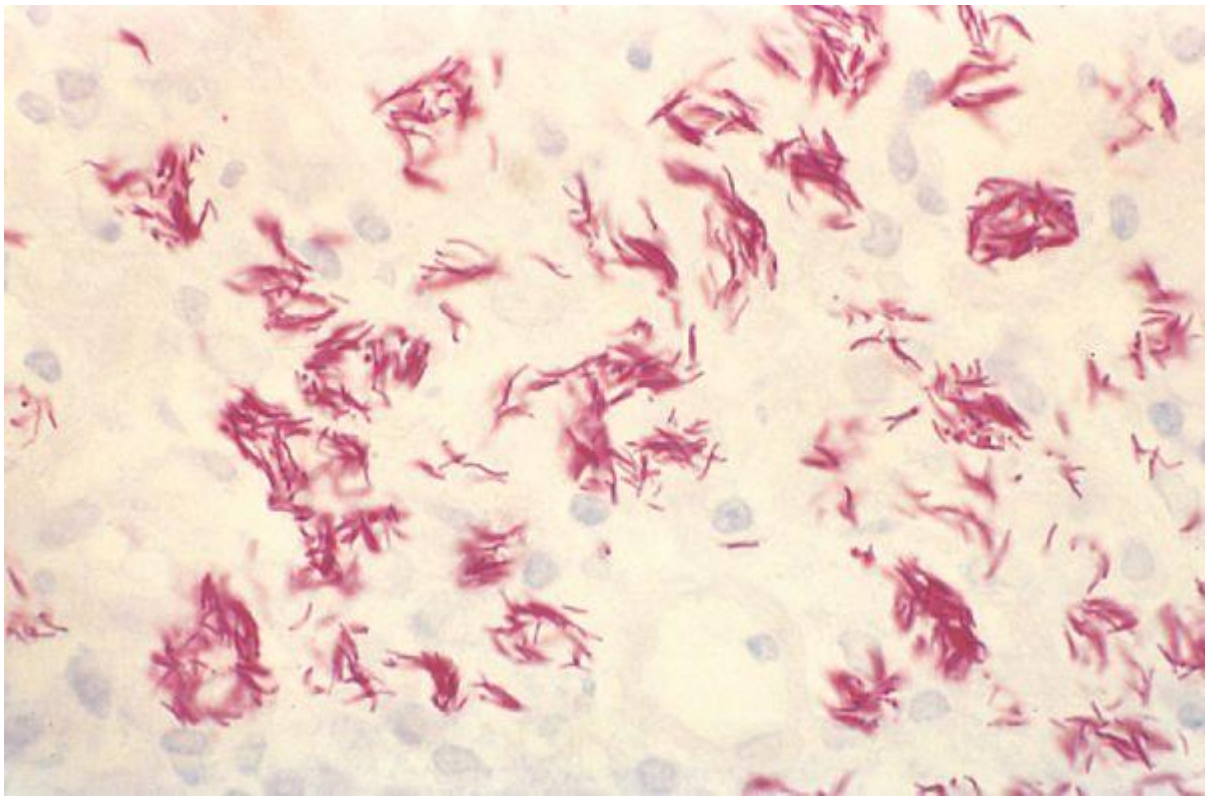

FIGURE 8-33 *Mycobacterium avium* infection in a patient with AIDS, showing massive infection with acid-fast organisms.

Leprosy

Leprosy, or Hansen's disease, is a slowly progressive infection caused by *Mycobacterium leprae* that mainly affects the skin and peripheral nerves and results in disabling deformities. *M. leprae* is likely to be transmitted from person to person through aerosols from asymptomatic lesions in the upper respiratory tract. Inhaled *M. leprae*, like *M. tuberculosis*, is taken up by alveolar macrophages and disseminates through the blood, but replicates only in relatively cool tissues of the skin and extremities. Despite its low communicability, leprosy remains endemic among an estimated 10 to 15 million people living in poor tropical countries.

Pathogenesis.

M. leprae is an acid-fast obligate intracellular organism that grows very poorly in culture but can be propagated in the armadillo. It proliferates best at 32° to 34°C, the temperature of the human skin and the core temperature of armadillos. Like *M. tuberculosis*, *M. leprae* secretes no toxins, and its virulence is based on properties of its cell wall. The cell wall is similar enough to that of *M. tuberculosis* that immunization with BCG confers some protection against *M. leprae* infection. Cell-mediated immunity is reflected by delayed-type hypersensitivity reactions to dermal injections of a bacterial extract called *lepromin*.

M. leprae causes *two strikingly different patterns of disease*. People with the less severe form, *tuberculoid leprosy*, have dry, scaly skin lesions that lack sensation. They often have asymmetric involvement of large peripheral nerves. The more severe form, *lepromatous leprosy*, includes symmetric skin thickening and nodules. This is also called *anergic leprosy*, because of the unresponsiveness (anergy) of the host immune system. Cooler areas of skin, including the earlobes and feet, are more severely affected than warmer areas, such as the axilla and groin. In lepromatous leprosy, widespread invasion of the mycobacteria into Schwann cells and into endoneural and perineural macrophages damages the peripheral nervous system. In advanced cases of lepromatous leprosy, *M. leprae* is present in sputum and blood. People can also have intermediate forms of disease, called *borderline leprosy*.

The T-helper lymphocyte response to *M. leprae* determines whether an individual has tuberculoid or lepromatous leprosy.[88] People with tuberculoid leprosy have a T_H1 response associated with production of IL-2 and IFN-γ. As with *M. tuberculosis*, IFN-γ is critical to mobilizing an effective host macrophage response. Lepromatous leprosy is associated with a weak T_H1 response and, in some cases, a relative increase in the T_H2 response. The net result is weak cell-mediated immunity and an inability to control the bacteria. Occasionally, most often in the lepromatous form, antibodies are produced against *M. leprae* antigens. Paradoxically, these antibodies are usually not protective, but they may form immune complexes with free antigens that can lead to erythema nodosum, vasculitis, and glomerulonephritis.

Morphology. Tuberculoid leprosy begins with localized flat, red skin lesions that enlarge and develop irregular shapes with indurated, elevated, hyperpigmented margins and depressed pale centers (central healing). Neuronal involvement dominates tuberculoid leprosy. Nerves become enclosed within granulomatous inflammatory reactions and, if small (e.g., the peripheral twigs), are

destroyed (Fig. 8-34). Nerve degeneration causes skin anesthesias and skin and muscle atrophy that render the person liable to trauma of the affected parts, leading to the development of chronic skin ulcers. Contractures, paralyses, and autoamputation of fingers or toes may ensue. Facial nerve involvement can lead to paralysis of the eyelids, with keratitis and corneal ulcerations. On microscopic examination, all sites of involvement have granulomatous lesions closely resembling those found in tuberculosis, and bacilli are almost never found, hence the name "paucibacillary" leprosy. The presence of granulomas and absence of bacteria reflect strong T-cell immunity. Because leprosy pursues an extremely slow course, spanning decades, most patients die with leprosy rather than of it.

Lepromatous leprosy involves the skin, peripheral nerves, anterior chamber of the eye, upper airways (down to the larynx), testes, hands, and feet. The vital organs and CNS are rarely affected, presumably because the core temperature is too high for growth of *M. leprae*. Lepromatous lesions contain large aggregates of lipid-laden macrophages (lepra cells), often filled with masses ("globi") of acid-fast bacilli (Fig. 8-35). Because of the abundant bacteria, lepromatous leprosy is referred to as **"multibacillary"**. Macular, papular, or nodular lesions form on the face, ears, wrists, elbows, and knees. With progression, the nodular lesions coalesce to yield a distinctive leonine facies. Most skin lesions are hypoesthetic or anesthetic. Lesions in the nose may cause persistent inflammation and bacilli-laden discharge. The peripheral nerves, particularly the ulnar and peroneal nerves where they approach the skin surface, are symmetrically invaded with mycobacteria, with minimal inflammation. Loss of sensation and trophic changes in the hands and feet follow the nerve lesions. Lymph nodes contain aggregates of bacteria-filled foamy macrophages in the paracortical (T-cell) areas and reactive germinal centers. In advanced disease, aggregates of macrophages are also present in the splenic red pulp and the liver. The testes are usually extensively involved, leading to destruction of the seminiferous tubules and consequent sterility.

SPIROCHETES

Spirochetes are gram-negative, slender corkscrew-shaped bacteria with axial periplasmic flagella wound around a helical protoplasm. The bacteria are covered in a membrane called an outer sheath, which may mask bacterial antigens from the host immune response. *Treponema pallidum* subsp. *pallidum* is the microaerophilic spirochete that causes syphilis, a chronic venereal disease with multiple clinical presentations. Other closely related treponemes cause yaws *(Treponema pallidum* subsp. *pertenue)* and pinta *(Treponema pallidum* subsp. *carateum).*

Syphilis

Syphilis is a chronic venereal disease with multiple presentations. The causative spirochete, *T. pallidum* subsp. *pallidum*, hereafter referred to simply as *T. pallidum*, is too slender to be seen in Gram stain, but it can be visualized by silver stains, dark-field examination, and immunofluorescence techniques (Fig. 8-36). Sexual contact is the usual mode of spread. Transplacental transmission of *T. pallidum* occurs readily, and active disease during pregnancy results in congenital syphilis. *T. pallidum* cannot be grown in culture.

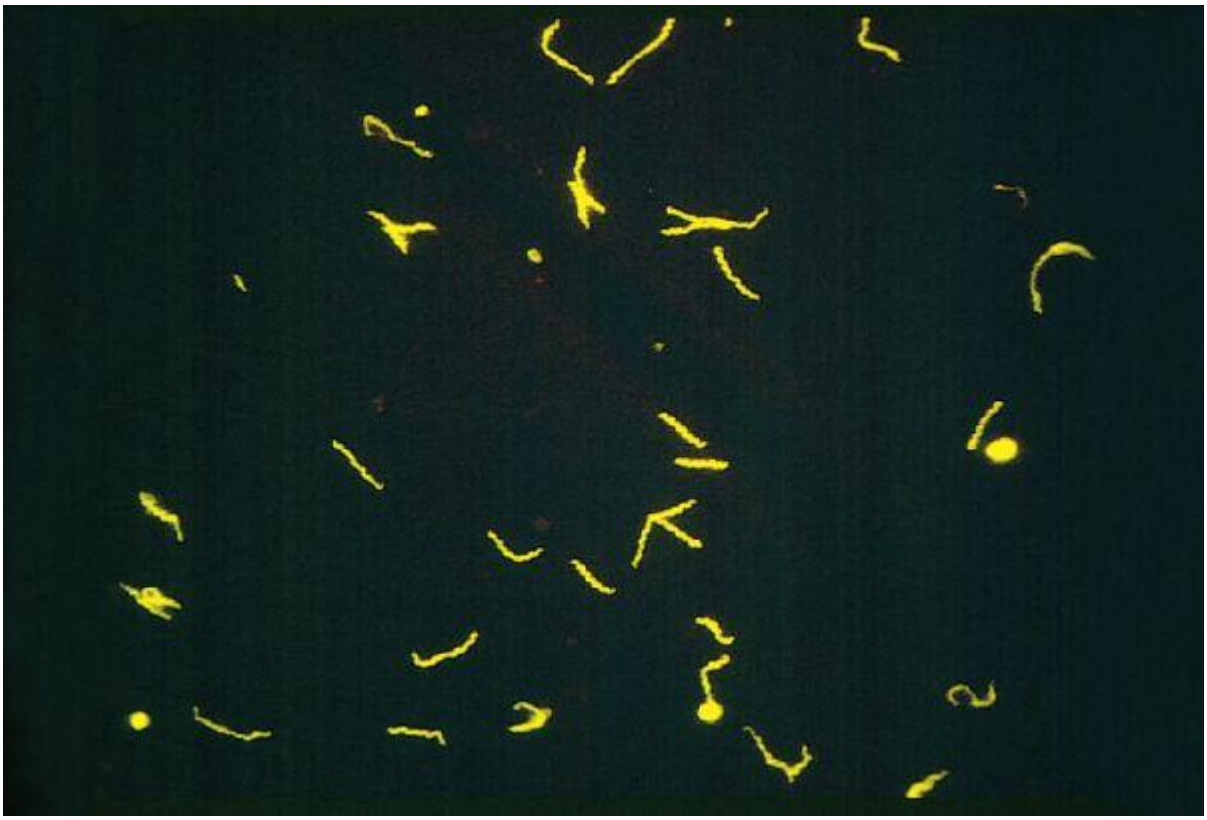

FIGURE 8-36 *Treponema pallidum* (dark-field microscopy) showing several spirochetes in scrapings from the base of a chancre. *(Courtesy of Dr. Paul Southern, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Public health programs and penicillin treatment reduced the number of cases of syphilis in the United States from the late 1940s until the 1970s. Cases of syphilis surged upward in the mid-1980s, reaching a total of 50,000 cases in 1990. Renewed public health efforts led to a sharp drop in the incidence of syphilis over the next 10 years, but since 2000 there has been a steady rise in the number of cases reported annually, to ~10,000 in 2006.

Syphilis is divided into three stages, with distinct clinical and pathologic manifestations (Fig. 8-37).

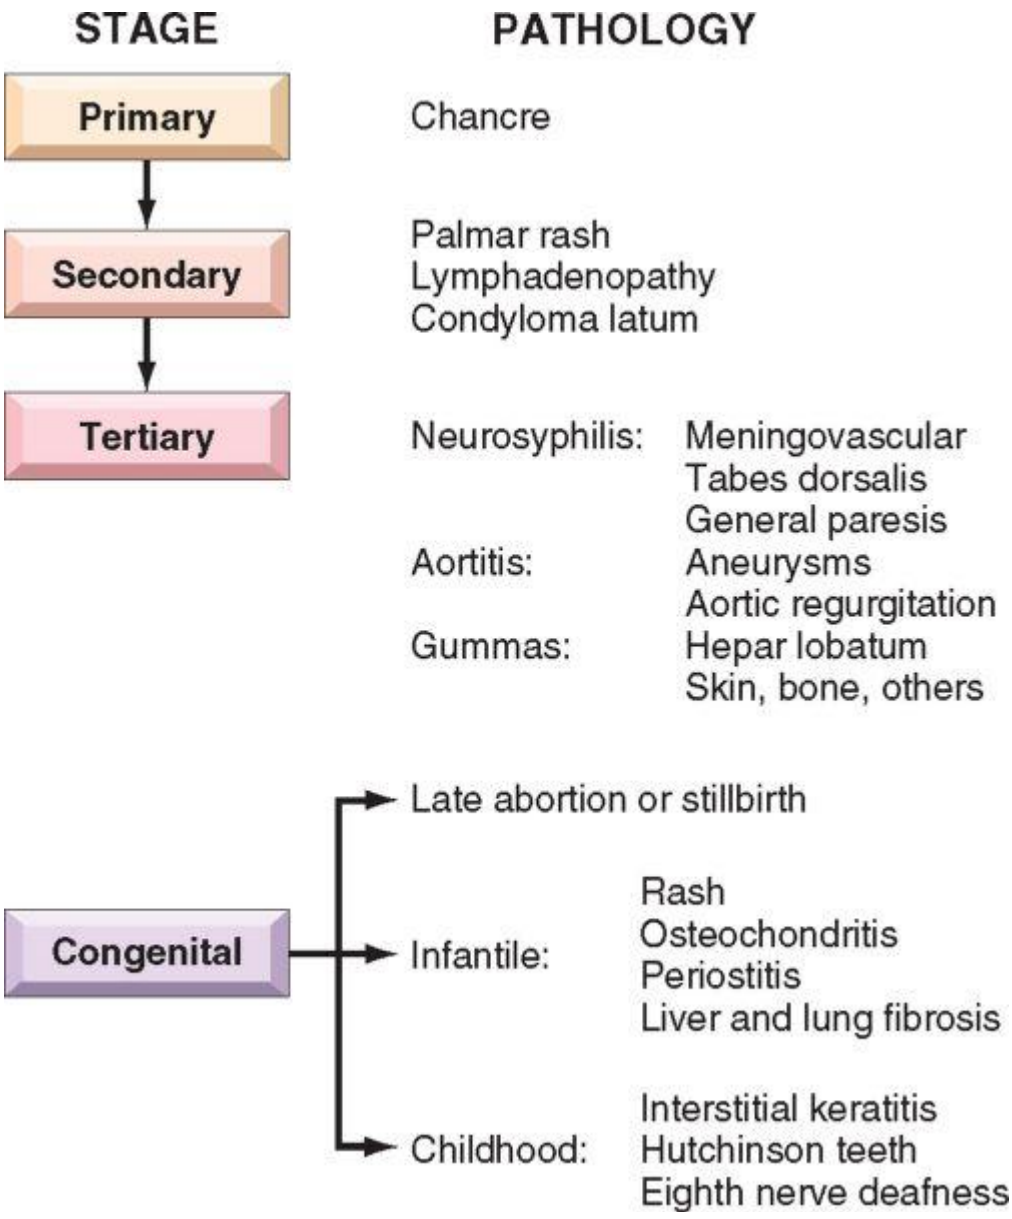

FIGURE 8-37 Protean manifestations of syphilis.

Primary Syphilis.

This stage, occurring approximately 3 weeks after contact with an infected individual, features a single firm, nontender, raised, red lesion (chancre) located at the site of treponemal invasion on the penis, cervix, vaginal wall, or anus. The chancre heals in 3 to 6 weeks with or without therapy. *Spirochetes are plentiful within the chancre and can be seen by immunofluorescent stains of serous exudate*. Treponemes spread throughout the body by hematologic and lymphatic dissemination even before the appearance of the chancre.

Secondary Syphilis.

This stage usually occurs 2 to 10 weeks after the primary chancre and is due to spread and proliferation of the spirochetes within the skin and mucocutaneous tissues. Secondary syphilis occurs in

approximately 75% of untreated people. *The skin lesions, which frequently occur on the palms or soles of the feet, may be maculopapular, scaly, or pustular*. Moist areas of the skin, such as the anogenital region, inner thighs, and axillae, may have *condylomata lata*, which are broad-based, elevated plaques. Silvery-gray superficial erosions may form on any of the mucous membranes but are particularly common in the mouth, pharynx, and external genitalia. All these painless superficial lesions contain spirochetes and so are infectious. Lymphadenopathy, mild fever, malaise, and weight loss are also common in secondary syphilis. The symptoms of secondary syphilis last several weeks, after which the person enters the latent phase of the disease. Superficial lesions may recur during the early latent phase, although they are milder.

Tertiary Syphilis.

This stage is rare where adequate medical care is available, but it occurs in approximately one third of untreated patients, usually after a latent period of 5 years or more. Tertiary syphilis has three main manifestations: cardiovascular syphilis, neurosyphilis, and so-called benign tertiary syphilis. These may occur alone or in combination.

Cardiovascular syphilis, in the form of syphilitic aortitis, accounts for more than 80% of cases of tertiary disease. The aortitis leads to slowly progressive dilation of the aortic root and arch, which causes aortic valve insufficiency and aneurysms of the proximal aorta (see Chapter 11).

Neurosyphilis may be symptomatic or asymptomatic. Symptomatic disease manifests in several ways, including chronic meningovascular disease, tabes dorsalis, and a generalized brain parenchymal disease called *general paresis*. These are discussed in Chapter 28 . Asymptomatic neurosyphilis, which accounts for about one third of neurosyphilis cases, is detected when a patient's CSF exhibits abnormalities such as pleocytosis (increased numbers of inflammatory cells), elevated protein levels, or decreased glucose. Antibodies stimulated by the spirochetes, discussed below, can also be detected in the CSF, and this is the most specific test for neurosyphilis. Antibiotics are given for a longer time if the spirochetes have spread to the CNS, and so patients with tertiary syphilis should be tested for neurosyphilis even if they do not have neurologic symptoms.

So-called *benign tertiary syphilis* is characterized by the formation of gummas in various sites. Gummas are nodular lesions probably related to the development of delayed hypersensitivity to the bacteria. They occur most commonly in bone, skin, and the mucous membranes of the upper airway and mouth, although any organ may be affected. Skeletal involvement characteristically causes local pain, tenderness, swelling, and sometimes pathologic fractures. Involvement of skin and mucous membranes may produce nodular lesions or, rarely, destructive, ulcerative lesions that mimic malignant neoplasms. Gummas are now very rare because of the use of effective antibiotics and are seen mainly in individuals with AIDS.

Congenital Syphilis.

Congenital syphilis occurs when *T. pallidum* crosses the placenta from an infected mother to the fetus. Maternal transmission happens most frequently during primary or secondary syphilis, when the spirochetes are most numerous. Because the manifestations of maternal syphilis may be subtle, routine serologic testing for syphilis is mandatory in all pregnancies. Intrauterine death and perinatal death each occurs in approximately 25% of cases of untreated congenital syphilis.

Manifestations of congenital disease are divided into early (infantile) and late (tardive) syphilis, depending on whether they occur in the first 2 years of life or later. Early congenital syphilis is often manifested by nasal discharge and congestion (snuffles) in the first few months of life. A desquamating

or bullous rash can lead to sloughing of the skin, particularly of the hands and feet and around the mouth and anus. Hepatomegaly and skeletal abnormalities are also common.

Nearly half of untreated children with neonatal syphilis will develop late manifestations, which are discussed below.

Serologic Tests for Syphilis.

Serology remains the mainstay of diagnosis, although microscopy and PCR are also useful. Serologic tests include nontreponemal antibody tests and antitreponemal antibody tests. Nontreponemal tests measure antibody to cardiolipin, a phospholipid present in both host tissues and *T. pallidum*. These antibodies are detected in the rapid plasma reagin and Venereal Disease Research Laboratory (VDRL) tests. Nontreponemal tests typically become positive 4 to 6 weeks after infection, and so immunofluorescence of exudate from the chancre is important for diagnosis early in infection. The nontreponemal tests are nearly always positive in secondary syphilis, but they usually become negative in tertiary syphilis. The VDRL and rapid plasma reagin tests are used as screening tests for syphilis and to monitor response to therapy, since these tests become negative after successful treatment of infection. False-positive VDRL test results are not uncommon and are associated with certain acute infections, collagen vascular diseases (e.g., systemic lupus erythematosus), drug addiction, pregnancy, hypergammaglobulinemia of any cause, and lepromatous leprosy.

Treponemal antibody tests measure antibodies that specifically react with *T. pallidum*. These include the fluorescent treponemal antibody absorption test and the microhemagglutination assay for *T. pallidum* antibodies. These tests also become positive 4 to 6 weeks after infection, but unlike nontreponemal antibody tests, they remain positive indefinitely, even after successful treatment. They are not recommended as primary screening tests because they are significantly more expensive than nontreponemal tests. While more specific than the nontreponemal tests, false-positive treponemal antibody tests can also occur.

Serologic response may be delayed, absent, or exaggerated (false-positive results) in people co-infected with syphilis and HIV. However, in most cases, these tests remain useful in the diagnosis and management of syphilis even in people infected with HIV.

Morphology. In **primary syphilis** a chancre occurs on the penis or scrotum of 70% of men and on the vulva or cervix of 50% of women. The chancre is a slightly elevated, firm, reddened papule, up to several centimeters in diameter, that erodes to create a clean-based shallow ulcer. The contiguous induration creates a button-like mass directly adjacent to the eroded skin, providing the basis for the designation hard chancre (Fig. 8-38). On histologic examination, treponemes are visible at the surface of the ulcer with silver stains (e.g., Warthin-Starry stain) or immunofluorescence techniques. The chancre contains an intense infiltrate of plasma cells, with scattered macrophages and lymphocytes and a proliferative endarteritis (see Fig. 8-8). The endarteritis, which is seen in all stages of syphilis, starts with endothelial cell activation and proliferation and progresses to intimal fibrosis. The regional nodes are usually enlarged due to nonspecific acute or chronic lymphadenitis, plasma cell–rich infiltrates, or granulomas.

In **secondary syphilis** widespread mucocutaneous lesions involve the oral cavity, palms of the hands, and soles of the feet. The rash frequently consists of discrete red-brown macules less than 5 mm in diameter, but it may be follicular, pustular, annular, or scaling. Red lesions in the mouth or vagina contain the most organisms and are the most infectious. Histologically, the mucocutaneous lesions of secondary syphilis show the same plasma cell infiltrate and obliterative endarteritis as the primary

chancre, although the inflammation is often less intense.

Tertiary syphilis most frequently involves the aorta; the CNS; and the liver, bones, and testes. The aortitis is caused by endarteritis of the vasa vasorum of the proximal aorta. Occlusion of the vasa vasorum results in scarring of the media of the proximal aortic wall, causing a loss of elasticity. There may be narrowing of the coronary artery ostia caused by subintimal scarring with resulting myocardial ischemia. The morphologic and clinical features of syphilitic aortitis are discussed in greater detail with diseases of the blood vessels (Chapter 11). **Neurosyphilis** takes one of several forms, designated meningovascular syphilis, tabes dorsalis, and general paresis (Chapter 28). **Syphilitic gummas** are white-gray and rubbery, occur singly or multiply, and vary in size from microscopic lesions resembling tubercles to large tumor-like masses. They occur in most organs but particularly in skin, subcutaneous tissue, bone, and joints. In the liver, scarring as a result of gummas may cause a distinctive hepatic lesion known as hepar lobatum (Fig. 8-39). On histologic examination, the gummas have centers of coagulated, necrotic material and margins composed of plump, palisading macrophages and fibroblasts surrounded by large numbers of mononuclear leukocytes, chiefly plasma cells. Treponemes are scant in gummas and are difficult to demonstrate.

The rash of **congenital syphilis** is more severe than that of adult secondary syphilis. It is a bullous eruption of the palms and soles of the feet associated with epidermal sloughing. **Syphilitic osteochondritis and periostitis** affect all bones, but lesions of the nose and lower legs are most distinctive. Destruction of the vomer causes collapse of the bridge of the nose and, later on, the characteristic saddle nose deformity. Periostitis of the tibia leads to excessive new bone growth on the anterior surfaces and anterior bowing, or saber shin. There is also widespread disturbance in endochondral bone formation. The epiphyses become widened as the cartilage overgrows, and cartilage is found in displaced islands within the metaphysis.

The **liver** is often severely affected in congenital syphilis. Diffuse fibrosis permeates lobules to isolate hepatic cells into small nests, accompanied by the characteristic lymphoplasmacytic infiltrate and vascular changes. Gummas are occasionally found in the liver, even in early cases. The **lungs** may be affected by a diffuse interstitial fibrosis. In the syphilitic stillborn, the lungs appear pale and airless (pneumonia alba). The generalized spirochetemia may lead to diffuse interstitial inflammatory reactions in virtually any other organ (e.g., the pancreas, kidneys, heart, spleen, thymus, endocrine organs, and CNS).

The late manifestations of congenital syphilis include a distinctive **triad of interstitial keratitis, Hutchinson teeth, and eighth-nerve deafness**. In addition to interstitial keratitis, the ocular changes include choroiditis and abnormal retinal pigmentation. Hutchinson teeth are small incisors shaped like a screwdriver or a peg, often with notches in the enamel. Eighth-nerve deafness and optic nerve atrophy develop secondary to meningovascular syphilis.

FIGURE 8-38 Syphilitic chancre in the scrotum (see Figure 8-8 for the histopathology of syphilis). *(Courtesy of Dr. Richard Johnson, Beth Israel–Deaconess Hospital, Boston, MA.)*

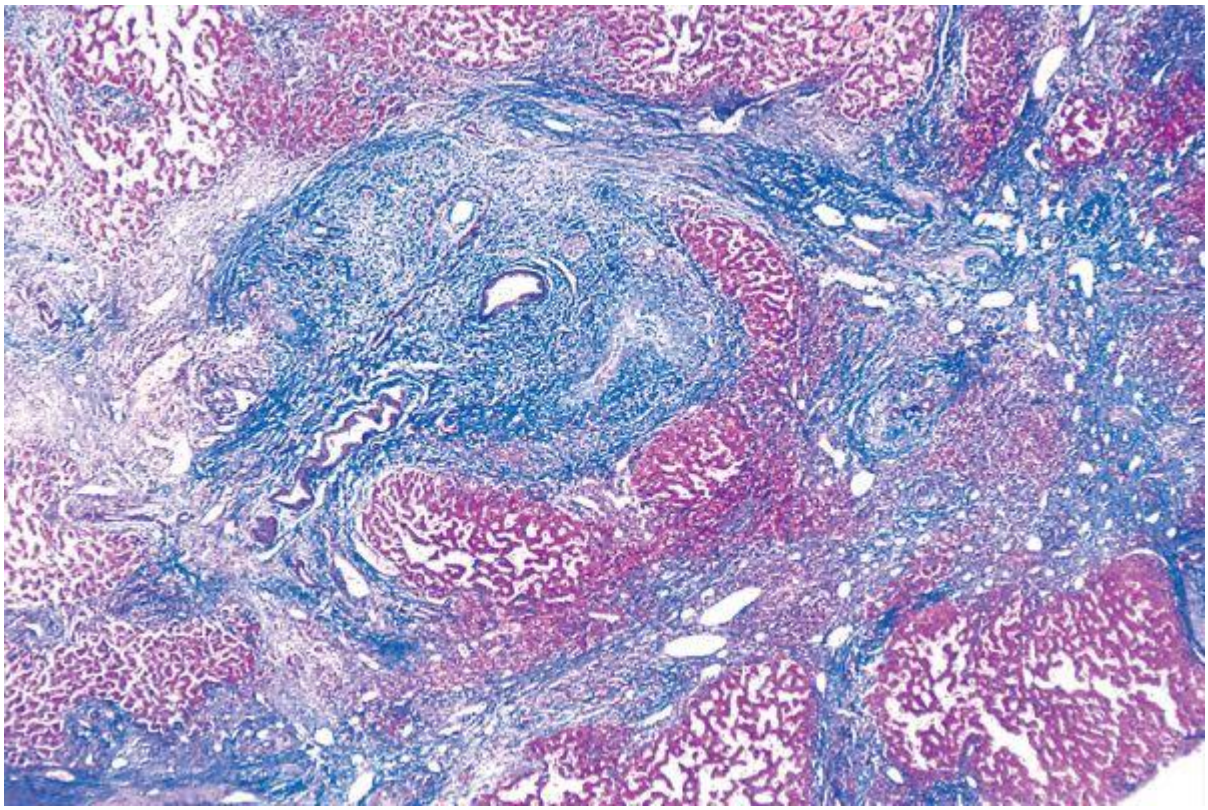

FIGURE 8-39 Trichrome stain of liver shows a gumma (scar), stained blue, caused by tertiary syphilis (the hepatic lesion is also known as hepar lobatum).

Pathogenesis.

There are no good animal models of syphilis, and *T. pallidum* has never been grown in culture (it lacks genes for making nucleotides, fatty acids, and most amino acids). As a result, our scant knowledge of *T. pallidum* pathogenesis comes mainly from observations of the disease in humans.

Proliferative endarteritis occurs in all stages of syphilis. The pathophysiology of the endarteritis is not known, although the scarcity of treponemes and the intense inflammatory infiltrate suggest that the immune response plays a role in the development of these lesions. Regardless of the mechanism, much of the pathology of the disease, such as syphilitic aortitis, can be ascribed to the vascular abnormalities.

The immune response to *T. pallidum* reduces the burden of bacteria, but it may also have a central role in the pathogenesis of the disease. The T cells that infiltrate the chancre are T_H1 cells, suggesting that activation of macrophages to kill bacteria may cause resolution of the local infection.[89] Although there are many plasma cells in the syphilitic lesions and treponeme-specific antibodies are readily detectable, the antibody response does not eliminate the infection. The outer membrane of *T. pallidum* seems to protect the bacteria from antibody binding. The mechanism of this effect is not well understood, but either the paucity of bacterial proteins in the membrane or absorption (coating) of the membrane by host proteins may play a role.[90] The immune response is ultimately inadequate, since the spirochetes disseminate, persist, and cause secondary and tertiary syphilis.

In passing, it should be noted that antibiotic treatment of syphilis, in patients with a high bacterial load, can cause a massive release of endotoxins, resulting in a cytokine storm that manifests with high fever, rigors, hypotension, and leukopenia. This syndrome, called the Jarisch-Herxheimer reaction, is seen not only in syphilis but in other spirochetal diseases, such as Lyme disease, and can be mistaken for drug allergy.

Relapsing Fever

Relapsing fever is an insect-transmitted disease characterized by recurrent fevers with spirochetemia. *Epidemic relapsing fever* is caused by body louse-transmitted *Borrelia recurrentis*, which infects only humans. *B. recurrentis*, which is associated with overcrowding due to poverty or war, caused multiple large epidemics in Africa, Eastern Europe, and Russia in the first half of the twentieth century, infecting 15 million people and killing 5 million, and is still a problem in some developing countries. *Endemic relapsing fever* is caused by several *Borrelia* species, which are transmitted from small animals to humans by *Ornithodorus* (soft-bodied) ticks.

In both louse- and tick-transmitted borreliosis, there is a 1- to 2-week incubation period after the bite as the spirochetes multiply in the blood. Clinical infection is heralded by shaking chills, fever, headache, and fatigue, followed by DIC and multi-organ failure. Spirochetes are temporarily cleared from the blood by anti-*Borrelia* antibodies, which target a single major surface protein called the variable major protein.[91] After a few days, bacteria bearing a different surface antigen emerge and reach high densities in the blood, and symptoms return until a second set of host antibodies clears these organisms. The lessening severity of successive attacks of relapsing fever and its spontaneous cure in many untreated patients have been attributed to the limited genetic repertoire of *Borrelia*, enabling the host to build up cross-reactive as well as clone-specific antibodies.

Morphology. The diagnosis can be made by identification of spirochetes in blood smears obtained during febrile periods. In fatal louse-borne disease, the spleen is moderately enlarged (300–400 gm) and contains focal necrosis and miliary collections of leukocytes, including neutrophils, and numerous borreliae. There is congestion and hypercellularity of the red pulp, which contains macrophages with phagocytosed red cells (erythrophagocytosis). The liver may also be enlarged and congested, with prominent Kupffer cells and septic foci. Scattered hemorrhages resulting from DIC may be found in serosal and mucosal surfaces, skin, and viscera. Pulmonary bacterial superinfection is a frequent complication.

Lyme Disease

Lyme disease is named for the Connecticut town where there was an epidemic of arthritis associated with skin erythema in the mid-1970s. It is caused by several subspecies of the spirochete *Borrelia burgdorferi*, which is transmitted from rodents to people by *Ixodes* deer ticks.[92,][93] Lyme disease is a common arthropod-borne disease in the United States, Europe, and Japan. In the United States the incidence of Lyme disease has risen, with approximately 23,000 cases in 2005. Most cases occur in the Northeastern states and in some parts of Midwestern states. In endemic areas, as many as 50% of ticks are infected with *B. burgdorferi*, and ticks may also be infected with *Ehrlichia* and *Babesia* (discussed later). Serology is the main method of diagnosis, but PCR can be done on infected tissue.

Lyme disease involves multiple organ systems and is divided into three stages (Fig. 8-40). In *stage 1*, spirochetes multiply and spread in the dermis at the site of a tick bite, causing an expanding area of redness, often with a pale center. This skin lesion, called *erythema chronicum migrans*, may be accompanied by fever and lymphadenopathy but usually disappears in 4 to 12 weeks. In *stage 2, the*

early disseminated stage, spirochetes spread hematogenously throughout the body and cause secondary skin lesions, lymphadenopathy, migratory joint and muscle pain, cardiac arrhythmias, and meningitis often associated with cranial nerve involvement. In *stage 3, the late disseminated stage*, 2 or 3 years after the initial bite, Lyme borreliae cause a chronic arthritis sometimes with severe damage to large joints and a polyneuropathy and encephalitis that vary from mild to debilitating.

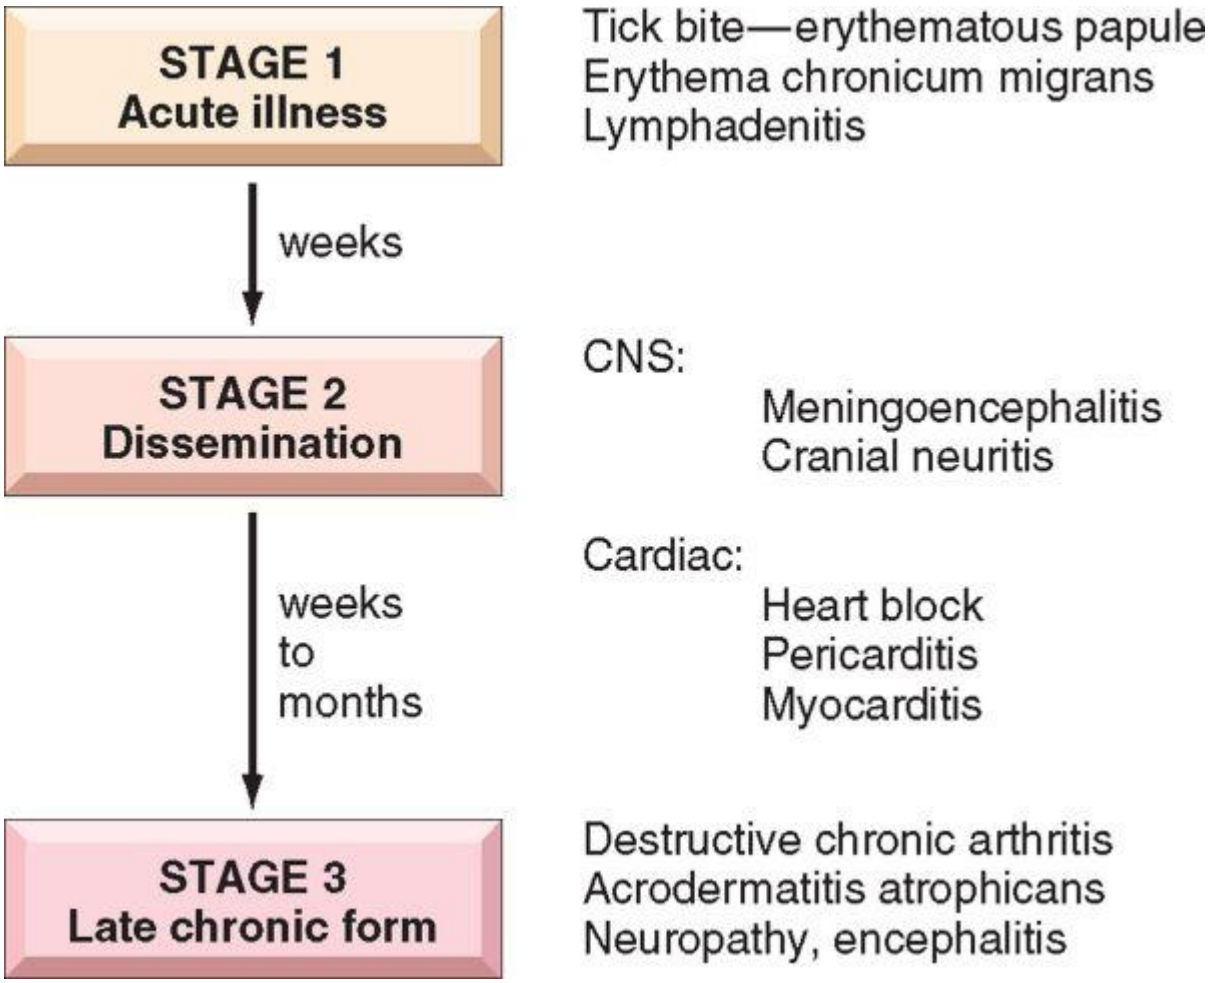

FIGURE 8-40 Clinical stages of Lyme disease.

Pathogenesis.

Borrelia burgdorferi does not produce LPS or exotoxins that damage the host. *Much of the pathology associated with B. burgdorferi is thought to be secondary to the immune response against the bacteria and the inflammation that accompanies it*. The initial immune response is stimulated by binding of bacterial lipoproteins to TLR2 expressed by macrophages. In response, these cells release proinflammatory cytokines (IL-6 and TNF) and generate bactericidal nitric oxide, reducing but usually not eliminating the infection.

The adaptive immune response to Lyme disease is mediated by CD4+ helper T cells and B cells. *Borrelia*-specific anti-bodies, made 2 to 4 weeks after infection, drive complement-mediated killing of the bacteria; however, *B. burgdorferi* escapes the antibody response through antigenic variation. Similar to *Borrelia hermsii*, a cause of endemic relapsing fever, *B. burgdorferi* has a plasmid with a single

promoter sequence and multiple coding sequences for an antigenic surface protein, VlsE, each of which can shuttle into position next to the promoter and be expressed. Thus, as the antibody response to one VlsE protein is mounted, bacteria expressing an alternate VlsE protein can escape immune recognition. Chronic manifestations of Lyme disease, such as the late arthritis, are probably caused by the immune response against persistent bacteria.

Morphology. Skin lesions caused by *B. burgdorferi* are characterized by edema and a lymphocytic–plasma cell infiltrate. In early Lyme arthritis, the synovium resembles early rheumatoid arthritis, with villous hypertrophy, lining-cell hyperplasia, and abundant lymphocytes and plasma cells in the subsynovium. A distinctive feature of Lyme arthritis is an arteritis, which produces onionskin-like lesions resembling those seen in lupus (Chapter 6). In late Lyme disease there may be extensive erosion of the cartilage in large joints. In Lyme meningitis the CSF is hypercellular, due to a marked lymphoplasmacytic infiltrate, and contains anti-spirochete IgGs.

ANAEROBIC BACTERIA

Many anaerobic bacteria are normal flora in sites of the body that have low oxygen levels. The anaerobic flora cause disease (abscesses or peritonitis) when they are introduced into normally sterile sites or when the balance of organisms is upset and pathogenic anaerobes overgrow (e.g., *Clostridium difficile* colitis with antibiotic treatment). Environmental anaerobes also cause disease (tetanus, botulism, and gas gangrene).

Abscesses Caused by Anaerobes

Abscesses are usually caused by mixed anaerobic and facultative aerobic bacteria (able to grow with or without oxygen). On average, abscesses have 2.5 species of bacteria, 1.6 of which are anaerobes and 0.9 of which are aerobic or facultative bacteria.[94] *Commensal bacteria from adjacent sites (oropharynx, intestine, and female genital tract) are the usual cause of abscesses, so the species found in the abscess reflect the normal flora*. Since most anaerobes that cause abscesses are part of the normal flora, it is not surprising that these organisms do not produce significant toxins.

The bacteria found in head and neck abscesses reflect oral and pharyngeal flora. Common anaerobes at this site include the gram-negative bacilli *Prevotella* and *Porphyromonas* species, often mixed with the facultative *S. aureus* and *S. pyogenes*. *Fusobacterium necrophorum*, an oral commensal, causes Lemierre syndrome, characterized by infection of the lateral pharyngeal space and septic jugular vein thrombosis. Abdominal abscesses are caused by the anaerobes of the gastrointestinal tract, including gram-positive *Peptostreptococcus* and *Clostridium* species, as well as the gram-negative *Bacteriodes fragilis* and *E. coli*. Genital tract infections in women are caused by anaerobic gram-negative bacilli, including *Prevotella* species that are found in Bartholin cyst abscesses and tubo-ovarian abscesses, often mixed with *E. coli* or *Streptococcus agalactiae*.

Morphology. Abscesses caused by anaerobes contain discolored and foul-smelling pus that is often poorly walled off. Otherwise, these lesions pathologically resemble those of the common pyogenic infections. Gram stain reveals mixed infection with grampositive and gram-negative rods and gram-positive cocci mixed with neutrophils.

Clostridial Infections

Clostridium species are gram-positive bacilli that grow under anaerobic conditions and produce spores that are present in the soil. Four types of disease are caused by *Clostridium*:

- *C. perfringens, C. septicum*, and other species cause cellulitis and myonecrosis of traumatic and surgical wounds *(gas gangrene)*, uterine myonecrosis often associated with illegal abortions, mild food poisoning, and infection of the small bowel associated with ischemia or neutropenia that often leads to severe sepsis.
- *C. tetani*, the cause of *tetanus*, proliferates in puncture wounds and in the umbilical stump of newborn infants and releases a potent neurotoxin, called tetanospasmin, that causes convulsive contractions of skeletal muscles (lockjaw). Tetanus toxoid (formalin-fixed neurotoxin) is part of the DPT (diphtheria, pertussis, and tetanus) immunization, which has greatly decreased the incidence of tetanus worldwide.
- *C. botulinum* grows in inadequately sterilized canned foods and releases a potent neurotoxin that blocks synaptic release of acetylcholine and causes a severe paralysis of respiratory and skeletal muscles (*botulism*).
- *C. difficile* overgrows other intestinal flora in antibiotic-treated people, releases toxins, and causes *pseudomembranous colitis* (Chapter 17).

Clostridial infections can be diagnosed by culture (cellulitis, myonecrosis), toxin assays (pseudomembranous colitis), or both (botulism).

Pathogenesis.

Clostridium perfringens does not grow in the presence of oxygen, so tissue death is essential for growth of the bacteria in the host. These bacteria release collagenase and hyaluronidase that degrade extracellular matrix proteins and contribute to bacterial invasiveness, but their most powerful virulence factors are the many toxins they produce. *C. perfringens* secretes 14 toxins, the most important of which is α-*toxin*.[95] This toxin has multiple actions. It is a phospholipase C that degrades lecithin, a major component of cell membranes, and so destroys red cells, platelets, and muscle cells, causing myonecrosis. It also has a sphingomyelinase activity that contributes to nerve sheath damage.

Ingestion of food contaminated with *C. perfringens* causes a brief diarrhea. Spores, usually in contaminated meat, survive cooking, and the organism proliferates in cooling food. *C. perfringens* enterotoxin forms pores in the epithelial cell membranes, lysing the cells and disrupting tight junctions between epithelial cells.[96]

The neurotoxins produced by *C. botulinum* and *C. tetani* both inhibit release of neurotransmitters, resulting in paralysis.[26] Botulism toxin, eaten in contaminated foods or absorbed from wounds infected with *C. botulinum*, binds gangliosides on motor neurons and is transported into the cell. In the cytoplasm, the A fragment of botulism toxin cleaves a protein, called synaptobrevin, that mediates fusion of neurotransmitter-containing vesicles with the neuron membrane. By blocking vesicle fusion, botulism toxin prevents the release of acetylcholine at the neuromuscular junction, resulting in flaccid paralysis. If the respiratory muscles are affected, botulism can lead to death. Indeed, the widespread use of botulism toxin (Botox) in cosmetic surgery is based on its ability to cause paralysis of strategically chosen muscles on the face. The mechanism of tetanus toxin is similar to that of botulism toxin, but tetanus toxin causes a violent spastic paralysis by blocking release of γ-aminobutyric acid, a neurotransmitter that inhibits motor neurons.

Clostridium difficile produces toxin A, an enterotoxin that stimulates chemokine production and thus attracts leukocytes, and toxin B, a cytotoxin, which causes distinctive cytopathic effects in cultured cells. Both toxins are glucosyl transferases and are part of a pathogenicity island that is absent from the chromosomes of nonpathogenic strains of *C. difficile*.[97]

Morphology. Clostridial cellulitis, which originates in wounds, can be differentiated from infection caused by pyogenic cocci by its foul odor, its thin, discolored exudate, and the relatively quick and wide tissue destruction. On microscopic examination, the amount of tissue necrosis is disproportionate to the number of neutrophils and gram-positive bacteria present (Fig. 8-41). Clostridial cellulitis, which often has granulation tissue at its borders, is treatable by debridement and antibiotics.

In contrast, **clostridial gas gangrene** is life-threatening and is characterized by marked edema and enzymatic necrosis of involved muscle cells 1 to 3 days after injury. An extensive fluid exudate, which is lacking in inflammatory cells, causes swelling of the affected region and the overlying skin, forming large, bullous vesicles that rupture. Gas bubbles caused by bacterial fermentation appear within the gangrenous tissues. As the infection progresses, the inflamed muscles become soft, blue-black, friable, and semifluid as a result of the massive proteolytic action of the released bacterial enzymes. On microscopic examination there is severe **myonecrosis**, extensive hemolysis, and marked vascular injury, with thrombosis. *C. perfringens* is also associated with dusk-colored, wedge-shaped infarcts in the small bowel, particularly in neutropenic people. Regardless of the site of entry, when *C. perfringens* disseminates hematogenously there is widespread formation of gas bubbles.

Despite the severe neurologic damage caused by botulinum and tetanus toxins, the neuropathologic changes are subtle and nonspecific.

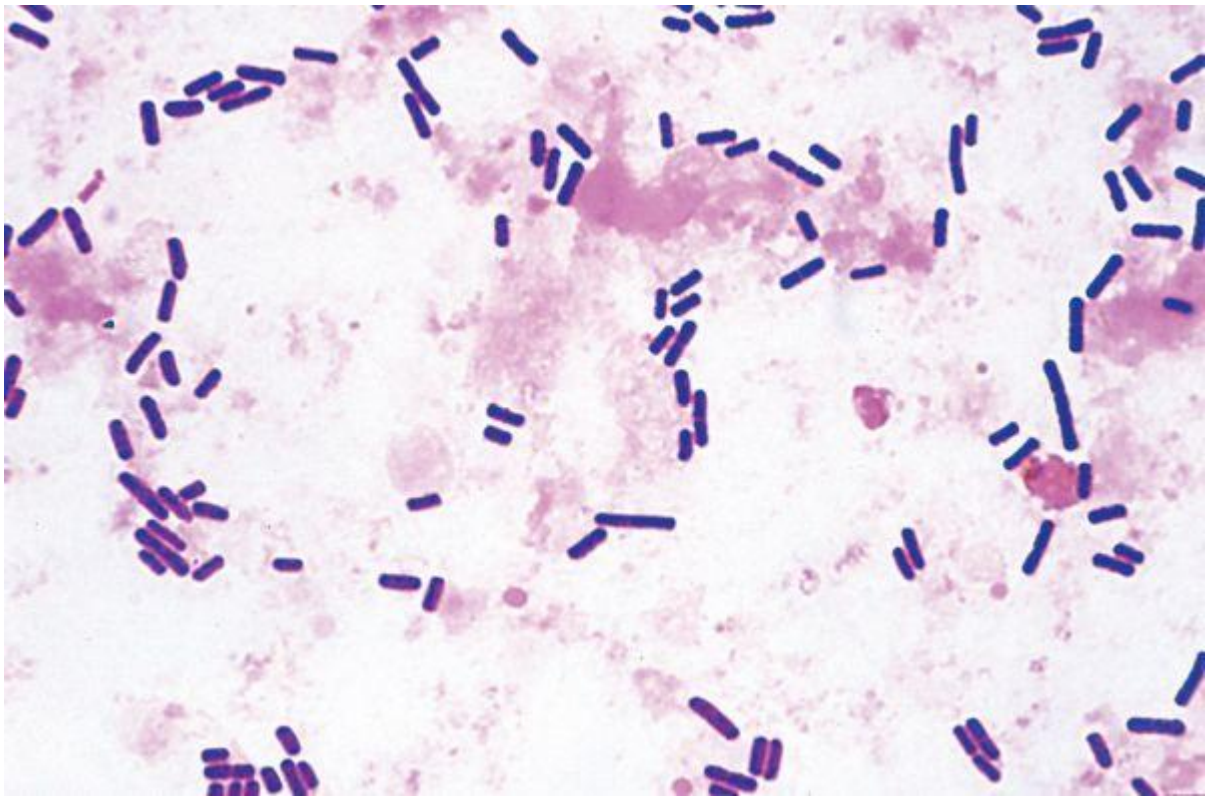

FIGURE 8-41 Boxcar-shaped gram-positive *Clostridium perfringens* in gangrenous tissue.

Obligate intracellular bacteria proliferate only within host cells, although some may survive outside of cells. These organisms are well adapted to the intracellular environment, with membrane pumps to capture amino acids and ATP for energy. Some are unable to synthesize ATP at all (e.g., *Chlamydia*), while others synthesize at least some of their own ATP (e.g., the rickettsiae).

Chlamydial Infections

Chlamydia trachomatis is a small gram-negative bacterium that is an obligate intracellular parasite. *C. trachomatis* exists in two forms during its unique life cycle. The infectious form, called the elementary body (EB), is a metabolically inactive, sporelike structure. The EB is taken up by host cells by receptor-mediated endocytosis. The bacteria prevent fusion of the endosome and lysosome by an unknown mechanism. Inside the endosome the elementary body differentiates into a metabolically active form, called the reticulate body. Using energy sources and amino acids from the host cell, the reticulate body replicates and ultimately forms new elementary bodies that are capable of infecting additional cells.

The various diseases caused by *C. trachomatis* infection are associated with different serotypes of the bacteria: urogenital infections and inclusion conjunctivitis (serotypes D through K), lymphogranuloma venereum (serotypes L1, L2, and L3), and an ocular infection of children, trachoma (serotypes A, B, and C). The venereal infections caused by *C. trachomatis* will be discussed here.

Genital infection by *C. trachomatis is the most common sexually transmitted bacterial disease in the world*.[98] In 2006 approximately a million cases of genital chlamydia were reported to the CDC; this is more than twice the number of cases of gonorrhea. Before the identification of *C. trachomatis*, people infected with this organism were diagnosed with non-gonococcal urethritis (NGU). Indeed, *C. trachomatis* is the cause of over half the cases of NGU. Current CDC recommendations call for treatment of both *N. gonorrhoeae* and *C. trachomatis* in patients who are diagnosed with either infection, because co-infection with both is common.

Genital *C. trachomatis* infections (other than lymphogranuloma venereum, discussed below) are associated with clinical features that are similar to those caused by *N. gonorrhoeae*. Patients may develop epididymitis, prostatitis, pelvic inflammatory disease, pharyngitis, conjunctivitis, perihepatic in-flammation, and proctitis. Unlike *N. gonorrhoeae* urethritis, *C. trachomatis* urethritis in men may be asymptomatic and so may go untreated. Both *N. gonorrhoeae* and *C. trachomatis* frequently cause asymptomatic infections in women. *C. trachomatis* urethritis can be diagnosed by culture of the bacteria in human cell lines, but amplified nucleic acid tests performed on genital swabs or urine specimens are more sensitive and have supplanted cultures.

Genital infection with the L serotypes of *C. trachomatis* causes *lymphogranuloma venereum*, a chronic, ulcerative disease. Lymphogranuloma venereum is a sporadic disease in the United States and Western Europe, but it is endemic in parts of Asia, Africa, the Caribbean region, and South America. The infection initially manifests as a small, often unnoticed, papule on the genital mucosa or nearby skin. Two to six weeks later, growth of the organism and the host response in draining lymph nodes produce swollen, tender lymph nodes, which may coalesce and rupture. If not treated, the infection can subsequently cause fibrosis and strictures in the anogenital tract. Rectal strictures are particularly common in women.

Morphology. The morphologic features of *C. trachomatis* **urethritis** are virtually identical to those of gonorrhea. The primary infection is characterized by a mucopurulent discharge containing a predominance of neutrophils. Organisms are not visible in Gram-stained smears or sections.

The lesions of **lymphogranuloma venereum** contain a mixed granulomatous and neutrophilic inflammatory response. Variable numbers of chlamydial inclusions are seen in the cytoplasm of epithelial cells or inflammatory cells. Regional lymphadenopathy is common, usually occurring within 30 days of infection. Lymph node involvement is characterized by a granulomatous inflammatory reaction associated with irregularly shaped foci of necrosis and neutrophilic infiltration (stellate abscesses). With time, the inflammatory reaction is dominated by nonspecific chronic inflammatory infiltrates and extensive fibrosis. The latter, in turn, may cause local lymphatic obstruction, lymphedema, and strictures. In active lesions, the diagnosis of lymphogranuloma venereum may be made by demonstration of the organism in biopsy sections or smears of exudate. In more chronic cases, the diagnosis rests with the demonstration of antibodies to the appropriate chlamydial serotypes in the patient's serum.

Rickettsial Infections

Members of the order *Rickettsiales* are vector-borne obligate intracellular bacteria that cause epidemic typhus *(Rickettsia prowazekii)*, scrub typhus *(Orienta tsutsugamushi)*, and spotted fevers (*Rickettsia rickettsii* and others).[6] These organisms have the structure of gram-negative, rod-shaped bacteria, although they stain poorly with Gram stain. Epidemic typhus, which is transmitted from person to person by body lice, is associated with wars and human deprivation, when individuals are forced to live in close contact without changing clothes. Scrub typhus, transmitted by chiggers, was a major problem for US soldiers in the Pacific in World War II and in Vietnam. Rocky Mountain spotted fever (RMSF), transmitted to humans by dog ticks, is most common in the southeastern and south-central United States. Rickettsiae of RMSF are transmitted after several hours of the tick feeding or, less commonly, when the tick is crushed during removal from the skin.

Ehrlichiosis is a recently discovered, tick-transmitted disease caused by *Rickettsiales*. The bacteria predominantly infect neutrophils *(Anaplasma phagocytophilum* and *Ehrlichia ewingii)* or macrophages *(Ehrlichia chaffeensis)*. Characteristic cytoplasmic inclusions (morulae), occasionally shaped like mulberries and composed of masses of bacteria, can be seen in leukocytes (Fig. 8-42). Ehrlichiosis is characterized by abrupt onset of fever, headache, and malaise, and may progress to respiratory insufficiency, renal failure, and shock. Rash occurs in approximately 40% of people with *E. chaffeensis* infections.

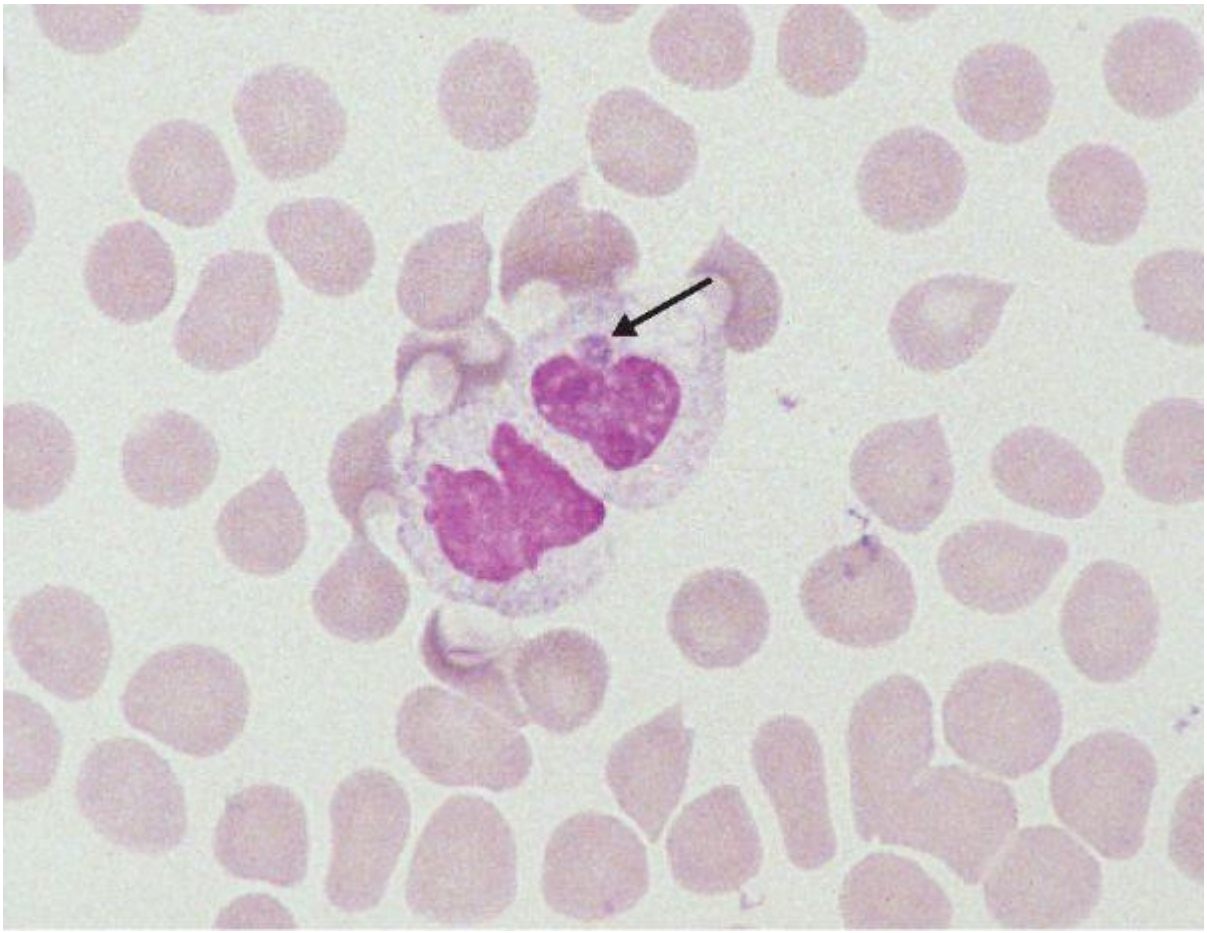

FIGURE 8-42 Peripheral blood granulocyte (band neutrophil) containing an *Ehrlichia* inclusion *(arrow). (Courtesy of Dr. Stephen Dumler, Johns Hopkins Medical Institution, Baltimore, MD.)*

Rickettsial diseases are usually diagnosed clinically and confirmed by serology.

Pathogenesis.

Rickettsiae do not produce significant toxins. The rickettsiae that cause typhus and spotted fevers predominantly infect vascular endothelial cells, especially those in the lungs and brain. The bacteria enter the endothelial cells by endocytosis, but they escape from the endosome into the cytoplasm before formation of the acidic phagolysosome. The organisms proliferate in the endothelial cell cytoplasm and then either lyse the cell (typhus group) or spread from cell to cell through actin-mobilized motion (spotted fever group). *The severe manifestations of rickettsial infection are primarily due to vascular leakage secondary to endothelial cell damage*.[6] This causes hypovolemic shock with peripheral edema, as well as pulmonary edema, renal failure, and a variety of CNS manifestations that can include coma.

The innate immune response to rickettsial infection is mounted by NK cells, which produce IFN-γ, reducing bacterial proliferation. Subsequent CTL responses are critical for elimination of rickettsial infections. IFN-γ and TNF, from activated NK cells and T cells, stimulate the production of bactericidal nitric oxide. CTLs lyse infected cells, reducing bacterial proliferation. Rickettsial infections are diagnosed by immunostaining of organisms or by detection of antirickettsial antibodies in the serum.

Morphology

Typhus Fever. In mild cases the gross changes are limited to a rash and small hemorrhages due to the vascular lesions. In more severe cases, there may be areas of necrosis of the skin and gangrene of the tips of the fingers, nose, earlobes, scrotum, penis, and vulva. In such cases, irregular ecchymotic hemorrhages may be found internally, principally in the brain, heart muscle, testes, serosal membrane, lungs, and kidneys.

The most prominent microscopic changes are small-vessel lesions and focal areas of hemorrhage and inflammation in various organs and tissues. Endothelial swelling in the capillaries, arterioles, and venules may narrow the lumens of these vessels. A cuff of mononuclear inflammatory cells usually surrounds the affected vessel. The vascular lumens are sometimes thrombosed. Necrosis of the vessel wall is unusual in typhus (as compared to RMSF). Vascular thromboses lead to gangrenous necrosis of the skin and other structures in a minority of cases. In the brain, characteristic typhus nodules are composed of focal microglial proliferations with an infiltrate of mixed T lymphocytes and macrophages (Fig. 8-43).

Scrub typhus, or mite-borne infection, is usually a milder version of typhus fever. The rash is usually transitory or might not appear. Vascular necrosis or thrombosis is rare, but there may be a prominent inflammatory lymphadenopathy.

Rocky Mountain Spotted Fever. A hemorrhagic rash that extends over the entire body, including the palms of the hands and soles of the feet, is the hallmark of RMSF. An eschar at the site of the tick bite is uncommon with RMSF but is common with *R. akari*, *R. africae*, and *R. conorii* infection. The vascular lesions that underlie the rash often lead to acute necrosis, fibrin extravasation, and occasionally thrombosis of the small blood vessels, including arterioles (Fig. 8-44). In severe RMSF, foci of necrotic skin appear, particularly on the fingers, toes, elbows, ears, and scrotum. The perivascular inflammatory response, similar to that of typhus, is seen in the brain, skeletal muscle, lungs, kidneys, testes, and heart muscle. The vascular lesions in the brain may involve larger vessels and produce microinfarcts. A noncardiogenic pulmonary edema causing adult respiratory distress syndrome is the major cause of death in patients with RMSF.

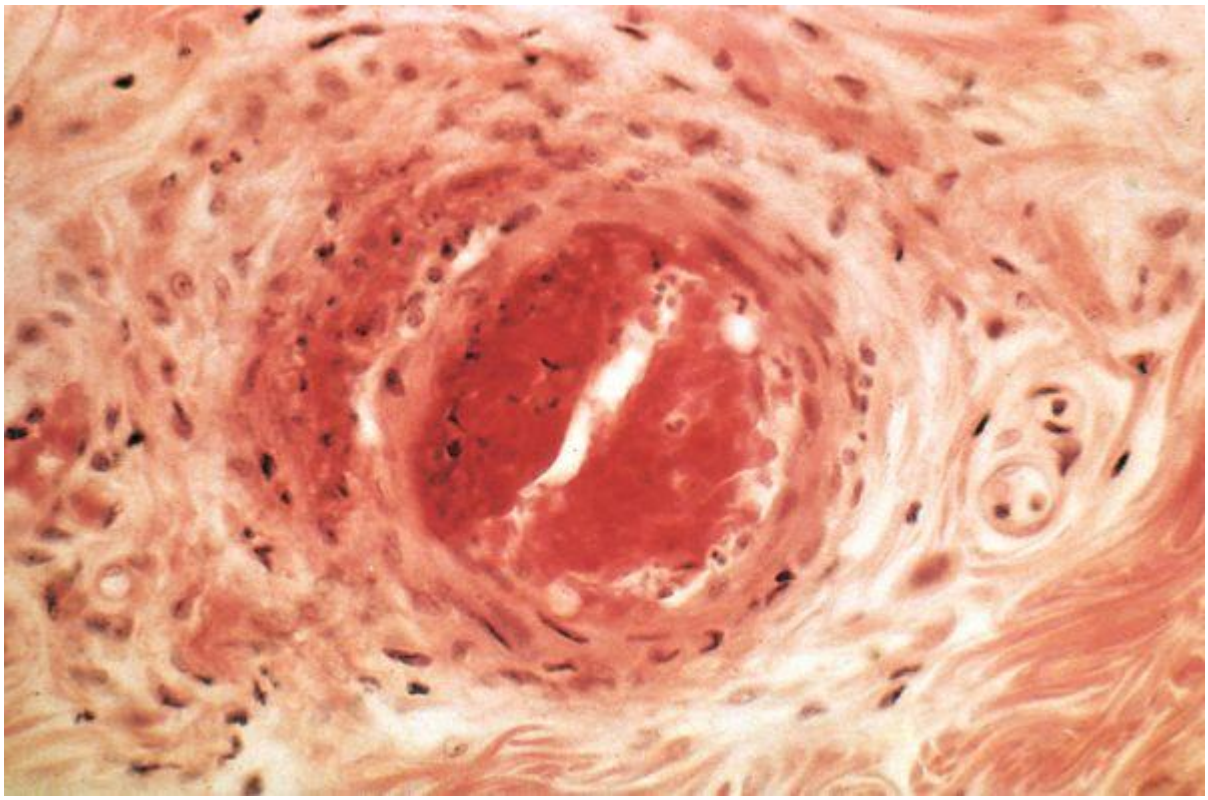

FIGURE 8-44 Rocky Mountain spotted fever with a thrombosed vessel and vasculitis.

2.8.4 Fungal Infections

Fungi are eukaryotes with cell walls that give them their shape. Fungal cells can grow as multicellular filaments called molds or as single cells or chains of cells called yeast. Most yeasts reproduce by budding. Some yeasts, such as *Candida albicans*, can produce buds that fail to detach and become elongated, producing a chain of elongated yeast cells called pseudohyphae. Molds consist of threadlike filaments (hyphae) that grow and divide at their tips. They can produce round cells, called conidia, that easily become airborne, disseminating the fungus. Many medically important fungi are dimorphic, existing as yeast or molds, depending on environmental conditions (yeast form at human body temperature and a mold form at room temperature).[99] Fungal infections can be diagnosed by histologic examination, although definitive identification of some species requires culture.

Fungal infections, also called *mycoses*, are of four major types: (1) superficial and cutaneous mycoses, which are common and limited to the very superficial or keratinized layers of skin, hair, and nails; (2) subcutaneous mycoses, which involve the skin, subcutaneous tissues, and lymphatics and rarely disseminate systemically; (3) endemic mycoses, which are caused by dimorphic fungi that can produce serious systemic illness in healthy individuals; and (4) opportunistic mycoses, which can cause life-threatening systemic diseases in individuals who are immunosuppressed or who carry implanted prosthetic devices or vascular catheters. Some of the fungi that cause opportunistic mycoses are discussed below; those involving specific organs are discussed in other chapters.

Candidiasis

Residing normally in the skin, mouth, gastrointestinal tract, and vagina, *Candida* species usually live as benign commensals and seldom produce disease in healthy people. However, *Candida* species, most often *C. albicans*, are the most frequent cause of human fungal infections. Most types of *Candida* infections originate when the normal commensal flora breach the skin or mucosal barriers. These infections may be confined to the skin or mucous membranes or disseminate widely.[99] In otherwise healthy people *Candida* organisms cause vaginitis and diaper rash. Diabetics and burn patients are particularly susceptible to superficial candidiasis. In individuals with indwelling intravenous lines or catheters, or undergoing peritoneal dialysis, *Candida* organisms can spread into the bloodstream. Severe disseminated candidiasis most commonly occurs in patients who are neutropenic due to leukemia, chemotherapy, or bone marrow transplantation, and may cause shock and DIC.

Pathogenesis.

A single strain of *Candida* can be successful as a commensal or a pathogen. *Candida* can shift between different phenotypes in a reversible and apparently random fashion. Phenotypic switching involves coordinated regulation of phase-specific genes and provides a way for *Candida* to adapt to changes in the host environment (produced by antibiotic therapy, the immune response, or altered host physiology). These variants can exhibit altered colony morphology, cell shape, antigenicity, and virulence.[100]

Candida produce a large number of functionally distinct adhesins that mediate adherence to host cells, some of which also function in *Candida* morphogenesis or signaling.[101] These adhesins include (1) an integrin-like protein, which binds arginine-glycine-aspartic acid (RGD) groups on fibrinogen, fibronectin, and laminin; (2) a protein that resembles transglutaminase substrates and binds to epithelial cells; and (3) several agglutinins that bind to endothelial cells or fibronectin. Adhesion is an important determinant of virulence, since strains with reduced adherence to cells in vitro are avirulent in experimental models in vivo. Differential expression of adhesins by yeast and filamentous forms leads to recognition of distinct receptors on host cells.

Candida produce a number of enzymes that contribute to invasiveness, including at least nine secreted aspartyl proteinases, which may promote tissue invasion by degrading extracellular matrix proteins, and catalases, which may enable the organism to resist oxidative killing by phagocytic cells.[101,][102] *Candida* also secrete adenosine, which blocks neutrophil oxygen radical production and degranulation.

The ability of *C. albicans* to grow as biofilms also contributes to its capacity to cause disease.[103] *Candida* biofilms are microbial communities consisting of mixtures of yeast, filamentous forms, and fungal-derived extracellular matrix. *C. albicans* can form biofilms on implanted medical devices that reduce susceptibility of the organism to immune responses and antifungal drug therapy.

The immune response to *Candida* is complex. Innate immunity and T-cell responses are important for protection against *Candida* infection.[104] Neutrophils and macrophages phagocytose *Candida*, and oxidative killing by these phagocytes is a first line of host defense. The important role of neutrophils and macrophages is illustrated by the increased risk of *Candida* infections in individuals with neutropenia or defects in NADPH oxidase or myeloperoxidase. Filamentous forms, but not yeast, can escape from phagosomes and enter the cytoplasm and proliferate. *Candida* yeast activate dendritic cells to produce IL-12 more than do the filamentous forms of the fungi. As a result, the yeast forms elicit a protective antifungal T_H1 response, while filamentous forms tend to stimulate a nonprotective T_H2 response. Like other fungi, *Candida* also elicit T_H17 responses, which are responsible for recruiting neutrophils and monocytes (Chapter 6). *Candida* T-cell responses are particularly important for protection against mucosal and cutaneous *Candida* infection, as shown by recurrent mucocutaneous *Candida* infections in individuals with HIV infection and low T-cell counts.

Morphology. In tissue sections, *C. albicans* can appear as yeastlike forms (blastoconidia), pseudohyphae, and, less commonly, true hyphae, defined by the presence of septae (Fig. 8-45). Pseudohyphae, an important diagnostic clue, represent budding yeast cells joined end to end at constrictions. All forms may be present together in the same tissue. The organisms may be visible with routine hematoxylin and eosin stains, but a variety of special "fungal" stains (Gomori methenamine–silver, periodic acid–Schiff) are commonly used to better visualize them.

Most commonly candidiasis takes the form of a superficial infection on mucosal surfaces of the oral cavity **(thrush)**. Florid proliferation of the fungi creates gray-white, dirty-looking pseudomembranes composed of matted organisms and inflammatory debris. Deep to the surface, there is mucosal hyperemia and inflammation. This form of candidiasis is seen in newborns, debilitated people, children receiving oral steroids for asthma, and following a course of broad-spectrum antibiotics that destroy competing normal bacterial flora. The other major risk group includes HIV-positive patients; people with oral thrush for no obvious reason should be evaluated for HIV infection.

Candida esophagitis is commonly seen in AIDS patients and in those with hematolymphoid malignancies. These patients present with dysphagia (painful swallowing) and retrosternal pain; endoscopy demonstrates white plaques and pseudomembranes resembling oral thrush on the esophageal mucosa (see Fig. 8-45).

Candida vaginitis is a common form of vaginal infection in women, especially those who are diabetic, pregnant, or on oral contraceptive pills. It is usually associated with intense itching and a thick, curdlike discharge.

Cutaneous candidiasis can present in many different forms, including infection of the nail proper ("onychomycosis"), nail folds ("paronychia"), hair follicles ("folliculitis"), moist, intertriginous skin such as armpits or webs of the fingers and toes ("intertrigo"), and penile skin ("balanitis"). "Diaper rash" is a cutaneous candidial infection seen in the perineum of infants, in the region of contact with wet diapers.

Invasive candidiasis is caused by blood-borne dissemination of organisms to various tissues or organs. Common patterns include (1) renal abscesses, (2) myocardial abscesses and endocarditis, (3) brain microabscesses and meningitis, (4) endophthalmitis (virtually any eye structure can be involved), and (5) hepatic abscesses. In any of these locations, depending on the immune status of the infected person, the fungus may evoke little inflammatory reaction, cause the usual suppurative response, or occasionally produce granulomas. People with acute leukemias who are profoundly neutropenic after chemotherapy are particularly prone to developing systemic disease. *Candida* endocarditis is the most common fungal endocarditis, usually occurring in the setting of prosthetic heart valves or in intravenous drug abusers.

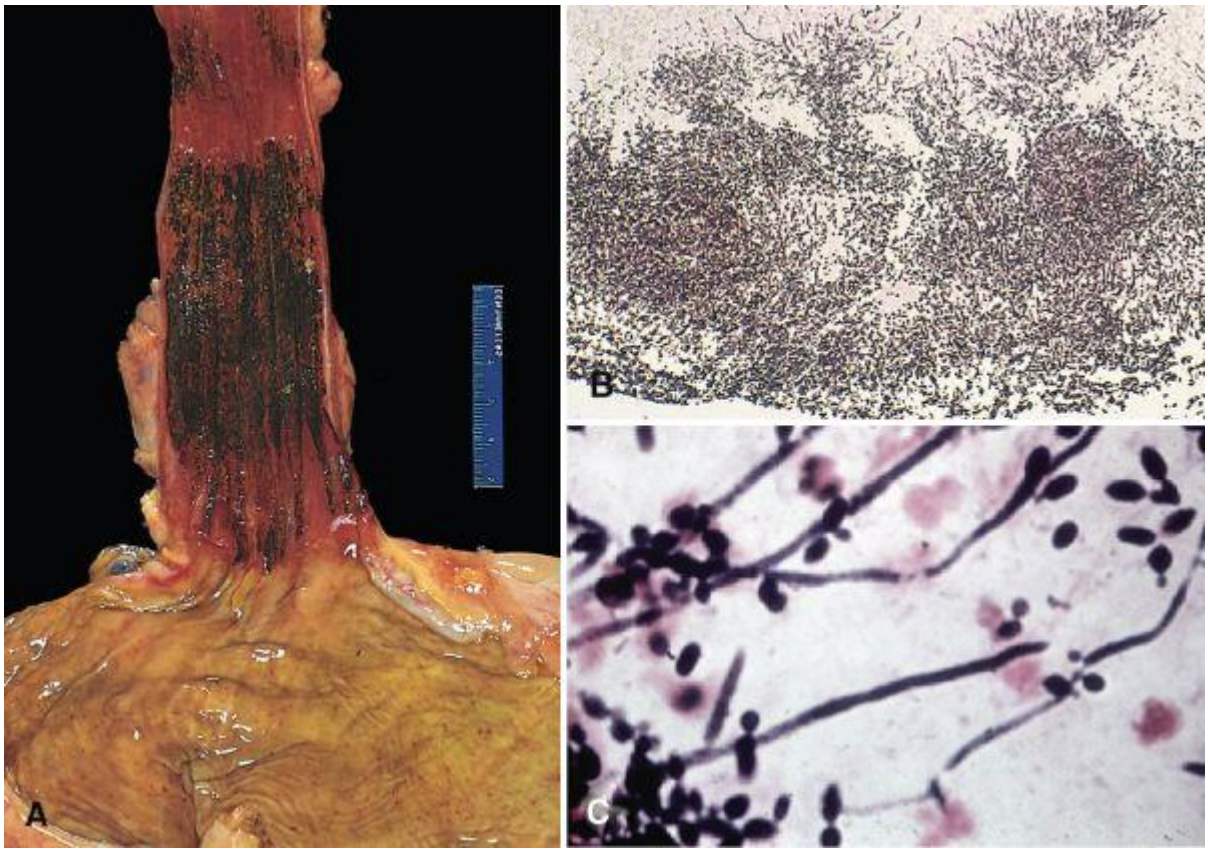

FIGURE 8-45 The morphology of *Candida* infections. **A**, Severe candidiasis of the distal esophagus. **B**, Silver stain of esophageal candidiasis reveals the dense mat of *Candida*. **C**, Characteristic pseudohyphae and blastoconidia (budding yeast) of *Candida*. ***(C**, Courtesy of Dr. Dominick Cuvuoti, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Cryptococcosis

Cryptococcus neoformans grows as an encapsulated yeast that causes meningoencephalitis in otherwise healthy individuals but more frequently presents as an opportunistic infection in people with AIDS, leukemia, lymphoma, systemic lupus erythematosus, or sarcoidosis, as well as in transplant recipients. Many of these patients receive high-dose corticosteroids, a major risk factor for *Cryptococcus* infection.

Pathogenesis.

Cryptococcus neoformans is present in the soil and in bird (particularly pigeon) droppings and infects people when it is inhaled. Several virulence factors enable it to evade host defenses, including (1) a polysaccharide capsule, (2) melanin production, and (3) enzymes.[105] These mechanisms are not very effective when *C. neoformans* infects hosts with intact immune defenses, but they can lead to disseminated disease in immunosuppressed individuals.

Glucuronoxylomannin, the principal capsular polysaccharide of *C. neoformans*, is a major virulence factor that inhibits phagocytosis by alveolar macrophages, leukocyte migration, and recruitment of inflammatory cells. *C. neoformans* can undergo phenotypic switching, which leads to changes in the structure and size of the capsule polysaccharide, providing a means to evade immune responses.[106]

Cryptococcus neoformans makes laccase, which catalyzes the formation of a melanin-like pigment.[105] Laccase mutants of *C. neoformans* have reduced virulence in animal models. The effects of melanin may be related to its antioxidant properties. These fungi also make a number of other enzymes, including a serine proteinase that cleaves fibronectin and other basement membrane proteins, which may aid tissue invasion.[107] *C. neoformans* can establish latent infections accompanied by granuloma formation that can reactivate in immunosuppressed hosts.[108]

Morphology. Cryptococcus has yeast but not pseudohyphal or hyphal forms. The 5- to 10-μm cryptococcal yeast has a highly characteristic thick gelatinous capsule. Capsular polysaccharide stains intense red with periodic acid–Schiff and mucicarmine in tissues and can be detected with antibody-coated beads in an agglutination assay. India ink preparations create a negative image, visualizing the thick capsule as a clear halo within a dark background. Although the lung is the primary site of infection, pulmonary involvement is usually mild and asymptomatic, even while the fungus is spreading to the CNS. *C. neoformans*, however, may form a solitary pulmonary granuloma similar to the circumscribed (coin) lesions caused by *Histoplasma*. The major lesions caused by *C. neoformans* are in the CNS, involving the meninges, cortical gray matter, and basal nuclei. The host response to cryptococci is extremely variable. In immunosuppressed people, organisms may evoke virtually no inflammatory reaction, so gelatinous masses of fungi grow in the meninges or expand the perivascular Virchow-Robin spaces within the gray matter, producing the so-called soap-bubble lesions (Fig. 8-46). In severely immunosuppressed persons, *C. neoformans* may disseminate widely to the skin, liver, spleen, adrenals, and bones. In nonimmunosuppressed people or in those with protracted disease, the fungi induce a chronic granulomatous reaction composed of macrophages, lymphocytes, and foreign body–type giant cells. Suppuration also may occur, as well as a rare granulomatous arteritis of the circle of Willis.

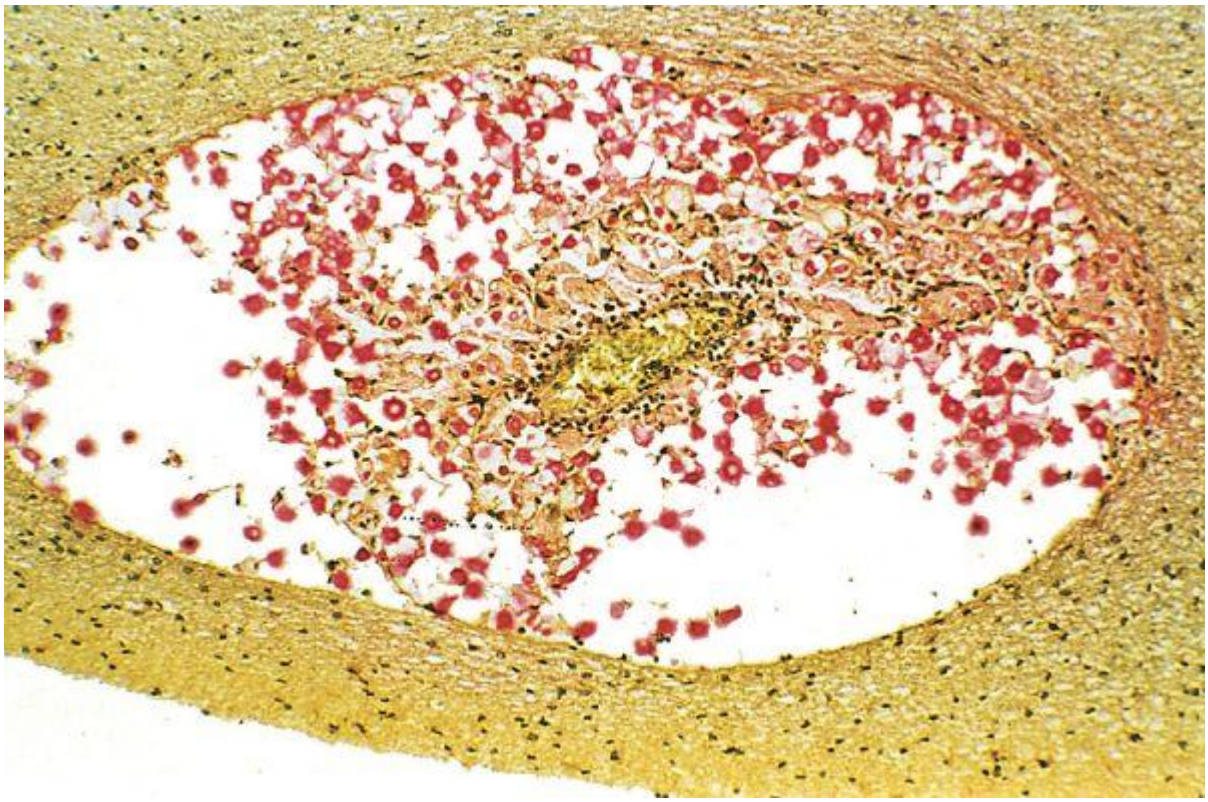

FIGURE 8-46 Mucicarmine stain of cryptococci (staining red) in a Virchow-Robin perivascular space of the brain (soap-bubble lesion).

Aspergillosis

Aspergillus is a ubiquitous mold that causes allergies (allergic bronchopulmonary aspergillosis) in otherwise healthy people and serious *sinusitis, pneumonia*, and invasive disease in immunocompromised individuals. The major conditions that predispose to *Aspergillus* infection are neutropenia and corticosteroids. *Aspergillus fumigatus* is the most common species to cause disease, and it produces severe invasive infections in immunocompromised individuals.

Pathogenesis.

Aspergillus species are transmitted by airborne conidia, and the lung is the major portal of entry. The small size of *A. fumigatus* spores, approximately 2 to 3 μm, enables them to reach alveoli. Conidia germinate into hyphae, which then invade tissues. Neutrophils and macrophages are the major host defenses against *Aspergillus*. Alveolar macrophages ingest and kill the conidia, while neutrophils produce reactive oxygen intermediates that kill hyphae. Invasive aspergillosis is highly associated with neutropenia and impaired neutrophil defenses.

Aspergillus produces several virulence factors, including adhesins, antioxidants, enzymes, and toxins.[108] Conidia can bind to fibrinogen, laminin, complement, fibronectin, collagen, albumin, and surfactant proteins, but receptor-ligand interactions are not well defined. *Aspergillus* produces several antioxidant defenses, including melanin pigment, mannitol, catalases, and superoxide dismutases. This fungus also produces phospholipases, proteases, and toxins, but their roles in pathogenicity are not yet clear. *Restrictocin* and *mitogillin* are ribotoxins that inhibit host-cell protein synthesis by degrading mRNAs. The carcinogen *aflatoxin* is made by *Aspergillus* species growing on the surface of peanuts and may be a cause of liver cancer in Africa.[109] Sensitization to *Aspergillus* spores produces an allergic alveolitis[110] (Chapter 15). *Allergic bronchopulmonary aspergillosis*, associated with hypersensitivity arising from superficial colonization of the bronchial mucosa, often occurs in asthmatic people.

Morphology. Colonizing aspergillosis (aspergilloma) usually implies growth of the fungus in pulmonary cavities with minimal or no invasion of the tissues (the nose also is often colonized). The cavities are usually the result of prior tuberculosis, bronchiectasis, old infarcts, or abscesses. Proliferating masses of hyphae form brownish “fungal balls” lying free within the cavities. The surrounding inflammatory reaction may be sparse, or there may be chronic inflammation and fibrosis. People with aspergillomas usually have recurrent hemoptysis.

Invasive aspergillosis is an opportunistic infection that is confined to immunosuppressed hosts. The primary lesions are usually in the lung, but widespread hematogenous dissemination with involvement of the heart valves and brain is common. The pulmonary lesions take the form of necrotizing pneumonia with sharply delineated, rounded, gray foci and hemorrhagic borders; they are often referred to as **target lesions** (Fig. 8-47A). *Aspergillus* forms fruiting bodies (usually in lung cavities) and septate filaments, 5 to 10 μm thick, branching at acute angles (40 degrees) (Fig. 8-47B). *Aspergillus* hyphae cannot be distinguished from *Pseudallescheria boydii* and *Fusarium* species by morphology alone. *Aspergillus* has a tendency to invade blood vessels; therefore, areas of hemorrhage and infarction are usually superimposed on the necrotizing, inflammatory tissue reactions. Rhinocerebral *Aspergillus* infection in immunosuppressed individuals resembles that

caused by Zygomycetes (e.g., mucormycosis).

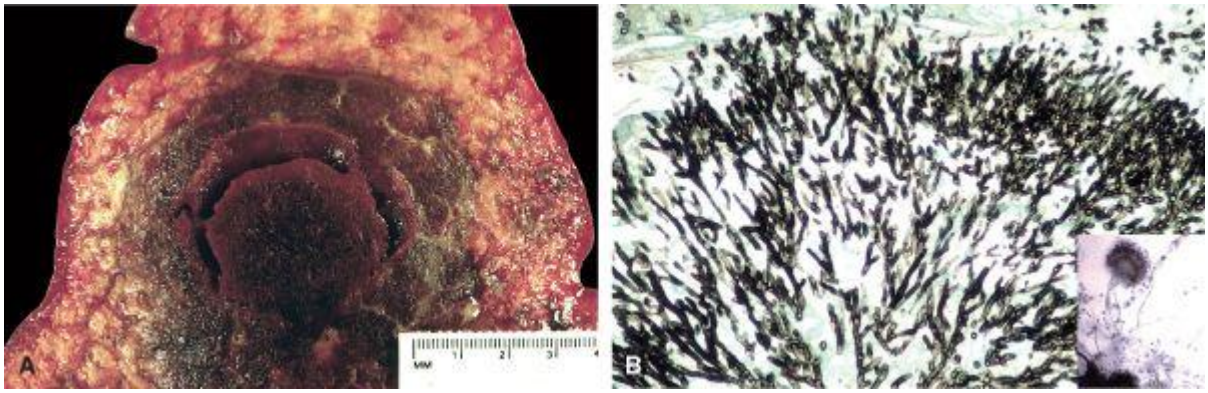

FIGURE 8-47 *Aspergillus* morphology. **A**, Invasive aspergillosis of the lung in a bone marrow transplant patient. **B**, Histologic sections from this case, stained with Gomori methenamine-silver stain, show septate hyphae with acute-angle branching, features consistent with *Aspergillus*. Occasionally, *Aspergillus* may demonstrate fruiting bodies *(inset)* when it grows in areas that are well aerated (such as the upper respiratory tract).

Zygomycosis (Mucormycosis)

Zygomycosis (mucormycosis, phycomycosis) is an opportunistic infection caused by "bread mold fungi," including *Mucor, Rhizopus, Absidia,* and *Cunninghamella,* which belong to the class Zygomycetes.[111] These fungi are widely distributed in nature and cause no harm to immunocompetent individuals, but they infect immunosuppressed people, albeit somewhat less frequently than do *Candida* and *Aspergillus*. Major predisposing factors are neutropenia, corticosteroid use, diabetes mellitus, iron overload, and breakdown of the cutaneous barrier (e.g., as a result of burns, surgical wounds, or trauma).

Pathogenesis.

Similar to *Aspergillus,* zygomycetes fungi are transmitted by airborne asexual spores. Most commonly, inhaled spores produce infection in the sinuses and the lungs, but percutaneous exposure or ingestion can also lead to infection. The thermotolerance of the spores of some species of zygomycetes might contribute to their spread. Macrophages provide the initial defenses by phagocytosis and oxidative killing of germinating spores.[111] Neutrophils have a key role in killing fungi during established infection.

Morphology. Zygomycetes form nonseptate, irregularly wide (6 to 50 μm) fungal hyphae with frequent right-angle branching, which are readily demonstrated in necrotic tissues by hematoxylin and eosin or special fungal stains (Fig. 8-48). The three primary sites of invasion are the nasal sinuses, lungs, and gastrointestinal tract, depending on whether the spores (which are widespread in dust and air) are inhaled or ingested. Most commonly in diabetics, the fungus may spread from nasal sinuses to the orbit and brain, giving rise to **rhinocerebral mucormycosis**. The zygomycetes cause local tissue necrosis, invade arterial walls, and penetrate the periorbital tissues and cranial vault. Meningoencephalitis follows, sometimes complicated by cerebral infarctions when fungi invade arteries and induce thrombosis.

Lung involvement with zygomycetes may be secondary to rhinocerebral disease, or it may be

primary in people with severe immunodeficiency. The lung lesions combine areas of hemorrhagic pneumonia with vascular thrombi and distal infarctions.

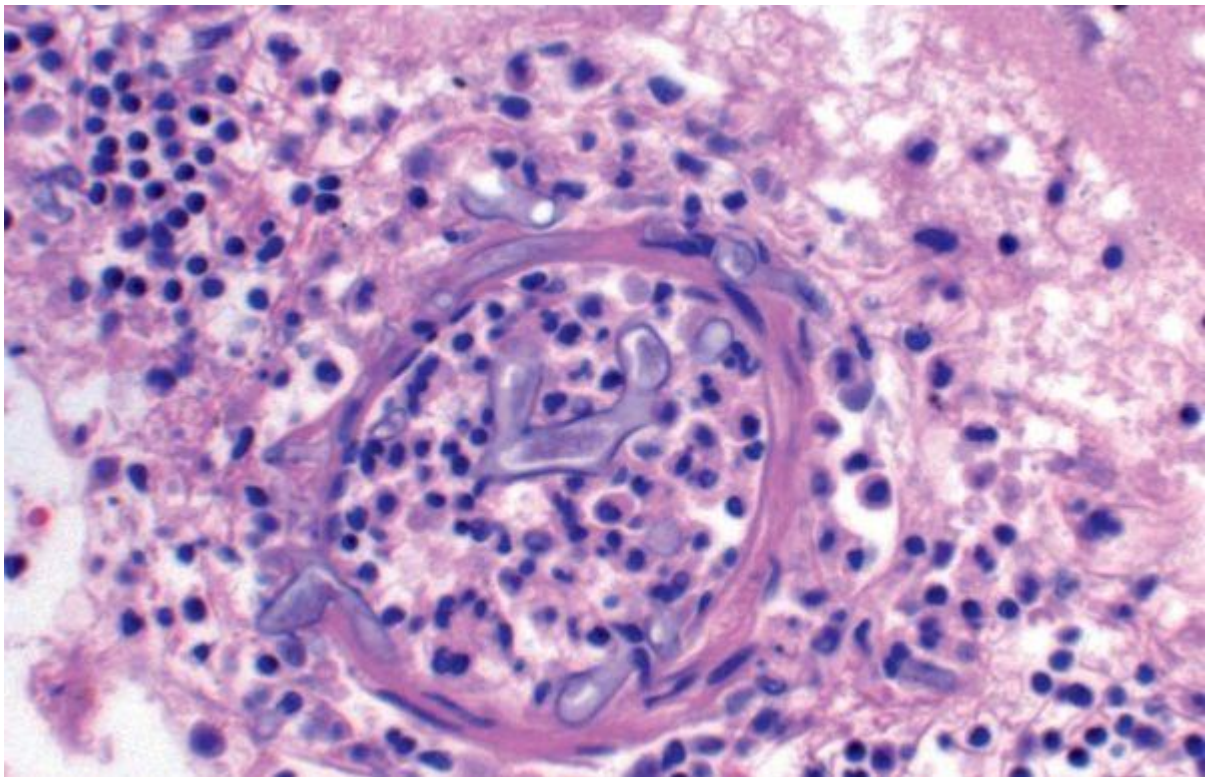

FIGURE 8-48 Meningeal blood vessels with angioinvasive *Mucor* species. Note the irregular width and near right-angle branching of the hyphae. *(Courtesy of Dr. Dan Milner, Department of Pathology, Brigham and Women's Hospital, Boston, MA.)*

2.8.5 Parasitic Infections

PROTOZOA

Protozoa are unicellular, eukaryotic organisms. The parasitic protozoa are transmitted by insects or by the fecal-oral route and, in humans, mainly reside in the blood or intestine (Table 8-9). Most of these infections are diagnosed by microscopic examination of blood smears or lesions.

TABLE 8-9 -- Selected Human Protozoal Diseases

Location	Species	Disease
Luminal or Epithelial	*Entamoeba histolytica*	Amebic dysentery; liver abscess
	Balantidium coli	Colitis
	Giardia lamblia	Diarrheal disease, malabsorption
	Isospora belli	Chronic enterocolitis or malabsorption or both
	Cryptosporidium sp.	
	Trichomonas vaginalis	Urethritis, vaginitis
Central Nervous System	*Naegleria fowleri*	Meningoencephalitis
	Acanthamoeba sp.	Meningoencephalitis or ophthalmitis

Location	Species	Disease
Bloodstream	*Plasmodium* sp.	Malaria
	Babesia microti, B. bovis	Babesiosis

Malaria

Malaria, caused by the intracellular parasite *Plasmodium*, is a worldwide infection that affects 500 million and kills more than 1 million people each year. According to the World Health Organization, 90% of deaths from malaria occur in sub-Saharan Africa, where malaria is the leading cause of death in children younger than 5 years old. *Plasmodium falciparum*, which causes severe malaria, and the three other malaria parasites that infect humans (*P. vivax*, *P. ovale*, and *P. malariae*) are transmitted by female *Anopheles* mosquitoes that are widely distributed throughout Africa, Asia, and Latin America. Nearly all of the approximately 1500 new cases of malaria each year in the United States occur in travelers or immigrants, although rare cases transmitted by *Anopheles* mosquitoes or blood transfusion do occur. Worldwide public health efforts to control malaria in the 1950s through 1980s failed, leaving mosquitoes resistant to DDT and malathion and *Plasmodium* resistant to chloroquine and pyrimethamine.

Life Cycle and Pathogenesis.

Plasmodium vivax, *P. ovale*, and *P. malariae* cause low levels of parasitemia, mild anemia, and, in rare instances, splenic rupture and nephrotic syndrome. *P. falciparum* causes high levels of parasitemia, severe anemia, cerebral symptoms, renal failure, pulmonary edema, and death. The life cycles of the *Plasmodium* species are similar, although *P. falciparum* differs in ways that contribute to its greater virulence.

The infectious stage of malaria, the *sporozoite*, is found in the salivary glands of female mosquitoes. When the mosquito takes a blood meal, sporozoites are released into the human's blood and within minutes attach to and invade liver cells by binding to the hepatocyte receptor for the serum proteins thrombospondin and properdin[112] (Fig. 8-49). Within liver cells, malaria parasites multiply rapidly, releasing as many as 30,000 *merozoites* (asexual, haploid forms) when each infected hepatocyte ruptures. *P. vivax* and *P. ovale* form latent *hypnozoites* in hepatocytes, which cause relapses of malaria long after initial infection.

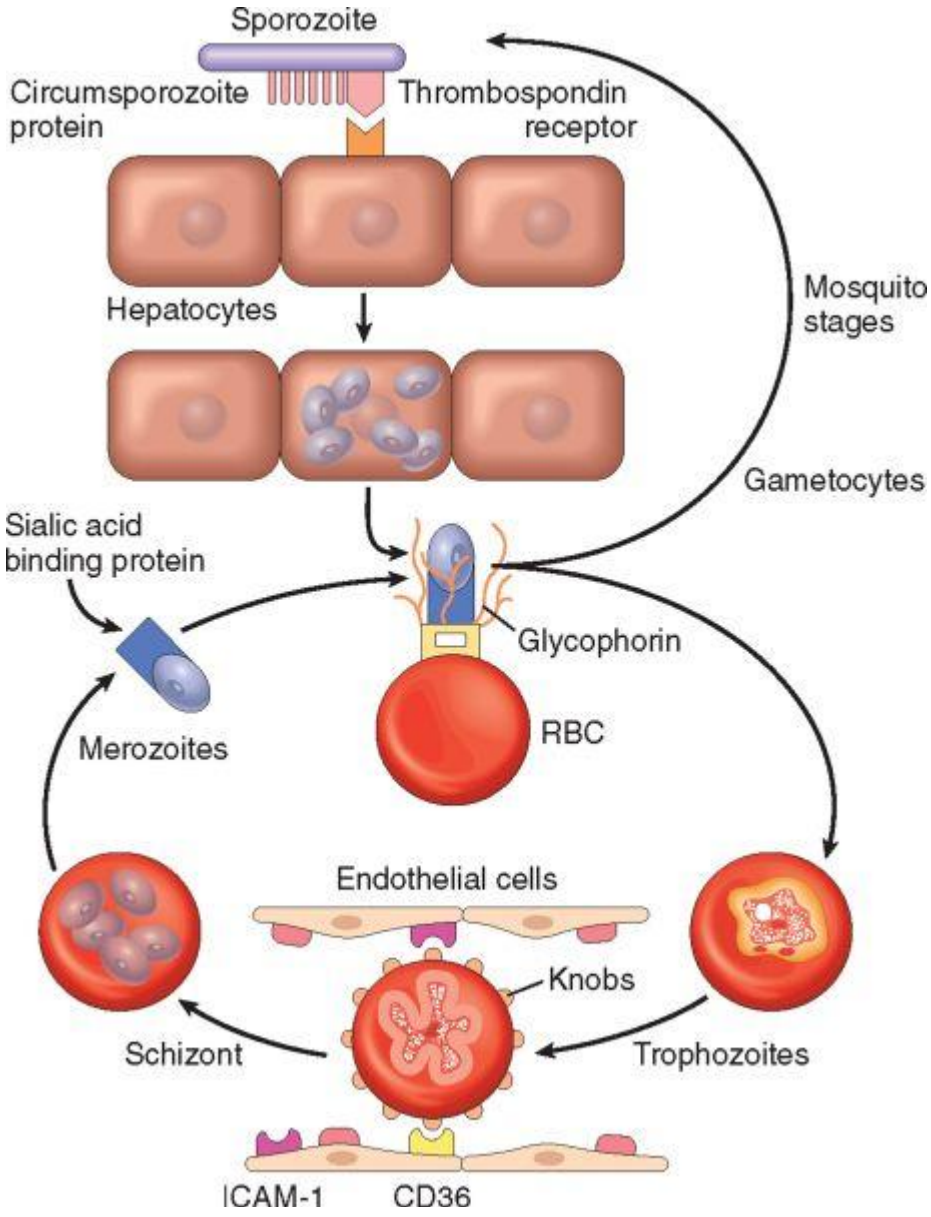

FIGURE 8-49 Life cycle of *Plasmodium falciparum*. ICAM-1, intercellular adhesion molecule 1; RBC, red blood cell. *(Drawn by Dr. Jeffrey Joseph, Beth Israel–Deaconess Hospital, Boston, MA.)*

Once released from the liver, *Plasmodium* merozoites bind by a parasite lectin-like molecule to sialic acid residues on glycophorin molecules on the surface of red cells. Within the red cells the parasites grow in a membrane-bound digestive vacuole, hydrolyzing hemoglobin through secreted enzymes. The *trophozoite* is the first stage of the parasite in the red cell and is defined by the presence of a single chromatin mass. The next stage, the *schizont*, has multiple chromatin masses, each of which develops into a merozoite. On lysis of the red cell, the new merozoites infect additional red cells. Although most malaria parasites within the red cells develop into merozoites, some parasites develop into sexual forms called *gametocytes* that infect the mosquito when it takes its blood meal.

Plasmodium falciparum causes more severe disease than the other *Plasmodium* species do. Several features of *P. falciparum* account for its greater pathogenicity:

- *P. falciparum* is able to infect red blood cells of any age, leading to high parasite burdens and profound anemia. The other species infect only young or old red cells, which are a smaller fraction of the red cell pool.
- *P. falciparum* causes infected red cells to clump together (rosette) and to stick to endothelial cells lining small blood vessels (sequestration), which blocks blood flow. Several proteins, including *P. falciparum* erythrocyte membrane protein 1 (PfEMP1), form knobs on the surface of red cells (Fig. 8-49).[113] PfEMP1 binds to ligands on endothelial cells, including CD36, thrombospondin, VCAM-1, ICAM-1, and E-selectin. *Ischemia due to poor perfusion causes the manifestations of cerebral malaria, which is the main cause of death due to malaria in children*.
- *P. falciparum* stimulates production of high levels of cytokines, including TNF, IFN-γ, and IL-1. GPI-linked proteins, including merozoite surface antigens, are released from infected red cells and induce cytokine production by host cells by a mechanism that is not yet understood. These cytokines suppress production of red blood cells, increase fever, stimulate nitric oxide production (leading to tissue damage), and induce expression of endothelial receptors for PfEMP1 (increasing sequestration).

Host Resistance to *Plasmodium*.

There are two general mechanisms of host resistance to *Plasmodium*. First, inherited alterations in red cells make people resistant to *Plasmodium*. Second, repeated or prolonged exposure to *Plasmodium* species stimulates an immune response that reduces the severity of the illness caused by malaria.

Several common mutations in hemoglobin genes confer resistance to malaria. People who are heterozygous for the sickle cell trait (HbS) become infected with *P. falciparum*, but they are less likely to die from infection. The HbS trait causes the parasites to grow poorly or die because of the low oxygen concentrations. The geographic distribution of the HbS trait is similar to that of *P. falciparum*, suggesting evolutionary selection of the HbS trait in people by the parasite. HbC, another common hemoglobin mutation, also protects against severe malaria by reducing parasite proliferation. People can also be resistant to malaria due to the absence of proteins to which the parasites bind. *P. vivax* enters red cells by binding to the Duffy blood group antigen. Many Africans, including most Gambians, are not susceptible to infection by *P. vivax* because they do not have the Duffy antigen.

Individuals living where *Plasmodium* is endemic often gain partial immune-mediated resistance to malaria, evidenced by reduced illness despite infection. Antibodies and T lymphocytes specific for *Plasmodium* reduce disease manifestations, although the parasite has developed strategies to evade the host immune response. *P. falciparum* uses antigenic variation to escape from antibody responses to PfEMP1. Each haploid *P. falciparum* genome has about 50 *var* genes, each encoding a variant of PfEMP1. The mechanism of *var* regulation is not known, but at least 2% of the parasites switch PfEMP1 genes each generation. CTLs may also be important in resistance to *P. falciparum*. Despite enormous efforts, there has been little progress in developing a vaccine for malaria.

Morphology. *Plasmodium falciparum* infection initially causes congestion and enlargement of the spleen, which may eventually exceed 1000 gm in weight. Parasites are present within red cells, which is the basis of the diagnostic test, and there is increased phagocytic activity of the macrophages in the spleen. In chronic malaria infection, the spleen becomes increasingly fibrotic and brittle, with a thick capsule and fibrous trabeculae. The parenchyma is gray or black because of phagocytic cells containing granular, brown-black, faintly birefringent hemozoin pigment. In addition, macrophages with engulfed parasites, red blood cells, and debris are numerous.

With progression of malaria, the liver becomes progressively enlarged and pigmented. Kupffer cells are heavily laden with malarial pigment, parasites, and cellular debris, while some pigment is also

present in the parenchymal cells. Pigmented phagocytic cells may be found dispersed throughout the bone marrow, lymph nodes, subcutaneous tissues, and lungs. The kidneys are often enlarged and congested with a dusting of pigment in the glomeruli and hemoglobin casts in the tubules.

In **malignant cerebral malaria** caused by *P. falciparum*, brain vessels are plugged with parasitized red cells (Fig. 8-50). Around the vessels there are ring hemorrhages that are probably related to local hypoxia incident to the vascular stasis and small focal inflammatory reactions (called **malarial** or **Dürck granulomas**). With more severe hypoxia, there is degeneration of neurons, focal ischemic softening, and occasionally scant inflammatory infiltrates in the meninges.

Nonspecific focal hypoxic lesions in the heart may be induced by the progressive anemia and circulatory stasis in chronically infected people. In some, the myocardium shows focal interstitial infiltrates. Finally, in the nonimmune patient, pulmonary edema or shock with DIC may cause death, sometimes in the absence of other characteristic lesions.

Babesiosis

Babesia microti and *Babesia divergens* are malaria-like protozoans transmitted by the same deer ticks that carry Lyme disease and granulocytic ehrlichiosis.[114] The white-footed mouse is the reservoir for *B. microti*, and in some areas, nearly all mice have a persistent low-level parasitemia. *B. microti* survives

well in refrigerated blood, and several cases of transfusion-acquired babesiosis have been reported. Babesiae parasitize red blood cells and cause fever and hemolytic anemia. The symptoms are mild except in debilitated or splenectomized individuals, who develop severe and fatal parasitemias.

Morphology. In blood smears, *Babesia* organisms resemble *P. falciparum* ring stages, although they lack hemozoin pigment and are more pleomorphic. They form characteristic tetrads (Maltese cross), which are diagnostic if found (Fig. 8-51). The level of *B. microti* parasitemia is a good indication of the severity of infection (about 1% in mild cases and up to 30% in splenectomized persons). In fatal cases the anatomic findings are related to shock and hypoxia, and include jaundice, hepatic necrosis, acute renal tubular necrosis, adult respiratory distress syndrome, erythrophagocytosis, and visceral hemorrhages.

Leishmaniasis

Leishmaniasis is a chronic inflammatory disease of the skin, mucous membranes, or viscera caused by obligate intracellular, kinetoplast-containing (kinetoplastid) protozoan parasites transmitted through the bite of infected sandflies. Leishmaniasis is endemic throughout the Middle East, South Asia, Africa, and Latin America. It may also be epidemic, as is tragically the case in Sudan, India, Bangladesh, and Brazil, where tens of thousands of people have died of visceral leishmaniasis. Leishmanial infection, like other intracellular organisms (mycobacteria, *Histoplasma*, *Toxoplasma*, and trypanosomes), is exacerbated by conditions that interfere with T-cell function, such as AIDS.[115] Culture or histologic examination is used to diagnose the infection.

Pathogenesis.

The life cycle of *Leishmania* involves two forms: the promastigote, which develops and lives extracellularly in the sandfly vector, and the amastigote, which multiplies intracellularly in host macrophages. Mammals, including rodents, dogs, and foxes, are reservoirs of *Leishmania*. When sandflies bite infected humans or animals, macrophages harboring amastigotes are ingested. The amastigotes differentiate into promastigotes, multiply within the digestive tract of the sandfly and migrate to the salivary gland, where they are poised for transmission by the fly bite. When the infected fly bites a person, the slender, flagellated infectious promastigotes are released into the host dermis along with the sandfly saliva, which potentiates parasite infectivity.[116] The promastigotes are phagocytosed by macrophages, and the acidity within the phagolysosome induces them to transform into round amastigotes that lack flagella but contain a single mitochondrion with its DNA massed into a unique sub-organelle, the kinetoplast.[117] Amastigotes proliferate within macrophages, and dying macrophages release progeny amastigotes that can infect additional macrophages.

How far the amastigotes spread throughout the body depends on the *Leishmania* species and host. Cutaneous disease is caused primarily by *Leishmania major* and *Leishmania tropica* in the Old World and *Leishmania mexicana* and *Leishmania braziliensis* in the New World; mucocutaneous disease (also called espundia) is caused by *L. braziliensis* in the New World; and visceral disease involving the liver, spleen, and bone marrow is caused by *Leishmania donovani* and *Leishmania infantum* in the Old World and *Leishmania chagasi* in the New World. Tropism of *Leishmania* species seems to be linked in part to the optimal temperature for their growth. Parasites that cause visceral disease grow better at 37°C in vitro, whereas parasites that cause mucocutaneous disease grow better at lower temperatures. However, "cutaneous" *Leishmania* species often are viscerotropic in HIV patients.

Leishmania manipulate innate host defenses to facilitate their entry and survival in host macrophages.[118] Promastigotes produce two abundant surface glycoconjugates, which seem to be important for their virulence. The first, *lipophosphoglycan*, forms a dense glycocalyx that both activates complement (leading to C3b deposition on the parasite surface) and inhibits complement action (by preventing membrane attack complex insertion into the parasite membrane). Thus, the parasite becomes coated with C3b but avoids destruction by the membrane attack complex. Instead, the C3b on the surface of the parasite binds to Mac-1 and CR1 on macrophages, targeting the promastigote for phagocytosis. Once inside the cell, lipophosphoglycan protects the parasites within the phagolysosomes by scavenging oxygen radicals and by inhibiting lysosomal enzymes. The second surface glycoprotein, *gp63*, is a zinc-dependent proteinase that cleaves complement and some lysosomal antimicrobial enzymes. Gp63 also binds to fibronectin receptors on macrophages and promotes promastigote adhesion to macrophages. *Leishmania* amastigotes also produce molecules that facilitate their survival and replication within macrophages. Amastigotes reproduce in macrophage phagolysosomes, which normally have a pH of 4.5. However, the amastigotes protect themselves from this hostile environment by expressing a proton-transporting ATPase, which maintains the intracellular parasite pH at 6.5.

Much of our knowledge of mechanisms of resistance and susceptibility to *Leishmania* comes from experimental mouse models.[118] Parasite-specific CD4+ helper T lymphocytes of the T_H1 subset are needed to control *Leishmania* in mice and humans. *Leishmania* evade host immunity by altering macrophage gene expression and impairing the development of the T_H1 response. In animal models, mice that are resistant to *Leishmania* infection produce high levels of T_H1-derived IFN-γ, which activates macrophages to kill the parasites through reactive oxygen species. In contrast, in mouse strains that are susceptible to leishmaniasis, there is a dominant T_H2 response, and T_H2 cytokines such as IL-4, IL-13, and IL-10 prevent effective killing of *Leishmania* by inhibiting the microbicidal activity of macrophages.

Morphology. *Leishmania* species produce four different types of lesions in humans: visceral, cutaneous, mucocutaneous, and diffuse cutaneous. In **visceral leishmaniasis**, *L. donovani* or *L. chagasi* parasites invade macrophages throughout the mononuclear phagocyte system (Figure 8-52), and cause severe systemic disease marked by hepatosplenomegaly, lymphadenopathy, pancytopenia, fever, and weight loss. The spleen may weigh as much as 3 kg, and the lymph nodes may measure 5 cm in diameter. Phagocytic cells are enlarged and filled with *Leishmania*, many plasma cells are present, and the normal architecture of the spleen is obscured. In the late stages the liver becomes increasingly fibrotic. Phagocytic cells crowd the bone marrow and also may be found in the lungs, gastrointestinal tract, kidneys, pancreas, and testes. Often there is hyperpigmentation of the skin in individuals of South Asian ancestry, which is why the disease is called kala-azar or "black fever" in Urdu (the language spoken in India and Pakistan). In the kidneys there may be an immune complex–mediated mesangioproliferative glomerulonephritis, and in advanced cases there may be amyloid deposition. The overloading of phagocytic cells with parasites predisposes the patients to secondary bacterial infections, the usual cause of death. Hemorrhages related to thrombocytopenia may also be fatal.

Cutaneous leishmaniasis, caused by *L. major*, *L. mexicana*, and *L. braziliensis*, is a relatively mild, localized disease consisting of ulcer(s) on exposed skin. The lesion begins as a papule surrounded by induration, changes into a shallow and slowly expanding ulcer, often with heaped-up borders, and usually heals by involution within 6 to 18 months without treatment. On microscopic examination, the lesion is granulomatous, usually with many giant cells and few parasites.

Mucocutaneous leishmaniasis, caused by *L. braziliensis*, is found only in the New World. Moist, ulcerating or nonulcerating lesions, which may be disfiguring, develop in the nasopharyngeal areas. Lesions may be progressive and highly destructive. Microscopic examination reveals a mixed inflammatory infiltrate composed of parasite-containing macrophages with lymphocytes and plasma cells. Later the tissue inflammatory response becomes granulomatous, and the number of parasites declines. Eventually, the lesions remit and scar, although reactivation may occur after long intervals by mechanisms that are not currently understood.

Diffuse cutaneous leishmaniasis is a rare form of dermal infection, thus far found in Ethiopia and adjacent East Africa and in Central and South America. Diffuse cutaneous leishmaniasis begins as a single skin nodule, which continues spreading until the entire body is covered by nodular lesions. Microscopically, they contain aggregates of foamy macrophages stuffed with leishmania.

African Trypanosomiasis

African trypanosomes are kinetoplastid parasites that proliferate as extracellular forms in the blood and cause sustained or intermittent fevers, lymphadenopathy, splenomegaly, progressive brain dysfunction (sleeping sickness), cachexia, and death. *Trypanosoma brucei rhodesiense* infections, which occur in East Africa, are often acute and virulent. *Trypanosoma brucei gambiense* infection tends to be chronic and occurs most frequently in the West African bush. Tsetse flies (genus *Glossina*) transmit African *Trypanosoma* to humans either from the reservoir of parasites found in wild and domestic animals *(T. brucei rhodesiense)* or from other humans *(T. brucei gambiense)*. Within the fly, the parasites multiply in the stomach and then in the salivary glands before developing into nondividing trypomastigotes, which are transmitted to humans and animals.

Pathogenesis.

African trypanosomes are covered by a single, abundant, glycolipid-anchored protein called the *variant surface glycoprotein (VSG)*.[119] As parasites proliferate in the bloodstream, the host produces antibodies to the VSG, which, in association with phagocytes, kill most of the organisms, causing a spike of fever.

A small number of parasites, however, undergo a genetic rearrangement and produce a different VSG on their surface and so escape the host immune response. These successor trypanosomes multiply until the host mounts an antibody response against their VSG and kills most of them, and another clone with a new VSG takes over. In this way, African trypanosomes escape the immune response to cause waves of fever before they finally invade the CNS.

Trypanosomes have many VSG genes, only one of which is expressed at a time. The parasite uses an elegant mechanism to turn VSG genes on and off.[119] Although VSG genes are scattered throughout the trypanosome genome, only VSG genes found within chromosomal regions called *bloodstream expression sites*, located in telomeres (the ends of chromosomes), are expressed. New VSG genes are moved into the bloodstream expression sites mainly by homologous recombination. A poorly understood transcription apparatus, which includes the RNA polymerase that transcribes VSG genes, associates with a single bloodstream expression site to limit expression to one VSG gene at a time.

Morphology. A large, red, rubbery chancre forms at the site of the insect bite, where large numbers of parasites are surrounded by a dense, predominantly mononuclear, inflammatory infiltrate. With chronicity, the lymph nodes and spleen enlarge due to infiltration by lymphocytes, plasma cells, and macrophages, which are filled with dead parasites. Trypanosomes, which are small and difficult to visualize (Fig. 8-53), concentrate in capillary loops, such as the choroid plexus and glomeruli. When parasites breach the blood-brain barrier and invade the CNS, a leptomeningitis develops that extends into the perivascular Virchow-Robin spaces, and eventually a demyelinating panencephalitis occurs. Plasma cells containing cytoplasmic globules filled with immunoglobulins are frequent and are referred to as **Mott cells**. Chronic disease leads to progressive cachexia, and patients, devoid of energy and normal mentation, waste away.

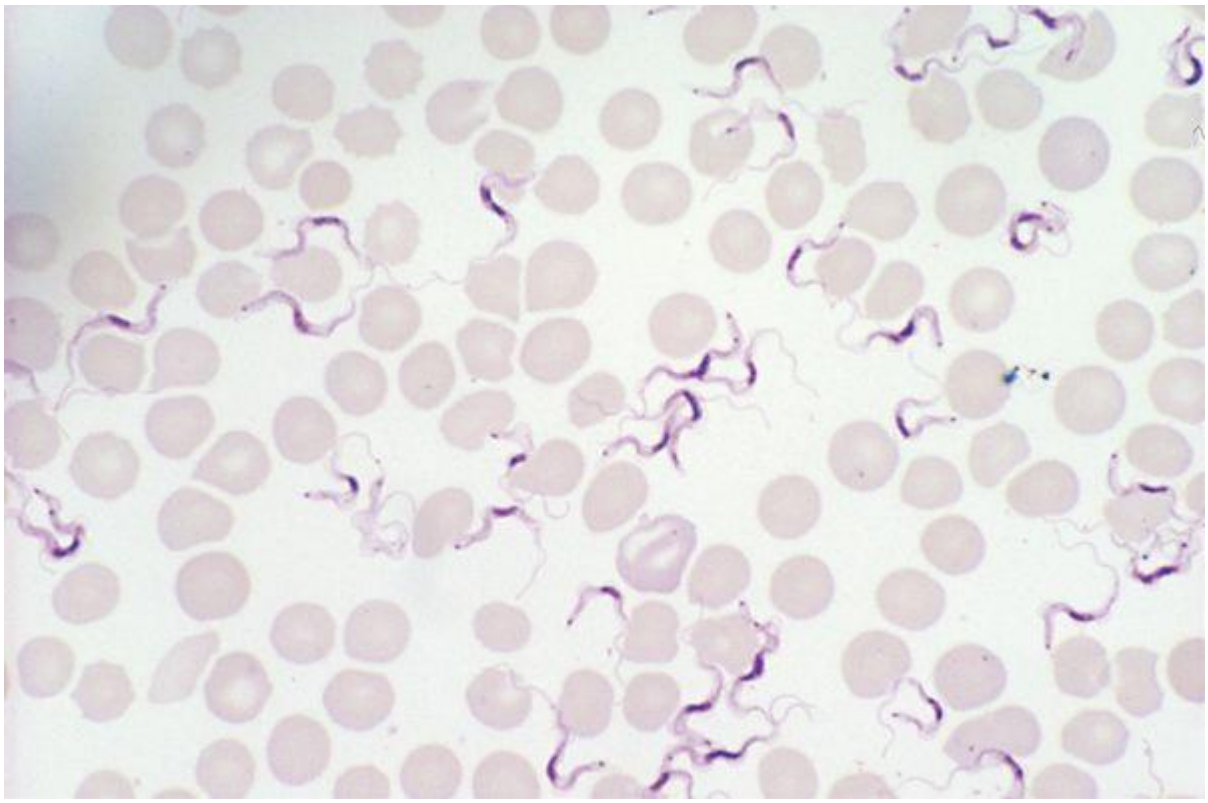

FIGURE 8-53 Slender bloodstream parasites of African trypanosomiasis.

Chagas Disease

Trypanosoma cruzi is a kinetoplastid, intracellular protozoan parasite that causes American trypanosomiasis, or Chagas disease. Chagas disease occurs rarely in the United States and Mexico but is more common in South America, particularly Brazil. *T. cruzi* parasites infect many animals, including cats, dogs, and rodents. The parasites are transmitted between animals and to humans by "kissing bugs" (triatomids), which hide in the cracks of loosely constructed houses, feed on the sleeping inhabitants, and pass the parasites in the feces; the infectious parasites enter the host through damaged skin or through mucous membranes. At the site of skin entry there may be a transient, erythematous nodule called a *chagoma*.

Pathogenesis.

While most intracellular pathogens avoid the toxic contents of lysosomes, *T. cruzi* actually requires brief exposure to the acidic phagolysosome to stimulate development of amastigotes, the intracellular stage of the parasite.[120] To gain exposure to lysosomes, *T. cruzi* trypomastigotes stimulate an increase in the concentration of cytoplasmic calcium in host cells, which promotes fusion of the phagosome and lysosome. In addition to stimulating amastigote development, the low pH of the lysosome activates pore-forming proteins that disrupt the lysosomal membrane, releasing the parasite into the cell cytoplasm. Parasites reproduce as rounded amastigotes in the cytoplasm of host cells and then develop flagella, lyse host cells, enter the bloodstream, and penetrate smooth, skeletal, and heart muscles.

In *acute Chagas disease*, which is mild in most individuals, cardiac damage results from direct invasion of myocardial cells by the organisms and the subsequent inflammation. Rarely, acute Chagas disease presents with high parasitemia, fever, or progressive cardiac dilation and failure, often with generalized lymphadenopathy or splenomegaly. In *chronic Chagas disease*, which occurs in 20% of people 5 to 15 years after initial infection, the mechanism of cardiac and digestive tract damage is controversial; it probably results from an immune response induced by *T. cruzi* parasites, which are still present in small numbers. A striking inflammatory infiltration of the myocardium may be induced by the scant organisms.[121] Alternatively, parasites may induce an autoimmune response, such that antibodies and T cells that recognize parasite proteins cross-react with host myocardial cells, nerve cells, and extracellular proteins such as laminin. Damage to myocardial cells and to conductance pathways causes a dilated cardiomyopathy and cardiac arrhythmias, whereas damage to the myenteric plexus causes dilation of the colon (megacolon) and esophagus.

Morphology. In lethal **acute myocarditis**, the changes are diffusely distributed throughout the heart. Clusters of amastigotes cause swelling of individual myocardial fibers and create intracellular pseudocysts. There is focal myocardial cell necrosis accompanied by extensive, dense, acute interstitial inflammatory infiltration throughout the myocardium, often associated with four-chamber cardiac dilation (Chapter 12).

In **chronic Chagas disease** the heart is typically dilated, rounded, and increased in size and weight. Often, there are mural thrombi that, in about half of autopsy cases, have given rise to pulmonary or systemic emboli or infarctions. On histologic examination, there are interstitial and perivascular inflammatory infiltrates composed of lymphocytes, plasma cells, and monocytes. There are scattered

foci of myocardial cell necrosis and interstitial fibrosis, especially toward the apex of the left ventricle, which may undergo aneurysmal dilation and thinning. In the Brazilian endemic foci, as many as half of the patients with lethal carditis also have dilation of the esophagus or colon, related to damage to the intrinsic innervation of these organs. At the late stages, however, when such changes appear, parasites cannot be found within these ganglia. Chronic Chagas cardiomyopathy is often treated by cardiac transplantation.

METAZOA

Metazoa are multicellular, eukaryotic organisms. The parasitic metazoa are contracted by consuming the parasite, often in undercooked meat, or by direct invasion of the host through the skin or via insect bites. Metazoa dwell in many sites of the body, including the intestine, skin, lung, liver, muscle, blood vessels, and lymphatics. The infections are diagnosed by microscopic identification of larvae or ova in excretions or tissues, and by serology.

Strongyloidiasis

Strongyloides stercoralis infects tens of million people worldwide. It is endemic in the southeastern United States, South America, sub-Saharan Africa, and Southeast Asia. The worms live in the soil and infect humans when larvae penetrate the skin, travel in the circulation to the lungs, and then travel up the trachea to be swallowed. Female worms reside in the mucosa of the small intestine, where they produce eggs by asexual reproduction (parthenogenesis). Most of the larvae are passed in the stool and then may contaminate soil to continue the cycle of infection.

In immunocompetent hosts, *S. stercoralis* may cause diarrhea, bloating, and occasionally malabsorption. Unlike other parasitic worms, *S. stercoralis* larvae hatched in the gut can invade the colon mucosa and reinitiate infection (autoinfection). *Immunocompromised hosts, particularly people on prolonged corticosteroid therapy, can have very high worm burdens due to uncontrolled autoinfection*. This hyperinfection can be complicated by sepsis caused by bacteria from the intestine, which are carried into the host's blood by the invading larvae.

Morphology. In mild strongyloidiasis, worms, mainly larvae, are present in the duodenal crypts but are not seen in the underlying tissue. There is an eosinophil-rich infiltrate in the lamina propria with mucosal edema. Hyperinfection with *S. stercoralis* results in invasion of larvae into the colonic submucosa, lymphatics, and blood vessels, with an associated mononuclear infiltrate. There are many adult worms, larvae, and eggs in the crypts of the duodenum and ileum (Fig. 8-54). Worms of all stages may be found in other organs, including skin and lungs, and may even be found in large numbers in sputum.

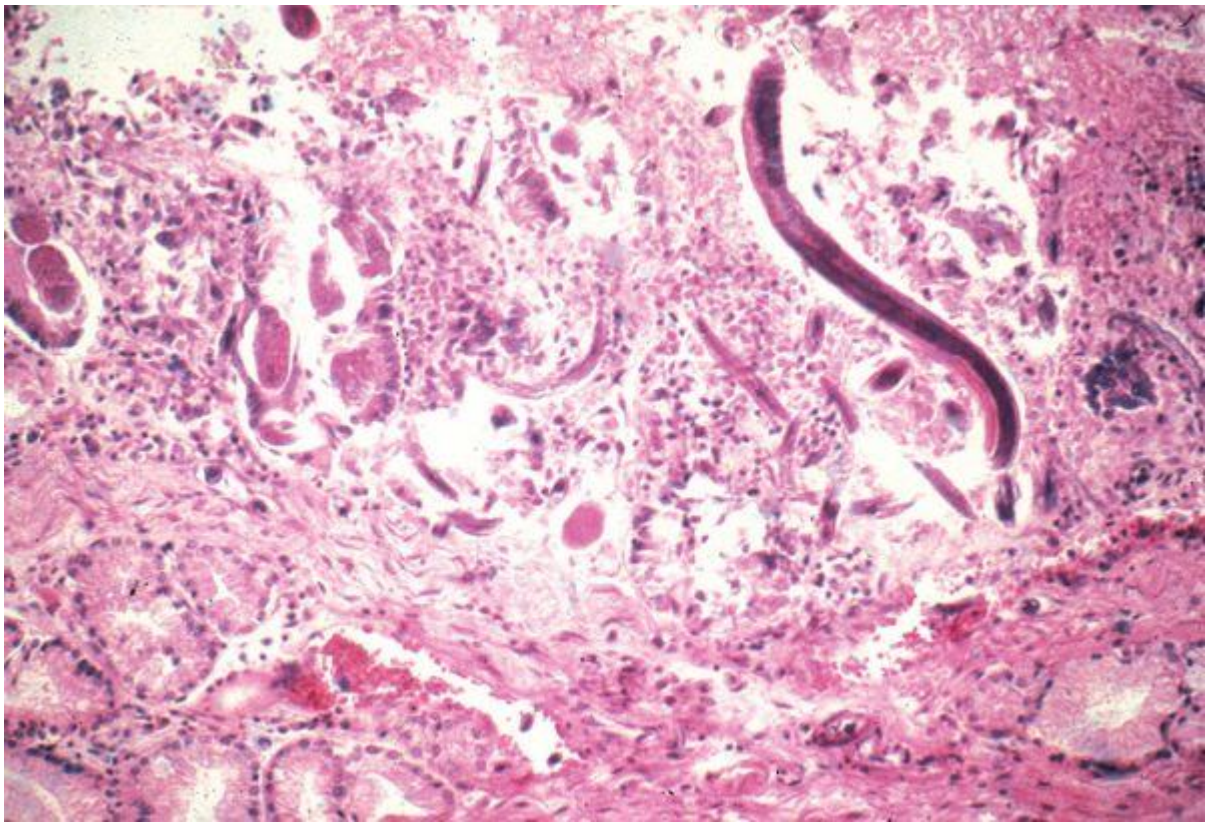

FIGURE 8-54 *Strongyloides* hyperinfection in a patient treated with high-dose cortisone. A female, her eggs, and rhabditoid larvae are in the duodenal crypts; filariform larvae are entering the blood vessels and muscularis mucosa. *(Courtesy of Dr. Franz C. Von Lichtenberg, Brigham and Women's Hospital, Boston, MA.)*

Tapeworms (Cestodes): Cysticercosis and Hydatid Disease

Taenia solium and *Echinococcus granulosus* are cestode parasites (tapeworms) that cause cysticercosis and hydatid infections, respectively.[122,][123] Both diseases are caused by larvae that develop after ingestion of tapeworm eggs. These tapeworms have a complex life cycle requiring two mammalian hosts: a definitive host, in which the worm reaches sexual maturity, and an intermediate host, in which the worm does not reach sexual maturity.

Taenia solium tapeworms consist of a head (scolex) that has suckers and hooklets that attach to the intestinal wall, a neck, and many flat segments called proglottids that contain both male and female reproductive organs. New proglottids develop behind the scolex. The most distal proglottids are mature and contain many eggs, and they can detach and be shed in the feces. *T. solium* can be transmitted to humans in two ways, with distinct outcomes. (1) Ingestion of undercooked pork containing larval cysts, called cysticerci, leads to development of adult tapeworms in the intestine. Ingested cysticerci attach to the intestinal wall and develop into mature adult tapeworms, which can grow to many meters in length and can produce mild abdominal symptoms. (2) When intermediate hosts (pigs or humans) ingest eggs in food or water contaminated with human feces, the larvae hatch, penetrate the gut wall, disseminate hematogenously, and encyst in many organs. Convulsions, increased intracranial pressure, and neurologic disturbances are caused by *T. solium* cysts in brain tissue.[124] Adult tapeworms are not produced with this mode of infection. Viable *T. solium* cysts often do not produce symptoms and can

evade host immune defenses by producing taeniaestatin and paramyosin, which seem to inhibit complement activation.[125] When the cysticerci die and degenerate, an inflammatory response develops. *Taenia saginata*, the beef tapeworm, and *Diphyllobothrium latum*, the fish tapeworm, are acquired by eating undercooked meat or fish. In humans these parasites live only in the gut, and they do not form cysticerci.

Hydatid disease is caused by ingestion of eggs of echinococcal species.[123] For *Echinococcus granulosus* the definitive hosts are dogs, and sheep are the usual intermediate hosts. For *Echinoccus multilocularis* foxes are the most important definitive host, and rodents are intermediate hosts. Humans are accidental intermediate hosts, infected by ingestion of food contaminated with eggs shed by dogs or foxes. Eggs hatch in the duodenum and invade the liver, lungs, or bones.

Morphology. Cysticerci may be found in any organ, but the more common locations include the brain, muscles, skin, and heart. Cerebral symptoms depend on the precise location of the cysts, which may be intraparenchymal, attached to the arachnoid, or freely floating in the ventricular system. The cysts are ovoid and white to opalescent, often grape-sized, and contain an invaginated scolex with hooklets that are bathed in clear cyst fluid (Fig. 8-55). The cyst wall is more than 100 μm thick, is rich in glycoproteins, and evokes little host reaction when it is intact. When cysts degenerate, however, there is inflammation, followed by focal scarring, and calcifications, which may be visible by radiography.

About two thirds of human *E. granulosus* cysts are found in the liver, 5% to 15% in the lung, and the rest in bones and brain or other organs. In the various organs the larvae lodge within the capillaries and first incite an inflammatory reaction composed principally of mononuclear leukocytes and eosinophils. Many such larvae are destroyed, but others encyst. The cysts begin at microscopic levels and progressively increase in size, so that in 5 years or more they may have achieved dimensions of more than 10 cm in diameter. Enclosing an opalescent fluid is an inner, nucleated, germinative layer and an outer, opaque, non-nucleated layer. The outer non-nucleated layer is distinctive and has innumerable delicate laminations. Outside this opaque layer, there is a host inflammatory reaction that produces a zone of fibroblasts, giant cells, and mononuclear and eosinophilic cells. In time a dense fibrous capsule forms. Daughter cysts often develop within the large mother cyst. These appear first as minute projections of the germinative layer that develop central vesicles and thus form tiny brood capsules. Degenerating scolices of the worm produce a fine, sandlike sediment within the hydatid fluid (“hydatid sand”).

FIGURE 8-55 Portion of a cysticercus cyst in the skin.

Trichinosis

Trichinella spiralis is a nematode parasite that is acquired by ingestion of larvae in undercooked meat from infected animals (usually pigs, boars, or horses) that have themselves been infected by eating *T. spiralis*–infected rats or meat products. In the United States the number of *T. spiralis*–infected pigs has been greatly reduced by laws requiring cooking of food or garbage fed to hogs, and this has reduced the number of reported human infections in the United States to about 100 each year. Still, trichinosis is widespread where undercooked meat is eaten.

In the human gut, *T. spiralis* larvae develop into adults that mate and release new larvae, which penetrate into the tissues. Larvae disseminate hematogenously and penetrate muscle cells, causing fever, myalgias, marked eosinophilia, and periorbital edema. Much less commonly, patients develop dyspnea, encephalitis, and cardiac failure. In striated skeletal muscle, *T. spiralis* larvae become intracellular parasites, increase dramatically in size, and modify the host muscle cell (referred to as the nurse cell) so that it loses its striations, gains a collagenous capsule, and develops a plexus of new blood vessels around itself.[126] The nurse cell–parasite complex is largely asymptomatic, and the worm may persist for years before it dies and calcifies. Antibodies to larval antigens, which include an immunodominant carbohydrate epitope called tyvelose, may reduce reinfection and are useful for serodiagnosis of the disease.[127]

Trichinella spiralis and other invasive nematodes stimulate a T_H2 response, with production of IL-4, IL-5, IL-10, and IL-13. The cytokines produced by T_H2 cells activate eosinophils and mast cells, both of

which are associated with the inflammatory response to these parasites. In animal models of *T. spiralis* infection, the T_H2 response is associated with increased contractility of the intestine, which expels adult worms from the gut and subsequently reduces the number of larvae in the muscles.[128] The mechanism by which the T_H2 response increases intestinal motility is unclear, although IL-4, IL-13, and mast cell degranulation have each been implicated. While the T_H2 response indirectly reduces the number of larvae in muscle by eliminating adults from the intestine, it is not clear whether the intramuscular inflammatory response, which is composed of mononuclear cells and eosinophils, is effective against the larvae.

Morphology. During the invasive phase of trichinosis, cell destruction can be widespread during heavy infections and may be lethal. In the heart there is a patchy interstitial myocarditis characterized by many eosinophils and scattered giant cells. The myocarditis can lead to scarring. Larvae in the heart do not encyst and are difficult to identify, because they die and disappear. In the lungs, trapped larvae cause focal edema and hemorrhages, sometimes with an allergic eosinophilic infiltrate. In the CNS, larvae cause a diffuse lymphocytic and eosinophilic infiltrate, with focal gliosis in and about small capillaries of the brain.

Trichinella spiralis preferentially encysts in striated skeletal muscles with the richest blood supply, including the diaphragm and the extraocular, laryngeal, deltoid, gastrocnemius, and intercostal muscles (Fig. 8-56). Coiled larvae are approximately 1 mm long and are surrounded by membrane-bound vacuoles within nurse cells, which in turn are surrounded by new blood vessels and an eosinophil-rich mononuclear cell infiltrate. This infiltrate is greatest around dying parasites, which eventually calcify and leave behind characteristic scars, which are useful for retrospective diagnosis of trichinosis.

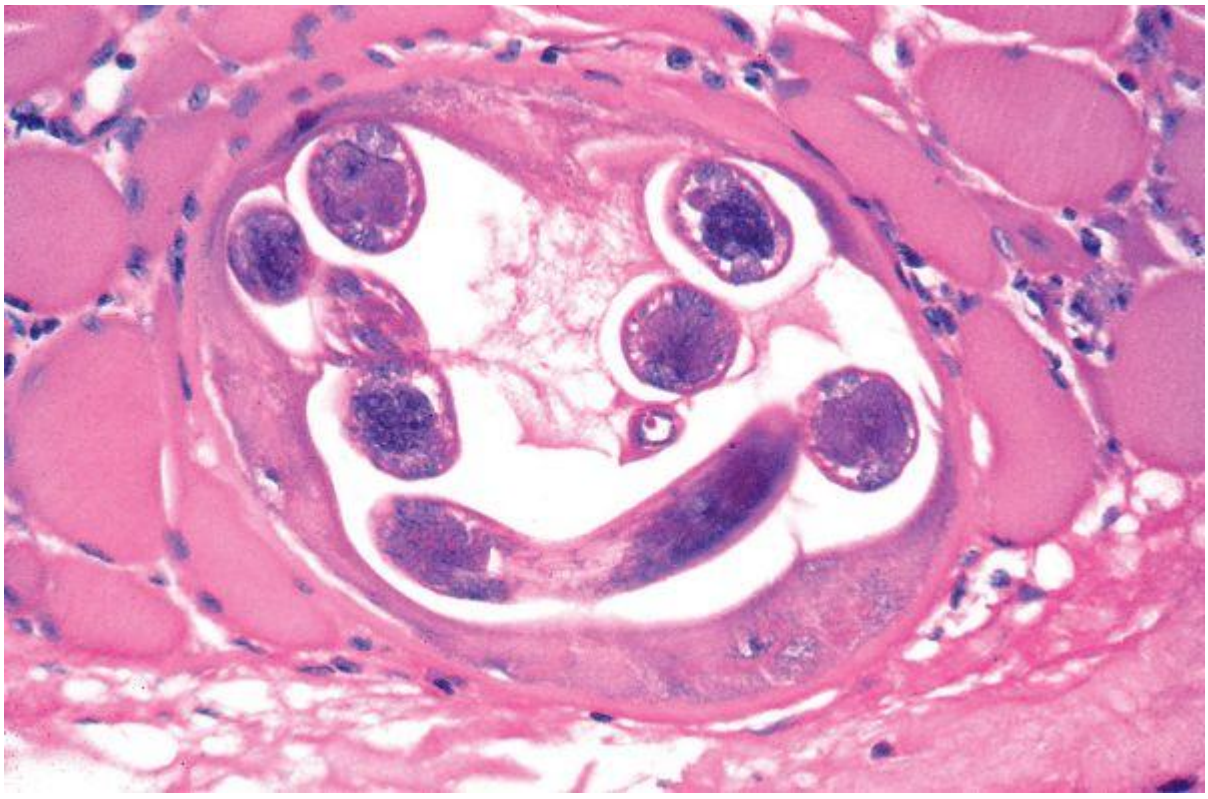

FIGURE 8-56 Coiled *Trichinella spiralis* larva within a skeletal muscle cell.

Schistosomiasis

Schistosomiasis infects approximately 200 million persons and kills over 100,000 individuals annually. Most of the mortality comes from hepatic cirrhosis, caused by *Schistosoma mansoni* in Latin America, Africa, and the Middle East and *Schistosoma japonicum* and *Schistosoma mekongi* in East Asia.[129] In addition, *Schistosoma haematobium*, found in Africa, causes hematuria and granulomatous disease of the bladder, resulting in chronic obstructive uropathy.

Pathogenesis.

Schistosomiasis is transmitted by freshwater snails that live in the slow-moving water of tropical rivers, lakes, and irrigation ditches, ironically linking agricultural development with spread of the disease. Infectious schistosome larvae (cercariae) swim through fresh water and penetrate human skin with the aid of powerful proteolytic enzymes that degrade the keratinized layer. Schistosomes migrate into the peripheral vasculature, travel to the lung, and mature and mate in hepatic vessels, then migrate out as male-female worm pairs and settle in the portal or pelvic venous system. Females produce hundreds of eggs per day, around which granulomas and fibrosis form. Schistosome eggs produce proteases and elicit prominent inflammatory reactions. This inflammatory response is necessary for passive transfer of eggs across the intestine and bladder walls, allowing the eggs to be shed in stool or urine, respectively. Infection of freshwater snails completes the life cycle.

Eggs that are carried by the portal circulation into the hepatic parenchyma cause prominent inflammatory reactions. This immune response to *S. mansoni* and *S. japonicum* eggs in the liver causes the severe pathology of schistosomiasis.[130] While the immune response does provide some protection in animal models, the price of this response is granuloma formation and hepatic fibrosis. Acute schistosomiasis in humans can be a severe febrile illness that peaks about 2 months after infection. The helper T-cell response in this early stage is dominated by T_H1 cells that produce IFN-γ, which stimulates macrophages to secrete high levels of the cytokines TNF, IL-1, and IL-6 that cause fever. Chronic schistosomiasis is associated with a dominant T_H2 response, although T_H1 cells persist. Stimulation of T_H2 cells may be due to proteins in the parasite egg that cause mast cells to produce IL-4, which induces further T_H2 differentiation and amplifies the response. Both types of helper T cells contribute to the formation of granulomas surrounding eggs in the liver. Severe hepatic fibrosis is a serious manifestation of chronic schistosomiasis. In animal models, IL-13, produced by T_H2 cells, increases fibrosis by stimulating the synthesis of collagen.

Morphology. In mild *S. mansoni* or *S. japonicum* infections, white, pinhead-sized granulomas are scattered throughout the gut and liver. At the center of the granuloma is the schistosome egg, which contains a miracidium; this degenerates over time and calcifies. The granulomas are composed of macrophages, lymphocytes, neutrophils, and eosinophils; eosinophils are distinctive for helminth infections (Fig. 8-57). The liver is darkened by regurgitated heme-derived pigments from the schistosome gut, which, like malaria pigments, are iron-free and accumulate in Kupffer cells and splenic macrophages.

In severe *S. mansoni* or *S. japonicum* infections, inflammatory patches or pseudopolyps may form in the colon. The surface of the liver is bumpy, and cut surfaces reveal granulomas and widespread

fibrosis and portal enlargement without intervening regenerative nodules. Because these fibrous triads resemble the stem of a clay pipe, the lesion is named **pipe-stem fibrosis** (Fig. 8-58). The fibrosis often obliterates the portal veins, leading to portal hypertension, severe congestive splenomegaly, esophageal varices, and ascites. Schistosome eggs, diverted to the lung through portal collaterals, may produce granulomatous pulmonary arteritis with intimal hyperplasia, progressive arterial obstruction, and ultimately heart failure (cor pulmonale). On histologic examination, arteries in the lungs show disruption of the elastic layer by granulomas and scars, luminal organizing thrombi, and angiomatoid lesions similar to those of idiopathic pulmonary hypertension (Chapter 15). Patients with hepatosplenic schistosomiasis also have an increased frequency of mesangioproliferative or membranous glomerulopathy (Chapter 20), in which glomeruli contain deposits of immunoglobulin and complement but rarely schistosome antigen.

In *S. haematobium* infection, inflammatory cystitis due to massive egg deposition and granulomas appear early, leading to mucosal erosions and hematuria (see Fig. 8-10). Later, the granulomas calcify and develop a "sandy" appearance, which, if severe, may line the wall of the bladder and cause a dense concentric rim (calcified bladder) on radiographic films. The most frequent complication of *S. haematobium* infection is inflammation and fibrosis of the ureteral walls, leading to obstruction, hydronephrosis, and chronic pyelonephritis. There is also an association between urinary schistosomiasis and squamous cell carcinoma of the bladder (Chapter 21).

FIGURE 8-58 Pipe-stem fibrosis of the liver due to chronic *Schistosoma japonicum* infection.

Lymphatic Filariasis

Lymphatic filariasis is transmitted by mosquitoes and is caused by closely related nematodes, *Wuchereria bancrofti* and *Brugia* species (*B. malayi* or *B. timori*), which are responsible for 90% and 10%, respectively, of the 90 million infections worldwide. In endemic areas, which include parts of Latin America, sub-Saharan Africa, and Southeast Asia, filariasis causes a spectrum of diseases, including (1) asymptomatic microfilaremia, (2) recurrent lymphadenitis, (3) chronic lymphadenitis with swelling of the dependent limb or scrotum (elephantiasis), and (4) tropical pulmonary eosinophilia. As is the case with leprosy and leishmanial infections, some of the different disease manifestations caused by lymphatic filariae are likely related to variations in host T-cell responses to the parasites.[131]

Pathogenesis.

Infective larvae released by mosquitoes into the tissues during a blood meal develop within lymphatic channels into adult males and females, which mate and release microfilariae that enter into the bloodstream. When mosquitoes bite infected individuals they can take up the microfilariae and transmit the disease. The filarial genome project has led to the identification of a number of filarial molecules that enable the organism to evade or inhibit immune defenses. *Brugia malayi* produces (1) several surface glycoproteins with antioxidant function, which may protect from superoxide and free oxygen radicals; (2) homologues of cystatins, cysteine protease inhibitors, which can impair the MHC class II antigen-processing pathway; (3) serpins, serine protease inhibitors, which can inhibit neutrophil proteases, critical inflammatory mediators; and (4) homologues of TGF-β, which can bind to mammalian TGF-β receptors and may downregulate inflammatory responses.[132,][133] In addition, endosymbiotic rickettsia-like *Wolbachia* bacteria infect filarial nematodes and contribute to pathogenesis of disease.[134] *Wolbachia* seem to be needed for nematode development and reproduction, since antibiotics that eradicate *Wolbachia* impair nematode survival and fertility. It has been hypothesized that LPS from *Wolbachia* also stimulates inflammatory responses.

In chronic lymphatic filariasis, damage to the lymphatics is caused directly by the adult parasites and by a T_H1-mediated immune response, which stimulates the formation of granulomas around the adult parasites. Microfilariae are most often absent from the bloodstream.

Finally, there may be an *IgE-mediated hypersensitivity* to microfilariae in *tropical pulmonary eosinophilia*. IgE and eosinophils may be stimulated by IL-4 and IL-5, respectively, secreted by filaria-specific T_H2 helper T cells. Tropical pulmonary eosinophilia is seen most commonly in individuals of Southern Asian descent or in northern Latin America, suggesting that host factors contribute to this disorder (Chapter 15).

Morphology. Chronic filariasis is characterized by persistent lymphedema of the extremities, scrotum, penis, or vulva (Fig. 8-59). Frequently there is hydrocele and lymph node enlargement. In severe and long-lasting infections, chylous weeping of the enlarged scrotum may ensue, or a chronically swollen leg may develop tough subcutaneous fibrosis and epithelial hyperkeratosis, termed **elephantiasis**. Elephantoid skin shows dilation of the dermal lymphatics, widespread lymphocytic infiltrates and focal cholesterol deposits; the epidermis is thickened and hyperkeratotic. Adult filarial worms—live, dead, or calcified—are present in the draining lymphatics or nodes, surrounded by (1) mild or no inflammation, (2) an intense eosinophilia with hemorrhage and fibrin (recurrent filarial funiculoepididymitis), or (3) granulomas. Over time, the dilated lymphatics develop polypoid infoldings. In the testis, hydrocele fluid, which often contains cholesterol crystals, red cells, and hemosiderin, induces thickening and calcification of the tunica vaginalis.

Lung involvement by microfilariae is marked by eosinophilia caused by T_H2 responses and cytokine production (tropical eosinophilia) or by dead microfilariae surrounded by stellate, hyaline, eosinophilic precipitates embedded in small epithelioid granulomas (Meyers-Kouvenaar bodies). Typically, these patients lack other manifestations of filarial disease.

Onchocerciasis

Onchocerca volvulus, a filarial nematode transmitted by black flies, affects millions of people in Africa, South America, and Yemen.[135] An aggressive campaign of ivermectin treatment has dramatically reduced the incidence of *Onchocerca* infection in West Africa; however, *O. volvulus* remains the second most common preventable cause of blindness in sub-Saharan Africa (called "river blindness" because of its prevalence near some rivers). It is estimated that there are half a million people who are blind due to onchocerciasis.

Adult *O. volvulus* parasites mate in the dermis, where they are surrounded by a mixed infiltrate of host cells that produces a characteristic subcutaneous nodule *(onchocercoma)*. The major pathologic process is caused by large numbers of microfilariae, released by females, that accumulate in the skin and in the eye chambers. *Punctate keratitis* is caused by inflammation around a degenerating microfilaria. Unfortunately, it is sometimes accentuated by treatment with antifilarial drugs (Mazzotti reaction). Ivermectin kills only immature worms, not adult worms, so parasites repopulate the host a few months after treatment. Doxycycline treatment blocks reproduction of *O. volvus* for up to 24 months. Doxycycline kills *Wolbachia*, symbiotic bacteria that live inside adult *O. volvulus* and are required for the fertility of the worm.[136]

Morphology. *Onchocerca volvulus* causes chronic, itchy dermatitis with focal darkening or loss of pigment and scaling, referred to as leopard, lizard, or elephant skin. Foci of epidermal atrophy and elastic fiber breakdown may alternate with areas of hyperkeratosis, hyperpigmentation with pigment incontinence, dermal atrophy, and fibrosis. The subcutaneous onchocercoma is composed of a fibrous capsule surrounding adult worms and a mixed chronic inflammatory infiltrate that includes fibrin, neutrophils, eosinophils, lymphocytes, and giant cells (Fig. 8-60). The progressive eye lesions begin with punctate keratitis along with small, fluffy opacities of the cornea caused by degenerating microfilariae, which evoke an eosinophilic infiltrate. This is followed by a sclerosing keratitis that opacifies the cornea, beginning at the scleral limbus. Microfilariae in the anterior chamber cause iridocyclitis and glaucoma, whereas involvement of the choroid and retina results in atrophy and loss of vision.

2.9 9. Environmental & Nutritional Diseases

2.9.1 The Global Burden of Disease

The term "environment" encompasses the outdoor, indoor, and occupational environments shared by small and large populations, and our own personal environment. In each of these environments, the air we collectively breathe, the food and water we consume, and exposure to toxic agents are major determinants of our health. Our personal environment is greatly influenced by tobacco use, alcohol ingestion, therapeutic and nontherapeutic drug consumption, and diet. Factors in the personal environment may have a larger effect on human health than the ambient environment. *The term environmental diseases refers to conditions caused by exposure to chemical or physical agents in the ambient, workplace, and personal environment, including diseases of nutritional origin*. Environmental diseases mostly come to the public's attention after major disasters, such as the methyl mercury contamination of Minamata Bay in Japan in the 1960s, the exposure to dioxin in Seveso, Italy, in 1976, the leakage of methyl isocyanate gas in Bhopal, India, in 1984, the Chernobyl nuclear accident in 1986, and the contamination of Tokyo subways by the organophosphate pesticide sarin. Fortunately, these are unusual and infrequent occurrences, but environmental diseases caused by chronic exposure to relatively low levels of contaminants, occupational injuries, and nutritional deficiencies are widespread. The International Labor Organization has estimated that work-related injuries and illnesses kill approximately 2 million people per year globally (more deaths than are caused by road accidents and wars combined). A comprehensive report from the Disease Control Priorities Project (http://www.dcp2.org) estimated that there are 130 million undernourished children worldwide, and that malnutrition alone is responsible for 2.67 million deaths per year. Estimating the burden of disease in the general population caused by nonoccupational exposures to toxic agents is complicated by the diversity of agents and difficulties in determining the extent and duration of exposures. Whatever the precise numbers, environmental (including nutritional) diseases are major causes of disability and suffering, and constitute a heavy financial burden, particularly in developing countries. During the last few years new concerns have been raised about air and water quality, and the potential health effects of climate change.

In this chapter, we first consider two key issues in global health: the global burden of disease, and the emerging problem of the health effects of climate change. We then discuss the mechanisms of toxicity

of chemical and physical agents, and address specific environmental disorders, including those of nutritional origin.

The Global Burden of Disease

Until about 1990 global health data were fragmented and lacked a uniform standard of measurement.[1] Since then, a project entitled The Global Burden of Disease (GBD) has set the standard for reporting health information. The GBD approach is now applied to the measurement of the burden imposed by environmental disease, including those caused by communicable and nutritional diseases. In addition, a unit of measurement ("metric") called DALY (disability-adjusted life year, a time based measure that adds the years of life lost to premature mortality with the years lived with illness and disability), has been used to assess both premature mortality and disease morbidity. DALY reporting provides a high degree of uniformity for health information gathered about acute and chronic diseases in different parts of the world and at multiple locations in a single country. The new methodology has revealed important trends in the worldwide morbidity and mortality of disease.

- *Undernutrition is the single leading global cause of health loss (defined as morbidity and premature death)*. It is estimated that about one third of the disease burden in developing countries is, directly or indirectly, due to poor general nutrition or deficiencies in specific nutrients that increase the risk of infections.
