Cowden syndrome, Bannayan-Ruvalcaba-Riley syndrome	<15	*PTEN*	Hamartomatous polyps, lipomas, ganglioneuromas, inflammatory polyps, risk of colon cancer	Benign skin tumors, benign and malignant thyroid and breast lesions
Cronkhite-Canada syndrome	>50	Nonhereditary	Hamartomatous colon polyps, crypt dilatation and edema in nonpolypoid mucosa	Nail atrophy, hair loss, abnormal skin pigmentation, cachexia, and anemia
Tuberous sclerosis		*TSC1, TSC2*	Hamartomatous polyps (rectal)	Facial angiofibroma, cortical tubers, renal angiomyolipoma
Familial adenomatous polyposis (FAP)				
Classic FAP	10–15	*APC, MUTYH*	Multiple adenomas	Congenital RPE hypertrophy
Attenuated FAP	40–50	*APC, MUTYH*	Multiple adenomas	
Gardner syndrome	10–15	*APC, MUTYH*	Multiple adenomas	Osteomas, desmoids, skin cysts
Turcot syndrome	10–15	*APC, MUTYH*	Multiple adenomas	CNS tumors, medulloblastoma

CNS, central nervous system; RPE, retinal pigmented epithelium.

Juvenile Polyps

Juvenile polyps are focal malformations of the mucosal epithelium and lamina propria. These may be *sporadic or syndromic*, but the morphology of the two forms may be indistinguishable. The vast majority of juvenile polyps occur in children less than 5 years of age. When present in adults, polyps with identical morphology are sometimes confusingly referred to as *inflammatory polyps*. *The majority of juvenile polyps are located in the rectum* and most present with rectal bleeding. In some cases prolapse occurs and the polyp protrudes through the anal sphincter. Sporadic juvenile polyps are usually solitary lesions and may be referred to as *retention polyps*. In contrast, individuals with the autosomal

dominant syndrome of juvenile polyposis have from 3 to as many as 100 hamartomatous polyps and may require colectomy to limit the chronic and sometimes severe hemorrhage associated with polyp ulceration. A minority of patients also have polyps in the stomach and small bowel. Pulmonary arteriovenous malformations are a recognized extra-intestinal manifestation of the syndrome.

Morphology. Most juvenile polyps are less than 3 cm in diameter. They are typically pedunculated, smooth-surfaced, reddish lesions with characteristic cystic spaces apparent after sectioning. Microscopic examination shows these cysts to be dilated glands filled with mucin and inflammatory debris (Fig. 17-42). The remainder of the polyp is composed of lamina propria expanded by mixed inflammatory infiltrates. The muscularis mucosa may be normal or attenuated.

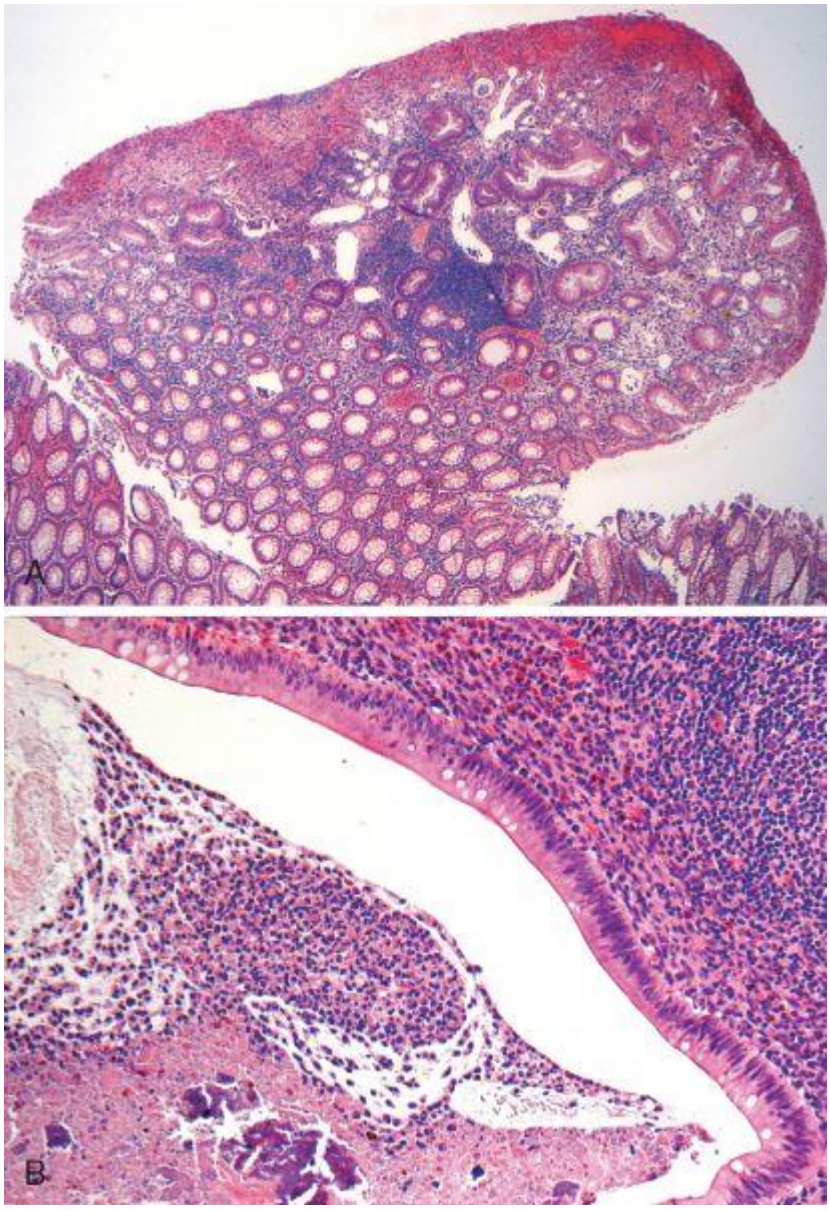

FIGURE 17-42 Juvenile polyposis. **A**, Juvenile polyp. Note the surface erosion and cystically dilated crypts. **B**, Inspissated mucous, neutrophils, and inflammatory debris can accumulate within dilated crypts.

Although the morphogenesis of juvenile polyps is incompletely understood, some have suggested that mucosal hyperplasia is the initiating event. This hypothesis is consistent with the discovery that mutations in pathways that regulate cellular growth cause autosomal dominant juvenile polyposis. The most common mutation identified is of *SMAD4*, which encodes a cytoplasmic intermediate in the TGF-β signaling pathway. *BMPR1A*, a kinase that is a member of the TGF-β superfamily, may be mutated in other cases (see Table 17-9). However, these mutations account for fewer than half of patients, suggesting that changes in other genes can also cause juvenile polyposis. Dysplasia occurs in a small proportion of juvenile polyps, and the juvenile polyposis syndrome is associated with an increased risk of colonic adenocarcinoma.

Peutz-Jeghers Syndrome

This rare autosomal dominant syndrome presents at a median age of 11 years with *multiple GI hamartomatous polyps and mucocutaneous hyperpigmentation*. The latter takes the form of dark blue to brown macules around the mouth, eyes, nostrils, buccal mucosa, palmar surfaces of the hands, genitalia, and perianal region. These lesions are similar to freckles but are distinguished by their presence in the buccal mucosa. Peutz-Jeghers polyps can initiate intussusception, which is occasionally fatal. Of greater importance, *Peutz-Jeghers syndrome is associated with an increased risk of several malignancies*, including cancers of the colon, pancreas, breast, lung, ovaries, uterus, and testicles, as well as other unusual neoplasms, such as sex cord tumors.

Pathogenesis.

Germline heterozygous loss-of-function mutations in the gene *LKB1/STK11* are present in approximately half of individuals with familial Peutz-Jeghers syndrome as well as a subset of patients with sporadic PeutzJeghers syndrome. LKB1/STK11 is a kinase that regulates cell polarization, growth, and metabolism. The function of the second "normal" copy of *LKB1/STK11* is often lost through somatic mutation in cancers occurring in Peutz-Jeghers syndrome, consistent with the view that *LKB1/STK11* is a tumor suppressor gene and providing an explanation for the high risk of neoplasia in affected patients. The GI adenocarcinomas arise independently of the hamartomatous polyps, indicating that the hamartomas are not preneoplastic precursor lesions.

Morphology. The polyps of Peutz-Jeghers syndrome are most common in the small intestine, although they may occur in the stomach and colon, and, with much lower frequency, in the bladder and lungs. Grossly, the polyps are large and pedunculated with a lobulated contour. Histologic examination demonstrates a characteristic arborizing network of connective tissue, smooth muscle, lamina propria, and glands lined by normal-appearing intestinal epithelium (Fig. 17-43). The arborization and presence of smooth muscle intermixed with lamina propria are helpful in distinguishing polyps of Peutz-Jeghers syndrome from juvenile polyps.

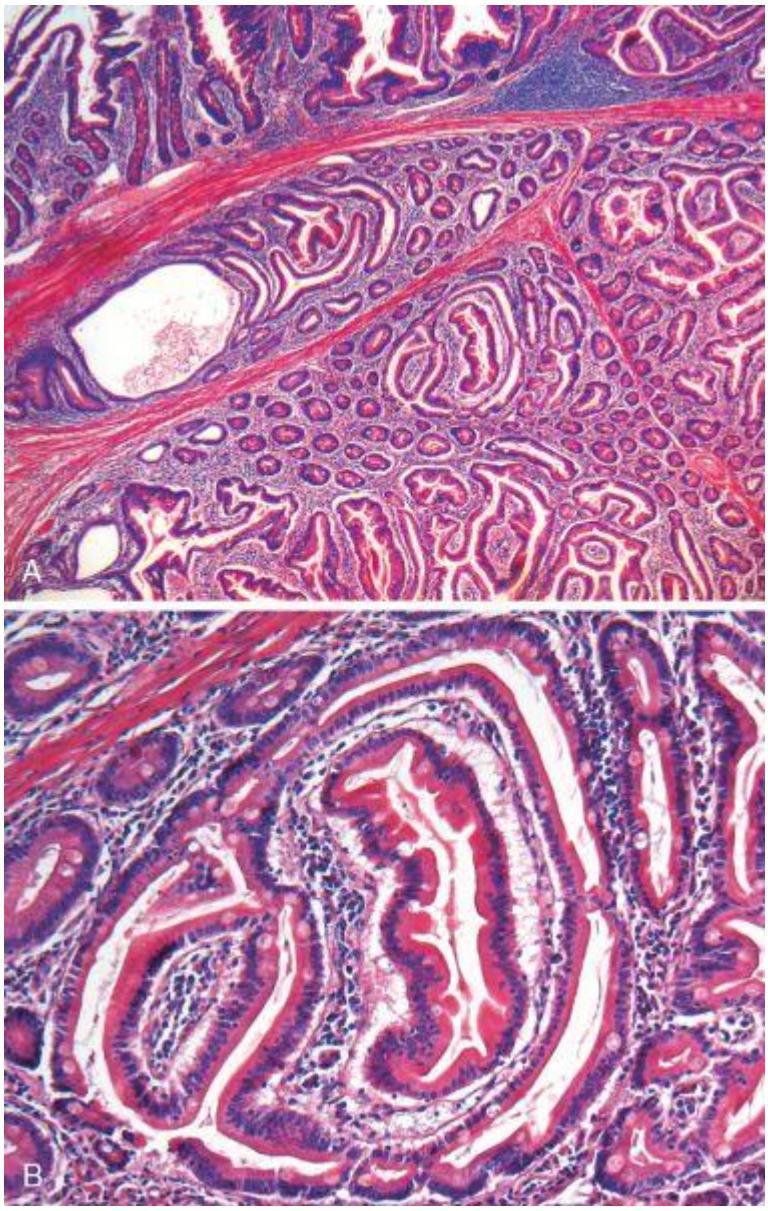

FIGURE 17-43 Peutz-Jeghers polyp. **A**, Polyp surface *(top)* overlies stroma composed of smooth muscle bundles cutting through the lamina propria. **B**, Complex glandular architecture and the presence of smooth muscle are features that distinguish Peutz-Jeghers polyps from juvenile polyps. Compare to Figure 17-42 .

Clinical Features.

Because the morphology of Peutz-Jeghers polyps can overlap with that of sporadic hamartomatous polyps, the presence of multiple polyps in the small intestine, mucocutaneous hyperpigmentation, and a positive family history are key to the diagnosis. Detection of *LKB1/STK11* mutations can be helpful diagnostically in patients with polyps who lack mucocutaneous hyperpigmentation. However, the absence of *LKB1/STK11* mutations does not exclude the diagnosis, since mutations in other presently unknown genes can also cause the syndrome. Because of the increased risk of cancer, routine surveillance of the GI tract, pelvis, and gonads is typically recommended.

Cowden Syndrome and Bannayan-Ruvalcaba-Riley Syndrome

Cowden syndrome and *Bannayan-Ruvalcaba-Riley syndrome* are autosomal dominant hamartomatous polyp syndromes associated with loss-of-function mutations in *PTEN*, a gene encoding a lipid phosphatase that inhibits signaling through the PI3K/AKT pathway. *PTEN*, a well-characterized tumor suppressor, is also mutated in a small number of patients presenting with juvenile polyposis. The multiple syndromes associated with *PTEN* mutations are sometimes grouped together under the heading "PTEN hamartoma syndrome." The basis for the differing presentations of these syndromes is not understood; interaction of PTEN loss-of-function mutations with other unknown modifying genes is suspected.

Cowden syndrome is characterized by macrocephaly, intestinal hamartomatous polyps, and benign skin tumors, typically trichilemmomas, papillomatous papules, and acral keratoses. A variety of other lesions derived from all three embryologic layers, including subcutaneous lipomas, leiomyomas, and hemangiomas, also occur. While individuals with Cowden syndrome do not have increased risk of GI malignancy, they are predisposed to breast carcinoma, follicular carcinoma of the thyroid, and endometrial carcinoma. Bannayan-Ruvalcaba-Riley syndrome can be distinguished from Cowden syndrome on clinical grounds; for example, mental deficiencies and developmental delays are only seen with the Bannayan-Ruvalcaba-Riley syndrome, which also seems to be associated with a lower incidence of neoplasia than Cowden syndrome. Features shared by these two syndromes include GI hamartomatous polyps, lipomas, macrocephaly, hemangiomas, and, in males, pigmented macules on the glans penis.

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome contrasts sharply with other hamartomatous polyposis syndromes in that it is nonhereditary and most often develops in individuals over 50 years of age. The clinical symptoms are nonspecific and include diarrhea, weight loss, abdominal pain, and weakness. The most characteristic feature is the presence of hamartomatous polyps of the stomach, small intestine, and colorectum that are histologically indistinguishable from juvenile polyps. However, the nonpolypoid intervening mucosa also shows cystic crypt dilatation and lamina propria edema and inflammation. Associated abnormalities include nail atrophy and splitting, hair loss, and areas of cutaneous hyperpigmentation and hypopigmentation. The cause of Cronkhite-Canada syndrome is unknown, and no specific therapies are available. Supportive nutritional therapy, which alleviates cachexia and anemia, can occasionally induce remission. Nonetheless, as many as 50% of cases are fatal.

HYPERPLASTIC POLYPS

Colonic hyperplastic polyps are common epithelial proliferations that are typically discovered in the sixth and seventh decades of life. The pathogenesis of hyperplastic polyps is incompletely understood, but they are thought to result from decreased epithelial cell turnover and delayed shedding of surface epithelial cells, leading to a "piling up" of goblet cells and absorptive cells. It is now appreciated that these lesions are without malignant potential. Their chief significance is that *they must be distinguished from sessile serrated adenomas, histologically similar lesions that have malignant potential*, as described later. It is also important to remember that epithelial hyperplasia can occur as a nonspecific reaction adjacent to or overlying any mass or inflammatory lesion and, therefore, can be a clue to the presence of an adjacent, clinically important lesion.

Morphology. Hyperplastic polyps are most commonly found in the left colon and are typically less than 5 mm in diameter. They are smooth, nodular protrusions of the mucosa, often on the crests of mucosal folds. They may occur singly but are more frequently multiple, particularly in the sigmoid colon and rectum. Histologically, hyperplastic polyps are composed of mature goblet and absorptive

cells. The delayed shedding of these cells leads to crowding that creates the serrated surface architecture that is the morphologic hallmark of these lesions (Fig. 17-44).

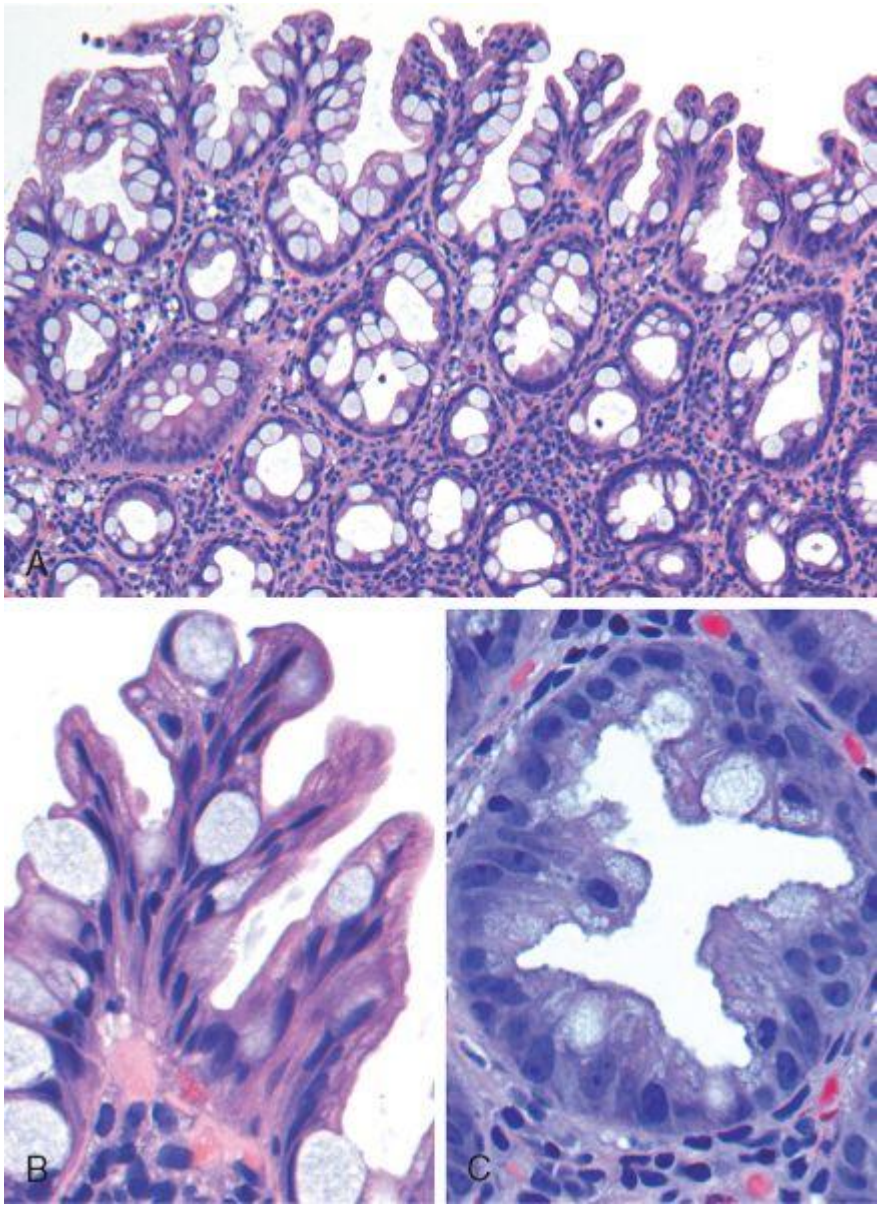

FIGURE 17-44 Hyperplastic polyp. **A**, Polyp surface with irregular tufting of epithelial cells. **B**, Tufting results from epithelial overcrowding. **C**, Epithelial crowding produces a serrated architecture when glands are cut in cross-section.

NEOPLASTIC POLYPS

Any neoplastic mass lesion in the GI tract may produce a mucosal protrusion, or polyp. This includes carcinoid tumors, stromal tumors, lymphomas, and even metastatic cancers from distant sites. However, the most common and clinically important neoplastic polyps are *colonic adenomas, benign polyps that are precursors to the majority of colorectal adenocarcinomas*.

Adenomas are intraepithelial neoplasms that range from small, often pedunculated polyps to large sessile lesions. There is no gender preference, and they are present in nearly 50% of adults living in the Western world by age 50. These polyps are precursors to colorectal cancer and it is recommended that all adults in the United States undergo surveillance colonoscopy by age 50. Because those with a family history are at risk for developing colon cancer earlier in life, these patients are typically screened at least 10 years before the youngest age at which a relative was diagnosed.[109] While adenomas are less common in Asia, their frequency has risen (in parallel with an increasing incidence of colorectal adenocarcinoma) in these populations as Western diets and lifestyles become more common.

Colorectal adenomas are characterized by the presence of epithelial dysplasia. Consistent with their role as precursor lesions, the prevalence of colorectal adenomas correlates with that of colorectal carcinoma and the distributions of adenomas and adenocarcinoma within the colon are similar. Large studies have demonstrated that regular surveillance colonoscopy and polyp removal reduces the incidence of colorectal adenocarcinoma. Despite this strong relationship, it must be emphasized that the majority of adenomas do not progress to become adenocarcinoma. However, there are no tools presently available to distinguish between those that will or will not undergo malignant transformation. Most adenomas are clinically silent, with the exception of large polyps that produce occult bleeding and anemia and rare villous adenomas that cause hypoproteinemic hypokalemia by secreting large amounts of protein and potassium.

Morphology. Typical adenomas range from 0.3 to 10 cm in diameter and can be **pedunculated** (Fig. 17-45A) or **sessile**, with the surface of both types having a texture resembling velvet (Fig. 17-45B) or a raspberry, due to the abnormal epithelial growth pattern. Histologically, the cytologic hallmark of epithelial **dysplasia** is nuclear hyperchromasia, elongation, and stratification. These changes are most easily appreciated at the surface of the adenoma and are often accompanied by the presence of large nucleoli, eosinophilic cytoplasm, and a reduction in the number of goblet cells. Notably, the epithelium fails to mature as cells migrate from crypt to surface. Pedunculated adenomas have slender fibromuscular stalks (Fig. 17-45C) containing prominent blood vessels derived from the submucosa. The stalk is usually covered by non-neoplastic epithelium, but dysplastic epithelium is sometimes present.

Adenomas can be classified as **tubular, tubulovillous**, or **villous** based on their architecture. These categories, however, have little clinical significance in isolation. Tubular adenomas tend to be small, pedunculated polyps composed of small rounded, or tubular, glands (Fig. 17-46A). In contrast, villous adenomas, which are often larger and sessile, are covered by slender villi (Fig. 17-46B). Tubulovillous adenomas have a mixture of tubular and villous elements. Although villous adenomas contain foci of invasion more frequently than tubular adenomas, villous architecture alone does not increase cancer risk when polyp size is considered.

Sessile serrated adenomas overlap histologically with hyperplastic polyps, but are more commonly found in the right colon.[110] Despite their malignant potential, sessile serrated adenomas lack typical cytologic features of dysplasia that are present in other adenomas (Fig. 17-46C). Histologic criteria include serrated architecture throughout the full length of the glands, including the crypt base, associated with lateral growth and crypt dilation (Fig. 17-46D). In contrast, serrated architecture is typically confined to the surface of hyperplastic polyps.

Intramucosal carcinoma occurs when dysplastic epithelial cells breach the basement membrane to invade the lamina propria or muscularis mucosa. Because lymphatic channels are absent in the colonic mucosa, intramucosal carcinoma has little or no metastatic potential and complete polypectomy is effective therapy (Fig. 17-47A). Invasion beyond the muscularis mucosa, including

into the submucosal stalk of a pedunculated polyp (Fig. 17-47B), constitutes invasive adenocarcinoma and carries a risk of spread to other sites. In such cases several factors, including the histologic grade of the invasive component, the presence of vascular or lymphatic invasion, and the distance of the invasive component from the margin of resection, must be considered in planning further therapy. Invasive adenocarcinoma in a polyp requires resection.

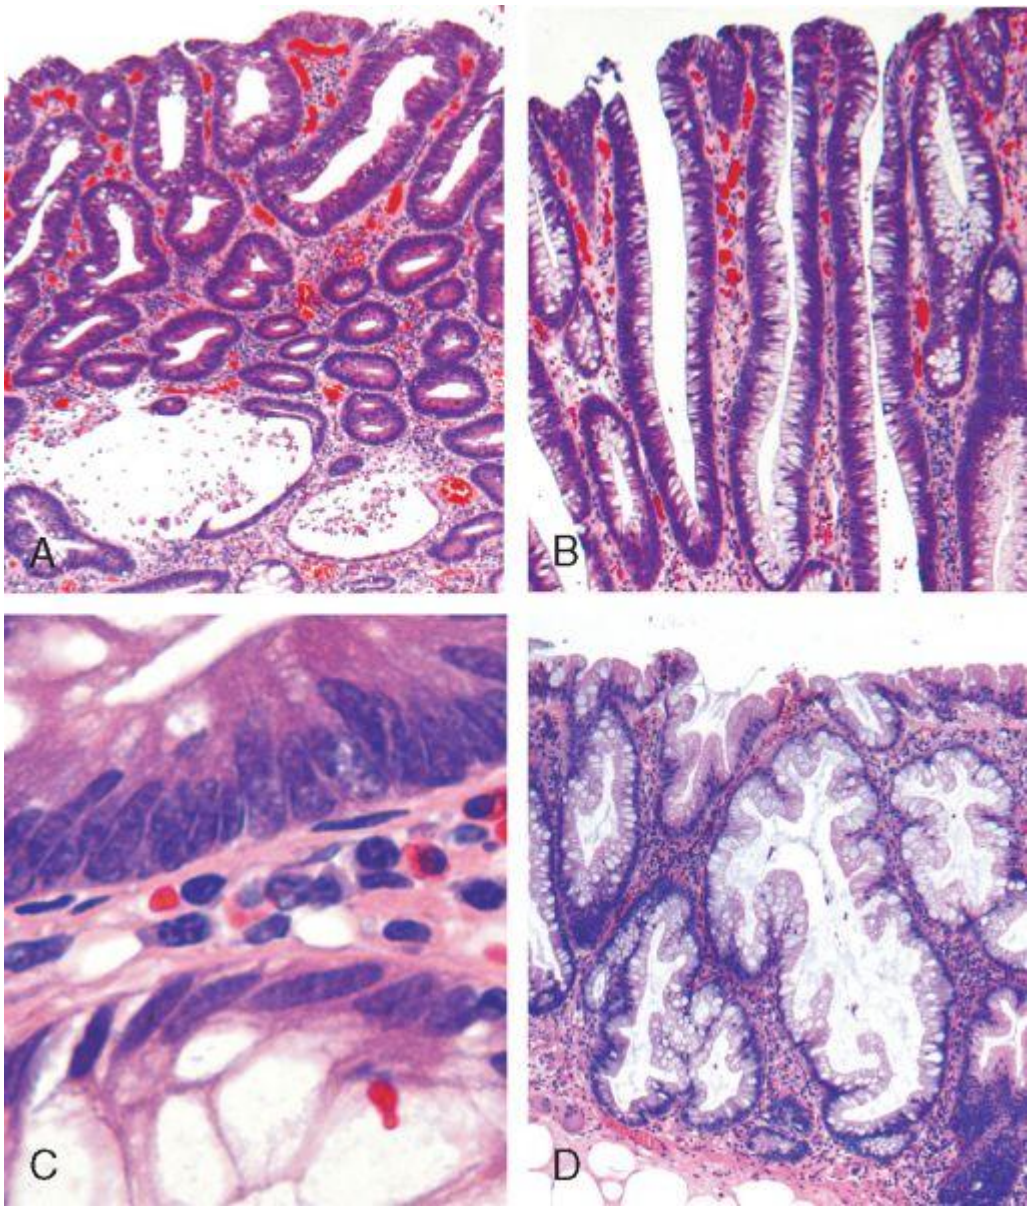

FIGURE 17-46 Histologic appearance of colonic adenomas. **A**, Tubular adenoma with a smooth surface and rounded glands. Active inflammation is occasionally present in adenomas, in this case, crypt dilation and rupture can be seen at the bottom of the field. **B**, Villous adenoma with long, slender projections that are reminiscent of small intestinal villi. **C**, Dysplastic epithelial cells *(top)* with an increased nuclear-to-cytoplasmic ratio, hyperchromatic and elongated nuclei, and nuclear pseudostratification. Compare to the nondysplastic epithelium below. **D**, Sessile serrated adenoma lined by goblet cells without typical cytologic features of dysplasia. This lesion is distinguished from a hyperplastic polyp by extension of the neoplastic process to the crypts, resulting in lateral growth. Compare to the hyperplastic polyp in Figure 17-44A .

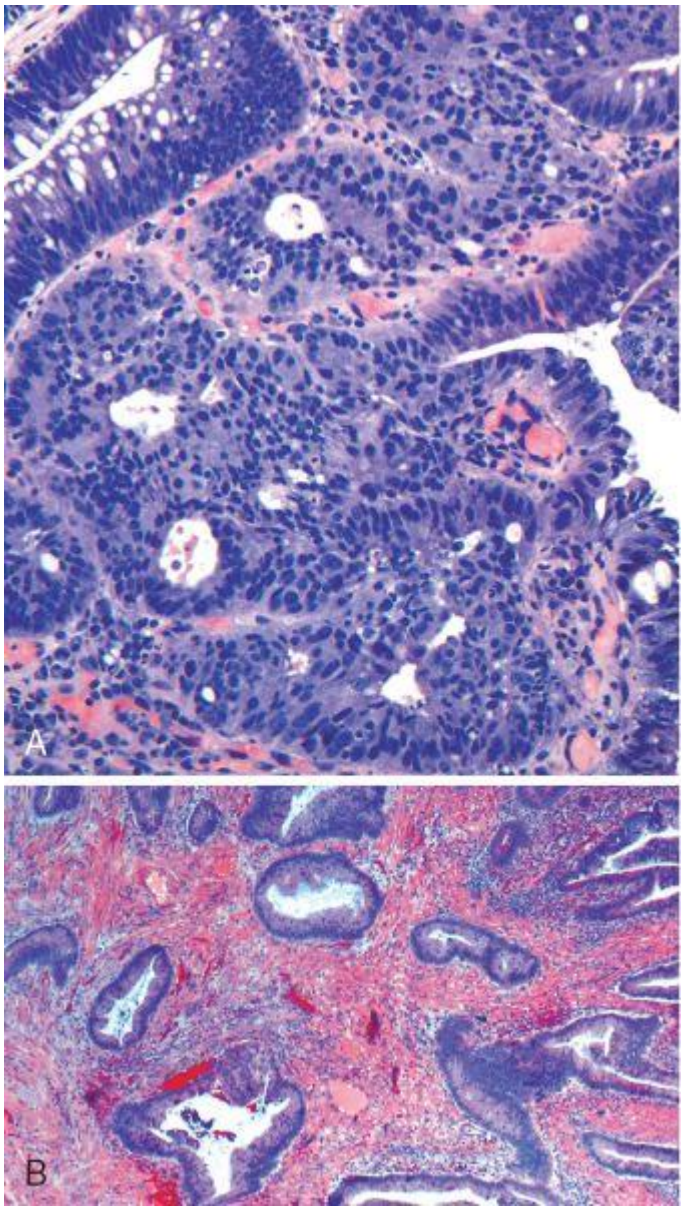

FIGURE 17-47 Adenoma with intramucosal carcinoma. **A**, Cribriform glands interface directly with the lamina propria without an intervening basement membrane. **B**, Invasive adenocarcinoma (left) beneath a villous adenoma (right). Note the desmoplastic response to the invasive components.

Although most colorectal adenomas are benign lesions, a small proportion may harbor invasive cancer at the time of detection. *Size is the most important characteristic that correlates with risk of malignancy*. For example, while cancer is extremely rare in adenomas less than 1 cm in diameter, some studies suggest that nearly 40% of lesions larger than 4 cm in diameter contain foci of cancer. In addition to size, high-grade dysplasia is a risk factor for cancer in an individual polyp (but not other polyps in the same patient).

3.7.4.11 Familial Syndromes

Several syndromes characterized by the presence of colonic polyps and increased rates of colon cancer have been described. The genetic basis of these disorders has been established and has greatly enhanced our understanding of sporadic colon cancer (Table 17-10).

TABLE 17-10 -- Common Patterns of Sporadic and Familial Colorectal Neoplasia

Etiology	Molecular Defect	Target Gene(s)	Transmission	Predominant Site(s)	Histology
Familial adenomatous polyposis (70% of FAP)	APC/WNT pathway	*APC*	Autosomal dominant	None	Tubular, villous; typical adenocarcinoma
Familial adenomatous polyposis (<10% of FAP)	DNA mismatch repair	*MUTYH*	None, recessive	None	Sessile serrated adenoma; mucinous adenocarcinoma
Hereditary nonpolyposis colorectal cancer	DNA mismatch repair	*MSH2, MLH1*	Autosomal	Right side	Sessile serrated adenoma; mucinous adenocarcinoma
Sporadic colon cancer (80%)	APC/WNT pathway	*APC*	None	Left side	Tubular, villous; typical adenocarcinoma
Sporadic colon cancer (10% to 15%)	DNA mismatch repair	*MSH2, MLH1*	None	Right side	Sessile serrated adenoma; mucinous adenocarcinoma

FAMILIAL ADENOMATOUS POLYPOSIS

Familial adenomatous polyposis (FAP) is an autosomal dominant disorder in which patients develop numerous colorectal adenomas as teenagers. It is caused by mutations of the *adenomatous polyposis coli*, or *APC*, gene.

At least *100 polyps are necessary for a diagnosis* of classic FAP, and as many as several thousand may be present (Fig. 17-48). Except for their remarkable numbers, these growths are *morphologically indistinguishable from sporadic adenomas*. In addition, however, flat or depressed adenomas are also prevalent in FAP, and microscopic adenomas, consisting of only one or two dysplastic glands, are frequently observed in otherwise normal-appearing mucosa.

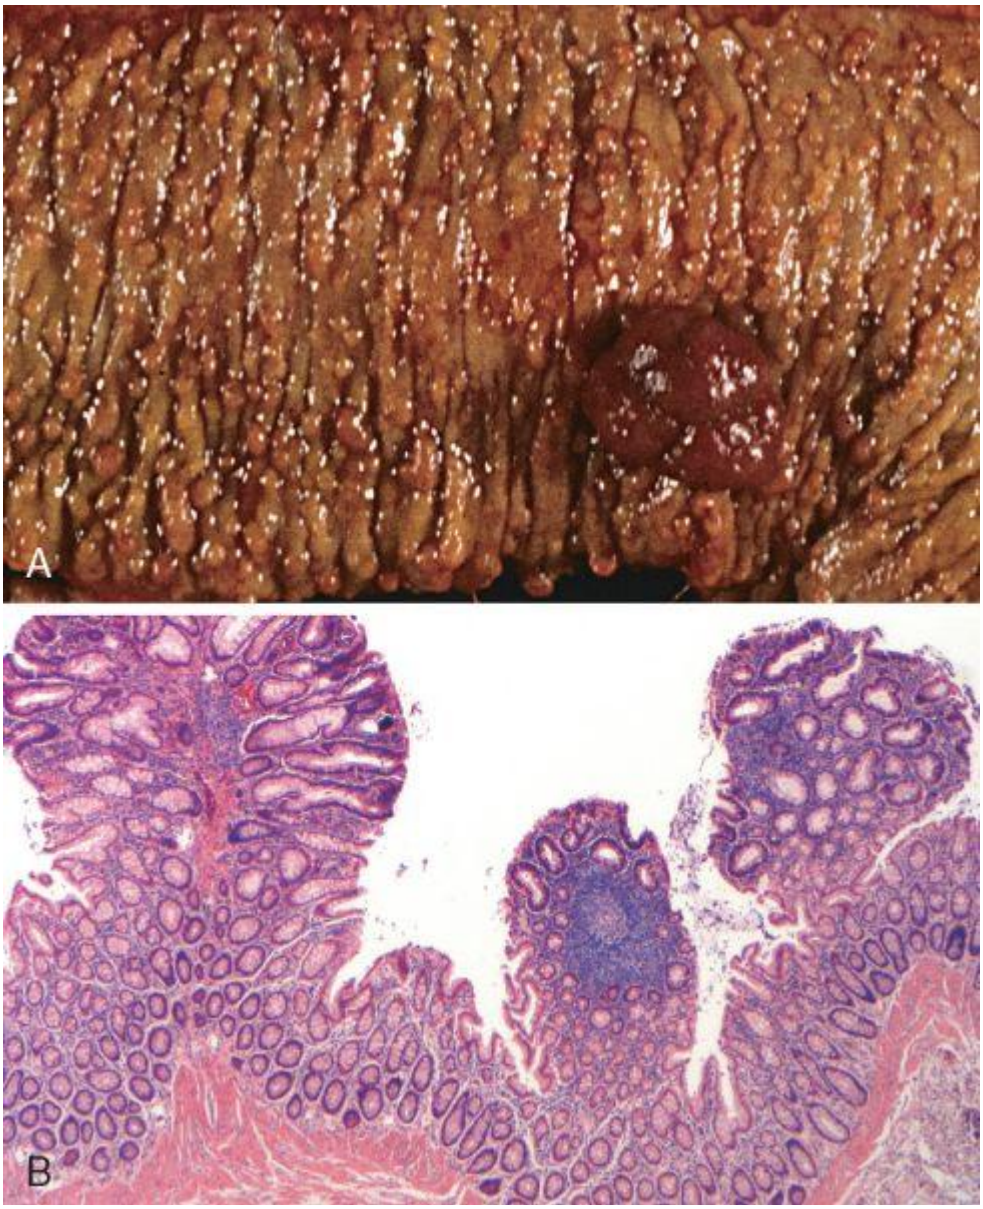

FIGURE 17-48 Familial adenomatous polyposis. **A**, Hundreds of small polyps are present throughout this colon with a dominant polyp *(right)*. **B**, Three tubular adenomas are present in this single microscopic field.

Colorectal adenocarcinoma develops in 100% of untreated FAP patients, often before age 30. As a result, prophylactic colectomy is the standard therapy for individuals carrying *APC* mutations.[111] Colectomy prevents colorectal cancer, but patients remain at risk for neoplasia at other sites. For example, adenomas may develop elsewhere in the GI tract, particularly adjacent to the ampulla of Vater and in the stomach.

FAP is associated with a variety of *extra-intestinal manifestations* including congenital hypertrophy of the retinal pigment epithelium, which can generally be detected at birth and can be an adjunct to early screening. Specific *APC* mutations have been associated with the development of other manifestations of FAP and explain variants such as Gardner syndrome and Turcot syndrome. In addition to intestinal polyps, *Gardner syndrome* families have osteomas of mandible, skull, and long bones, epidermal cysts,

desmoid tumors, thyroid tumors, and dental abnormalities, including unerupted and supernumerary teeth. *Turcot syndrome* is rarer and characterized by intestinal adenomas and tumors of the central nervous system. Two thirds of patients with Turcot syndrome have *APC* gene mutations and develop medulloblastomas. The remaining one third have mutations in one of several genes involved in DNA repair and develop glioblastomas.

Some FAP patients without *APC* loss have mutations of the base-excision repair gene *MUTYH*.[112] The role of these genes in tumor development is discussed below. In addition, certain *APC* and *MUTYH* mutations are associated with attenuated forms of FAP, which are characterized by delayed polyp development, the presence of fewer than 100 adenomas, and the delayed appearance of colon cancer, often to ages of 50 or above.[113]

HEREDITARY NON-POLYPOSIS COLORECTAL CANCER

Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch syndrome, was originally described based on familial clustering of cancers at several sites including the colorectum, endometrium, stomach, ovary, ureters, brain, small bowel, hepatobiliary tract, and skin. Colon cancers in HNPCC patients tend to occur at *younger ages* than sporadic colon cancers and are often located in the *right colon* (see Table 17-10). Just as identification of *APC* mutations in FAP has provided molecular insights into the pathogenesis of the majority of sporadic colon cancers, dissection of the defects in HNPCC has shed light on the mechanisms responsible for most of the remaining sporadic cases. HNPCC is caused by inherited mutations in genes that encode proteins responsible for the detection, excision, and repair of errors that occur during DNA replication (Chapter 7). There are at least five such mismatch repair genes, but the majority of HNPCC cases involve *MSH2* and *MLH1*. Patients with HNPCC inherit one mutated DNA repair gene and one normal allele. When the second copy is lost through mutation or epigenetic silencing, defects in mismatch repair lead to the accumulation of mutations at rates up to 1000 times higher than normal, mostly in regions containing short repeating DNA sequences referred to as microsatellite DNA. The human genome contains approximately 50,000 to 100,000 microsatellites, which are prone to undergo expansion during DNA replication and represent the most frequent sites of mutations in HNPCC. The consequences of mismatch repair deficiency and the resulting *microsatellite instability* are discussed in the context of colonic adenocarcinoma.

3.7.4.12 Adenocarcinoma

Adenocarcinoma of the colon is the most common malignancy of the GI tract and is a major cause of morbidity and mortality worldwide. In contrast, the small intestine, which accounts for 75% of the overall length of the GI tract, is an uncommon site for benign and malignant tumors. Among malignant small intestinal tumors, adenocarcinomas and carcinoid tumors have roughly equal incidence, followed by lymphomas and sarcomas. Hence, our discussion is focused on colorectal adenocarcinomas.

Epidemiology.

Each year in the United States there are more than 130,000 new cases and 55,000 deaths from colorectal adenocarcinoma. This represents nearly 15% of all cancer-related deaths, and is second only to lung cancer. Colorectal cancer incidence peaks at 60 to 70 years of age, and fewer than 20% of cases occur before age 50. Males are affected slightly more often than females. Colorectal carcinoma is most prevalent in the United States, Canada, Australia, New Zealand, Denmark, Sweden, and other developed countries. The incidence of this cancer is as much as 30-fold lower in India, South America, and Africa. In Japan, where incidence was previously very low, rates have now risen to intermediate levels (similar to those in the United Kingdom), presumably as a result of changes in lifestyle and diet.

The dietary factors most closely associated with increased colorectal cancer rates are low intake of unabsorbable vegetable fiber and high intake of refined carbohydrates and fat. Although these associations are clear, the mechanistic relationship between diet and risk remains poorly understood. However, it is theorized that reduced fiber content leads to decreased stool bulk and altered composition of the intestinal microbiota. This change may increase synthesis of potentially toxic oxidative by-products of bacterial metabolism, which would be expected to remain in contact with the colonic mucosa for longer periods of time as a result of reduced stool bulk. Deficiencies of vitamins A, C, and E, which act as free-radical scavengers, may compound damage caused by oxidants. High fat intake enhances the hepatic synthesis of cholesterol and bile acids, which can be converted into carcinogens by intestinal bacteria.

In addition to dietary modification, pharmacologic chemoprevention has become an area of great interest. Several epidemiologic studies suggest that aspirin or other NSAIDs have a protective effect. This is consistent with studies showing that some NSAIDs cause polyp regression in FAP patients in whom the rectum was left in place after colectomy. It is suspected that this effect is mediated by inhibition of the enzyme cyclooxygenase-2 (COX-2), which is highly expressed in 90% of colorectal carcinomas and 40% to 90% of adenomas. COX-2 is necessary for production of prostaglandin E_2, which promotes epithelial proliferation, particularly after injury.[114] Of further interest, COX-2 expression is regulated by TLR4, which recognizes lipopolysaccharide and is also overexpressed in adenomas and carcinomas.[115]

Pathogenesis.

Studies of colorectal carcinogenesis have provided fundamental insights into the general mechanisms of cancer evolution. These were discussed in Chapter 7 ; concepts that pertain specifically to colorectal carcinogenesis will be reviewed here.

The combination of molecular events that lead to colonic adenocarcinoma is heterogeneous and includes genetic and epigenetic abnormalities. At least two distinct genetic pathways have been described. In simplest terms, these are the *APC/*β*-catenin pathway*, which is associated with *WNT* and the classic adenoma-carcinoma sequence; and the *microsatellite instability pathway*, which is associated with defects in DNA mismatch repair (see Table 17-10). Both pathways involve the stepwise accumulation of multiple mutations, but the genes involved and the mechanisms by which the mutations accumulate differ. Epigenetic events, the most common of which is methylation-induced gene silencing, may enhance progression along both pathways.

- The classic *adenoma-carcinoma sequence*, which accounts for as much as 80% of sporadic colon tumors, typically includes mutation of *APC* early in the neoplastic process (Fig. 17-49). Both copies of the *APC* gene must be functionally inactivated, either by mutation or epigenetic events, for adenomas to develop. *APC is a key negative regulator of* β*-catenin, a component of the WNT signaling pathway* (see Chapter 7). The APC protein normally binds to and promotes degradation of β-catenin. With loss of APC function, β-catenin accumulates and translocates to the nucleus, where it activates the transcription of genes, such as those encoding MYC and cyclin D1, which promote proliferation. This is followed by additional mutations, including activating mutations in *KRAS*, which also promote growth and prevent apoptosis. The conclusion that mutation of *KRAS* is a late event is supported by the observation that mutations are present in fewer than 10% of adenomas less than 1 cm in diameter but are found in 50% of adenomas greater than 1 cm in diameter and 50% of invasive adenocarcinomas. Neoplastic progression is also associated with mutations in other tumor suppressor genes such as those encoding SMAD2 and SMAD4, which are effectors of TGF-β signaling. Because TGF-β signaling normally inhibits the cell cycle, loss of these genes may allow unrestrained cell growth. The tumor suppressor *p53* is mutated in 70% to 80% of colon cancers, but is uncommonly affected in adenomas, suggesting that *p53* mutations also occur at late stages of tumor progression. “Loss of function” of *p53* and other tumor suppressor genes is often caused by chromosomal deletions, pointing out that chromosomal instability is a hallmark of the APC/β-catenin pathway. Alternatively, tumor suppressor genes may be silenced by methylation of a CpG-rich zone, or CpG island, a

5′ region of some genes that frequently includes the promoter and transcriptional start site. Expression of telomerase also increases as lesions become more advanced.

- In patients with DNA mismatch repair deficiency (due to loss of mismatch repair genes, as discussed earlier) mutations accumulate in microsatellite repeats, a condition referred to as *microsatellite instability*. While these mutations are generally silent because microsatellites are typically in noncoding regions, some microsatellite sequences are located in the coding or promoter region of genes involved in regulation of cell growth, such as those encoding the type II TGF-β receptor and the pro-apoptotic protein BAX (Fig. 17-50). Because TGF-β inhibits colonic epithelial cell proliferation, type II TGF-β receptor mutants can contribute to uncontrolled cell growth, while loss of *BAX* may enhance the survival of genetically abnormal clones. Mutations in the oncogene *BRAF* and silencing of distinct groups of genes due to CpG island hypermethylation are also common in cancers that develop through DNA mismatch repair defects. In contrast, *KRAS* and *p53* are not typically mutated. Thus, the combination of microsatellite instability, *BRAF* mutation, and methylation of specific targets, such as *MLH1*, is the signature of this pathway of carcinogenesis.[116]
- A third group of colon cancers with increased CpG island methylation in the absence of microsatellite instability also exists. Many of these tumors harbor *KRAS* mutations, but *p53* and *BRAF* mutations are uncommon. In contrast, *p53* mutations are common in colon cancers that do not display a CpG island methylator phenotype.[116,][117]

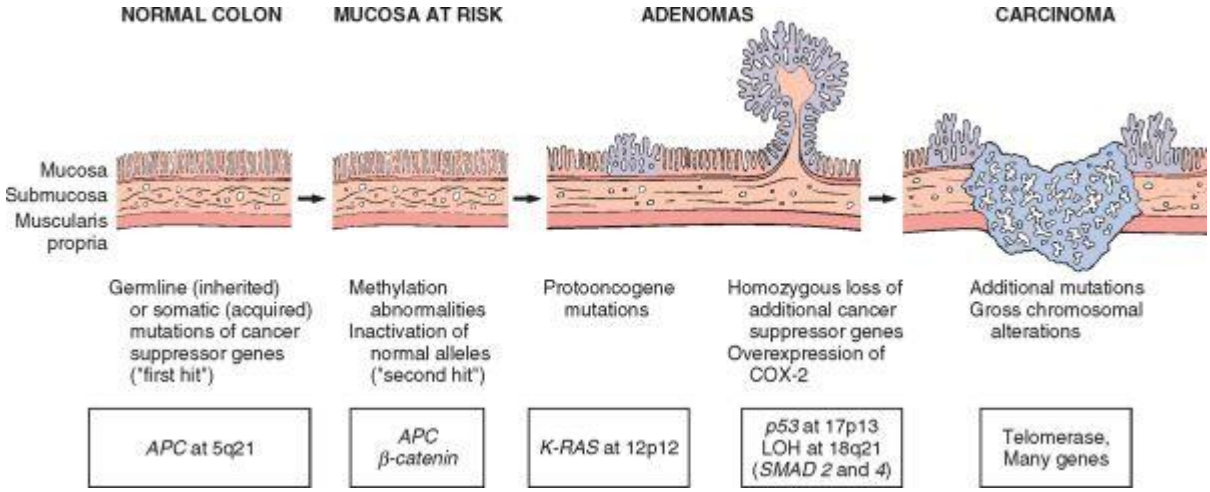

FIGURE 17-49 Morphologic and molecular changes in the adenoma-carcinoma sequence. It is postulated that loss of one normal copy of the tumor suppressor gene *APC* occurs early. Individuals may be born with one mutant allele, making them extremely prone to develop colon cancer, or inactivation of *APC* may occur later in life. This is the "first hit" according to Knudson's hypothesis (Chapter 7). The loss of the intact copy of *APC* follows ("second hit"). Other mutations include those on *KRAS*, losses at 18q21 involving *SMAD2* and *SMAD4*, and inactivation of the tumor suppressor gene *p53*, lead to the emergence of carcinoma, in which additional mutations occur. Although there seems to be a temporal sequence of changes, the accumulation of mutations, rather than their occurrence in a specific order, is most critical.

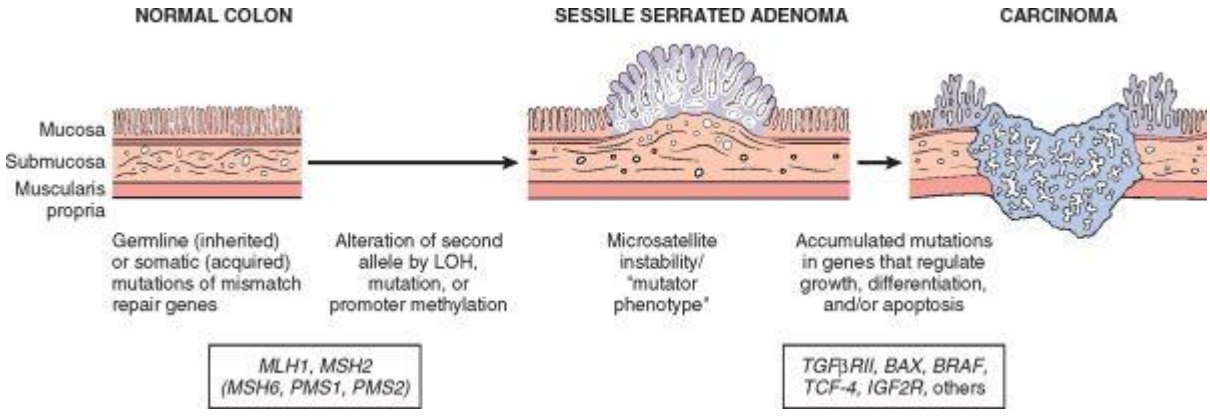

FIGURE 17-50 Morphologic and molecular changes in the mismatch repair pathway of colon carcinogenesis. Defects in mismatch repair genes result in microsatellite instability and permit accumulation of mutations in numerous genes. If these mutations affect genes involved in cell survival and proliferation, cancer may develop.

While morphology cannot reliably predict the underlying molecular events that led to carcinogenesis, certain correlations have been associated with mismatch repair deficiency and microsatellite instability. These molecular alterations are common in sessile serrated adenomas. In addition, invasive carcinomas with microsatellite instability often have prominent mucinous differentiation and peritumoral lymphocytic infiltrates. These tumors, as well as those with a CpG island methylator phenotype, are frequently located in the right colon. Tumors with microsatellite instability can be recognized by the absence of immunohistochemical staining for mismatch repair proteins or by molecular genetic analysis of microsatellite sequences. It is important to identify those with HNPCC because of the implications for genetic counseling, the elevated risk of a second malignancy of the colon and other organs, and, in some settings, differences in prognosis and therapy.

Morphology. Overall, adenocarcinomas are distributed approximately equally over the entire length of the colon. Tumors in the proximal colon often grow as polypoid, exophytic masses that extend along one wall of the large-caliber cecum and ascending colon; these tumors rarely cause obstruction. In contrast, carcinomas in the distal colon tend to be annular lesions that produce "napkin-ring" constrictions and luminal narrowing (Fig. 17-51), sometimes to the point that obstruction occurs. Both forms grow into the bowel wall over time and may be palpable as firm masses. The general microscopic characteristics of right- and left-sided colonic adenocarcinomas are similar. Most tumors are composed of tall columnar cells that resemble dysplastic epithelium found in adenomas (Fig. 17-52A). The invasive component of these tumors elicits a strong stromal desmoplastic response, which is responsible for their characteristic firm consistency. Some poorly differentiated tumors form few glands (Fig. 17-52B). Others may produce abundant mucin that accumulates within the intestinal wall, and these are associated with poor prognosis. Tumors may also be composed of signet-ring cells that are similar to those in gastric cancer (Fig. 17-52C). Others may display features of neuroendocrine differentiation.

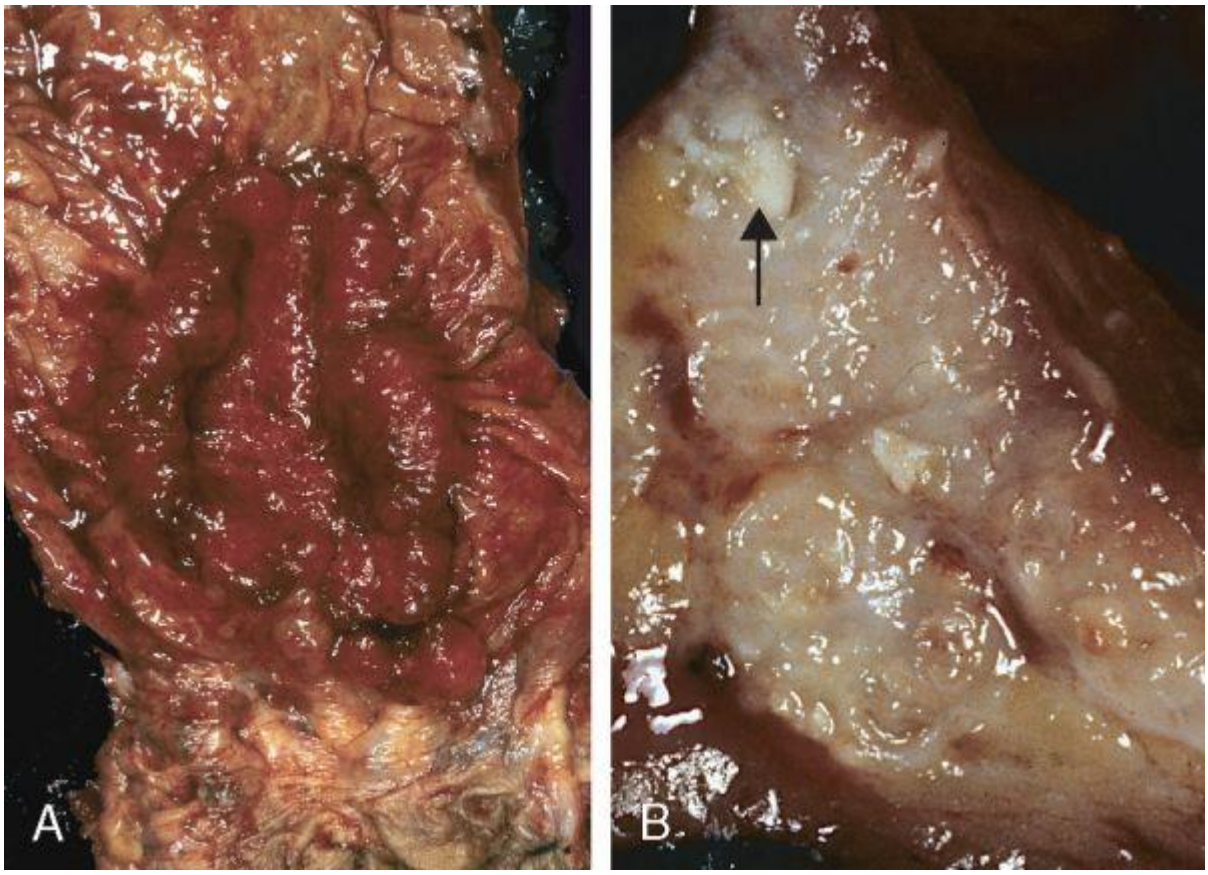

FIGURE 17-51 Colorectal carcinoma. **A**, Circumferential, ulcerated rectal cancer. Note the anal mucosa at the bottom of the image. **B**, Cancer of the sigmoid colon that has invaded through the muscularis propria and is present within subserosal adipose tissue *(left)*. Areas of chalky necrosis are present within the colon wall (*arrow*).

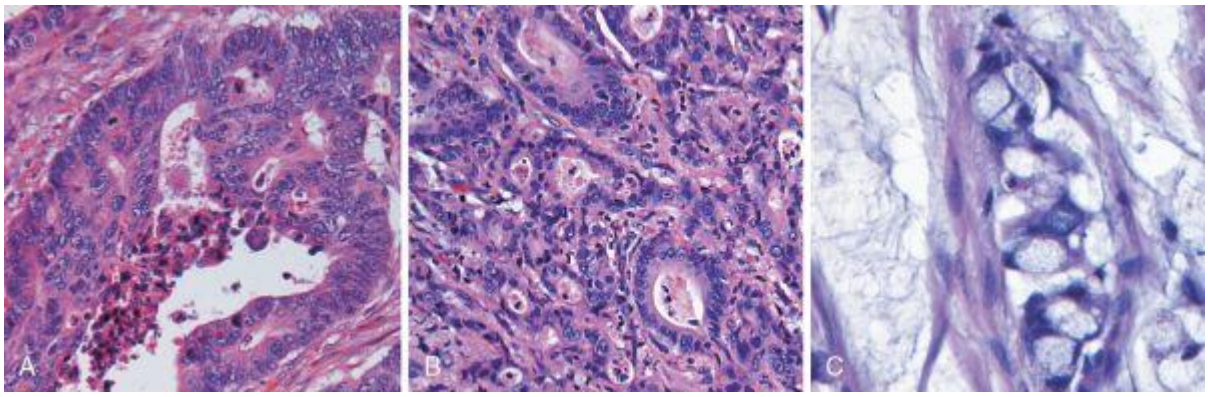

FIGURE 17-52 Histologic appearance of colorectal carcinoma. **A**, Well-differentiated adenocarcinoma. Note the elongated, hyperchromatic nuclei. Necrotic debris, present in the gland lumen, is typical. **B**, Poorly differentiated adenocarcinoma forms a few glands but is largely composed of infiltrating nests of tumor cells. **C**, Mucinous adenocarcinoma with signet-ring cells and extracellular mucin pools.

Clinical Features.

The availability of endoscopic screening combined with the knowledge that most carcinomas arise within adenomas presents a unique opportunity for cancer prevention. Unfortunately, colorectal cancers develop insidiously and may therefore go undetected for long periods. Cecal and other *right-sided colon cancers* are most often called to clinical attention by the appearance of *fatigue and weakness due to iron deficiency anemia*. Thus, it is a clinical maxim that the underlying cause of iron deficiency anemia in an older man or postmenopausal woman is GI cancer until proven otherwise. *Left-sided colorectal adenocarcinomas* may produce *occult bleeding, changes in bowel habits, or cramping* left lower quadrant discomfort.

Although poorly differentiated and mucinous histologies are associated with poor prognosis, *the two most important prognostic factors are depth of invasion and the presence or absence of lymph node metastases*. Invasion into the muscularis propria confers significantly reduced survival that is decreased further by the presence of lymph node metastases (Fig. 17-53A).[118] These factors were originally recognized by Dukes and Kirklin and form the core of the TNM (tumor-nodes-metastasis) classification (Table 17-11) and staging system (Table 17-12) from the American Joint Committee on Cancer. Regardless of stage, it must be remembered that some patients with small numbers of metastases do well for years following resection of distant tumor nodules. This, once again, emphasizes the clinical and molecular heterogeneity of colorectal carcinomas. Metastases may involve regional lymph nodes, lungs (Fig. 17-53B) and bones, but as a result of portal drainage of the colon, the liver is the most common site of metastatic lesions (Fig. 17-53C). The rectum does not drain via the portal circulation, and carcinomas of the anal region that metastasize often circumvent the liver.

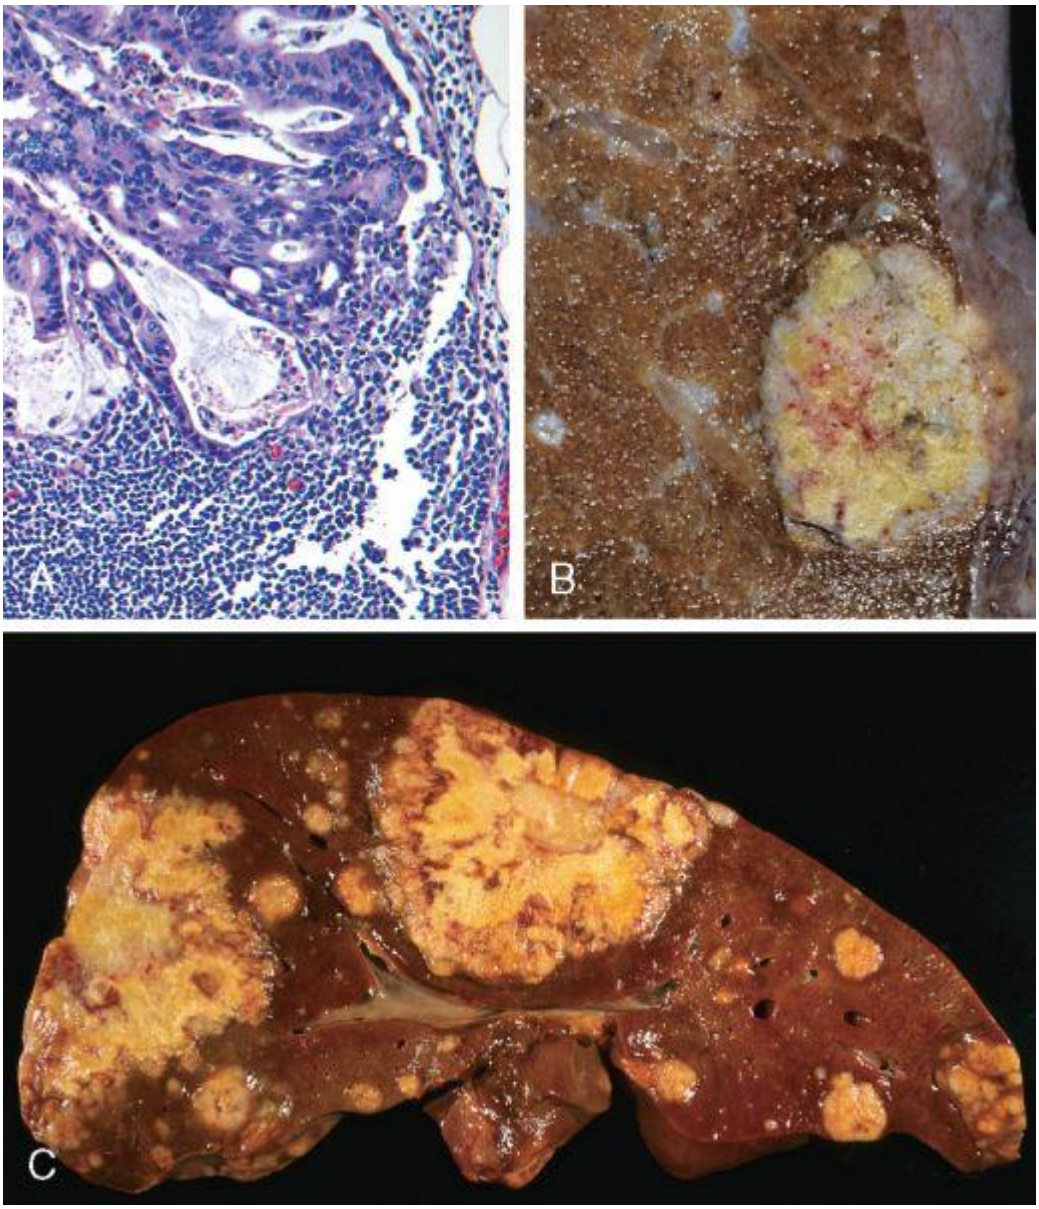

FIGURE 17-53 Metastatic colorectal carcinoma. **A**, Lymph node metastasis. Note the glandular structures within the subcapsular sinus. **B**, Solitary subpleural nodule of colorectal carcinoma metastatic to the lung. **C**, Liver containing two large and many smaller metastases. Note the central necrosis within metastases.

TABLE 17-11 -- American Joint Committee on Cancer (AJCC) TNM Classification of Colorectal Carcinoma

TNM	
TUMOR	
Tis	In situ dysplasia or intramucosal carcinoma
T1	Tumor invades submucosa
T2	Tumor invades into, but not through, muscularis propria
T3	Tumor invades through muscularis propria
T3a	Invasion <0.1 cm beyond muscularis propria

TNM	
T3b	Invasion 0.1 to 0.5 cm beyond muscularis propria
T3c	Invasion >0.5 to 1.5 cm beyond muscularis propria
T3d	Invasion >1.5 cm beyond muscularis propria
T4	Tumor invades adjacent organs or visceral peritoneum
T4a	Invasion into other organs or structures
T4b	Invasion into visceral peritoneum
REGIONAL LYMPH NODES	
NX	Lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one to three regional lymph nodes
N2	Metastasis in four or more regional lymph nodes
DISTANT METASTASIS	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis or seeding of abdominal organs

TABLE 17-12 -- American Joint Committee on Cancer (AJCC) Colorectal Cancer Staging and Survival

STAGE[*]				
	T	**N**	**M**	**5-YEAR SURVIVAL (%)**
I	**T1, T2**	**N0**	**M0**	**93**
II				
IIA	**T3**	**N0**	**M0**	**85**
IIB	**T4**	**N0**	**M0**	**72**
III				
IIIA	**T1, T2**	**N1**	**M0**	**83**
IIIB	**T3, T4**	**N1**	**M0**	**64**
IIIC	**Any T**	**N2**	**M0**	**44**
IV	**Any T**	**Any N**	**M1**	**8**

[*] Colorectal cancer staging is based on the TNM classification (Table 17-11). For example, a T3 tumor without nodal or distant metastases is classified as stage IIA and is associated with a 5-year survival rate of 85%.

3.7.4.13 Tumors of the Anal Canal

The anal canal can be divided into thirds. The upper zone is lined by columnar rectal epithelium; the middle third by transitional epithelium; and the lower third by stratified squamous epithelium. Carcinomas of the anal canal may have typical glandular or squamous (Fig. 17-54A) patterns of differentiation, recapitulating the normal epithelium of the upper and lower thirds, respectively. An additional differentiation pattern, termed *basaloid*, is present in tumors populated by immature cells derived from the basal layer of transitional epithelium (Fig. 17-54B). When the entire tumor displays a basaloid pattern, the archaic term *cloacogenic carcinoma* is still often applied. Alternatively, basaloid differentiation may be mixed with squamous or mucinous differentiation. All are considered variants of

anal canal carcinoma. Pure squamous cell carcinoma of the anal canal is frequently associated with HPV infection, which also causes precursor lesions such as *condyloma accuminatum* (Fig. 17-54C).

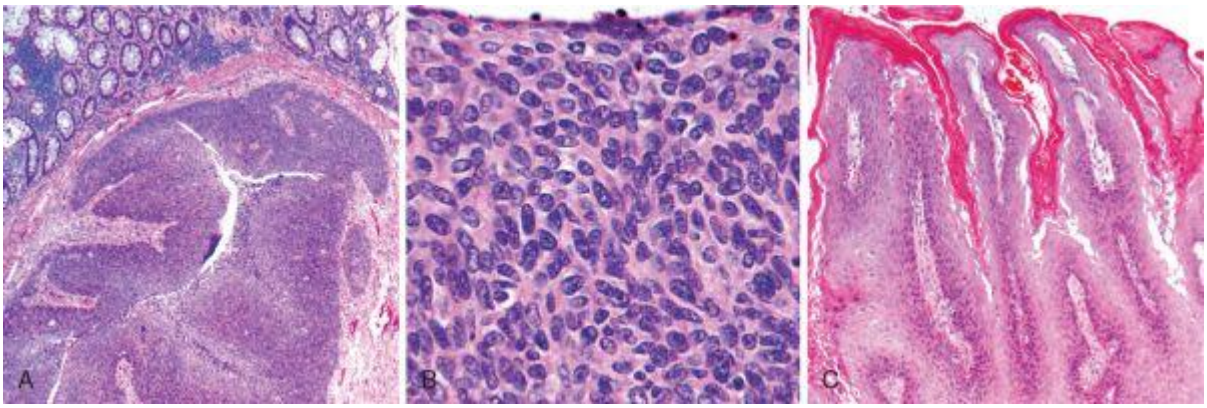

FIGURE 17-54 Anal tumors. **A**, This squamous anal transition zone tumor forms nests with central necrosis. The adjacent rectal mucosa is intact. **B**, This basaloid anal transition zone tumor is composed of hyperchromatic cells that resemble the basal layer of normal squamous mucosa. **C**, Condyloma accuminatum with verrucous architecture.

3.7.4.14 Hemorrhoids

Hemorrhoids affect about 5% of the general population and develop secondary to persistently elevated venous pressure within the hemorrhoidal plexus. The most frequent predisposing influences are straining at stool because of constipation and the venous stasis of pregnancy.

Pathogenesis.

The pathogenesis of hemorrhoids (anal varices) is similar to that of esophageal varices, although anal varices are both more common and less serious. Variceal dilations of the anal and perianal venous plexuses form collaterals that connect the portal and caval venous systems, thereby relieving the venous hypertension.

Morphology. Collateral vessels within the inferior hemorrhoidal plexus are located below the anorectal line and are termed **external hemorrhoids**, while those that result from dilation of the superior hemorrhoidal plexus within the distal rectum are referred to as **internal hemorrhoids**. Histologically, hemorrhoids consist of thin-walled, dilated, submucosal vessels that protrude beneath the anal or rectal mucosa. In their exposed position, they are subject to trauma and tend to become inflamed, thrombosed, and, in the course of time, recanalized. Superficial ulceration may occur.

Clinical Features.

Hemorrhoids often present with pain and rectal bleeding, particularly bright red blood seen on toilet tissue. Except for pregnant women, hemorrhoids are rarely encountered in persons under age 30. Hemorrhoids may also develop as a result of portal hypertension, where the implications are more ominous. Hemorrhoidal bleeding is not generally a medical emergency and can be treated by sclerotherapy, rubber band ligation, or infrared coagulation. Extensive or severe internal or external hemorrhoids may be removed surgically by *hemorrhoidectomy*.

3.7.4.15 Acute Appendicitis

The appendix is a normal true diverticulum of the cecum that is prone to acute and chronic inflammation. Acute appendicitis is most common in adolescents and young adults, but may occur in any age group. The lifetime risk for appendicitis is 7%; males are affected slightly more often than females. Despite the prevalence of acute appendicitis, the diagnosis can be difficult to confirm preoperatively and may be confused with mesenteric lymphadenitis (often secondary to unrecognized *Yersinia* infection or viral enterocolitis), acute salpingitis, ectopic pregnancy, mittelschmerz (pain caused by minor pelvic bleeding at the time of ovulation), and Meckel diverticulitis.

Pathogenesis.

Acute appendicitis is thought to be initiated by progressive increases in intraluminal pressure that compromise venous outflow. In 50% to 80% of cases, acute appendicitis is associated with overt luminal obstruction, usually caused by a small stone-like mass of stool, or *fecalith*, or, less commonly, a gallstone, tumor, or mass of worms *(oxyuriasis vermicularis)*. Ischemic injury and stasis of luminal contents, which favor bacterial proliferation, trigger inflammatory responses including tissue edema and neutrophilic infiltration of the lumen, muscular wall, and periappendiceal soft tissues.

Morphology. In early acute appendicitis subserosal vessels are congested and there is a modest perivascular neutrophilic infiltrate within all layers of the wall. The inflammatory reaction transforms the normal glistening serosa into a dull, granular, erythematous surface. Diagnosis of acute appendicitis requires neutrophilic infiltration of the muscularis propria. Although mucosal neutrophils and focal superficial ulceration are often present, these are not specific markers of acute appendicitis. In more severe cases a prominent neutrophilic exudate generates a serosal fibrinopurulent reaction. As the process continues, focal abscesses may form within the wall **(acute suppurative appendicitis)**. Further appendiceal compromise leads to large areas of hemorrhagic ulceration and gangrenous necrosis that extends to the serosa creating **acute gangrenous appendicitis**, which is often followed by rupture and suppurative peritonitis.

Clinical Features.

Typically, early acute appendicitis produces periumbilical pain that ultimately localizes to the right lower quadrant, followed by nausea, vomiting, low-grade fever, and a mildly elevated peripheral white cell count. A classic physical finding is *McBurney's sign*, deep tenderness located two thirds of the distance from the umbilicus to the right anterior superior iliac spine (McBurney's point). Regrettably, these signs and symptoms are often absent, creating difficulty in clinical diagnosis. In some cases, a retrocecal appendix may generate right flank or pelvic pain, while a malrotated colon may give rise to appendicitis in the left upper quadrant. In other cases the peripheral leukocytosis may be minimal or, alternatively, so great that other causes are considered. The diagnosis of acute appendicitis in young children and the very elderly is particularly problematic, since other causes of abdominal emergencies are prevalent in these populations, and the very young and old are also more likely to have atypical clinical presentations. Given these diagnostic challenges, it should be no surprise that even highly skilled surgeons remove normal appendices. This is preferred to delayed resection of a diseased appendix, given the significant morbidity and mortality associated with appendiceal perforation. Other complications of appendicitis include pyelophlebitis, portal venous thrombosis, liver abscess, and bacteremia.

3.7.4.16 Tumors of the Appendix

The most common tumor of the appendix is the *carcinoid*. It is usually discovered incidentally at the time of surgery or examination of a resected appendix. This neoplasm most frequently involves the distal tip of the appendix, where it produces a solid bulbous swelling up to 2 to 3 cm in diameter. Although intramural and transmural extension may be evident, nodal metastases are very infrequent, and distant spread is exceptionally rare. Conventional adenomas or non-mucin-producing adenocarcinomas also occur in the appendix and may cause obstruction and enlargement that mimics acute appendicitis. *Mucocele*, a dilated appendix filled with mucin, may simply represent an obstructed appendix containing inspissated mucin or be a consequence of *mucinous cystadenoma* or *mucinous cystadenocarcinoma*. In the latter instance, invasion through the appendiceal wall can lead to intraperitoneal seeding and spread. In women the resulting peritoneal implants may be mistaken for mucinous ovarian tumors. In the most advanced cases the abdomen fills with tenacious, semisolid mucin, a condition called *pseudomyxoma peritoneii* (Chapter 22). This disseminated intraperitoneal disease may be held in check for years by repeated debulking but, in most instances, follows an inexorably fatal course.

3.7.5 Peritoneal Cavity

The peritoneal cavity houses the abdominal viscera and is lined by a single layer of mesothelial cells; these cover the visceral and parietal surfaces and are supported by a thin layer of connective tissue to form the peritoneum. Here we discuss inflammatory, infectious, and neoplastic disorders of the peritoneal cavity and retroperitoneal space. Although they are less common than inflammatory and infectious processes, tumors can carry a grave prognosis and, thus, deserve discussion.

3.7.5.1 Inflammatory Disease

Peritonitis may result from bacterial invasion or chemical irritation and is most often due to:

- Leakage of bile or pancreatic enzymes, which produces *sterile peritonitis*
- *Perforation or rupture of the biliary system* that evokes a highly irritating peritonitis, usually complicated by bacterial superinfection
- *Acute hemorrhagic pancreatitis* (see Chapter 19), which is associated with leakage of pancreatic enzymes and fat necrosis. Globules of fat may be found in the peritoneal fluid. Damage to the bowel wall may allow bacteria to spread to the peritoneal cavity, leading to a frank suppurative exudate after 24 to 48 hours.
- *Foreign material*, including that introduced surgically (e.g., talc and sutures), that induces foreign body–type granulomas and fibrous scarring
- *Endometriosis*, which causes hemorrhage into the peritoneal cavity, where it acts as an irritant
- *Ruptured dermoid cysts* release keratins that invoke an intense granulomatous reaction
- *Perforation* of abdominal viscera, as described below

PERITONEAL INFECTION

Bacterial peritonitis occurs when bacteria from the gastrointestinal lumen are released into the abdominal cavity, typically following perforation. This occurs most commonly as a complication of *acute appendicitis, peptic ulcer, cholecystitis, diverticulitis*, and *intestinal ischemia. Acute salpingitis, abdominal trauma,* and *peritoneal dialysis* are other potential sources of contaminating bacteria. Although *E. coli*, streptococci, *S. aureus*, enterococci, and *C. perfringens* are implicated most often, virtually any bacteria can be associated with bacterial peritonitis.

Spontaneous bacterial peritonitis develops in the absence of an obvious source of contamination. It is an uncommon disorder that is seen most often in patients with cirrhosis and ascites; 10% of such

individuals develop spontaneous bacterial peritonitis. Children, particularly those with nephrotic syndrome, may also develop spontaneous bacterial peritonitis. The manner by which bacteria gain access to the peritoneal cavity is unknown, but the organisms identified most often are *E. coli* and pneumococci, suggesting sources in the GI tract or the lungs, respectively.

Morphology. Normally glistening serosal and peritoneal surfaces become dull and lusterless, and serous or slightly turbid fluid begins to accumulate within 2 to 4 hours of infection. As the infection progresses, creamy suppurative material that may be extremely viscous accumulates. The volume of fluid varies enormously; it may be localized by the omentum and viscera to a small area or may fill the abdominal cavity. Exudate may collect around the liver to form subhepatic and subdiaphragmatic abscesses.

The cellular inflammatory response is composed primarily of dense collections of neutrophils and fibrinopurulent debris that coat the viscera and abdominal wall. The reaction usually remains superficial and does not penetrate deeply. One exception is tuberculous peritonitis, which typically studs the serosal and peritoneal surfaces with small, pale granulomas.

While bacterial peritonitis can be fatal, the inflammatory process can also heal, either spontaneously or as a result of therapy. It may resolve completely; undergo organization into fibrous adhesions; or become walled off in abscesses that may persist (potentially serving as new sources of infection) or heal.

SCLEROSING RETROPERITONITIS

Sclerosing retroperitonitis, also known as *idiopathic retroperitoneal fibrosis* or *Ormond disease*, is characterized by dense fibrosis that may extend to involve the mesentery. Although the cause of sclerosing retroperitonitis is unknown, it is thought to be an inflammatory process. Because the process frequently compresses the ureters, this entity is described in more detail in Chapter 21 .

CYSTS

Cysts may develop within the abdominal cavity and are frequently attached to the peritoneum. They can be quite large, sometimes presenting as palpable abdominal masses. The origins of such cysts are diverse; they can develop from “blind” lymphatic channels; foregut or hindgut diverticulae that pinch off during development; the urogenital ridge or its derivatives (i.e., the urinary tract and male and female genital tracts); walled-off infections; or as a sequela of pancreatitis *(pseudocysts)*.

3.7.5.2 Tumors

Most tumors of the peritoneum are malignant and can be divided into primary and secondary forms.

Primary tumors arising from peritoneal lining are *mesotheliomas* that are similar to tumors of the pleura and pericardium. Peritoneal mesotheliomas are almost always associated with significant asbestos exposure. It has been hypothesized that swallowed asbestos fibers somehow penetrate through the intestinal wall to reach the peritoneum. As with pleural mesothelioma, the histopathologic diagnosis can be difficult. The differential diagnosis includes metastatic adenocarcinoma, which can be distinguished from mesothelioma using a variety of immunohistochemical markers (Chapter 15).

Rarely, primary benign and malignant soft-tissue tumors develop within the peritoneum and retroperitoneum. The most common of these is *desmoplastic small round cell tumor*. This aggressive tumor occurs in children and young adults. The neoplasm is characterized by a reciprocal chromosomal

translocation, t(11;22)(p13;q12) that results in fusion of genes associated with Ewing sarcoma *(EWS)* and Wilms tumor *(WT1)*. Morphologically, the tumor bears a resemblance to Ewing sarcoma and related tumors.

Secondary tumors of the peritoneum are, in contrast, quite common. In any form of advanced cancer, direct spread to the serosal surface or metastatic seeding (peritoneal carcinomatosis) may occur. The most common tumors producing diffuse serosal implants are ovarian and pancreatic adenocarcinoma. Appendiceal mucinous carcinomas may produce *pseudomyxoma peritonei*. However, any intra-abdominal malignancy, as well as a wide variety of tumors of extra-abdominal origin, may spread to the peritoneum.

3.8 18. Liver & Biliary Tract

3.8.1 The Liver

THE LIVER

The normal adult liver weighs 1400 to 1600 gm, constituting approximately 2.5% of body weight. The liver has a dual blood supply: the portal vein provides 60% to 70% of hepatic blood flow, and the hepatic artery supplies 30% to 40%. The portal vein and the hepatic artery enter the liver through the hilum, also called *porta hepatis*, which is a transverse fissure in the inferior surface of the liver. Within the liver, the branches of the portal veins, hepatic arteries, and bile ducts travel in parallel in *portal tracts*, ramifying variably through 17 to 20 orders of branches.

Terminology of the hepatic microarchitecture is based on two different concepts: the hepatic lobule and the hepatic acinus. According to the lobular model, the liver is divided into 1- to 2-mm diameter hexagonal *lobules* oriented around the terminal tributaries of the hepatic vein *(terminal hepatic veins)*, with portal tracts at the periphery of the lobule. The hepatocytes in the vicinity of the terminal hepatic vein are called “centrilobular”; those near the portal tract are “periportal” (Fig. 18-1). In the acinar model the hepatocytes near the terminal hepatic veins are the distal apices of roughly triangular *acini*, whose bases are formed by the penetrating septal venules from the portal vein extending out from the portal tracts.[1] In the acinus the parenchyma is divided into three zones, zone 1 being closest to the vascular supply, zone 3 abutting the terminal hepatic venule and most remote from the afferent blood

supply, and zone 2 being intermediate. Regardless of the model used, zonation of the parenchyma is an important concept because of the gradient of activity displayed by many hepatic enzymes, and the zonal distribution of certain types of hepatic injury. While the acinar model best describes the physiologic relationships between hepatocytes and their vascular supply, *the histopathology of the liver is usually discussed on the basis of a lobular architecture*.

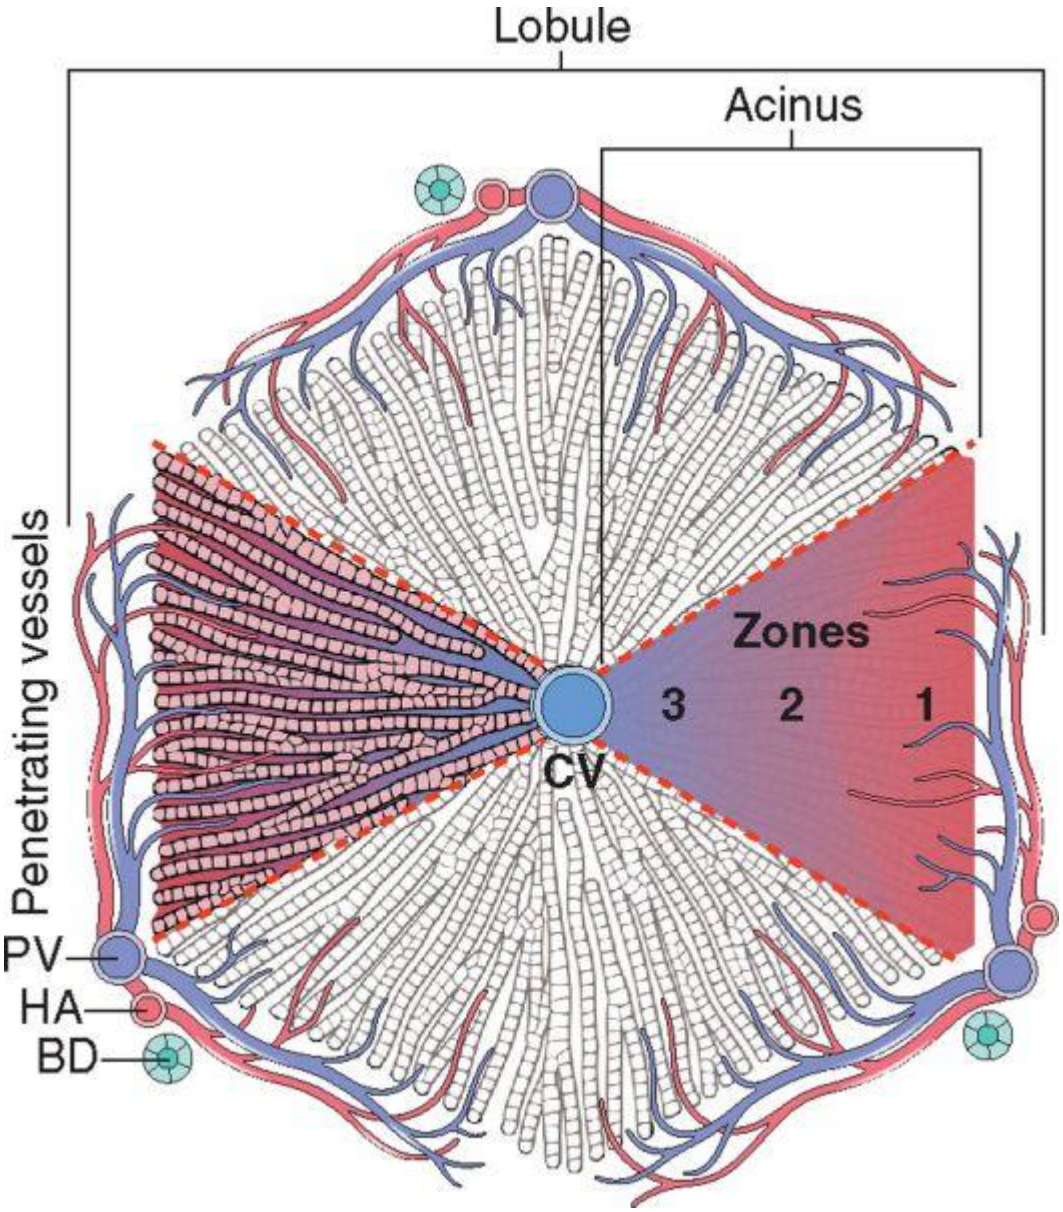

FIGURE 18-1 Microscopic anatomy of the liver; the two models, hepatic lobular model and acinar model, are illustrated. In the lobular model the terminal hepatic vein (CV) is at the center of a "lobule," while the portal tracts (PV) are at the periphery. Pathologists refer to the regions of the parenchyma as "periportal and centrilobular." In the acinar model, on the basis of blood flow, three zones can be defined, zone 1 being the closest to the blood supply and zone 3 being the farthest. BD, bile duct; HA, hepatic artery.

Hepatocytes are organized into cribriform, anastomosing sheets or "plates" extending from portal tracts to the terminal hepatic veins. Between the plates of hepatocytes are vascular sinusoids. Blood traverses the sinusoids and exits into the terminal hepatic veins through numerous orifices in the vein wall. Hepatocytes are thus bathed on two sides by well-mixed portal venous and hepatic arterial blood, making hepatocytes among the most richly perfused cells in the body. The sinusoids are lined by

fenestrated and discontinuous endothelial cells. Deep to the endothelial cells lies the *space of Disse*, into which protrude abundant microvilli of hepatocytes. Scattered *Kupffer cells* of the mononuclear phagocyte system are attached to the luminal face of endothelial cells, and fat-containing *hepatic stellate cells (HSCs)* are found in the space of Disse. Between abutting hepatocytes are *bile canaliculi*, which are channels 1 to 2 μm in diameter, formed by grooves in the plasma membranes of facing hepatocytes and separated from the vascular space by tight junctions. These channels drain into the *canals of Hering*, ductular structures that connect the bile canaliculi to *bile ductules* in the periportal region. The ductules empty into the *terminal bile ducts* within the portal tracts.[2] The liver also contains lymphocytes, including relatively large numbers of natural killer cells, and NK-T cells (Chapter 6).

3.8.1.1 General Features of Hepatic Disease

The liver is vulnerable to a wide variety of metabolic, toxic, microbial, circulatory, and neoplastic insults. The major primary diseases of the liver are viral hepatitis, alcoholic liver disease, nonalcoholic fatty liver disease (NAFLD), and hepatocellular carcinoma (HCC). Hepatic damage also occurs secondary to some of the most common diseases in humans, such as cardiac decompensation, disseminated cancer, and extrahepatic infections. The enormous functional reserve of the liver masks the clinical impact of mild liver damage, but with progression of diffuse disease or disruption of bile flow, the consequences of deranged liver function may become life-threatening.

With the rare exception of fulminant hepatic failure, liver disease is an insidious process in which clinical detection and symptoms of hepatic decompensation may occur weeks, months, or many years after the onset of injury. The ebb and flow of hepatic injury may be imperceptible to the patient and detectable only by abnormal laboratory tests (Table 18-1), and liver injury and healing may also occur without clinical detection. Hence, individuals with hepatic abnormalities who are referred to hepatologists most frequently have chronic liver disease. Surveillance studies in the United States document an annual incidence of newly diagnosed chronic liver disease of 72 per 100,000 population.[3] Liver disease accounts for over 27,000 deaths per year in the United States (1.1% of all deaths).

TABLE 18-1 -- Laboratory Evaluation of Liver Disease

Test Category	Serum Measurement[*]
Hepatocyte integrity	Cytosolic hepatocellular enzymes[†] *Serum aspartate aminotransferase* (AST) *Serum alanine aminotransferase* (ALT) Serum lactate dehydrogenase (LDH)
Biliary	Substances normally secreted in bile[†] *Serum bilirubin* *Total:* unconjugated plus conjugated *Direct:* conjugated only *Delta:* covalently linked to albumin Urine bilirubin Serum bile acids Plasma membrane enzymes (from damage to bile canaliculus)[†] *Serum alkaline phosphatase* Serum γ-glutamyl transpeptidase

Test Category	Serum Measurement[*]
	Serum 5′-nucleotidase
Hepatocyte function	Proteins secreted into the blood *Serum albumin*[‡] *Prothrombin time*[†] (factors V, VII, X, prothrombin, fibrinogen) Hepatocyte metabolism Serum ammonia[†] Aminopyrine breath test (hepatic demethylation)[‡] Galactose elimination (intravenous injection)[‡]

[*] The most common tests are in italics.

[†] An elevation implicates liver disease.

[‡] A decrease implicates liver disease.

PATTERNS OF HEPATIC INJURY

The liver has a relatively limited repertoire of cellular and tissue responses to injury, regardless of cause. The most common are:

- Hepatocyte degeneration and intracellular accumulations
- Hepatocyte necrosis and apoptosis
- Inflammation
- Regeneration
- Fibrosis

Clinically, a few common syndromes occur that are a consequence of many different diseases. Before considering specific diseases, we will discuss some of these syndromes, which include hepatic failure, cirrhosis, portal hypertension, and disturbances of bilirubin metabolism causing jaundice and cholestasis.

HEPATIC FAILURE

The most severe clinical consequence of liver disease is *hepatic failure*. It may be the result of sudden and massive hepatic destruction (fulminant hepatic failure), which accounts for about 2000 cases per year in the United States, or, more often, represents the end stage of progressive chronic damage to the liver. End-stage liver disease may occur by insidious destruction of hepatocytes or by repetitive discrete waves of parenchymal damage. In cases of severe hepatic dysfunction, hepatic failure is often triggered by intercurrent diseases. Whatever the sequence, 80% to 90% of hepatic functional capacity must be lost before hepatic failure ensues. When the liver can no longer maintain homeostasis, transplantation offers the best hope for survival; the mortality of hepatic failure without liver transplantation is about 80%.

The alterations that cause liver failure fall into three categories:[4]

1. *Acute liver failure*. This is defined as an acute liver illness that is associated with encephalopathy within 6 months after the initial diagnosis. The condition is known as *fulminant liver failure* when the encephalopathy develops rapidly, within 2 weeks of the onset of jaundice, and as sub-fulminant liver failure when the

encephalopathy develops within 3 months of the onset of jaundice. Acute liver failure is caused by massive hepatic necrosis, most often induced by drugs or toxins (discussed later). Accidental or deliberate ingestion of acetaminophen (Chapter 9) accounts for almost 50% of cases in the United States. Exposure to halothane, antimycobacterial drugs (rifampin, isoniazid), antidepressant monoamine oxidase inhibitors, industrial chemicals such as carbon tetrachloride, and mushroom poisoning (*Amanita phalloides*) collectively accounts for an additional 14% of cases. Hepatitis A virus (HAV) infection accounts for an additional 4% of cases and hepatitis B (HBV) infection for 8%. Autoimmune hepatitis and unknown causes (15% of cases) account for the remaining cases. Hepatitis C (HCV) infection only rarely causes massive hepatic necrosis. The mechanism of hepatocellular necrosis may be direct toxic damage (e.g., acetaminophen, mushroom toxins) but more often is a variable combination of toxicity and immunemediated hepatocyte destruction (e.g., hepatitis virus infection).[5]

2. *Chronic liver disease*. This is the most common route to hepatic failure and is the end point of relentless chronic hepatitis ending in *cirrhosis*, described later.

3. *Hepatic dysfunction without overt necrosis*. Hepatocytes may be viable but unable to perform normal metabolic function, as with tetracycline toxicity and acute fatty liver of pregnancy.

Clinical Features.

The clinical signs of hepatic failure are much the same regardless of cause, and are the result of hepatocytes failing to perform their homeostatic functions. *Jaundice* is an almost invariable finding. *Hypoalbuminemia*, which predisposes to peripheral edema, and *hyperammonemia*, which plays a major role in cerebral dysfunction, are worrisome developments. *Fetor hepaticus* is a characteristic body odor that is variously described as “musty” or “sweet and sour.” It is related to the formation of mercaptans by the action of gastrointestinal bacteria on the sulfurcontaining amino acid methionine, and shunting of splanchnic blood from the portal into the systemic circulation (portosystemic shunting). Impaired estrogen metabolism and consequent hyperestrogenemia are the putative causes of *palmar erythema* (a reflection of local vasodilatation) and *spider angiomas* of the skin. Each angioma is a central, pulsating, dilated arteriole from which small vessels radiate. In the male, hyperestrogenemia also leads to *hypogonadism* and *gynecomastia*.

Hepatic failure is life-threatening, because *with severely impaired liver function, patients are highly susceptible to encephalopathy and failure of multiple organ systems*. Respiratory failure with pneumonia, and sepsis combined with renal failure, claim the lives of many individuals with hepatic failure. A *coagulopathy* develops, attributable to impaired hepatic synthesis of several blood clotting factors. These defects can lead to massive gastrointestinal bleeding. Intestinal absorption of blood places a further metabolic load on the liver, which worsens the extent of hepatic failure. A rapid downhill course is usual, death occurring within weeks to a few months. A fortunate few survive acute episodes of hepatic failure, and hepatic function can be restored by hepatocellular regeneration if the liver does not have advanced fibrosis. As noted, liver transplantation may be life-saving.

Three particular complications associated with hepatic failure merit separate consideration, since they have grave implications.

- *Hepatic encephalopathy* is manifested by a spectrum of disturbances in consciousness, ranging from subtle behavioral abnormalities, to marked confusion and stupor, to deep coma and death. These changes may progress over hours or days in acute hepatic failure, or more insidiously in a person with marginal hepatic function due to chronic liver disease. Associated fluctuating neurologic signs include rigidity, hyper-reflexia, and asterixis: nonrhythmic, rapid extension-flexion movements of the head and extremities, best seen when the arms are held in extension with dorsiflexed wrists. *Hepatic encephalopathy is regarded as a disorder of neurotransmission in the central nervous system and neuromuscular system*, and seems to be associated with elevated ammonia levels in blood and the central nervous system, which impair neuronal function and promote generalized brain edema.[6] *In the great majority of instances there are only minor morphologic changes in the brain, such as astrocyte swelling*. The encephalopathy is reversible if the underlying hepatic condition can be corrected.

- *Hepatorenal syndrome* refers to the appearance of renal failure in individuals with severe chronic liver disease in whom there are no intrinsic morphologic or functional causes for the renal failure. Sodium retention, impaired free-water excretion, and decreased renal perfusion and glomerular filtration rate are the main renal functional abnormalities.[7] The incidence of this syndrome is about 8% per year among patients who have cirrhosis and ascites. Several factors are involved in its development, including decreased renal perfusion pressure due to systemic vasodilation, activation of the renal sympathetic nervous system with vasoconstriction of the afferent renal arterioles, and increased synthesis of renal vasoactive mediators, which further decrease glomerular filtration. The onset of this syndrome is typically heralded by a drop in urine output, associated with rising blood urea nitrogen and creatinine. Rapid development of renal failure is usually associated with a precipitating stress factor such as infection, gastrointestinal hemorrhage, or a major surgical procedure. The prognosis is poor, with a median survival of only 2 weeks in the rapid-onset form and 6 months with the insidious-onset form. The treatment of choice is liver transplantation.
- *Hepatopulmonary syndrome* (HPS) is characterized by the clinical triad of chronic liver disease, hypoxemia, and intra-pulmonary vascular dilations (IVPD)[8]. The possible causes of hypoxemia are: ventilation perfusion mismatch (the predominant cause), because of lack of uniform blood flow in the presence of stable alveolar ventilation; limitation of oxygen diffusion (“diffusion-perfusion” defect), which occurs because there is inadequate time for oxygen exchange at the alveolo-capillary junction due to rapid flow of blood in the dilated vessels; and shunting of blood from pulmonary arteries to pulmonary veins. Many vasoactive substances have been implicated in the pathogenesis of this syndrome, although enhanced production of nitric oxide (NO) by the lung appears to be the key mediator. Clinically, patients may have decreased arterial oxygen saturation and increased dyspnea on moving from supine to upright position (known, respectively, as orthodeoxia and platypnea); cutaneous spider nevi may be present in patients with IVPD. Most patients respond to oxygen therapy, although liver transplantation is the only curative treatment.

CIRRHOSIS

Cirrhosis is the twelfth most common cause of death in the United States, accounting for most liver-related deaths. The chief worldwide causes of cirrhosis are alcohol abuse, viral hepatitis, and non-alcoholic steatohepatitis (NASH). Other etiologies include biliary disease and iron overload. Cirrhosis, as the end stage of chronic liver disease, is defined by three main morphologic characteristics:

- *Bridging fibrous septa* in the form of delicate bands or broad scars linking portal tracts with one another and portal tracts with terminal hepatic veins. *Fibrosis is the key feature of progressive damage to the liver*. As discussed in Chapter 3 , fibrosis is a dynamic process of collagen deposition and remodeling.[9]
- *Parenchymal nodules* containing hepatocytes encircled by fibrosis, with diameters varying from very small (<0.3 cm, micronodules) to large (several centimeters, macronodules). *Nodularity* results from cycles of hepatocyte regeneration and scarring.
- *Disruption of the architecture of the entire liver. The parenchymal injury and consequent fibrosis are diffuse*, extending throughout the liver. Focal injury with scarring does not constitute cirrhosis, nor does diffuse nodular transformation without fibrosis.

Pathogenesis.

The central pathogenic processes in cirrhosis are death of hepatocytes, extracellular matrix (ECM) deposition, and vascular reorganization.[10] In the normal liver, interstitial collagens (types I and III) are concentrated in portal tracts and around central veins, and thin strands of type IV collagen are present in the space of Disse. In cirrhosis, types I and III collagen are deposited in the space of Disse, creating fibrotic septal tracts. The vascular architecture of the liver is disrupted by the parenchymal damage and scarring, with the formation of new vascular channels in the fibrotic septa that connect the vessels in the portal region (hepatic arteries and portal veins) to terminal hepatic veins, shunting blood from the parenchyma. The deposition of collagen in the space of Disse is accompanied by the loss of fenestrations of sinusoidal endothelial cells *(capillarization of sinusoids)*, impairing the function of sinusoids as channels that permit the exchange of solutes between hepatocytes and plasma (Fig. 18-2).

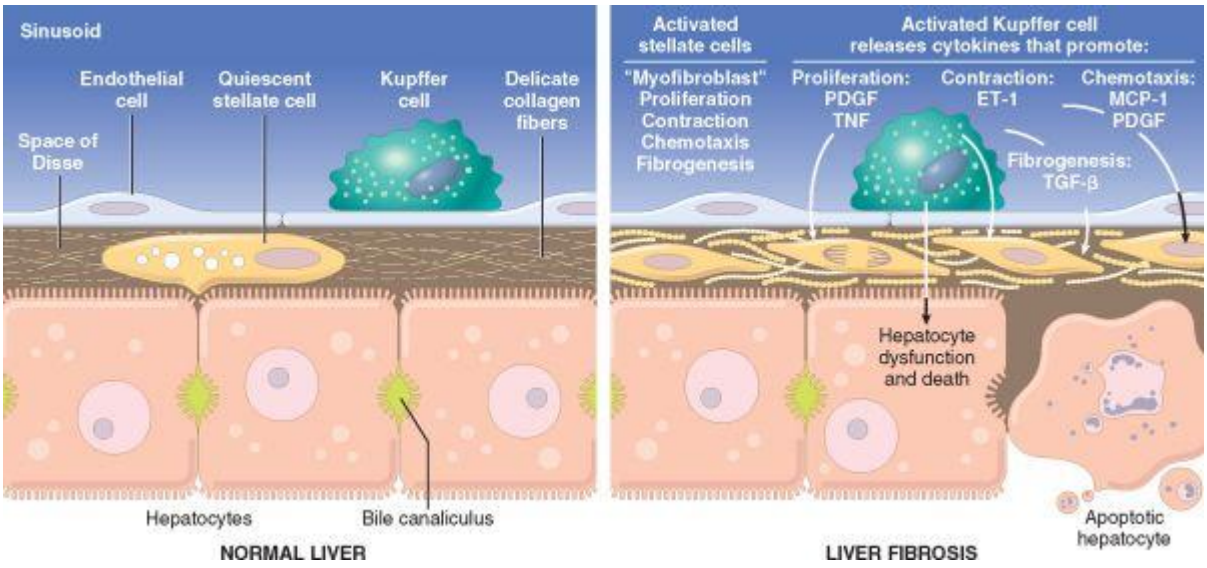

FIGURE 18-2 Stellate cell activation and liver fibrosis. Kupffer cell activation leads to secretion of multiple cytokines. Platelet-derived growth factor (PDGF) and tumor necrosis factor (TNF) activate stellate cells, and contraction of the activated stellate cells is stimulated by endothelin-1 (ET-1). Fibrogenesis is stimulated by transforming growth factor β (TGF-β). Chemotaxis of activated stellate cells to areas of injury is promoted by PDGF and monocyte chemotactic protein-1 (MCP-1). See text for details.

The predominant mechanism of fibrosis is the *proliferation of hepatic stellate cells and their activation into highly fibrogenic cells*, but other cell types, such as portal fibroblasts, fibrocytes, and cells derived from epithelium-mesenchymal transitions may also produce collagen. Proliferation of hepatic stellate cells and their activation into myofibroblasts is initiated by a series of changes that include an increase in the expression of platelet-derived growth factor receptor β (PDGFR-β) in the stellate cells. At the same time, Kupffer cells and lymphocytes release cytokines and chemokines that modulate the expression of genes in stellate cells that are involved in fibrogenesis. These include transforming growth factor β (TGF-β) and its receptors, metalloproteinase 2 (MMP-2), and tissue inhibitors of metalloproteinases 1 and 2 (TIMP-1 and -2). As they are converted into myofibroblasts, the cells release chemotactic and vasoactive factors, cytokines, and growth factors. Myofibroblasts are contractile cells, capable of constricting sinusoidal vascular channels and increasing vascular resistance within the liver parenchyma; their contraction is stimulated by endothelin-1 (ET-1). The stimuli for stellate cell activation may originate from several sources (Fig 18-2): (a) chronic inflammation, with production of inflammatory cytokines such as tumor necrosis factor (TNF), lymphotoxin, and interleukin 1β (IL-1β), and lipid peroxidation products; (b) cytokine and chemokine production by Kupffer cells, endothelial cells, hepatocytes, and bile duct epithelial cells; in response to (c) disruption of the ECM; and (d) direct stimulation of stellate cells by toxins.

Throughout the process of liver damage and fibrosis in the development of cirrhosis, the surviving hepatocytes are stimulated to regenerate and proliferate as spherical nodules within the confines of the fibrous septa. The net outcome is a fibrotic, nodular liver in which delivery of blood to hepatocytes is severely compromised, as is the ability of hepatocytes to secrete substances into plasma. Disruption of the interface between the parenchyma and portal tracts may also obliterate biliary channels, leading to the development of jaundice.

Clinical Features.

About 40% of individuals with cirrhosis are asymptomatic until late in the course of the disease. When symptomatic, they present with nonspecific clinical manifestations: anorexia, weight loss, weakness, and, in advanced disease, symptoms and signs of hepatic failure discussed earlier. Incipient or overt hepatic failure may develop, usually precipitated by a superimposed metabolic load on the liver, usually from systemic infection or gastrointestinal hemorrhage. Imbalances of pulmonary blood flow may lead to severely impaired oxygenation (hepatopulmonary syndrome, already discussed under liver failure), further stressing the patient. *The ultimate mechanism of deaths in most cirrhotic patients is (1) progressive liver failure, (2) a complication related to portal hypertension, or (3) the development of hepatocellular carcinoma*. In a small number of cases, cessation of liver injury may give the necessary time for resorption of the fibrous tissue and "reversal" of the cirrhosis.[11] Even in such instances, the portal hypertension and risk of hepatocellular carcinoma remain.

PORTAL HYPERTENSION

Increased resistance to portal blood flow may develop in a variety of circumstances, which can be divided into *prehepatic, intrahepatic, and posthepatic causes*. The major *prehepatic conditions* are obstructive thrombosis, narrowing of the portal vein before it ramifies within the liver, or massive splenomegaly with increased splenic vein blood flow. The main *post-hepatic causes* are severe right-sided heart failure, constrictive pericarditis, and hepatic vein outflow obstruction. *The dominant intrahepatic cause is cirrhosis, accounting for most cases of portal hypertension*. Far less frequent intrahepatic causes are schistosomiasis, massive fatty change, diffuse fibrosing granulomatous disease such as sarcoidosis, and diseases affecting the portal microcirculation such as nodular regenerative hyperplasia (discussed later).

The pathophysiology of portal hypertension is complex and involves the resistance to portal flow at the level of sinusoids and the increase in portal flow caused by hyperdynamic circulation.

- *The increased resistance to portal flow* at the level of the sinusoids is caused by contraction of vascular smooth muscle cells and myofibroblasts, and disruption of blood flow by scarring and the formation of parenchymal nodules. Sinusoidal endothelial cells contribute to intrahepatic vasoconstriction associated with portal hypertension through a decrease in nitric oxide production, the release of endothelin-1 (ET-1), angiotensinogen, and eicosanoids.[10] Sinusoidal remodeling and anastomosis between the arterial and portal system in the fibrous septa contribute to portal hypertension by imposing arterial pressures on the low pressure portal venous system. Sinusoidal remodeling and intrahepatic shunts also interfere with the metabolic exchange between sinusoidal blood and hepatocytes.
- Another major factor in the development of portal hypertension is an *increase in portal venous blood flow resulting from a hyperdynamic circulation*.[13,][14] This is caused by arterial vasodilation, primarily in the splanchnic circulation. The increased splanchnic arterial blood flow in turn leads to increased venous efflux into the portal venous system. While various mediators such as prostacyclin and TNF have been implicated in the causation of the splanchnic arterial vasodilation, NO has emerged as the most significant one. It is thought that NO production is stimulated by reduced clearance of bacterial DNA absorbed from the gut, due to decreased function of the mononuclear phagocyte system and shunting of blood from the portal to systemic circulation, thereby bypassing the vast pool of Kupffer cells in the liver. In keeping with this hypothesis, treatment with antibiotics appears to be beneficial in experimental models of portal hypertension.

The four major clinical consequences of portal hypertension are (1) ascites, (2) the formation of portosystemic venous shunts, (3) congestive splenomegaly, and (4) hepatic encephalopathy (discussed earlier). These are illustrated in Figure 18-3 .

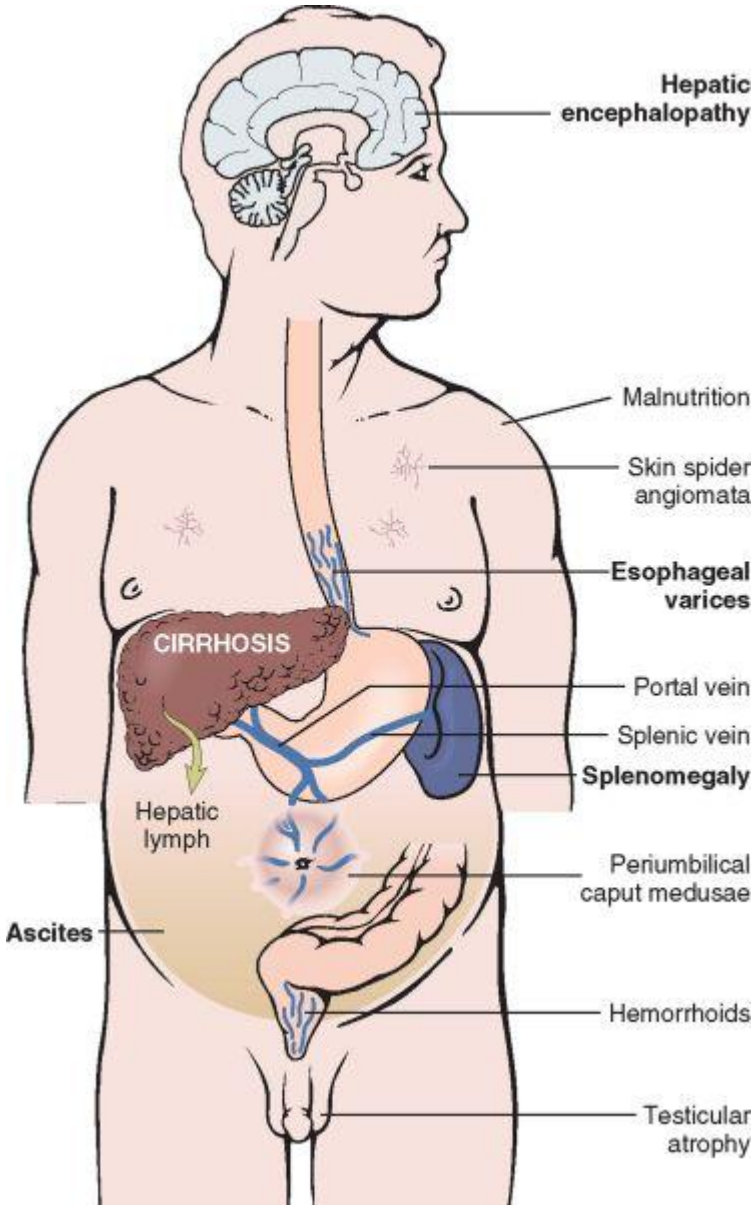

FIGURE 18-3 The major clinical consequences of portal hypertension in the setting of cirrhosis, shown for the male. In women, oligomenorrhea, amenorrhea, and sterility are frequent, as a result of hypogonadism.

Ascites.

Ascites is the accumulation of excess fluid in the peritoneal cavity. In 85% of cases, ascites is caused by cirrhosis. Ascites usually becomes clinically detectable when at least 500 mL have accumulated. The fluid is generally serous, having less than 3 gm/dL of protein (largely albumin), and a serum to ascites albumin gradient of ≥1.1 gm/dL. The concentration of solutes such as glucose, sodium, and potassium are similar to that in the blood. The fluid may contain a scant number of mesothelial cells and mononuclear leukocytes. Influx of neutrophils suggests secondary infection, whereas the presence of blood cells points to possible disseminated intra-abdominal cancer. With long-standing ascites, seepage of peritoneal fluid through transdiaphragmatic lymphatics may produce hydrothorax, more often on the right side.

The *pathogenesis of ascites* is complex, involving the following mechanisms:[11,][12]

- *Sinusoidal hypertension*, altering Starling's forces and driving fluid into the space of Disse, which is then removed by hepatic lymphatics; this movement of fluid is also promoted by *hypoalbuminemia*.
- *Percolation of hepatic lymph into the peritoneal cavity*: Normal thoracic duct lymph flow approximates 800 to 1000 mL/day. With cirrhosis, hepatic lymphatic flow may approach 20 L/day, exceeding thoracic duct capacity. Hepatic lymph is rich in proteins and low in triglycerides, which explains the presence of protein in the ascitic fluid.
- *Splanchnic vasodilation and hyperdynamic circulation*. These conditions were described earlier, in relationship to the pathogenesis of portal hypertension. Arterial vasodilation in the splanchnic circulation tends to reduce arterial blood pressure. With worsening of the vasodilation, the heart rate and cardiac output are unable to maintain the blood pressure. This triggers the activation of vasoconstrictors, including the renin-angiotensin system, and also increases the secretion of antidiuretic hormone. The combination of portal hypertension, vasodilation, and sodium and water retention increases the perfusion pressure of interstitial capillaries, causing extravasation of fluid into the abdominal cavity.

Portosystemic Shunts.

With the rise in portal system pressure, the flow is reversed from portal to systemic circulation by dilation of collateral vessels and development of new vessels. Venous bypasses develop wherever the systemic and portal circulation share common capillary beds (see Fig. 18-3). Principal sites are veins around and within the rectum (manifest as hemorrhoids), the esophagogastric junction (producing varices), the retroperitoneum, and the falciform ligament of the liver (involving periumbilical and abdominal wall collaterals). Although hemorrhoidal bleeding may occur, it is rarely massive or life-threatening. *Much more important are the esophagogastric varices that appear in about 40% of individuals with advanced cirrhosis of the liver and cause massive hematemesis and death in about half of them*. Each episode of bleeding is associated with a 30% mortality. Abdominal wall collaterals appear as dilated subcutaneous veins extending from the umbilicus toward the rib margins *(caput medusae)* and constitute an important clinical hallmark of portal hypertension.

Splenomegaly.

Long-standing congestion may cause congestive splenomegaly. The degree of splenic enlargement varies widely and may reach as much as 1000 gm, but it is not necessarily correlated with other features of portal hypertension. The massive splenomegaly may secondarily induce hematologic abnormalities attributable to hypersplenism, such as thrombocytopenia or even pancytopenia.

JAUNDICE AND CHOLESTASIS

The common causes of jaundice are bilirubin overproduction, hepatitis, and obstruction of the flow of bile. Hepatic bile serves two major functions: (1) the emulsification of dietary fat in the lumen of the gut through the detergent action of bile salts, and (2) the elimination of bilirubin, excess cholesterol, xenobiotics, and other waste products that are insufficiently water-soluble to be excreted into urine. Alterations of bile formation become clinically evident as yellow discoloration of the skin and sclera (*jaundice* and *icterus*, respectively) due to retention of bilirubin, and as *cholestasis*, characterized by systemic retention of not only bilirubin but also other solutes eliminated in bile. To understand the pathophysiology of jaundice it is important first to become familiar with the major aspects of bile formation and metabolism. The metabolism of bilirubin by the liver consists of four separate but interrelated events: uptake from the circulation; intracellular storage; conjugation with glucoronic acid; and biliary excretion. These are described next.

Bilirubin and Bile Formation

Bilirubin is the end product of heme degradation (Fig. 18-4). The majority of daily production (0.2 to 0.3 gm, 85%) is derived from breakdown of senescent red cells by the mononuclear phagocytic system, especially in the spleen, liver, and bone marrow. Most of the remainder (15%) of bilirubin is derived from the turnover of hepatic heme or hemoproteins (e.g., the P-450 cytochromes) and from premature destruction of red cell precursors in the bone marrow (Chapter 13). Whatever the source, intracellular heme oxygenase oxidizes heme to biliverdin (step 1 in Fig. 18-4), which is immediately reduced to bilirubin by biliverdin reductase. Bilirubin thus formed outside the liver is released and bound to serum albumin (step 2). Albumin binding is necessary to transport bilirubin because bilirubin is virtually insoluble in aqueous solutions at physiologic pH. Hepatic processing of bilirubin involves carrier-mediated uptake at the sinusoidal membrane (step 3), conjugation with one or two molecules of glucuronic acid by bilirubin uridine diphosphate (UDP)–glucuronyltransferase (UGT1A1, step 4) in the endoplasmic reticulum, and excretion of the water-soluble, nontoxic bilirubin glucuronides into bile. Most bilirubin glucuronides are deconjugated in the gut lumen by bacterial β-glucuronidases and degraded to colorless urobilinogens (step 5). The urobilinogens and the residue of intact pigment are largely excreted in feces. Approximately 20% of the urobilinogens formed are reabsorbed in the ileum and colon, returned to the liver, and re-excreted into bile. A small amount of reabsorbed urobilinogen is excreted in the urine.

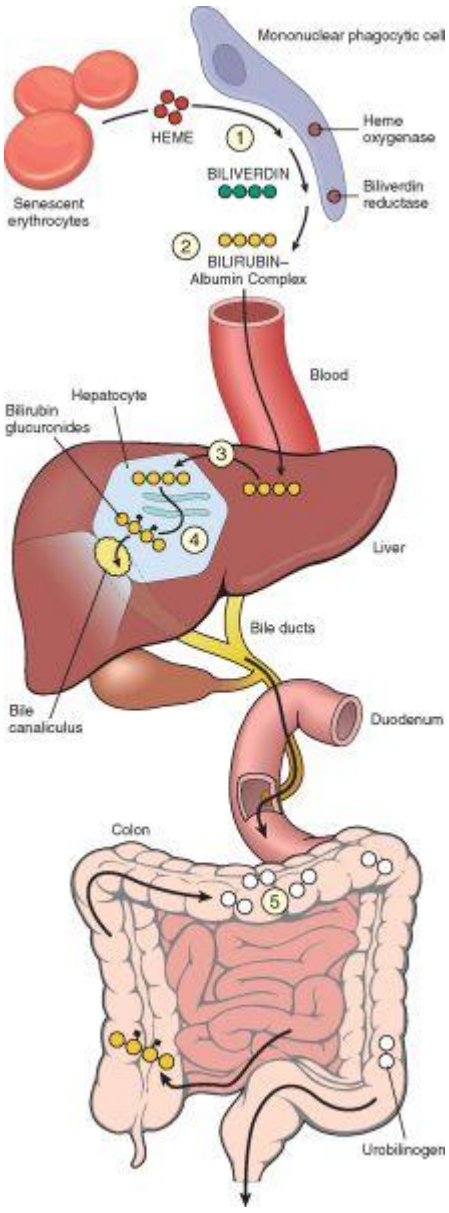

FIGURE 18-4 Bilirubin metabolism and elimination. (1) Normal bilirubin production from heme (0.2–0.3 gm/day) is derived primarily from the breakdown of senescent circulating erythrocytes. (2) Extrahepatic bilirubin is bound to serum albumin and delivered to the liver. (3) Hepatocellular uptake and (4) glucuronidation in the endoplasmic reticulum generate bilirubin monoglucuronides and diglucuronides, which are water soluble and readily excreted into bile. (5) Gut bacteria deconjugate the bilirubin and degrade it to colorless urobilinogens. The urobilinogens and the residue of intact pigments are excreted in the feces, with some reabsorption and excretion into urine.

The hepatic conjugating enzyme UGT1A1 is a product of the *UGT1* gene located on chromosome 2q37. It is a member of a family of enzymes that catalyze the glucuronidation of an array of substrates such as steroid hormones, carcinogens, and drugs. In humans, UGT1A1, generated from the exon 1A of the *UGT1* gene, is the only isoform responsible for bilirubin glucuronidation. Mutations of *UGT1A1* cause hereditary unconjugated hyperbilirubinemias: Crigler-Najjar syndrome types I and II, and Gilbert syndrome.

Two thirds of the organic materials in bile are bile salts, which are formed by the conjugation of bile acids with taurine or glycine. Bile acids, the major catabolic products of cholesterol, are a family of water-soluble sterols with carboxylated side chains. The primary human bile acids are cholic acid and chenodeoxycholic acid. Bile acids in bile salts act as highly effective detergents. Their primary physiologic role is to solubilize water-insoluble lipids secreted by hepatocytes into bile, and also to solubilize dietary lipids in the gut lumen. Ninety-five percent of secreted bile acids, conjugated or unconjugated, are reabsorbed from the gut lumen and recirculate the liver *(enterohepatic circulation)*, thus helping to maintain a large endogenous pool of bile acids for digestive and excretory purposes.

Pathophysiology of Jaundice

Both unconjugated bilirubin and conjugated bilirubin (bilirubin glucuronides) may accumulate systemically. There are two important pathophysiologic differences between the two forms of bilirubin. *Unconjugated bilirubin is virtually insoluble in water at physiologic pH and exists in tight complexes with serum albumin. This form cannot be excreted in the urine even when blood levels are high*. Normally, a very small amount of unconjugated bilirubin is present as an albumin-free anion in plasma. This fraction of unbound bilirubin may diffuse into tissues, particularly the brain in infants, and produce toxic injury. The unbound plasma fraction may increase in severe hemolytic disease or when protein-binding drugs displace bilirubin from albumin. Hence, *hemolytic disease of the newborn (erythroblastosis fetalis) may lead to accumulation of unconjugated bilirubin in the brain, which can cause severe neurologic damage, referred to as kernicterus* (Chapter 10). In contrast, *conjugated bilirubin is water-soluble, nontoxic, and only loosely bound to albumin. Because of its solubility and weak association with albumin, excess conjugated bilirubin in plasma can be excreted in urine*. With prolonged conjugated hyperbilirubinemia, a portion of circulating pigment may become covalently bound to albumin; this is termed the *bilirubin delta fraction*.

Serum bilirubin levels in the normal adult vary between 0.3 and 1.2 mg/dL, and the rate of systemic bilirubin production is equal to the rates of hepatic uptake, conjugation, and biliary excretion. Jaundice becomes evident when the serum bilirubin levels rise above 2.0 to 2.5 mg/dL; levels as high as 30 to 40 mg/dL can occur with severe disease. *Jaundice occurs when the equilibrium between bilirubin production and clearance is disturbed* by one or more of the following mechanisms (Table 18-2): *(1) excessive extrahepatic production of bilirubin; (2) reduced hepatocyte uptake; (3) impaired conjugation; (4) decreased hepatocellular excretion; and (5) impaired bile flow*. The first three mechanisms produce unconjugated hyperbilirubinemia, and the latter two produce predominantly conjugated hyperbilirubinemia. Although more than one mechanism may be operative, generally one mechanism

predominates, so knowledge of the major form of plasma bilirubin is of value in evaluating possible causes of hyperbilirubinemia.

TABLE 18-2 -- Causes of Jaundice

PREDOMINANTLY UNCONJUGATED HYPERBILIRUBINEMIA
Excess production of bilirubin
Hemolytic anemias
Resorption of blood from internal hemorrhage (e.g., alimentary tract bleeding, hematomas)
Ineffective erythropoiesis (e.g., pernicious anemia, thalassemia)
Reduced hepatic uptake
Drug interference with membrane carrier systems
Some cases of Gilbert syndrome
Impaired bilirubin conjugation
Physiologic jaundice of the newborn (decreased UGT1A1 activity, decreased excretion)
Breast milk jaundice (β-glucuronidases in milk)
Genetic deficiency of UGT1A1 activity (Crigler-Najjar syndrome types I and II)
Gilbert syndrome
Diffuse hepatocellular disease (e.g., viral or drug-induced hepatitis, cirrhosis)
PREDOMINANTLY CONJUGATED HYPERBILIRUBINEMIA
Deficiency of canalicular membrane transporters (Dubin-Johnson syndrome, Rotor syndrome)
Impaired bile flow

UGT, uridine diphosphate–glucuronyltransferase.

Two conditions result from specific defects in hepatocellular bilirubin metabolism.

Neonatal Jaundice.

Because the hepatic machinery for conjugating and excreting bilirubin does not fully mature until about 2 weeks of age, almost every newborn develops transient and mild unconjugated hyperbilirubinemia, termed neonatal jaundice or *physiologic jaundice of the newborn*. This may be exacerbated by breastfeeding, as a result of the presence of bilirubin-deconjugating enzymes in breast milk. Nevertheless, sustained jaundice in the newborn is abnormal, discussed later under *neonatal hepatitis*.

Hereditary Hyperbilirubinemias.

Multiple genetic mutations can cause hereditary hyperbilirubinemia[15] (Table 18-3). In *Crigler-Najjar syndrome type I* hepatic UGT1A1 (described earlier) is completely absent, and the colorless bile contains only trace amounts of unconjugated bilirubin. *The liver is morphologically normal by light and electron microscopy*. However, serum unconjugated bilirubin reaches very high levels, producing severe jaundice and icterus. Without liver transplantation, this condition is invariably fatal, causing death secondary to kernicterus within 18 months of birth.

TABLE 18-3 -- Hereditary Hyperbilirubinemias

Disorder	Inheritance	Defects in Bilirubin Metabolism	Liver Pathology	Clinical Course
UNCONJUGATED HYPERBILIRUBINEMIA				
Crigler-Najjar syndrome type I	Autosomal recessive	Absent UGT1A1 activity	None	Fatal in neonatal period
Crigler-Najjar syndrome type II	Autosomal dominant with variable penetrance	Decreased UGT1A1 activity	None	Generally mild, occasional kernicterus
Gilbert syndrome	Autosomal recessive	Decreased UGT1A1 activity	None	Innocuous
CONJUGATED HYPERBILIRUBINEMIA				
Dubin-Johnson syndrome	Autosomal recessive	Impaired biliary excretion of bilirubin glucuronides due to mutation in canalicular multidrug resistance protein 2 (MRP2)	Pigmented cytopasmic globules; ?epinephrine metabolites	Innocuous
Rotor syndrome	Autosomal recessive	Decreased hepatic uptake and storage? Decreased biliary excretion?	None	Innocuous

UGT, uridine diphosphate–glucuronyltransferase.

Crigler-Najjar syndrome type II is a less severe, nonfatal disorder in which UGT1A1 enzyme activity is greatly reduced, and the enzyme is capable of forming only monoglucuronidated bilirubin. Unlike Crigler-Najjar syndrome type I, the only major consequence is extraordinarily yellow skin. Phenobarbital treatment can improve bilirubin glucuronidation by inducing hypertrophy of the hepatocellular endoplasmic reticulum.

Gilbert syndrome is a relatively common, benign, inherited condition presenting with mild, fluctuating hyperbilirubinemia, in the absence of hemolysis or liver disease. It affects 3% to 10% of the U.S. population. In Gilbert syndrome, hepatic bilirubin-glucuronidating activity is about 30% of normal, a less severe reduction than in Crigler-Najjar syndromes. It is caused in most patients by the homozygous insertion of two extra bases in the 5′ promoter region of the *UGT1* gene, leading to reduced transcription. The mild hyperbilirubinemia may go undiscovered for years and is not associated with functional derangements. When detected in adolescence or adult life it is typically in association with stress, such as an intercurrent illness, strenuous exercise, or fasting. Gilbert syndrome itself has no clinical consequence except for the anxiety that a jaundiced sufferer might justifiably experience with this otherwise innocuous condition. However, individuals who have Gilbert syndrome may be more susceptible to adverse effects of drugs that are metabolized by UGT1A1.

Dubin-Johnson syndrome is an autosomal recessive disorder characterized by chronic conjugated hyperbilirubinemia. It is caused by a defect in hepatocellular excretion of bilirubin glucuronides across the canalicular membrane. The molecular basis for this syndrome is absence of the canalicular protein, *multidrug resistance protein 2*, which is responsible for transport of bilirubin glucuronides and related organic anions into bile.[16] The liver is darkly pigmented because of coarse pigmented granules within

the cytoplasm of hepatocytes (Fig. 18-5). Electron microscopy reveals that the pigment is located in lysosomes: it appears to be composed of polymers of epinephrine metabolites. The liver is otherwise normal. Apart from chronic or recurrent jaundice of fluctuating intensity, most patients are asymptomatic and have a normal life expectancy.

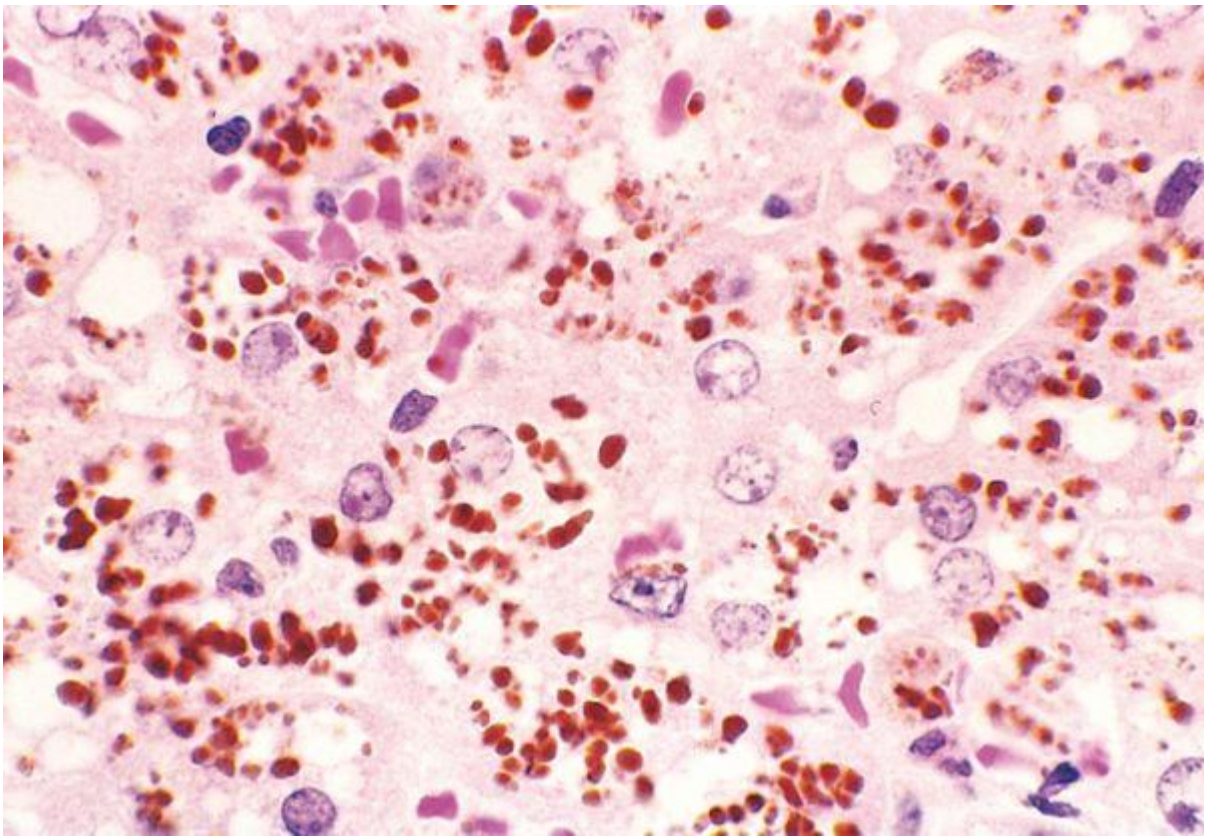

FIGURE 18-5 Dubin-Johnson syndrome, showing abundant pigment inclusions in otherwise normal hepatocytes.

Rotor syndrome is a rare form of asymptomatic conjugated hyperbilirubinemia associated with multiple defects in hepatocellular uptake and excretion of bilirubin pigments. The precise molecular basis for this syndrome is unknown. The liver is morphologically normal. As with Dubin-Johnson syndrome, patients with Rotor syndrome have jaundice but otherwise have normal lives.

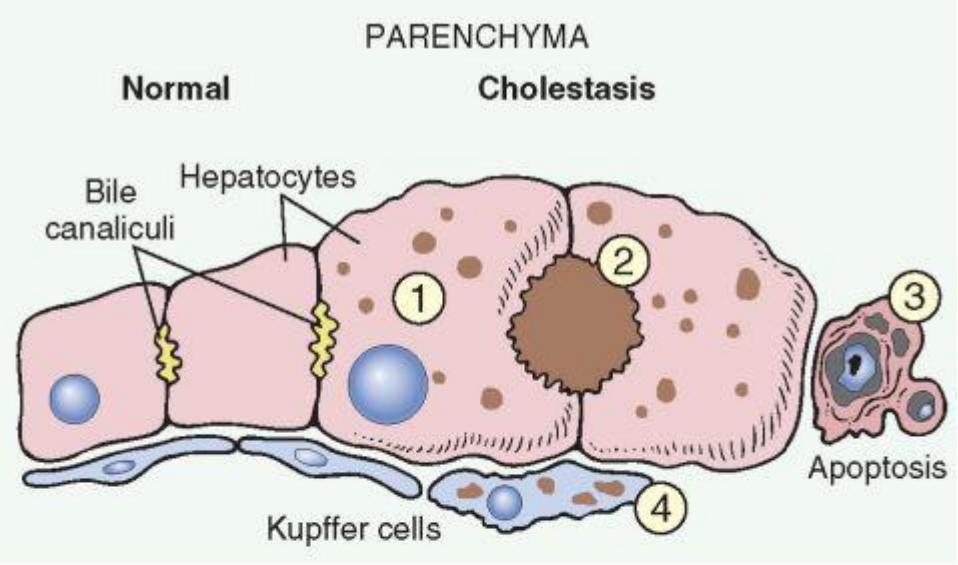
Cholestasis

Cholestasis denotes a pathologic condition of impaired bile formation and bile flow, leading to accumulation of bile pigment in the hepatic parenchyma.[17] *It can be caused by extrahepatic or intrahepatic obstruction of bile channels, or by defects in hepatocyte bile secretion*. Patients may have jaundice, pruritus, skin xanthomas (focal accumulation of cholesterol), or symptoms related to intestinal malabsorption, including nutritional deficiencies of the fat-soluble vitamins A, D, or K. *A characteristic laboratory finding is elevated serum alkaline phosphatase and γ-glutamyl transpeptidase (GGT)*, enzymes present on the apical membranes of hepatocytes and bile duct epithelial cells.

Morphology. The morphologic features of cholestasis depend on its severity, duration, and

underlying cause. **Common to both obstructive and nonobstructive cholestasis is the accumulation of bile pigment within the hepatic parenchyma** (Figs. 18-6 and 18-7). Elongated green-brown plugs of bile are visible in dilated bile canaliculi (Fig. 18-7B). Rupture of canaliculi leads to extravasation of bile, which is quickly phagocytosed by Kupffer cells. Droplets of bile pigment also accumulate within hepatocytes, which can take on a fine, foamy appearance (**feathery degeneration**).

Obstruction of the biliary tree, either intrahepatic or extrahepatic, causes distention of upstream bile ducts and ductules by bile. The bile stasis and back-pressure induce proliferation of the duct epithelial cells, and looping and reduplication of ducts and ductules in the portal tracts. The labyrinthine ductules reabsorb secreted bile salts, serving to protect the downstream obstructed bile ducts from the toxic detergent action of bile salts. Associated histologic findings include portal tract edema and periductular infiltrates of neutrophils. Prolonged obstructive cholestasis leads not only to feathery change of hepatocytes but also to focal dissolution of hepatocytes by detergents, giving rise to bile lakes filled with cellular debris and pigment. Unrelieved obstruction leads to portal tract fibrosis, and ultimately, to biliary cirrhosis.



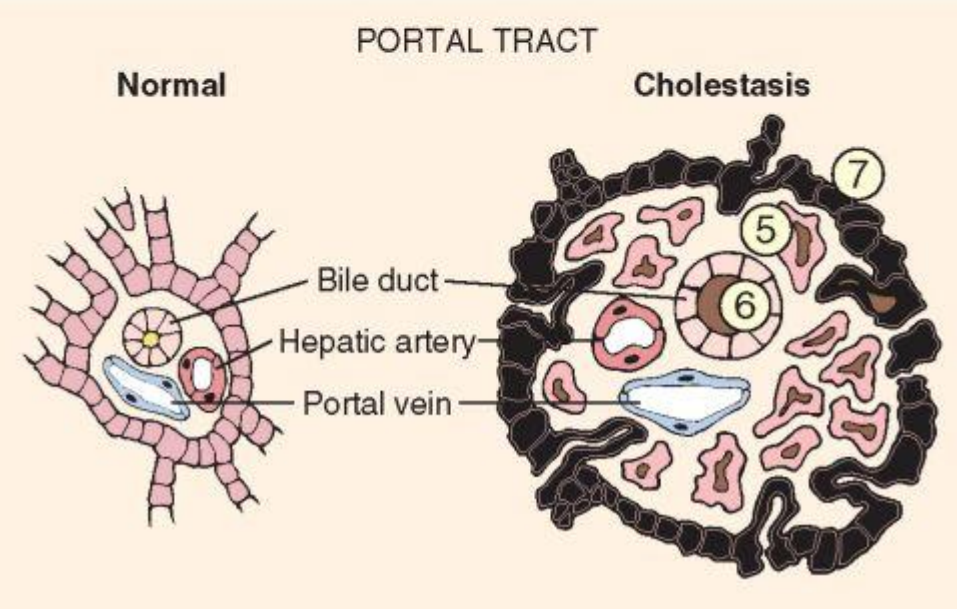


FIGURE 18-6 Morphologic features of cholestasis *(right)* and comparison with normal liver *(left)*. In the parenchyma *(upper panel)* cholestatic hepatocytes (1) are enlarged with dilated canalicular spaces (2). Apoptotic cells (3) may be seen, and Kupffer cells (4) frequently contain regurgitated bile pigments. In the portal tracts of obstructed liver *(lower panel)* there is also bile ductular proliferation (5), edema, bile pigment retention (6), and eventually neutrophilic inflammation (not shown). Surrounding hepatocytes (7) are swollen and undergoing degeneration.

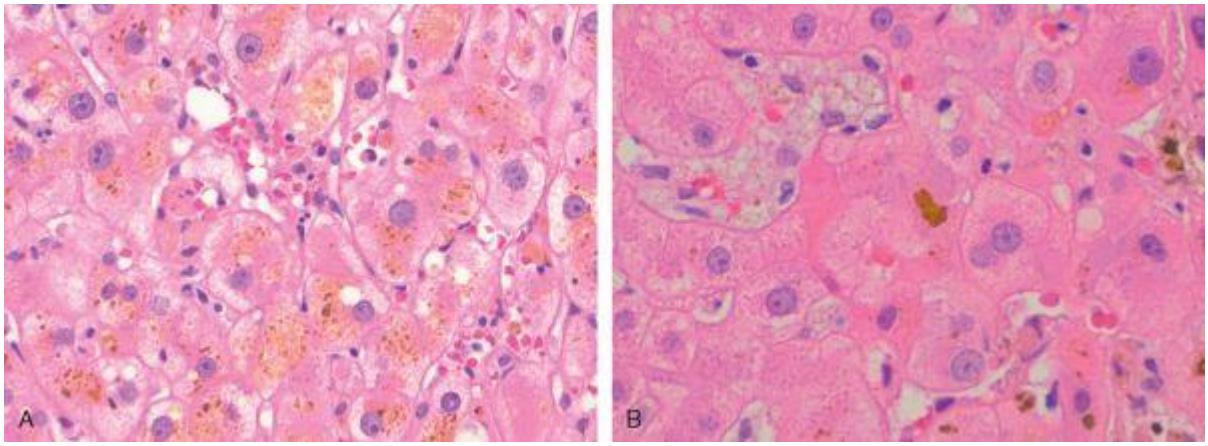

FIGURE 18-7 Histology of cholestasis. **A**, Intracellular cholestasis showing the bile pigments in the cytoplasm; **B**, bile plug showing the expansion of bile canaliculus by bile.

Since extrahepatic biliary obstruction is frequently amenable to surgical alleviation, correct and prompt diagnosis is imperative. In contrast, cholestasis due to diseases of the intrahepatic biliary tree or hepatocellular secretory failure (collectively termed *intrahepatic cholestasis*) is not benefited by surgery (short of transplantation), and the patient's condition may be worsened by an operative procedure. *There is thus some urgency in making a correct diagnosis of the cause of jaundice and cholestasis*.

Progressive Familial Intrahepatic Cholestasis (PFIC).

Here we discuss a striking but heterogeneous group of autosomal-recessively inherited cholestatic conditions known as PFICs.[17] PFIC-1 (also known as Byler disease as it was first identified in the descendents of Jacob Byler, an Amish patient), PFIC-2, and PFIC-3 are caused by mutations of three different genes. PFIC-1 and PFIC-2 share a similar phenotype, which includes normal or near normal GGT activity, and lack of bile ductular proliferation in portal tracts.

Progressive familial intrahepatic cholestasis 1 (PFIC-1) is characterized by cholestasis beginning in infancy, with severe pruritus due to high serum bile acid levels, and relentlessly progresses to liver failure before adulthood. The genetic defect is usually a mutation in the *ATP8B1* gene on chromosome 18q21 that causes impaired bile secretion, through mechanisms that are not yet fully elucidated.[18] In the mild form of PFIC-1 called *benign recurrent intrahepatic cholestasis*, there are intermittent attacks of cholestasis over life without progression to chronic liver disease.

Progressive familial intrahepatic cholestasis 2 (PFIC-2) is caused by mutations in the hepatocyte canalicular bile salt export pump (BSEP), encoded by the *ABCB11* gene. BSEP is a member of the adenosine triphosphate–binding cassette (ABC) family of transporters.[19] Mutations of the *ABCB11*

gene cause severely impaired bile salt secretion into bile. Patients suffer extreme pruritus, growth failure, and progression to cirrhosis in the first decade of life. These patients also have higher risk for cholangiocarcinoma.

Progressive familial intrahepatic cholestasis 3 (PFIC-3) is caused by mutations in the *ABCB4* gene, and is characterized by cholestasis with a *high* serum GGT.[20] The *ABCB4*-encoded protein, MDR3, is a liver-specific canalicular transport protein. In individuals with PFIC-3, there is absence of secreted phosphatidylcholine in bile, which leaves the apical surfaces of the biliary tree epithelia subject to the full detergent action of secreted bile salts, with resultant toxic destruction of these epithelia and release of GGT into the circulation.

3.8.1.2 Infectious Disorders

Inflammatory disorders of the liver dominate the clinical practice of hepatology. This is partly because virtually any insult to the liver can kill hepatocytes and recruit inflammatory cells, but also because inflammatory diseases are frequently long-term chronic conditions. Among inflammatory disorders, viral infection is by far the most frequent.

VIRAL HEPATITIS

Systemic viral infections can involve the liver as in (1) infectious mononucleosis (Epstein-Barr virus), which may cause a mild hepatitis during the acute phase; (2) cytomegalovirus infection, particularly in the newborn or immunosuppressed patient; and (3) yellow fever (yellow fever virus), which has been a major and serious cause of hepatitis in tropical countries. Infrequently, in children and immunosuppressed patients, the liver is affected in the course of rubella, adenovirus, herpesvirus, or enterovirus infections. However, unless otherwise specified, *the term viral hepatitis is applied for hepatic infections caused by a group of viruses known as hepatotropic virus (hepatitis viruses A, B, C, D, and E)* that have a particular affinity for the liver (Table 18-4). We first present the main features of each hepatotropic virus, followed by a discussion of the clinicopathologic characteristics of acute and chronic viral hepatitis.

TABLE 18-4 -- The Hepatitis Viruses

Virus	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Type of virus	ssRNA	partially dsDNA	ssRNA	Circular defective ssRNA	ssRNA
Viral family	Hepatovirus; related to picornavirus	Hepadnavirus	Flaviridae	Subviral particle in Deltaviridae family	Calicivirus
Route of transmission	Fecal-oral (contaminated food or water)	Parenteral, sexual contract, perinatal	Parenteral; intranasal cocaine use is a risk factor	Parenteral	Fecal-oral
Mean incubation period	2–4 weeks	1–4 months	7–8 weeks	Same as HBV	4–5 weeks
Frequency of chronic liver disease	Never	10%	~80%	5% (coinfection); ≤70% for superinfection	Never
Diagnosis	Detection of serum IgM antibodies	Detection of HBsAg or antibody to HBcAg	PCR for HCV RNA; 3rd-generation ELISA for antibody	Detection of IgM and IgG antibodies; HDV RNA serum; HDAg in liver	PCR for HEV RNA; detection of serum IgM and IgG antibodies

Virus	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
			detection		

From Washington K: Inflammatory and infectious diseases of the liver. In Iacobuzio-Donahue CA, Montgomery EA (eds): Gastrointestinal and Liver Pathology. Philadelphia, Churchill Livingstone; 2005.

dsDNA, double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDAg, hepatitis D antigen; HDV, hepatitis D virus; HEV, hepatitis E virus; IV, intravenous; PCR, polymerase chain reaction; ssRNA, single stranded RNA.

Hepatitis A Virus

Hepatitis A virus (HAV), the scourge of military campaigns since antiquity, is a benign, self-limited disease with an incubation period of 3 to 6 weeks. *HAV does not cause chronic hepatitis or a carrier state and only rarely causes fulminant hepatitis, so the fatality rate associated with HAV is about 0.1%*. HAV occurs throughout the world and is endemic in countries with substandard hygiene and sanitation, where populations may have detectable antibodies to HAV by the age of 10 years. Clinical disease tends to be mild or asymptomatic, and is rare after childhood. In developed countries, the prevalence of seropositivity (indicative of previous exposure) increases gradually with age, reaching 50% by age 50 years in the United States. In this population acute HAV tends to be a sporadic febrile illness. Affected individuals have nonspecific symptoms such as fatigue and loss of appetite, and often develop jaundice. Overall, HAV accounts for about 25% of clinically evident acute hepatitis worldwide and an estimated 30,000 to 50,000 new cases per year in the United States.

HAV, discovered in 1973, is a small, nonenveloped, positive-strand RNA picornavirus that occupies its own genus, *Hepatovirus*. Ultrastructurally, HAV is an icosahedral capsid 27 nm in diameter and can be cultured in vitro. The receptor for HAV is HAVcr-1, a 451–amino acid class I integralmembrane mucin-like glycoprotein of unknown normal function.[21] HAV is spread by ingestion of contaminated water and foods and is shed in the stool for 2 to 3 weeks before and 1 week after the onset of jaundice. Thus, close personal contact with an infected individual or fecal-oral contamination during this period accounts for most cases and explains the outbreaks in institutional settings such as schools and nurseries, and the water-borne epidemics in places where people live in overcrowded, unsanitary conditions. HAV can also be detected in serum and saliva. *Because HAV viremia is transient, blood-borne transmission of HAV occurs only rarely; therefore, donated blood is not specifically screened for this virus*. In developed countries, sporadic infections may be contracted by the consumption of raw or steamed shellfish (oysters, mussels, clams), which concentrate the virus from seawater contaminated with human sewage. Infected workers in the food industry may also be the source of outbreaks. HAV itself does not seem to be cytopathic. Cellular immunity, particularly CD8+ T cells, plays a key role in hepatocellular injury during HAV infection.[22]

Specific IgM antibody against HAV appears in blood at the onset of symptoms, constituting a reliable marker of acute infection (Fig. 18-8). Fecal shedding of the virus ends as the IgM titer rises. The IgM response usually begins to decline in a few months and is followed by the appearance of IgG anti-HAV. The latter persists for years, perhaps conferring lifelong immunity against reinfection by all strains of HAV. However, there are no routinely available tests for IgG anti-HAV. The presence of this antibody is inferred from the difference between total and IgM anti-HAV. HAV vaccine, available since 1992, is effective in preventing infection.[23]

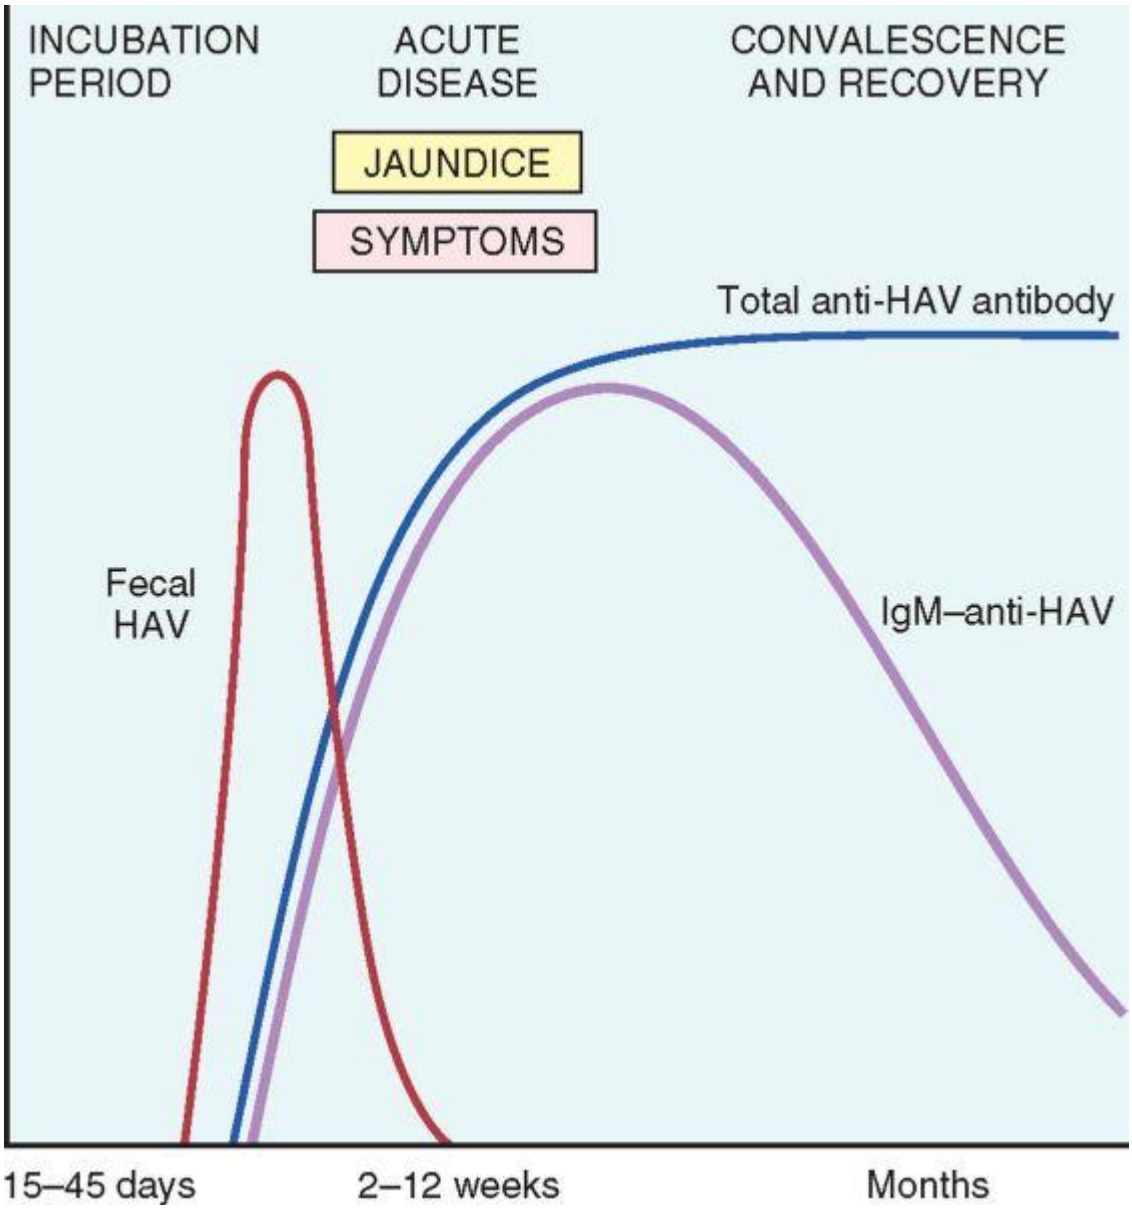

FIGURE 18-8 The sequence of serologic markers in acute hepatitis A infection. HAV, hepatitis A virus.

Hepatitis B Virus (HBV)

HBV can produce (1) acute hepatitis with recovery and clearance of the virus, (2) nonprogressive chronic hepatitis, (3) progressive chronic disease ending in cirrhosis, (4) fulminant hepatitis with massive liver necrosis, and (5) an asymptomatic carrier state. HBV-induced chronic liver disease is an important precursor for the development of hepatocellular carcinoma.[24] The approximate frequencies of clinical outcomes of HBV infection are depicted in Figure 18-9 .

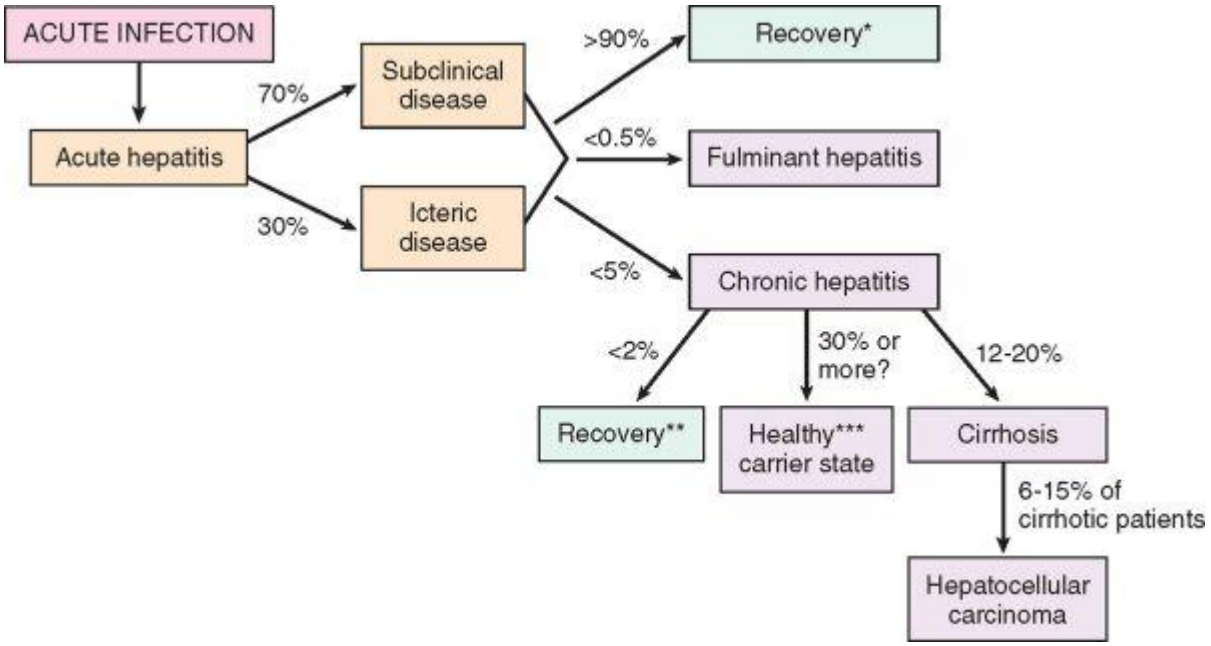

FIGURE 18-9 Potential outcomes of hepatitis B infection in adults, with their approximate frequencies in the United States. *Recovery from acute hepatitis refers to complete recovery as well as latent infections with maintenance of T cell response. **Recovery from chronic hepatitis is indicated by negative test for HBsAg. ***Healthy carrier state is indicated by positive HBsAg >6 months; HBeAg negative; serum HBV DNA $<10^5$ copies/mL; persistently normal AST and ALT levels; absence of significant inflammation and necrosis on liver biopsy.

Liver disease due to HBV is an enormous global health problem. One third of the world population (2 billion people) have been infected with HBV, and 400 million people have chronic infection. Seventy-five percent of all chronic carriers live in Asia and the Western Pacific rim. The global prevalence of chronic hepatitis B infection varies widely, from high (>8%) in Africa, Asia, and the Western Pacific to intermediate (2% to 7%) in southern and eastern Europe to low (<2%) in western Europe, North America, and Australia. As will be discussed later, the carrier rate is largely dictated by the age at infection, being the highest when infection occurs in children perinatally and the lowest when adults are infected. In the United States, incidence of HBV infection has dramatically decreased; there are now an estimated 46,000 new infections per year with about 5,000 acute symptomatic cases.

The mode of transmission of HBV varies with geographical areas. In high prevalence regions of the world, perinatal transmission during childbirth accounts for 90% of cases. In areas with intermediate prevalence, horizontal transmission, especially in early childhood, is the dominant mode of transmission. Such spread occurs through minor cuts and breaks in the skin or mucous membranes among children with close bodily contact. In low prevalence areas such as the United States, unprotected heterosexual or homosexual intercourse and intravenous drug abuse (sharing of needles and syringes) are the chief modes of spread. The incidence of transfusion-related spread has dwindled greatly in recent years due to screening of donated blood and HBsAg and exclusion of paid blood donors.

HBV has a prolonged incubation period (4–26 weeks). Unlike HAV, HBV remains in the blood until and during active episodes of acute and chronic hepatitis. In the United States acute HBV infection mostly affects adults. Approximately 70% have mild or no symptoms and do not develop jaundice. The remaining 30% have nonspecific constitutional symptoms such as anorexia, fever, jaundice, and upper right quadrant pain. In almost all cases the infection is self-limited and resolves without treatment.

Chronic disease rarely occurs in adults in non-endemic areas. Fulminant hepatitis is also rare, occurring in approximately 0.1 to 0.5% of cases.

HBV was first linked to hepatitis in the 1960s when Australia antigen (later known as HBV surface antigen) was identified.[25] The virus is a member of the *Hepadnaviridae*, a family of DNA viruses that cause hepatitis in multiple animal species. There are eight HBV genotypes with geographic distribution around the globe. The mature HBV virion is a 42-nm, spherical double-layered "Dane particle" that has an outer surface envelope of protein, lipid, and carbohydrate enclosing an electron-dense, 28-nm, slightly hexagonal core. The genome of HBV is a partially double-stranded circular DNA molecule having 3200 nucleotides (Fig. 18-10). The HBV genome contains four open reading frames coding for:[26]

- A nucleocapsid "core" protein (HBcAg, hepatitis B core antigen) and a longer polypeptide transcript with a precore and core region, designated HBeAg (hepatitis B "e" antigen). The precore region directs the HBeAg polypeptide toward secretion into blood, whereas HBcAg remains in hepatocytes for the assembly of complete virions.
- Envelope glycoproteins (HBsAg, hepatitis B surface antigen), which consist of three related proteins: large HBsAg (containing Pre-S1, Pre-S2, and S), middle HBsAg (containing Pre-S2 and S), and small HBsAg (containing S only). Infected hepatocytes are capable of synthesizing and secreting massive quantities of noninfective surface protein (mainly small HBsAg).
- A polymerase (Pol) that exhibits both DNA polymerase activity and reverse transcriptase activity. Genomic replication occurs via an intermediate RNA template, through a unique replication cycle: DNA → RNA → DNA.
- HBx protein, which is necessary for virus replication and may act as a transcriptional transactivator of the viral genes and a wide variety of host genes. It has been implicated in the pathogenesis of liver cancer in HBV infection.

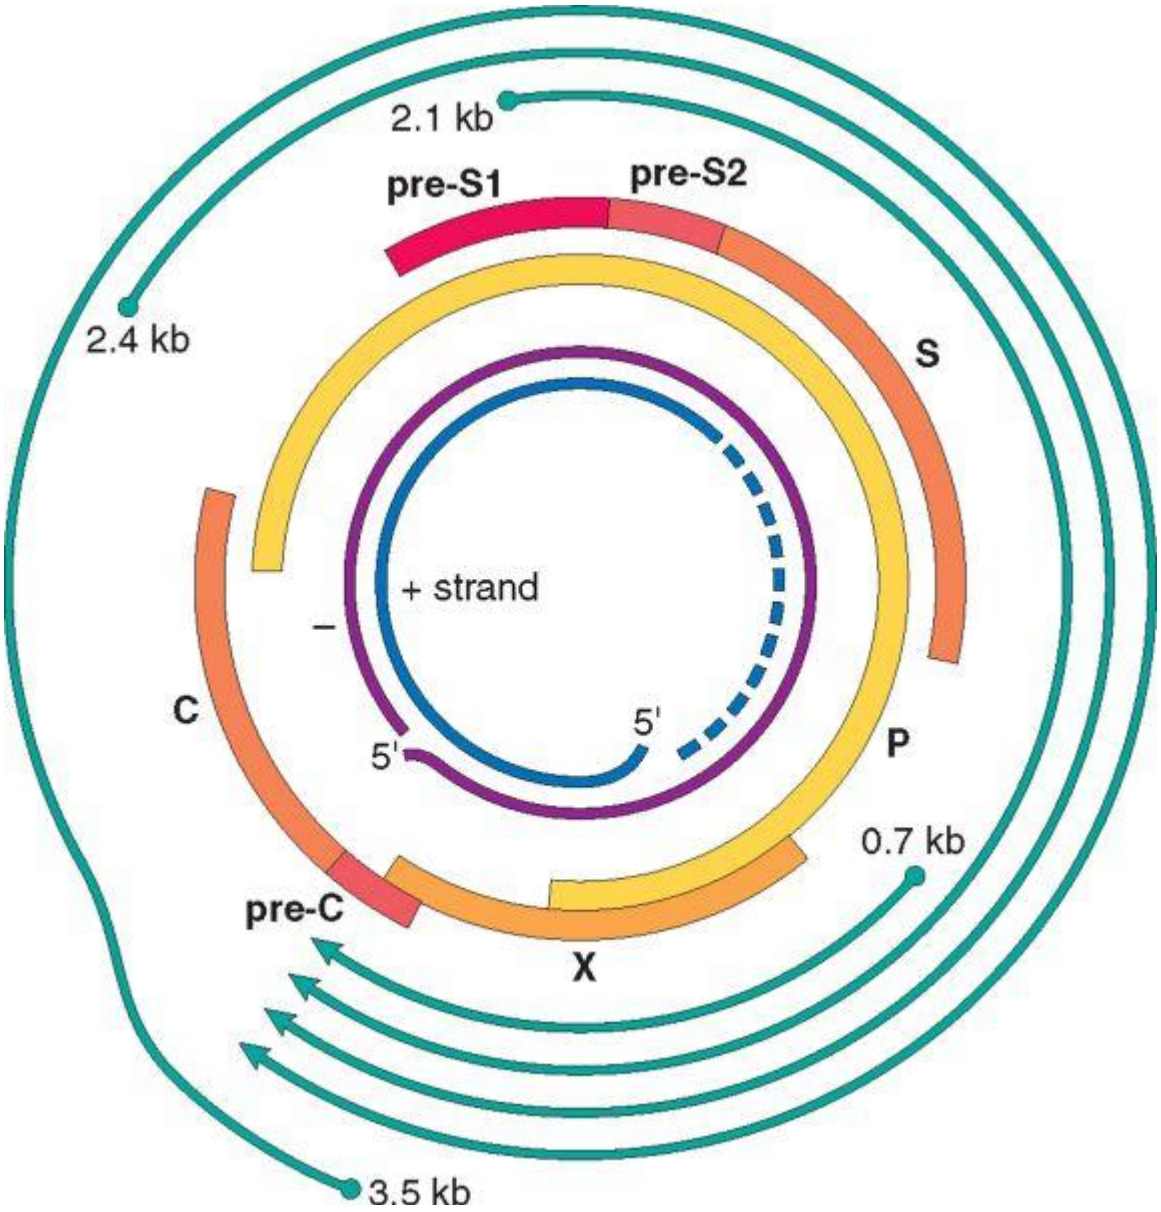

FIGURE 18-10 Diagrammatic representation of genomic structure and transcribed components of the hepatitis B virion. The innermost circles represent the DNA (+) strand and the DNA (-) strand of the virion. The thick bars labeled P, X, pro-C, C, pre-SI, pre-S2, and S denote the peptides derived from the virion. The outermost lines denote the mRNA transcripts of the virion.

The natural course of the disease can be followed by serum markers (18-11).

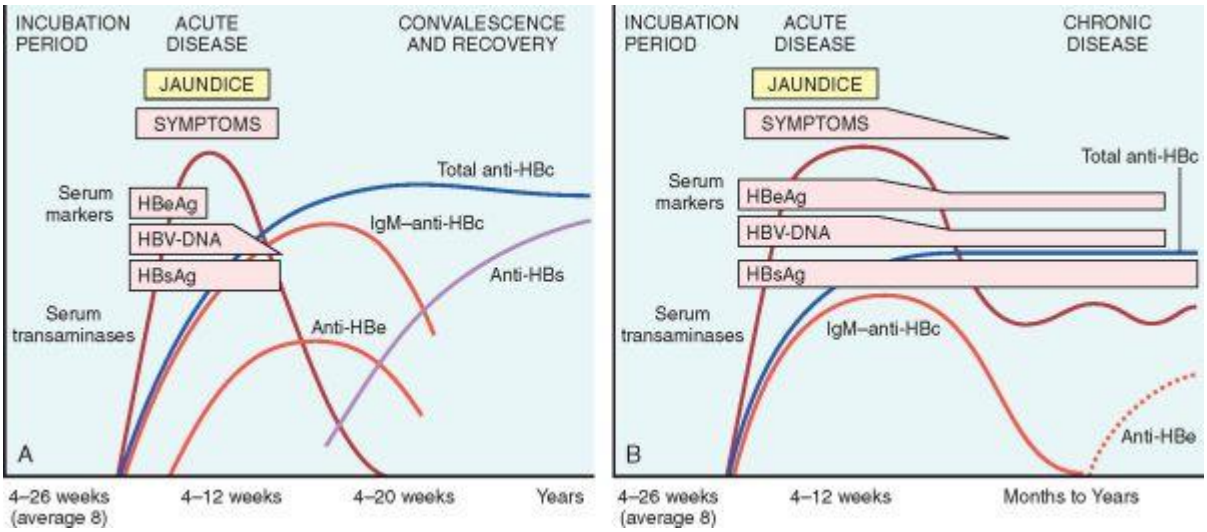

FIGURE 18-11 Sequence of serologic markers for hepatitis B viral hepatitis demonstrating (**A**) acute infection with resolution and (**B**) progression to chronic infection.

- HBsAg appears before the onset of symptoms, peaks during overt disease, and then declines to undetectable levels in 3 to 6 months.
- Anti-HBs antibody does not rise until the acute disease is over and is usually not detectable for a few weeks to several months after the disappearance of HBsAg. Anti-HBs may persist for life, conferring protection; this is the basis for current vaccination strategies using noninfectious HBsAg.
- HBeAg, HBV-DNA, and DNA polymerase appear in serum soon after HBsAg, and all signify active viral replication. Persistence of HBeAg is an important indicator of continued viral replication, infectivity, and probable progression to chronic hepatitis. The appearance of anti-HBe antibodies implies that an acute infection has peaked and is on the wane.
- IgM anti-HBc becomes detectable in serum shortly before the onset of symptoms, concurrent with the onset of elevated serum aminotransferase levels (indicative of hepatocyte destruction). Over a period of months the IgM anti-HBc antibody is replaced by IgG anti-HBc. As in the case of anti-HAV, there is no direct assay for IgG anti-HBc, but its presence is inferred from decline of IgM anti-HBc in the face of rising levels of total anti-HBc.

Occasionally, mutated strains of HBV emerge that do not produce HBeAg but are replication competent and express HBcAg. In such patients, the HBeAg may be low or undetectable despite the presence of HBV viral load. A second ominous development is the appearance of vaccine-induced escape mutants, which replicate in the presence of vaccine-induced immunity. For instance, in one such viral mutant, replacement of arginine at amino acid 145 of HBsAg with glycine significantly alters recognition of HBsAg by anti-HBsAg antibodies.

Despite the self-limited nature of acute HBV infection, recent studies show that very low levels of HBV DNA can be detected by PCR analysis in the blood of some individuals who may have anti-HBe antibodies. It is unclear at this time whether the viral material detected is composed of virus fragments, infectious virus, or non-infectious virus, but the material persists for many years.

The host immune response to the virus is the main determinant of the outcome of the infection.[27] The mechanisms of innate immunity protect the host during the initial phases of the infection, and a strong response by virus-specific CD4+ and CD8+ interferon γ-producing cells is associated with the resolution of acute infection. There are several reasons to believe that HBV does not cause direct

hepatocyte injury. Most importantly, many chronic carriers have virions in their hepatocytes with no evidence of cell injury. Hepatocyte damage is believed to result from damage to the virus-infected cells by CD8+ cytotoxic T cells.

Hepatitis B can prevented by vaccination and by the screening of donor blood, organs, and tissues. The vaccine is prepared from purified HbsAg produced in yeast. Vaccination induces a protective anti-HBs antibody response in 95% of infants, children, and adolescents. Universal vaccination has had notable success in Taiwan and Gambia, but unfortunately, it has not been adopted worldwide.

Hepatitis C Virus

Hepatitis C virus (HCV) is a major cause of liver disease worldwide, with approximately 170 million people affected. Approximately 4.1 million Americans, or 1.6% of the population, have chronic HCV infection. This makes HCV the most common chronic blood-borne infection and accounts for almost half of all US individuals with chronic liver disease. Notably, there has been a decrease in the annual incidence of infection from its mid-1980s peak of over 230,000 new infections per year to a current 19,000 new infections per year. This welcome decline resulted primarily from a marked reduction in transfusion-associated causes as a result of screening procedures. Nevertheless, the number of patients with chronic infection will continue to increase, as a result of potential lifelong persistence of HCV infection. *In contrast to HBV, progression to chronic disease occurs in the majority of HCV-infected individuals, and cirrhosis eventually occurs in 20% to 30% of individuals with chronic HCV infection*. Thus, HCV is the most common cause of chronic liver disease in the United States and the most common indication for liver transplantation.

According to the 2008 data from the USA Centers for Disease Control, the most common risk factors for HCV infection are:

- Intravenous drug abuse (54%)
- Multiple sex partners (36%)
- Having had surgery within the last 6 month (16%)
- Needle stick injury (10%)
- Multiple contacts with an HCV-infected person (10%)
- Employment in medical or dental fields (1.5%)
- Unknown (32%)

Currently, transmission of HCV by blood transfusion is close to zero in the United States; the risk of acquiring HCV by needle sticks is about six times higher than that for HIV (1.8 vs 0.3%). For children, the major route of infection is perinatal, but is much lower than for HBV (6% vs. 20%). Note that patients may have multiple risk factors (the total of the listed risks above is >100%).

HCV, discovered in 1989, is a member of the Flaviviridae family. It is a small, enveloped, single-stranded RNA virus with a 9.6-kilobase (kb) genome that codes for a single polyprotein with one open reading frame, which is subsequently processed into functional proteins (Fig. 18-12). We review, briefly, the genomic structure of HCV because this has a bearing on the pathogenesis of hepatitis C. The 5′ end of the genome encodes a highly conserved nucleocapsid core protein, followed by envelope proteins E1 and E2. Two hypervariable regions (HVR 1 and 2) are present in the E2 sequence. A protein, p7, is believed to function as an ion channel. Toward the 3′ end are six less conserved nonstructural proteins: NS2, NS3, NS4A, NS4B, NS5A, and NS5B. NS5B is the viral RNA-dependent RNA polymerase. The 3′ sequences of both the positive- and negative-strand RNAs contribute *cis*-acting functions that are essential for viral replication. The secondary structure and protein-binding properties

of these highly conserved nontranslated regions are thought to promote HCV RNA synthesis and genome stability through the binding of various host and viral proteins.

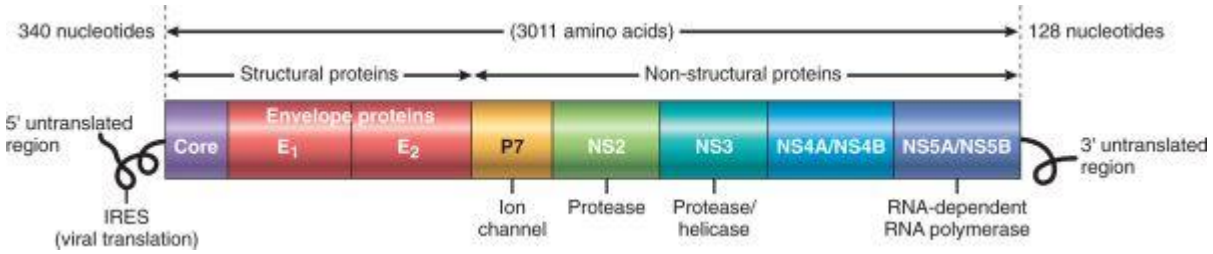

FIGURE 18-12 Diagrammatic representation of the hepatitis C viral (HCV) genomic structure. HCV is a (+) strand RNA virus containing two untranslated regions at the 5′ and the 3′ ends. The virus encodes a single polypeptide that is processed into multiple viral proteins. The potential function of each individual protein is highlighted.

Because of the poor fidelity of the HCV RNA polymerase (NS5B), the virus is inherently unstable, giving rise to multiple genotypes and subtypes. Indeed, within any given patient HCV circulates as a population of divergent but closely related variants known as *quasispecies*.[28] Over time, dozens of quasispecies can be detected within one individual and mapped as derivative strains of the original HCV strain that infected the patient. The E2 protein of the envelope is the target of many anti-HCV antibodies but is also the most variable region of the entire viral genome, enabling emergent virus strains to escape from neutralizing antibodies. This genomic instability and antigenic variability have seriously hampered efforts to develop an HCV vaccine. In particular, *elevated titers of anti-HCV IgG occurring after an active infection do not consistently confer effective immunity*. A characteristic feature of HCV infection, therefore, is repeated bouts of hepatic damage, the result of reactivation of a preexisting infection or emergence of an endogenous, newly mutated strain.

The incubation period for HCV hepatitis ranges from 2 to 26 weeks, with a mean between 6 and 12 weeks. In about 85% of individuals, the clinical course of the acute infection is asymptomatic and easily missed. HCV RNA is detectable in blood for 1 to 3 weeks, coincident with elevations in serum transaminases. In symptomatic acute HCV infection, anti-HCV antibodies are detected in only 50% to 70% of patients; in the remaining patients, the anti-HCV antibodies emerge after 3 to 6 weeks. The clinical course of acute HCV hepatitis is milder than that of HBV; rare cases may be severe and indistinguishable from HAV or HBV hepatitis. Strong immune responses involving CD4+ and CD8+ T cells are associated with self-limited HCV infections, but it is not known why only a small minority of individuals are capable of clearing HCV infection.

Persistent infection and chronic hepatitis are the hallmarks of HCV infection, despite the generally asymptomatic nature of the acute illness. This occurs in 80% to 85% of cases. *Cirrhosis may develop over 5 to 20 years after acute infection in 20% to 30% of patients with persistent infection*. The mechanisms that lead to the chronicity of HCV infection are not well understood, but it is clear that the virus has developed multiple strategies to evade host antiviral immunity.[29] HCV is able to actively inhibit the interferon (IFN)-mediated cellular antiviral response at multiple steps, including Toll-like receptor signaling in response to viral RNA recognition and signaling downstream of IFN receptors that confers on cells an anti-viral state.

In chronic HCV infection, circulating HCV RNA persists in many patients despite the presence of neutralizing antibodies, including more than 90% of patients with chronic disease (Fig. 18-13). Hence, in persons with chronic hepatitis, HCV RNA testing must be performed to assess viral replication and to

confirm the diagnosis of HCV infection. *A clinical feature that is quite characteristic of chronic HCV infection is episodic elevations in serum aminotransferases, with intervening normal or near-normal periods. Fulminant hepatic failure rarely occurs.*

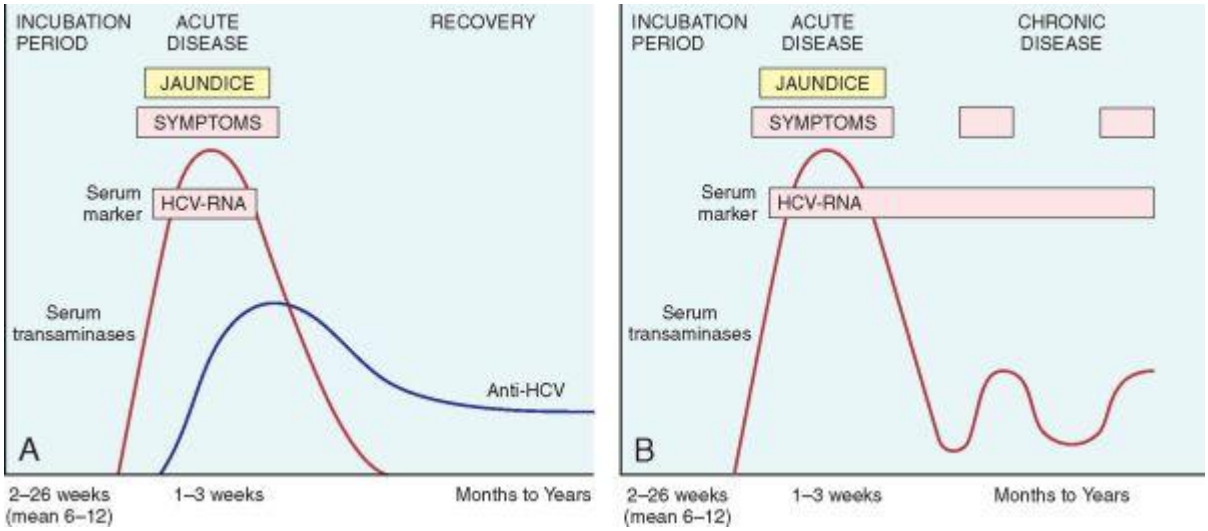

FIGURE 18-13 Sequence of serologic markers for HCV hepatitis. **A**, Acute infection with resolution; **B**, progression to chronic infection.

Hepatitis D Virus

Also called "hepatitis D virus," hepatitis D virus (HDV) is a unique RNA virus that is dependent for its life cycle on HBV. Infection with HDV arises in the following settings.[30]

- *Acute coinfection* occurs following exposure to serum containing both HDV and HBV. The HBV must become established first to provide the HBsAg necessary for development of complete HDV virions.
- *Superinfection* occurs when a chronic carrier of HBV is exposed to a new inoculum of HDV. This results in disease 30–50 days later.
- *Helper-independent latent infection* observed in the liver transplant setting.

Coinfection of HBV and HDV results in acute hepatitis B + D which is clinically indistinguishable from classical acute hepatitis B and is usually transient and self-limited. Elimination of hepatitis B leads to elimination of HDV. The rate of progression to chronic infection is not different from that observed after classical acute hepatitis B. However, a high incidence of liver failure has been reported among drug addicts.

Superinfection with HDV in a chronic HBsAg carrier may present as severe acute hepatitis in a previously unrecognized HBV carrier, or as an exacerbation of preexisting chronic hepatitis B. Chronic HDV infection occurs in 80% to 90% of such patients. The superinfection may have two phases; an acute phase with active HDV replication and suppression of HBV with high ALT levels; and a chronic phase in which HDV replication decreases, HBV replication increases, ALT levels fluctuate, and the disease progresses to cirrhosis and hepatocellular cancer (HCC).

Helper-independent latent infection may be seen in liver transplants. HDV can be detected in nuclei of the grafted liver within a few hours after transplantation without evidence of productive HDV infection or HBV reinfection. This likely occurs due to infection of the allograft by HDV alone, while

concomitant infection by HBV is prevented by hepatitis B immunoglobulin administered to prevent HBV reinfection. During this latent phase, there is no evidence of liver disease. HD viremia and hepatitis ensues only when HBV escapes neutralization and coinfection of the graft with high levels of HBV replication occurs, leading to activation of the HDV by the helper virus.

Infection by HDV is worldwide with an estimate of 15 million affected individuals (about 5% of 300 million of HBV infected persons). The prevatence varies widely in different countries. It is high in the Amazonian basin, and in Africa, the Middle East and southern Italy. Twenty to forty percent of HbsAg carriers may have anti-HDV antibody, although there has been a definite decline in recent years. In the United States HDV has virtually disappeared from hemophiliacs and other individuals who receive blood transfusion, because of the HBV screening procedures. Surprisingly HDV infection is uncommon in the large population of HBsAg carriers in Southeast Asia and China.

HDV, discovered in 1977, is a 35-nm, double-shelled particle that by electron microscopy resembles the "Dane particle" of HBV. The external coat antigen of HBsAg surrounds an internal polypeptide assembly, designated delta antigen (HDAg), the only protein produced by the virus. Associated with HDAg is a small circular molecule of single-stranded RNA, whose length is smaller than the genome of any known animal virus. Replication of the virus is through RNA-directed RNA synthesis by host RNA polymerase, mainly Pol II.

Diagnosis.

HDV RNA is detectable in the blood and liver just before and in the early days of acute symptomatic disease. IgM anti-HDV is the most reliable indicator of recent HDV exposure, although its appearance is late and frequently short-lived. Nevertheless, acute co-infection by HDV and HBV is best indicated by detection of IgM against both HDAg and HBcAg (denoting new infection with hepatitis B). With chronic delta hepatitis arising from HDV superinfection, HBsAg is present in serum, and anti-HDV antibodies (IgG and IgM) persist for months or longer. Treatment of HDV infection is limited to IFN-α.[30] Other antiviral agents for HBV have not shown effectiveness. Vaccination for HBV can also prevent HDV infection.

Hepatitis E Virus

Hepatitis E virus (HEV) hepatitis is an enterically trans-mitted, water-borne infection that occurs primarily in young to middle-aged adults; sporadic infection and overt illness in children are rare. HEV is a zoonotic disease with animal reservoirs, such as monkeys, cats, pigs, and dogs.[31] Epidemics have been reported in Asia and the Indian subcontinent, sub-Saharan Africa, and Mexico. Sporadic infection may occur in travelers to these regions, but, most importantly, HEV infection accounts for more than 30% to 60% of cases of sporadic acute hepatitis in India, exceeding the frequency of HAV. *A characteristic feature of HEV infection is the high mortality rate among pregnant women, approaching 20%*. In most cases the disease is self-limiting; HEV is not associated with chronic liver disease or persistent viremia. The average incubation period following exposure is 6 weeks.

Discovered in 1983, HEV is an unenveloped, positive-stranded RNA virus in the *Hepevirus* genus.[31] Viral particles are 32 to 34 nm in diameter, and the RNA genome is approximately 7.3 kb in size. A specific antigen (HEV Ag) can be identified in the cytoplasm of hepatocytes during active infection, and virions are shed in stool during the acute illness.

Diagnosis.

Before the onset of clinical illness, HEV RNA and HEV virions can be detected by PCR in stool and serum. The onset of rising serum aminotransferases, clinical illness, and elevated IgM anti-HEV titers

are virtually simultaneous. Symptoms resolve in 2 to 4 weeks, during which time the IgM is replaced with a persistent IgG anti-HEV titer.

Hepatitis G Virus

A flavivirus bearing similarities to HCV was cloned in 1995 and designated hepatitis G virus (HGV, also referred to as GBV-C). HGV is transmitted by contaminated blood or blood products, and via sexual contact. However, HGV is inappropriately named: *it is not hepatotropic and does not cause elevations in serum aminotransferases*. Instead, the virus appears to replicate in the bone marrow and spleen. The prevalence of HGV RNA in American blood donors ranges from 1% to 4%; but since the virus does not cause known human disease, blood donors do not need screening. HGV commonly co-infects individuals infected with the human immunodeficiency virus (HIV; prevalence 35%); curiously this dual infection is somewhat protective against HIV disease.[32]

Clinicopathologic Syndromes of Viral Hepatitis

Several clinical syndromes may develop following exposure to hepatitis viruses: (1) acute asymptomatic infection with recovery (serologic evidence only); (2) acute symptomatic hepatitis with recovery, anicteric or icteric; (3) chronic hepatitis, without or with progression to cirrhosis; and (4) fulminant hepatitis with massive to submassive hepatic necrosis.

Each of the hepatotropic viruses can cause acute asymptomatic or symptomatic infection. A small number of HBV-infected adult patients develop chronic hepatitis. In contrast, HCV is notorious for chronic infection. HAV and HEV do not cause chronic hepatitis. Fulminant hepatitis is unusual and is seen primarily with HBV. Although HBV and HCV are responsible for most cases of chronic hepatitis, there are many other causes of chronic hepatitis (described later), including chronic alcoholism, drugs (e.g., isoniazid, α-methyldopa, methotrexate), toxins, Wilson disease, α_1-antitrypsin deficiency, and autoimmunity. Therefore, serologic and molecular studies are essential for the diagnosis of viral hepatitis, and for distinguishing between the various types.

Acute Asymptomatic Infection with Recovery.

Patients in this group are identified only incidentally on the basis of minimally elevated serum transaminases or, after the fact, by the presence of antiviral antibodies. Worldwide, HAV and HBV infection are frequently subclinical events in childhood, verified only in adulthood by the presence of anti-HAV or anti-HBV antibodies.

Acute Symptomatic Infection with Recovery.

Any one of the hepatotropic viruses can cause symptomatic acute viral hepatitis. Whatever the agent, the disease is more or less the same and can be divided into four phases: (1) an incubation period, (2) a symptomatic preicteric phase, (3) a symptomatic icteric phase, and (4) convalescence. The incubation period for the different viruses is given in Table 18-4 . Peak infectivity occurs during the last asymptomatic days of the incubation period and the early days of acute symptoms.

Chronic Hepatitis.

Chronic hepatitis is defined as symptomatic, biochemical, or serologic evidence of continuing or relapsing hepatic disease for more than 6 months. As mentioned earlier, HCV infection causes chronic hepatitis at a high frequency while only a small number of patients with HBV infection develop chronic disease. The clinical features of chronic hepatitis are extremely variable and are not predictive of outcome. In some patients the only signs of chronic disease are persistent elevations of serum transaminases. The most common symptom is fatigue; less common symptoms are malaise, loss of

appetite, and occasional bouts of mild jaundice. Physical findings are few, the most common being spider angiomas, palmar erythema, mild hepatomegaly, hepatic tenderness, and mild splenomegaly. Laboratory studies may reveal prolongation of the prothrombin time and, in some instances, hyperglobulinemia, hyperbilirubinemia, and mild elevations in alkaline phosphatase levels. Occasionally, in cases of HBV and HCV, immune complex disease may develop secondary to the presence of circulating antibody-antigen complexes, in the form of vasculitis (subcutaneous or visceral, Chapter 11) and glomerulonephritis (Chapter 20). Cryoglobulinemia is found in about 35% of individuals with chronic hepatitis C.

The development of chronic infection after exposure to HBV is an important clinical problem. *Age at the time of infection is the best determinant of chronicity*. The younger the age at the time of infection, the higher the probability of chronicity. In many endemic areas, maternal-to-infant transmission is a major risk factor for chronic HBV infection. Though uncommon, patients can recover completely from chronic HBV infection.[33] Despite progress in the treatment of chronic HBV infection, complete cure is extremely difficult to achieve. Thus, the goal of the treatment of chronic hepatitis B is to slow disease progression, reduce liver damage, and prevent liver cirrhosis or liver cancer. The major problems associated with the current treatment regimens are viral resistance and side effects.

HCV is by far the most common cause of chronic viral hepatitis. The clinical diagnosis may not be apparent because patients with chronic HCV infection often have mild or no symptoms. However, even patients with normal transaminases are at high risk of developing permanent liver damage. Therefore, *any individual with detectable HCV RNA in the serum needs medical attention*.

HCV infection is potentially curable. Treatment is currently based on combination of pegylated IFN-α and ribavirin. The response to therapy depends on the viral genotype; patients with genotype 2 or 3 infection generally have the best responses. Several new drugs targeting viral protease and polymerase are under investigation.

The Carrier State.

A “carrier” is an individual who harbors and can transmit an organism, but has no manifest symptoms. In the case of hepatotropic virus this definition is somewhat confusing, as it can be interpreted to mean: (1) individuals who carry one of the viruses but have no liver disease; (2) those who harbor one of the viruses and have non-progressive liver damage, but are essentially free of symptoms or disability. In both cases, particularly the latter, these individuals constitute reservoirs for infection. In the case of HBV infection a “healthy carrier” is often defined as an individual without HBeAg, but with presence of anti-HBe, normal aminotransferases, low or undetectable serum HBV DNA, and a liver biopsy showing a lack of significant inflammation and necrosis (Fig. 18-9). In non-endemic areas such as the United States, less than 1% of HBV infections acquired by adults produces a carrier state. This frequency is larger in those who have chronic hepatitis B (Fig. 18-9). In contrast, HBV infection acquired early in life in endemic areas (such as Southeast Asia, China, and Sub-Saharan Africa) gives rise to a carrier state of the two categories described above, in more than 90% of cases. It has been estimated that HCV infection in the United States may yield a carrier state in 10% to 40% of cases, but in most of the studies, absence of liver disease was assessed by persistent normal levels of aminotransferases, rather than liver biopsy. This is a limitation of such studies.

HIV and Chronic Viral Hepatitis.

Because of the similar transmission mode and the similar high-risk patient population, co-infection of HIV and hepatitis viruses is becoming a common clinical problem. Among HIV patients, 10% are infected with HBV and 30% with HCV. Chronic HBV and HCV infection is now a leading cause of morbidity and mortality for HIV-infected patients, and liver disease is the second most common cause

of death in individuals with acquired immunodeficiency syndrome (AIDS).[34] It is clear that HIV infection significantly exacerbates the severity of liver disease caused by HBV or HCV. Less clear is the impact of HBV or HCV on the course of HIV infection. In addition, anti-HIV agents may cause hepatotoxicity in some patients with HBV or HCV co-infection.

Morphology of Acute and Chronic Hepatitis. The general morphologic features of viral hepatitis are depicted schematically in Figure 18-14 . The morphologic changes in acute and chronic viral hepatitis are shared among the hepatotropic viruses and can be mimicked by drug reactions or autoimmune liver disease. Tissue alterations caused by acute infection with HAV, HBV, HCV, and HEV are generally similar, as is the chronic hepatitis caused by HBV, HCV, and HBV + HDV. A few histologic changes may be indicative of a particular type of virus. HBV-infected hepatocytes may show a cytoplasm packed with spheres and tubules of HBsAg, producing a finely granular cytoplasm ("ground-glass hepatocytes," Fig. 18-15). HCV-infected livers frequently show lymphoid aggregates within portal tracts and focal lobular regions of hepatocyte macrovesicular steatosis, which are to be distinguished from the extensive panlobular microvesicular and macrovesicular steatosis seen in many forms of toxic hepatitis (e.g., alcohol-induced).

Acute Hepatitis. With acute hepatitis (Fig. 18-16) hepatocyte injury takes the form of diffuse swelling (**"ballooning degeneration"**;), so the cytoplasm looks empty and contains only scattered eosinophilic remnants of cytoplasmic organelles. An inconstant finding is **cholestasis**, with bile plugs in canaliculi and brown pigmentation of hepatocytes. The canalicular bile plugs result from cessation of the contractile activity of the hepatocyte pericanalicular actin microfilament web. Several patterns of hepatocyte cell death are seen.

- Rupture of the cell membrane leads to cell death and focal loss of hepatocytes. The sinusoidal collagen reticulin framework collapses where the cells have disappeared, and scavenger **macrophage aggregates** mark sites of hepatocyte loss.
- **Apoptosis**, caused by anti-viral cytotoxic (effector) T cells. Apoptotic hepatocytes shrink, become intensely eosinophilic, and have fragmented nuclei; effector T cells may still be present in the immediate vicinity. Apoptotic cells are rapidly phagocytosed by macrophages and hence might be difficult to find, despite a brisk rate of hepatocyte injury.
- In severe cases of acute hepatitis, confluent necrosis of hepatocytes may lead to **bridging necrosis** connecting portal-to-portal, central-to-central, or portal-to-central regions of adjacent lobules. Hepatocyte swelling and regeneration compress sinusoids, and the more or less radial array of hepatocyte plates around terminal hepatic veins is lost.

Inflammation is a characteristic and usually prominent feature of acute hepatitis. **Kupffer cells undergo hypertrophy and hyperplasia** and are often laden with lipofuscin pigment as a result of phagocytosis of hepatocellular debris. **The portal tracts are usually infiltrated with a mixture of inflammatory cells**. The inflammatory infiltrate may spill over into the adjacent parenchyma, causing apoptosis of periportal hepatocytes. This is known as **interface hepatitis**, which can occur in acute and chronic hepatitis. Cells in the canals of Hering proliferate, forming ductular structures at the parenchymal interface (ductular reaction).

***Chronic Hepatitis*.** The histologic features of chronic hepatitis range from exceedingly mild to severe (Fig. 18-17). In the mildest forms, inflammation is limited to portal tracts and consists of lymphocytes, macrophages, occasional plasma cells, and rare neutrophils or eosinophils. Liver architecture is usually well preserved, but smoldering hepatocyte apoptosis throughout the lobule may occur in all forms of chronic hepatitis. In chronic HCV infection, common findings (occurring in 55% of HCV infections) are **lymphoid aggregates** and **bile duct reactive changes** in the portal tracts, and

focal mild to moderate macrovesicular **steatosis**. The steatosis is more prevalent and prominent in HCV genotype 3 infections. In all forms of chronic hepatitis, continued **interface hepatitis** and **bridging necrosis** between portal tracts and portal tracts-to-terminal hepatic veins, are harbingers of progressive liver damage.

The hallmark of chronic liver damage is the deposition of fibrous tissue. At first, only portal tracts show increased fibrosis, but with time periportal septal fibrosis occurs, followed by linking of fibrous septa (bridging fibrosis), especially between portal tracts. In clinical practice, several systems have been used to score the severity and progression of liver damage due to HBV and HCV infection.[35] In each system the key elements are inflammation and hepatocyte destruction (grade), and the severity of fibrosis (stage)

Continued loss of hepatocytes and fibrosis results in cirrhosis. It is characterized by irregularly sized nodules separated by variable but mostly broad scars, and is often referred to as post-necrotic cirrhosis (Fig. 18-18). However, this term is not specific to viral etiology, and is applied to all forms of cirrhosis in which the liver shows large, irregular-sized nodules with broad scars. In addition to viral hepatitis, autoimmune hepatitis, hepatotoxins (carbon tetrachloride, mushroom poisoning), pharmaceutical drugs (acetaminophen, α-methyldopa), and even alcohol (discussed later) can give rise to cirrhotic livers with irregular-sized large nodules. In about 20% of cases the inciting cause of the cirrhosis cannot be determined, and these are labeled as **cryptogenic cirrhosis**. Thus, the morphology of the end-stage cirrhotic liver is often not helpful in determining the basis of the liver injury.

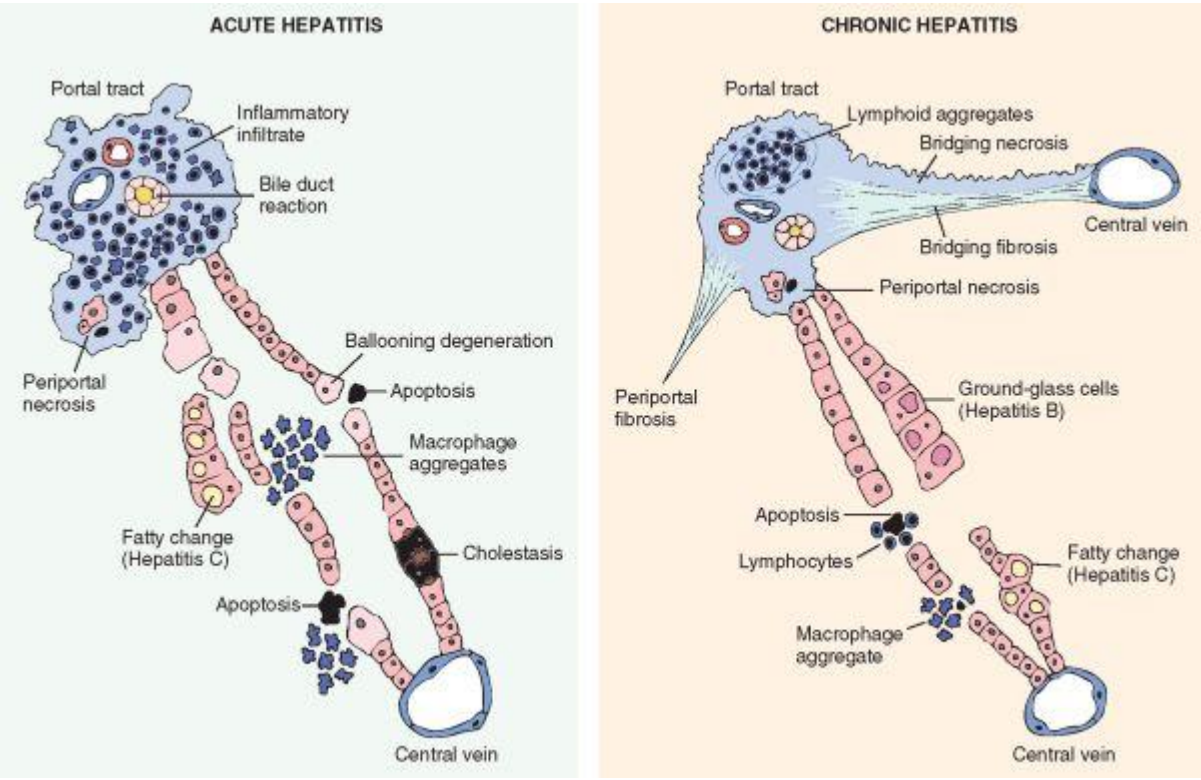

FIGURE 18-14 Diagrammatic representation of the morphologic features of acute and chronic hepatitis. Bridging necrosis (and fibrosis) is shown only for chronic hepatitis but may also occur in acute hepatitis (not shown).

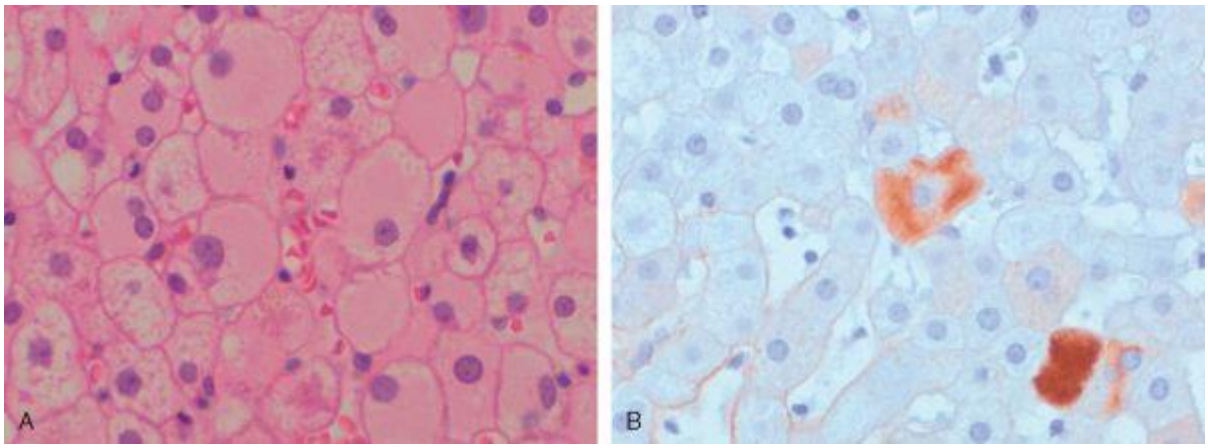

FIGURE 18-15 Chronic HBV infection. **A**, Showing the diffuse granular cytoplasm, so-called ground-glass hepatocytes. **B**, Immunoperoxidase stain for HBsAg from the same case, showing cytoplasmic inclusions of viral particles.

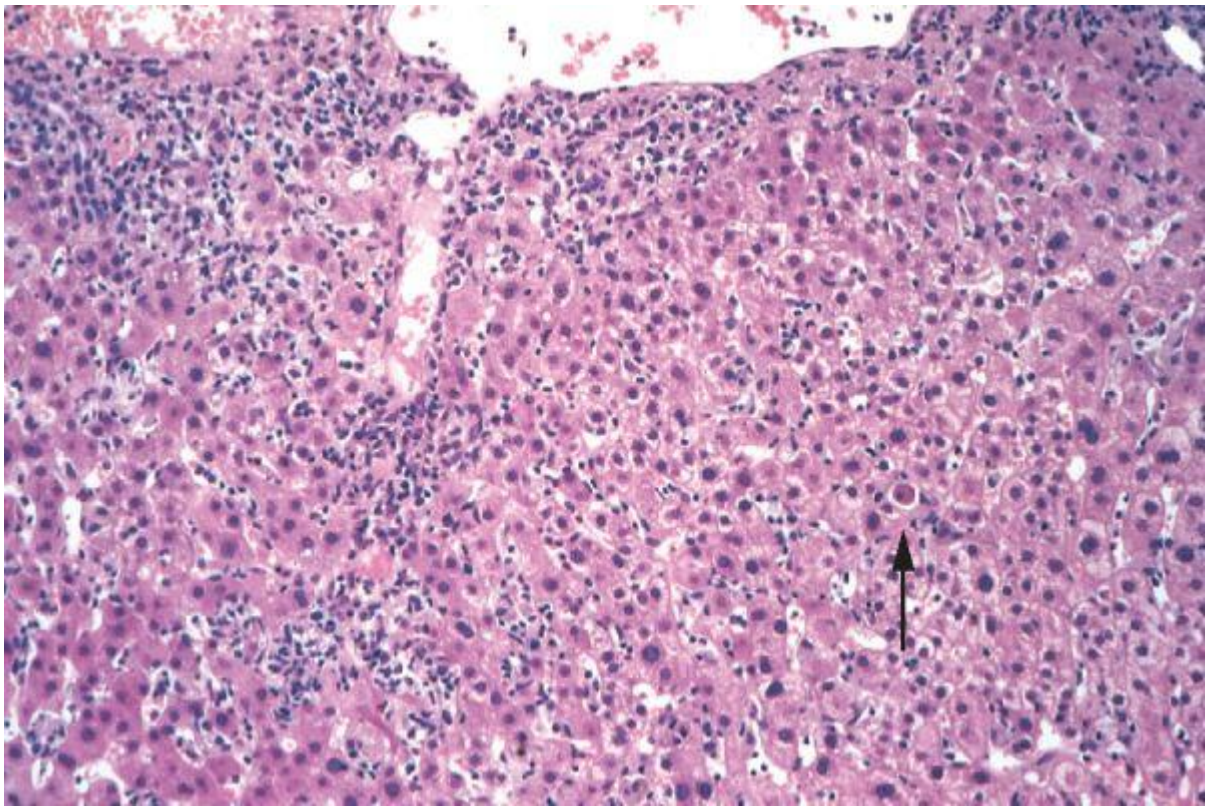

FIGURE 18-16 Acute viral hepatitis showing disruption of lobular architecture, inflammatory cells in the sinusoids, and hepatocyte apoptosis *(arrow)*.

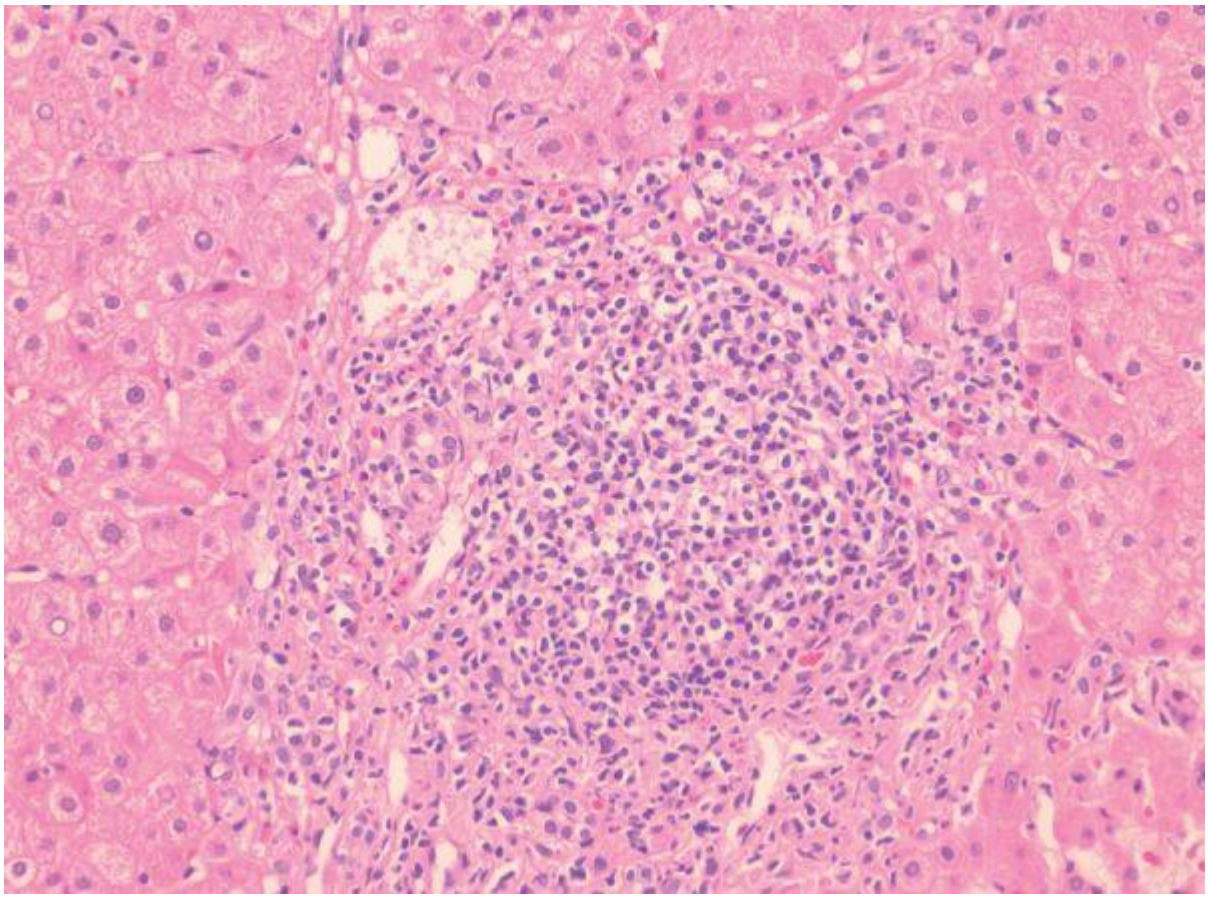

FIGURE 18-17 Chronic viral hepatitis due to HCV, showing portal tract expansion with inflammatory cells and fibrous tissue and interface hepatitis with spillover of inflammation into the adjacent parenchyma. A lymphoid aggregate is present.

FIGURE 18-18 Cirrhosis resulting from chronic viral hepatitis. Note the broad scar and coarse nodular surface.

The clinical course of viral hepatitis is unpredictable. Patients may experience spontaneous remission or may have indolent disease without progression for many years. Conversely, some patients have rapidly progressive disease and develop cirrhosis within a few years. The major causes of death from cirrhosis are: liver failure and hepatic encephalopathy, massive hematemesis from esophageal varices, and HCC in those with long-standing HBV (particularly neonatal) or HCV infection.

Fulminant Hepatic Failure.

Hepatic insufficiency that progresses from onset of symptoms to hepatic encephalopathy within 2 to 3 weeks in individuals who do not have chronic liver disease is termed *fulminant hepatic failure*. Viral hepatitis is responsible for about 12% of cases of fulminant hepatic failure; of these 8% are caused by HBV infection and the rest by HAV. Occasionally, HCV, herpesvirus infection, and Dengue virus cause fulminant hepatitis. Noninfectious causes, such as acetaminophen toxicity, were mentioned earlier. In about 15% of cases, the cause of fulminant hepatic failure is unknown.

The pathogenesis of fulminant hepatic failure varies depending on etiology. In the case of HBV-induced fulminant hepatitis, there is massive apoptosis.[36]

Morphology of Fulminant Hepatitis. Viral hepatitis and all other causative agents produce essentially identical morphologic changes that vary with the severity of the necrotizing process. The distribution of liver destruction is extremely capricious, since **the entire liver or only random areas may be involved**. With massive loss of mass, the liver may shrink to as little as 500 to 700 gm, and becomes a limp, red organ covered by a wrinkled, too-large capsule. On transection (Fig. 18-19A), necrotic areas have a muddy red, mushy appearance with hemorrhage. Microscopically, complete destruction of hepatocytes in contiguous lobules leaves only a collapsed reticulin framework and preserved portal tracts. There may be surprisingly little inflammatory reaction. Alternatively, with survival for several days, there is a massive influx of inflammatory cells to begin the phagocytic cleanup process (Fig. 18-19B).

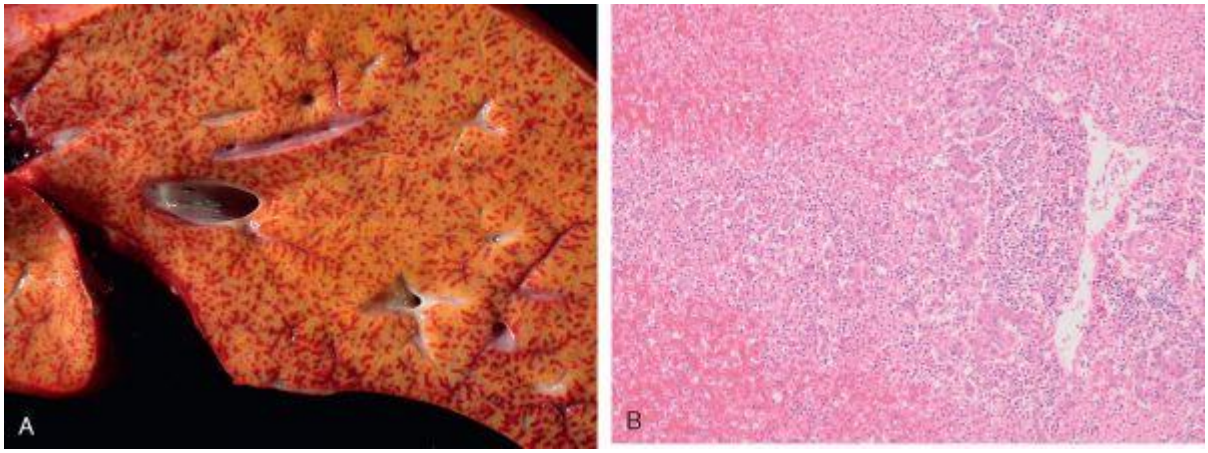

FIGURE 18-19 Massive necrosis. **A**, Cut section of liver. The liver is small (700 gm), bile-stained, and soft. The capsule is wrinkled. **B**, Microscopic section. Portal tracts and terminal hepatic veins are closer together than normal, as a result of necrosis and collapse of the intervening parenchyma. The rudimentary ductal structures are the result of early ductular regeneration. An infiltrate of mononuclear inflammatory cells is present.

Survival for more than a week may permit the replication of residual hepatocytes. The proliferation and differentiation of a quiescent stem/progenitor cell population in the canals of Hering, known as oval cells (Chapter 3), creates a *ductular reaction*. Maturation of these proliferating cells can generate both hepatocytes and bile duct cells. If the parenchymal framework is preserved, regeneration resulting mostly from hepatocyte replication can completely restore the liver architecture. With more massive destruction of confluent lobules, regeneration is disorderly, yielding nodular masses of liver cells that produce a more irregular liver on healing. Fibrous scarring may occur in patients with a protracted course of submassive or patchy necrosis, leading to cirrhosis.

The treatment for fulminant hepatic failure is to correct the underlying liver abnormality and provide supportive care. Liver transplantation is the only option for patients whose disease does not resolve before secondary infection and other organ failure develop. The mortality of fulminant hepatic failure is approximately 80% without liver transplantation, and about 35% with transplantation.

BACTERIAL, PARASITIC, AND HELMINTHIC INFECTIONS

Extrahepatic bacterial infections, particularly sepsis, can induce mild hepatic inflammation and varying degrees of hepatocellular cholestasis. The latter effect is attributable to the effects of pro-inflammatory

cytokines released by Kupffer cells and endothelial cells, in response to circulating endotoxin. Several bacteria can infect the liver directly, including *Staphylococcus aureus* in the setting of toxic shock syndrome, *Salmonella typhi* in the setting of typhoid fever, and *T. pallidum* in secondary or tertiary syphilis. Alternatively, bacteria may proliferate in a biliary tree especially when outflow is compromised by partial or complete obstruction. The intra-biliary bacterial composition reflects the gut flora, and the severe acute inflammatory response within the intrahepatic biliary tree is called *ascending cholangitis*.

Parasitic and helminthic infections are major causes of morbidity worldwide, and the liver is frequently involved (Chapter 8). These diseases include malaria, schistosomiasis, strongyloidiasis, cryptosporidiosis, leishmaniasis, echinococcosis, and infections by the liver flukes *Fasciola hepatica* and *Clonorchis sinensis*.

Liver abscesses, a form of liver infection that is common in developing countries, deserve special mention. They are usually caused by echinococcal and amebic infections (Chapter 8), and less commonly, by other protozoal and helminthic organisms. In developed countries liver abscesses are uncommon; the incidence of amebic infections is low and is usually present in immigrants from endemic regions. Most such abscesses are pyogenic, representing a complication of a bacterial infection elsewhere. The organisms reach the liver by (1) the portal vein, (2) arterial supply, (3) ascending infection in the biliary tract (ascending cholangitis), (4) direct invasion of the liver from a nearby source, or (5) a penetrating injury. The majority of hepatic abscesses used to result from portal spread of intra-abdominal infections (e.g., appendicitis, diverticulitis, colitis). With improved management of these conditions, spread now occurs primarily through the biliary tree or the arterial supply in patients suffering from some form of immune deficiency (e.g., old age with debilitating disease, immunosuppression, or cancer chemotherapy with marrow failure). In these settings, abscesses may develop without a primary focus elsewhere.

Morphology. Liver abscesses may occur as solitary or multiple lesions, ranging in size from millimeters to massive lesions many centimeters in diameter. Bacteremic spread through the arterial or portal system tends to produce multiple small abscesses, whereas direct extension and trauma usually cause solitary large abscesses. Biliary abscesses, which are usually multiple, may contain purulent material from adjacent bile ducts. Gross and microscopic features are similar to those seen in any abscess. The causative organism can occasionally be identified in the case of fungal or parasitic abscesses. On rare occasions, abscesses located in the subdiaphragmatic region, particularly amebic, may burrow into the thoracic cavity to produce empyema or a lung abscess. Rupture of subcapsular liver abscesses can lead to peritonitis or localized peritoneal abscesses. Echinococcal infection has a characteristic cystic structure; the wall is laminated, and hooklets and intact organisms can be identified (Fig. 18-20). Calcification in the cystic wall is common.

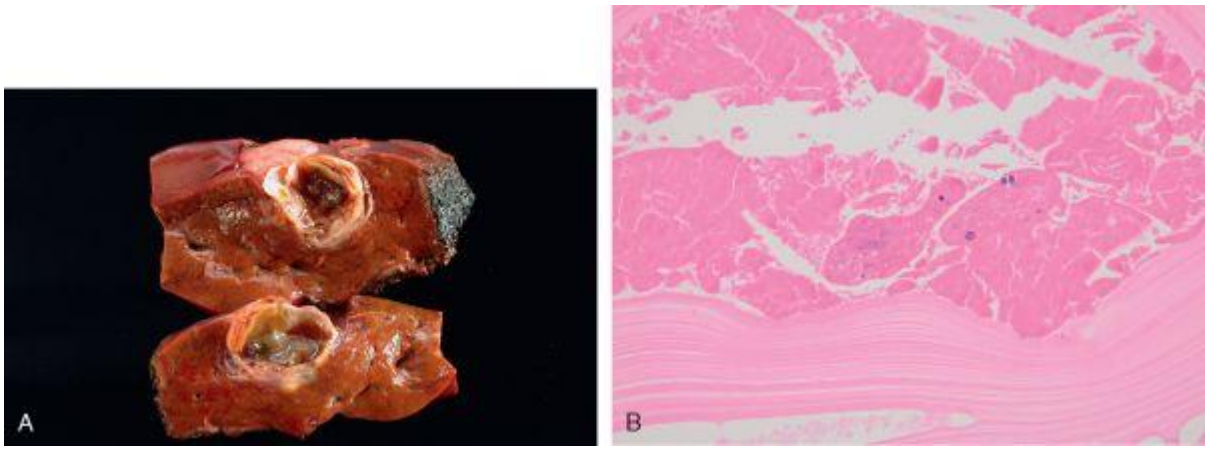

FIGURE 18-20 Echinococcal infection (**A**) demonstrating the cyst and (**B**) showing the laminated cystic wall with hooklet.

Liver abscesses are associated with fever and, in many instances, right upper quadrant pain and tender hepatomegaly. Jaundice may result from extrahepatic biliary obstruction. Although antibiotic therapy may control smaller lesions, surgical drainage is often necessary for the larger lesions. Because diagnosis is frequently delayed since the patients are elderly and have serious coexistent disease, the mortality rate of patients with large liver abscesses ranges from 30% to 90%. With early recognition and management as many as 80% of patients can survive. In the case of echinococcal cysts, rupture of this cyst has severe clinical consequences, including systemic spread of the organism and resultant shock from massive immune response.

3.8.1.3 Autoimmune Hepatitis

Autoimmune hepatitis is a chronic and progressive hepatitis of unknown etiology.[37] The pathogenesis is attributed to T cell–mediated autoimmunity, in which hepatocyte injury is caused by IFN-γ produced by CD4+ and CD8+ T cells and by CD8+ T-cell–mediated cytotoxicity. A defect in regulatory T-cells may underlie the uncontrolled activation of pathogenic, self-reactive lymphocytes. Genetic factors likely play a role in the autoimmunity (Chapter 6). The injurious immune reaction may be triggered by viral infections, certain drugs such as minocycline, atorvastatin, simvastatin, methyldopa, interferons, nitrofurantoin, and pemoline, and herbal products (such as black cohosh). Autoimmune hepatitis commonly occurs concurrently with other autoimmune disorders, such as celiac disease, systemic lupus erythematosus, rheumatoid arthritis, thyroiditis, Sjögren syndrome, and ulcerative colitis.

Clinicopathologic Features.

The disease may run an indolent or severe course (including fulminant hepatitis). There is a *female predominance* (78%), particularly in young and perimenopausal women. The annual incidence is highest among white northern Europeans at 1.9 per 100,000, but all ethnic groups are susceptible. The salient features[38] include the absence of serologic markers of viral infection, elevated serum IgG and γ-globulin levels (1.2 to 3.0 times normal), and high serum titers of autoantibodies. *Autoimmune hepatitis is classified into types 1 and 2, based on the patterns of circulating antibodies*. Type 1 is characterized by the presence of antinuclear (ANA), anti–smooth muscle (SMA), anti–actin (AAA), and anti–soluble liver antigen/liver-pancreas antigen (anti-SLA/LP) antibodies. The main antibodies detected in Type 2 autoimmune hepatitis are anti–liver kidney microsome-1 (ALKM-1) antibodies, which are mostly

directed against CYP2D6, and anti–liver cytosol-1 (ACL-1). Type 1 is much more common than Type 2 in the United States and is associated with the HLA-DR3 serotype. There is a female predominance, but the disease occurs in children and adults of both sexes.

The entire histologic spectrum of chronic hepatitis may be seen in autoimmune hepatitis, but it is marked by prominent inflammatory infiltrates of lymphocytes and plasma cells. *Clusters of plasma cells in the interface of portal tracts and hepatic lobules are fairly characteristic for autoimmune hepatitis* (Fig. 18-21). Symptomatic patients with autoimmune hepatitis tend to show substantial liver destruction and scarring at the time of diagnosis. Alternatively, autoimmune hepatitis may present in an atypical fashion with symptoms primarily from involvement of other organ systems, or may be asymptomatic and progress to cirrhosis without clinical diagnosis. An acute appearance of clinical illness is common (40%), and a fulminant presentation with onset of hepatic encephalopathy within 8 weeks of disease onset is possible. In a small subset of patients, autoimmune hepatitis diagnosed clinically may show histologic destruction of bile ducts (“autoimmune cholangitis”), making distinction from primary biliary cirrhosis (PBC) or primary sclerosing cholangitis (PSC) quite difficult. In some cases there is overlap of the clinical and histologic features of autoimmune hepatitis with those of PBC or PSC.

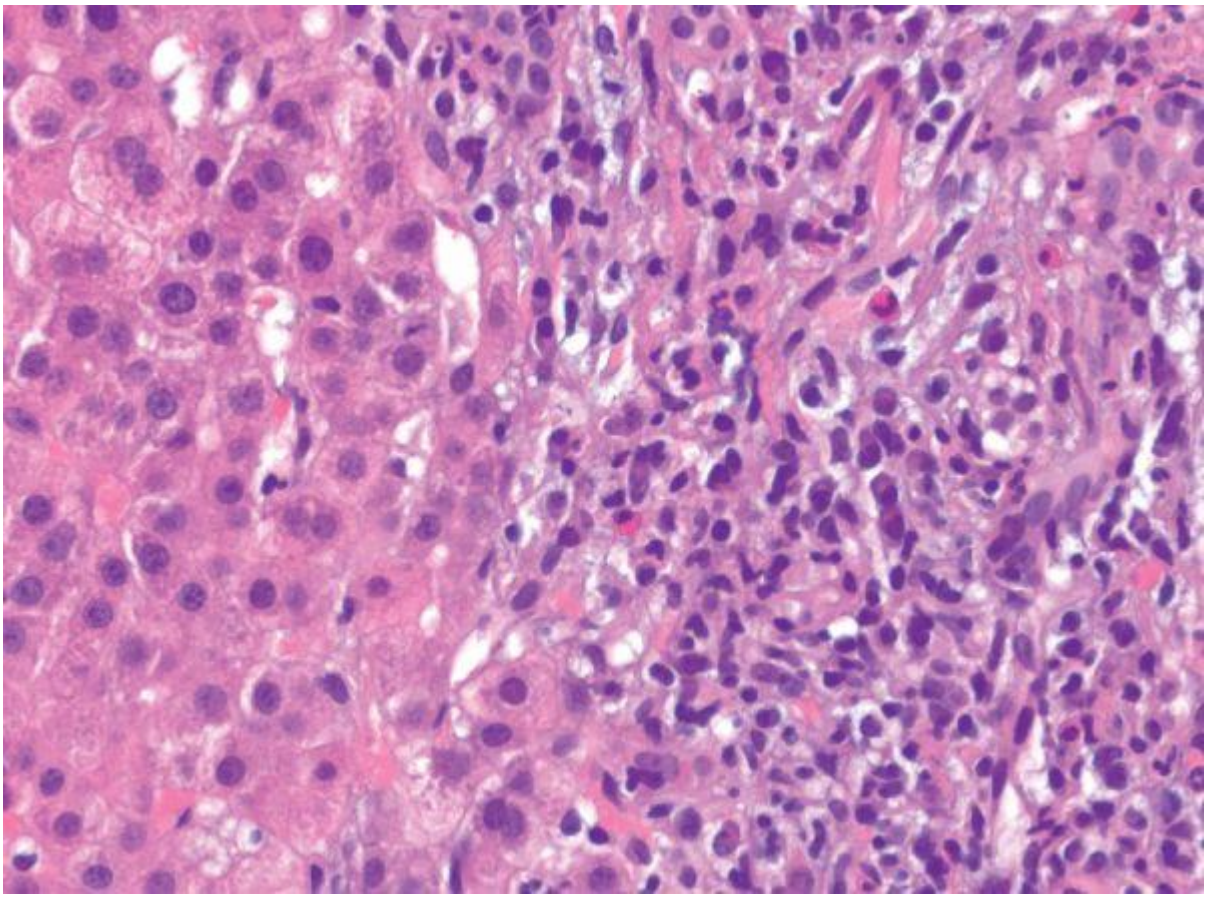

FIGURE 18-21 Autoimmune hepatitis. The photograph shows the interface hepatitis with prominent plasma cells.

The mortality of patients with severe untreated autoimmune hepatitis is approximately 40% within 6 months of diagnosis, and cirrhosis develops in at least 40% of survivors. Hence, diagnosis and

intervention are clinical imperatives. Prednisone alone or in combination with azathioprine is the mainstay of therapy. Other immunosuppressants such as cyclosporine, tacrolimus, azathioprine, mycophenolate mofetil, and rapamycin are also used in various clinical settings. Liver transplantation is indicated for patients with end-stage liver disease. The ten-year survival rate after transplantation is 75%, but the disease recurs in 22% to 42% of transplanted patients.

3.8.1.4 Drug- & Toxin-Induced Liver Disease

The liver is subject to potential damage from an enormous array of pharmaceutical and environmental chemicals.[39] Drug-induced liver injury accounts for about 10% of adverse drug reactions, and is the *most common cause of fulminant hepatitis in the United States*. The incidence of liver injury induced by prescribed drugs is estimated to be between 14 and 40 per 100,000 patients. Genetic variability is a critical factor that influences the susceptibility to drug-induced injury. Injury may result (1) from direct toxicity to hepatocytes or biliary epithelial cells, causing necrosis, apoptosis, or disruption of cellular function; (2) through hepatic conversion of a xenobiotic to an active toxin; or (3) through immune mechanisms, usually by a drug or a metabolite acting as a hapten to convert a cellular protein into an immunogen.[40]

The main principles of drug and toxic injury are discussed in Chapter 9 . Here it suffices to recall that drug reactions may be *predictable (intrinsic)* or *unpredictable (idiosyncratic)*. Predictable drug reactions can occur in anyone who receives a sufficient dose of an agent. Unpredictable reactions depend on idiosyncracies of the host, particularly the rate at which the host metabolizes the agent, and the intensity of the immune response. Idiosyncratic drug reaction should be considered in any patient receiving a therapeutic drug who develops evidence of liver damage. Generally, adults are more susceptible than children, and women are affected more than men. Important examples include chlorpromazine, an agent that causes cholestasis in patients who are slow to metabolize it to an innocuous byproduct, and halothane, which can cause a fatal immune-mediated hepatitis in some patients who are exposed to this anesthetic on multiple occasions. Table 18-5 lists more common offending agents, grouped according to the type of morphologic injury. It should be noted that the injury may be immediate or may take weeks to months to develop, presenting only after severe liver damage has developed. It may take the form of *hepatocyte necrosis*, *cholestasis*, or *insidious onset of liver dysfunction*. *Drug-induced chronic hepatitis is clinically and histologically indistinguishable from chronic viral hepatitis; hence, serologic markers of viral infection are critical for making the distinction*.

TABLE 18-5 -- Patterns of Injury in Drug- and Toxin-Induced Hepatic Injury

Pattern of Injury	Morphologic Findings	Examples of Associated Agents
Cholestatic	Bland hepatocellular cholestasis, without inflammation	Contraceptive and anabolic steroids; estrogen replacement therapy
Cholestatic hepatitis	Cholestasis with lobular necroinflammatory activity; may show bile duct destruction	Numerous antibiotics; phenothiazines
Hepatocellular necrosis	Spotty hepatocyte necrosis	Methyldopa, phenytoin
	Submassive necrosis, zone 3	Acetaminophen, halothane
	Massive necrosis	Isoniazid, phenytoin
Steatosis	Macrovesicular	Ethanol, methotrexate, corticosteroids, total parenteral nutrition
Steatohepatitis	Microvesicular, Mallory bodies	Amiodarone, ethanol
Fibrosis and cirrhosis	Periportal and pericellular fibrosis	Methotrexate, isoniazid, enalapril

Pattern of Injury	Morphologic Findings	Examples of Associated Agents
Granulomas	Noncaseating epithelioid granulomas	Sulfonamides, numerous other agents
Vascular lesions	Sinusoidal obstruction syndrome (veno-occlusive disease): obliteration of central veins	High-dose chemotherapy, bush teas
	Budd-Chiari syndrome	Oral contraceptives
	Sinusoidal dilatation	Oral contraceptives, numerous other agents
	Peliosis hepatis: blood-filled cavities, not lined by endothelial cells	Anabolic steroids, tamoxifen
Neoplasms	Hepatic adenoma	Oral contraceptives, anabolic steroids
	Hepatocellular carcinoma	Thorotrast
	Cholangiocarcinoma	Thorotrast
	Angiosarcoma	Thorotrast, vinyl chloride

From Washington K: Metabolic and toxic conditions of the liver. In Iacobuzio-Donahue CA, Montgomery EA (eds): Gastrointestinal and Liver Pathology. Philadelphia, Churchill Livingstone; 2005.

Among the agents listed in Table 18-5 , hepatic injury is considered predictable with overdoses of acetaminophen, exposure to *Amanita phalloides* toxin, carbon tetrachloride, and, to a certain extent, alcohol. However, individual genetic differences in the hepatic metabolism of xenobiotics through activating and detoxification pathways play a major role in individual susceptibility to even "predictable" hepatotoxins. Many other xenobiotics, such as sulfonamides, α-methyldopa, and allopurinol, cause idiosyncratic reactions. As already mentioned (in this chapter and in Chapter 9), *acetaminophen is the leading cause of drug-induced acute liver failure*. The most common prescription drugs causing idiosyncratic injury (that is, drug toxicity unrelated to drug dosage) include antibiotics and, in particular, isonazid, nonsteroidal analgesics, and anti-seizure medications. Idiosyncratic reactions evolve with a subacute course and are usually characterized by high bilirubin levels. Herbal preparations can be responsible for both predictable and idiosyncratic liver damage. *Reye syndrome*, a rare and potentially fatal syndrome of mitochondrial dysfunction in liver, brain, and elsewhere, occurs predominantly in children and is characterized morphologically by extensive accumulation of fat droplets within hepatocytes (microvesicular steatosis). Its development has been associated with the administration of acetylsalicylic acid (aspirin) for the relief of fever, but a causal relationship between aspirin and Reye syndrome has not been established. Nevertheless, aspirin should be avoided in children with febrile illness. Long-term methotrexate administration, an effective treatment for moderate to severe psoriasis, can cause liver injury, including hepatic steatosis and fibrosis.[41]

Drug-induced liver disease is usually followed by recovery upon removal of the drug. *Exposure to a toxin or therapeutic agent should always be included in the differential diagnosis of liver disease*.

ALCOHOLIC LIVER DISEASE

Excessive alcohol (ethanol) consumption is the leading cause of liver disease in most Western countries. In the United States, 50% of the population 18 years of age or older drink alcohol. A subset of these individuals suffer serious health consequences associated with alcoholism (Chapter 9). Of greatest impact is alcoholic liver disease, which affects more than 2 million Americans and causes 27,000 deaths a year. There are three distinctive, albeit overlapping, forms of alcoholic liver disease: (1) *hepatic steatosis (fatty liver disease)*, (2) *alcoholic hepatitis*, and (3) *cirrhosis* (Fig. 18-22). The morphology of

the three forms of alcoholic liver disease is presented first, followed by a discussion of their pathogenesis.

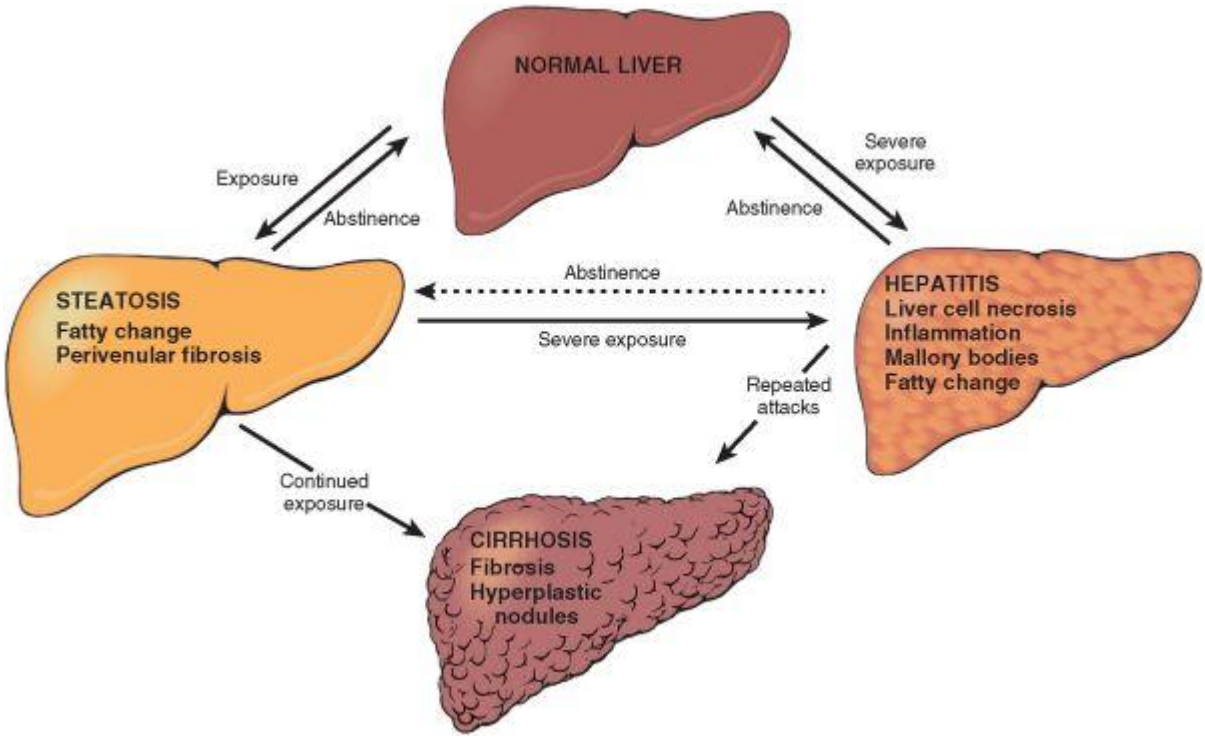

FIGURE 18-22 Alcoholic liver disease. The interrelationships among hepatic steatosis, hepatitis, and cirrhosis are shown, depicting key morphologic features.

Morphology.

Hepatic Steatosis (Fatty Liver). After even moderate intake of alcohol, **microvesicular** lipid droplets accumulate in hepatocytes. With chronic intake of alcohol, lipid accumulates creating large, clear **macrovesicular** globules that compress and displace the hepatocyte nucleus to the periphery of the cell. Macroscopically, the fatty liver of chronic alcoholism is a large (as heavy as 4 to 6 kg), soft organ that is yellow and greasy. Although there is little or no fibrosis at the outset, with continued alcohol intake fibrous tissue develops around the terminal hepatic veins and extends into the adjacent sinusoids. **The fatty change is completely reversible if there is abstention from further intake of alcohol**.

Alcoholic Hepatitis (Alcoholic Steatohepatitis). Alcoholic hepatitis is characterized by:

1. **Hepatocyte swelling and necrosis**: Single or scattered foci of cells undergo swelling (ballooning) and necrosis. The swelling results from the accumulation of fat and water, as well as proteins that normally are exported. In some cases there is cholestasis in surviving hepatocytes and mild deposition of hemosiderin (iron) in hepatocytes and Kupffer cells.
2. **Mallory bodies**: Scattered hepatocytes accumulate tangled skeins of cytokeratin intermediate filaments such as cytokeratin 8 and 18, in complex with other proteins such as ubiquitin. Mallory bodies are visible as eosinophilic cytoplasmic clumps in hepatocytes (Fig. 18-23). These inclusions are a characteristic but not specific feature of alcoholic liver disease, since they also present in NAFLD, PBC, Wilson

disease, chronic cholestatic syndromes, and hepatocellular tumors.

3. **Neutrophilic reaction**: Neutrophils permeate the hepatic lobule and accumulate around degenerating hepatocytes, particularly those having Mallory bodies. Lymphocytes and macrophages also enter portal tracts and spill into the parenchyma.
4. **Fibrosis**: Alcoholic hepatitis is almost always accompanied by prominent activation of sinusoidal stellate cells and portal tract fibroblasts, giving rise to fibrosis. Most frequently fibrosis is sinusoidal and perivenular, separating parenchymal cells; occasionally, periportal fibrosis may predominate, particularly with repeated bouts of heavy alcohol intake.

Cirrhosis. The final and irreversible form of alcoholic liver disease usually evolves slowly and insidiously but may develop in 1 or 2 years in some cases. At first the cirrhotic liver is yellowtan, fatty, and enlarged, usually weighing over 2 kg. Over the span of years, it is transformed into a brown, shrunken, nonfatty organ, sometimes less than 1 kg in weight. Initially the developing fibrous septa are delicate and extend through sinusoids from central to portal regions as well as from portal tract to portal tract. Regenerative activity of entrapped parenchymal hepatocytes generates uniform micronodules. With time the nodularity becomes more prominent; scattered larger nodules create a "hobnail" appearance on the surface of the liver (Fig. 18-24A). As fibrous septa dissect and surround nodules, the liver becomes more fibrotic, loses fat, and shrinks progressively in size. Parenchymal islands are engulfed by wider bands of fibrous tissue, and the liver is converted into a mixed micronodular and macronodular pattern (Fig. 18-24B). Ischemic necrosis and fibrous obliteration of nodules eventually create broad expanses of tough, pale scar tissue ("Laennec cirrhosis"). Bile stasis often develops; Mallory bodies are only rarely evident at this stage. Thus, **end-stage alcoholic cirrhosis comes to resemble, both macroscopically and microscopically, the cirrhosis developing from viral hepatitis and other causes**.

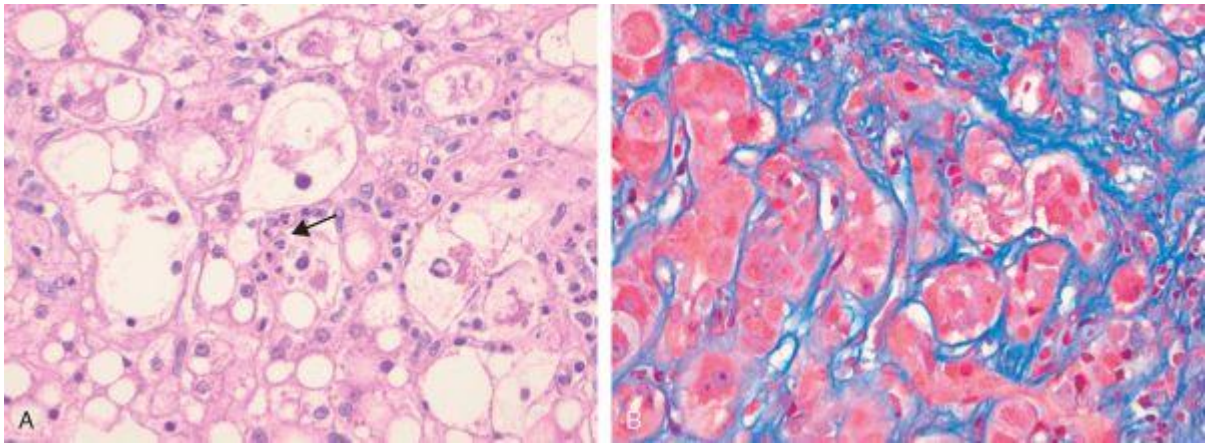

FIGURE 18-23 Alcoholic hepatitis. **A**, The cluster of inflammatory cells marks the site of a necrotic hepatocyte *(arrow)*. **B**, Eosinophilic Mallory bodies are seen in hepatocytes, which are surrounded by fibrous (Masson stain) tissue.

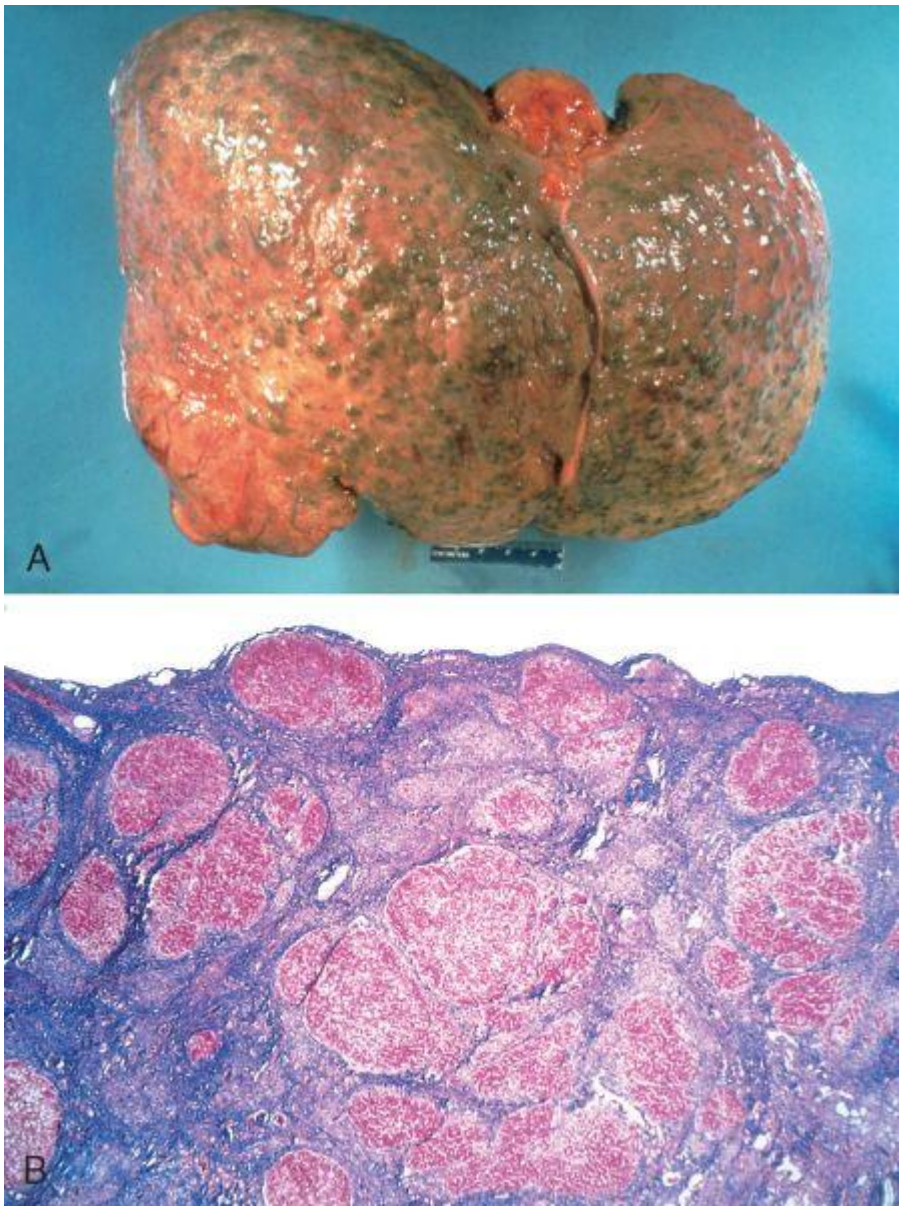

FIGURE 18-24 Alcoholic cirrhosis. **A**, The characteristic diffuse nodularity of the surface reflects the processes of nodular regeneration and scarring. The greenish tint of some nodules is due to bile stasis. A hepatocellular carcinoma is present as a budding mass at the lower edge of the right lobe *(lower left)*. **B**, The microscopic view shows nodules of varying sizes entrapped in blue-staining fibrous tissue. The liver capsule is at the top (Masson trichrome).

Pathogenesis.

Short-term ingestion of as much as 80 gm of alcohol (six beers or 8 ounces of 80-proof liquor) over one to several days generally produces mild, reversible hepatic steatosis. Daily intake of 80 gm or more of ethanol generates significant risk for severe hepatic injury, and daily ingestion of 160 gm or more for 10 to 20 years is associated more consistently with severe injury. *Only 10% to 15% of alcoholics, however, develop cirrhosis*. Thus, other factors must also influence the development and severity of alcoholic liver disease. These factors include:

- *Gender*. Women seem to be more susceptible to hepatic injury than men are, although the majority of

patients are men. This difference may be related to alcohol pharmacokinetics and metabolism, and the estrogen-dependent response to gut-derived endotoxin (LPS) in the liver.[42] Estrogen increases gut permeability to endotoxins, which, in turn, increase the expression of the LPS receptor CD14 in Kupffer cells. This predisposes to increased production of pro-inflammatory cytokines and chemokines.

- *Ethnic differences*. In the United States, cirrhosis rates are higher for African Americans than for white Americans. The difference cannot be explained by the amount of alcohol consumption, since there is no significant difference in consumption among the ethnic groups.
- *Genetic factors*. Studies with twins suggest that there is a genetic component in alcohol-induced liver disease. There is also a strong family association, but in these cases it is difficult to separate genetic from environmental influences. Current attention is being given to genetic polymorphisms in detoxifying enzymes and some cytokine promoters. ALDH*2, a genetic variant of aldehyde-dehydrogenase (ALDH), found in 50% of Asians, has a very low activity (Chapter 9). Individuals who are homozygous for ALDH*2 are unable to oxidize acetaldehyde and do not tolerate alcohol.
- *Co-morbid conditions*. Iron overload and infections with HCV and HBV increase the severity of alcoholic liver disease.

The pharmacokinetics and metabolism of alcohol were described in Chapter 9 . Pertinent to our discussion here are the detrimental effects of alcohol and its byproducts on hepatocellular function. *Exposure to alcohol causes steatosis, dysfunction of mitochondrial and cellular membranes, hypoxia, and oxidative stress*. At millimolar concentrations, alcohol directly affects microtubular and mitochondrial function and membrane fluidity.

Hepatocellular steatosis results from (1) shunting of normal substrates away from catabolism and toward lipid biosynthesis, as a result of generation of excess reduced nicotinamide adenine dinucleotide ($NADH + H^+$) by the two major enzymes of alcohol metabolism, alcohol dehydrogenase and acetaldehyde dehydrogenase; (2) impaired assembly and secretion of lipoproteins; and (3) increased peripheral catabolism of fat.

The causes of *alcoholic hepatitis* are uncertain but some of the factors in its pathogenesis are discussed next. *Acetaldehyde* (the major intermediate metabolite of alcohol) induces lipid peroxidation and acetaldehyde-protein adduct formation, further disrupting cytoskeletal and membrane function. Cytochrome P-450 metabolism produces *reactive oxygen species (ROS)* that react with cellular proteins, damage membranes, and alter hepatocellular function. In addition, alcohol-induced impaired hepatic metabolism of methionine leads to decreased intrahepatic glutathione levels, thereby sensitizing the liver to oxidative injury. The induction of CYP2E1 and other cytochrome P-450 enzymes in the liver by alcohol increases alcohol catabolism in the endoplasmic reticulum and enhances the conversion of other drugs (e.g., acetaminophen) to toxic metabolites.

Alcohol can become a major source of calories in the diet of an alcoholic, displacing other nutrients and leading to *malnutrition and deficiencies of vitamins* (such as thiamine). This is compounded by impaired digestive function, primarily related to chronic gastric and intestinal mucosal damage, and pancreatititis.

Alcohol causes the *release of bacterial endotoxin from the gut* into the portal circulation, inducing inflammatory responses in the liver, such as the activation of NF-κB, and release of TNF, IL-6, and TGF-α. In addition, alcohol stimulates the *release of endothelins* from sinusoidal endothelial cells, causing vasoconstriction and the contraction of activated stellate cells (“myofibroblasts”), leading to a decrease in hepatic sinusoidal perfusion (already discussed under “Portal Hypertension”).

In summary, alcoholic liver disease is a chronic disorder featuring steatosis, hepatitis, progressive fibrosis, cirrhosis, and marked derangement of vascular perfusion. It can be regarded as a maladaptive state in which cells in the liver respond in an increasingly pathologic manner to a stimulus (alcohol) that

originally was only marginally harmful. For some unknown reason, cirrhosis develops in only a small fraction of chronic alcoholics.

Clinical Features.

Hepatic steatosis (fatty liver) may become evident as hepatomegaly, with mild elevation of serum bilirubin and alkaline phosphatase levels. Severe hepatic dysfunction is unusual. Alcohol withdrawal and the provision of an adequate diet are sufficient treatment. In contrast, *alcoholic hepatitis* tends to appear acutely, usually following a bout of heavy drinking. Symptoms and laboratory manifestations may range from minimal to fulminant hepatic failure. Between these two extremes are the nonspecific symptoms of malaise, anorexia, weight loss, upper abdominal discomfort, tender hepatomegaly, and the laboratory findings of hyperbilirubinemia, elevated alkaline phosphatase, and often a neutrophilic leukocytosis. An acute cholestatic syndrome may appear, resembling large bile duct obstruction. The outlook is unpredictable; each bout of hepatitis incurs about a 10% to 20% risk of death. With repeated bouts, cirrhosis appears in about one third of patients within a few years. Alcoholic hepatitis also may be superimposed on established cirrhosis. With proper nutrition and total cessation of alcohol consumption, the alcoholic hepatitis may clear slowly. However, in some patients, the hepatitis persists, despite abstinence, and progresses to cirrhosis.

The manifestations of *alcoholic cirrhosis* are similar to those of other forms of cirrhosis. Laboratory findings reflect the hepatic dysfunction, with elevated serum aminotransferase, hyperbilirubinemia, variable elevation of serum alkaline phosphatase, hypoproteinemia (globulins, albumin, and clotting factors), and anemia. In some instances, liver biopsy may be indicated, since in about 10% to 20% of cases of presumed alcoholic cirrhosis, another disease process is found. Finally, cirrhosis may be clinically silent, discovered only at autopsy or when stress such as infection or trauma tips the balance toward hepatic insufficiency.

The long-term outlook for alcoholics with liver disease is variable. Five-year survival approaches 90% in abstainers who are free of jaundice, ascites, or hematemesis; it drops to 50% to 60% in those who continue to imbibe. In the end-stage alcoholic the proximate causes of death are (1) hepatic coma, (2) massive gastrointestinal hemorrhage, (3) intercurrent infection (to which these patients are predisposed), (4) hepatorenal syndrome following a bout of alcoholic hepatitis, and (5) hepatocellular carcinoma (the risk of developing this tumor in alcoholic cirrhosis is 1% to 6% of cases annually).

3.8.1.5 Metabolic Liver Disease

A distinct group of liver diseases is attributable to disorders of metabolism, either acquired or inherited. The most common acquired metabolic disorder is non-alcoholic fatty liver disease. Among inherited metabolic diseases, hemochromatosis, Wilson disease, and α_1-antitrypsin deficiency are most prominent. Also included among liver metabolic diseases is neonatal hepatitis, a broad disease category encompassing rare inherited diseases and neonatal infections.

NONALCOHOLIC FATTY LIVER DISEASE (NAFLD)

NAFLD is a group of conditions that have in common the presence of hepatic steatosis (fatty liver), in individuals who do not consume alcohol, or do so in very small quantities (less than 20 g of ethanol/week). It has become *the most common cause of chronic liver disease in the United States*, and in its various forms, probably affects more than 30% of the population. However, these estimates are approximate, because fatty liver without other complications may not be detected clinically. NAFLD includes simple *hepatic steatosis, steatosis accompanied by minor, non-specific inflammation, and non-alcoholic steatohepatitis (NASH)*.[43] Steatosis with or without non-specific inflammation is generally a stable condition without significant clinical problems. In contrast, NASH is a condition in which there is

hepatocyte injury that may progress to cirrhosis in 10% to 20% of cases. The main components of NASH are hepatocyte ballooning, lobular inflammation, and steatosis.[44] With progressive disease fibrosis occurs. NASH affects men and women equally and the condition is strongly associated with obesity and the other components of the metabolic syndrome, such as dyslipidemia, hyperinsulinemia and insulin resistance. It is estimated that more than 70% of obese individuals have some form of NAFLD. It is the most common cause of so-called cryptogenic cirrhosis, namely cirrhosis of "unknown" origin. NAFLD contributes to the progression of other liver diseases such as HCV infection and HCC. The epidemic of obesity in the United States heightens concern that NAFLD will increase in prevalence.

Pathogenesis.

The precise mechanisms of steatosis and hepatocellular damage in NAFLD are not entirely known, but genetics and environment play a role in the pathogenesis.[44] A "two-hit" model of pathogenesis has been proposed, encompassing two sequential events: (1) hepatic fat accumulation and, (2) hepatic oxidative stress.[45] The oxidative stress acts upon the accumulated hepatic lipids, resulting in lipid peroxidation and the release of lipid peroxides, which can produce reactive oxygen species.

Clinical Features.

Individuals with simple steatosis are generally asymptomatic. Clinical presentation is often related to other metabolic derangements, such as obesity, insulin resistance, and diabetes.[46] Imaging studies may reveal fat accumulation in the liver. However, liver biopsy is the most reliable diagnostic tool for NASH and helps determine the extent of steatosis, presence of steatohepatitis, and degree of fibrosis. Serum AST and ALT are elevated in about 90% of patients with NASH. The AST/ALT ratio is usually less than 1, in contrast to alcoholic steatohepatitis in which the ratio is generally above 2.0 to 2.5. Despite the enzyme elevations, patients may be asymptomatic. Others have general symptoms such as fatigue and right-sided abdominal discomfort caused by hepatomegaly. Because of the association between NASH and the metabolic syndrome, cardiovascular disease is a frequent cause of death in patients with NASH. The goal of treating individuals with NASH is to reverse the steatosis and prevent cirrhosis. The current management strategy seeks to correct the underlying risk factors, such as obesity and hyperlipidemia, and to treat insulin resistance.

Morphology. Steatosis usually involves more than 5% of the hepatocytes and sometimes more than 90%. Large (macrovesicular) and small (microvesicular) droplets of fat, predominantly triglycerides, accumulate within hepatocytes (Fig. 18-25A). At the most clinically benign end of the spectrum, there is no appreciable hepatic inflammation, hepatocyte death, or scarring, despite persistent elevation of serum liver enzymes. **Steatohepatitis** (NASH) is characterized by steatosis and multifocal parenchymal inflammation, mainly neutrophils, Mallory bodies, hepatocyte death (both ballooning degeneration and apoptosis), and sinusoidal fibrosis. Fibrosis also occurs within portal tracts and around terminal hepatic venules (Fig. 18-25B). These histological changes are similar to those of alcoholic steatohepatitis. **Cirrhosis** may develop, presumably the result of years of subclinical progression of the necroinflammatory and fibrotic processes. When cirrhosis is established, the steatosis or steatohepatitis tends to be reduced and sometimes is not identifiable.

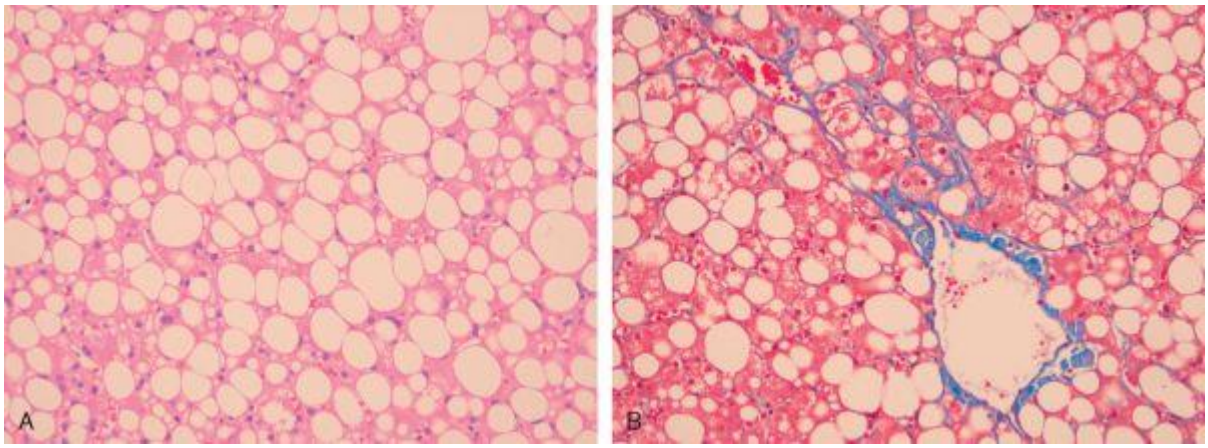

FIGURE 18-25 Histologic appearance of nonalcoholic fatty liver disease. **A**, Liver tissue with macrovesicular steatosis (H&E stain). **B**, NASH, showing perivenular fibrosis and perisinusoidal fibrosis *(blue fibers)* in this trichrome stain.

HEMOCHROMATOSIS

Hemochromatosis was first described by von Recklinghausen in 1889. It is characterized by the excessive accumulation of body iron, most of which is deposited in parenchymal organs such as the liver and pancreas. Iron can also accumulate in the heart, joints, or endocrine organs. Hemochromatosis (also known as primary or hereditary hemochromatosis) is a homozygous-recessive inherited disorder[47] that is caused by excessive iron absorption. Accumulation of iron in tissues, which may occur as a consequence of parenteral administration of iron, usually in the form of transfusions, or other causes (Table 18-6), is variably known as secondary hemochromatosis, acquired hemochromatosis, or *hemosiderosis*. We will use the terms *hemochromatosis* for the hereditary disease and *hemosiderosis* for the acquired deposition of iron in some tissues.

TABLE 18-6 -- Classification of Iron Overload

I.	**HEREDITARY HEMOCHROMATOSIS**
	Mutations of genes encoding HFE, transferrin receptor 2 (TfR2), or hepcidin
	Mutations of genes encoding HJV (hemojuvelin: juvenile hemochromatosis)
	(Neonatal hemochromatosis)[*]
II.	**HEMOSIDEROSIS (SECONDARY HEMOCHROMATOSIS)**
A.	Parenteral iron overload
	Transfusions
	Long-term hemodialysis
	Aplastic anemia
	Sickle cell disease
	Myelodysplastic syndromes
	Leukemias
	Iron-dextran injections

B. Ineffective erythropoiesis with increased erythroid activity

β-Thalassemia

Sideroblastic anemia

Pyruvate kinase deficiency

C. Increased oral intake of iron

African iron overload (Bantu siderosis)

D. Congenital atransferrinemia

E. Chronic liver disease

Chronic alcoholic liver disease

Porphyria cutanea tarda

F. Neonatal hemochromatosis

* Neonatal hemochromatosis develops in utero and does not appear to be a hereditary condition.

As was discussed in Chapter 14 , the total body iron pool ranges from 2 to 6 gm in normal adults; about 0.5 gm is stored in the liver, 98% of which is in hepatocytes. In hemochromatosis, total iron accumulation may exceed 50 gm, over one third of which accumulates in the liver. The following features characterize this disease:

- Fully developed cases exhibit (1) *micronodular cirrhosis* in all patients; (2) *diabetes mellitus* in 75% to 80% of patients; and (3) *skin pigmentation* in 75% to 80% of patients.
- Iron accumulation is lifelong but the injury caused by excessive iron is slow and progressive; hence symptoms usually first appear in the fifth to sixth decades of life.
- Males predominate (5 to 7 : 1) with slightly earlier clinical presentation, partly because physiologic iron loss (menstruation, pregnancy) delays iron accumulation in women.

Pathogenesis.

Because there is no regulated iron excretion from the body, the total body content of iron is tightly regulated by intestinal absorption as described below. *In hemochromatosis, regulation of intestinal absorption of dietary iron is abnormal, leading to net iron accumulation of 0.5 to 1.0 gm/year, mainly in the liver*. The disease manifests itself typically after 20 gm of stored iron have accumulated. *Excessive iron appears to be directly toxic to host tissues*, by the following mechanisms: (1) lipid peroxidation via iron-catalyzed free radical reactions, (2) stimulation of collagen formation by activation of hepatic stellate cells, and (3) interaction of reactive oxygen species and of iron itself with DNA, leading to lethal cell injury or predisposition to hepatocellular carcinoma. The actions of iron are reversible in cells that are not fatally injured, and removal of excess iron with therapy promotes recovery of tissue function.

The main regulator of iron absorption is the protein hepcidin (also known as liver expressed antimicrobial peptide or LEAP1), encoded by the *HAMP* gene. Hepcidin, which also has antibacterial activity, is produced in hepatocytes as an 84 amino acid propeptide that is cleaved into a mature form of 25 amino acids and smaller circulating forms of 20 and 23 amino acids. *Transcription of hepcidin is increased by inflammatory cytokines and iron, and decreased by iron deficiency, hypoxia and ineffective erythropoiesis*. Hepcidin binds to the cellular iron efflux channel ferroportin (FPN), causing internalization and proteolysis of the channel. This prevents the release of iron from intestinal cells and

macrophages; *thus hepcidin lowers plasma iron levels. Conversely, a deficiency in hepcidin causes iron overload*.

Other proteins involved in iron metabolism, do so by regulating hepcidin levels. These include: (1) hemojuvelin (HJV), which is expressed in the liver, heart, and skeletal muscle; (2) transferrin receptor 2 (TfR2), which is highly expressed in hepatocytes, where it mediates the uptake of transferrin-bound iron, and (3) HFE, the product of the hemochromatosis gene. *Lack of hepcidin expression caused by mutations in hepcidin, HJV, TfR2, and HFE cause hemochromatosis*. Of these mutations, those in HFE are the most common, as discussed below. Mutations of *HAMP* and *HJV* cause a severe form of hereditary hemochromatosis, known as juvenile hemochromatosis. Mutations of *HFE* and *TfR2* cause the classic form of hereditary adult hemochromatosis, a milder disease than the juvenile form. Mutations of ferroportin cause a distinctive iron storage disease that is different from hereditary hemochromatosis. The precise mechanisms by which HFE, HJV, and TfR2 regulate hepcidin and ferroportin remain to be determined. A serine protease (TMPRSS6) was recently identified as an iron sensor that suppresses *HAMP expression*.[48]

The adult form of hemochromatosis is almost always caused by mutations of HFE, a gene located on the short arm of chromosome 6 at 6p21.3, close to the *HLA* gene locus. It encodes an HLA class I-like molecule that regulates intestinal absorption of dietary iron. The most common *HFE* mutation is a cysteine-to-tyrosine substitution at amino acid 282 (called C282Y), due to a single G to A transition at nucleotide 845 (G845A). This mutation, which causes inactivation of the protein, is present in 70% to 100% of the patients diagnosed with hereditary hemochromatosis. The other common mutation is H63D (histidine at position 63 to aspartate). The H63D homozygous state and C282Y/H63D compound heterozygous mutations often cause only mild iron accumulation.

The C282Y mutation is largely confined to white populations of European origin, while the H63D has a worldwide distribution. The frequency of C282Y homozygosity is 0.45% (1 of every 220 persons), and the heterozygous frequency is 11%, making hereditary hemochromatosis one of the most common genetic disorders in humans. However, the penetrance of this disorder is low in patients with the homozygous C282Y mutation, so the genetic condition does not lead to clinical disease in all individuals.

Morphology. The morphologic changes in hereditary hemochromatosis are characterized principally by: (1) **deposition of hemosiderin** in the following organs (in decreasing order of severity): liver, pancreas, myocardium, pituitary gland, adrenal gland, thyroid and parathyroid glands, joints, and skin (detected by the Prussian blue histologic reaction or by atomic absorption analysis of tissue); (2) **cirrhosis**; and (3) **pancreatic fibrosis**. In the liver, iron becomes evident first as golden-yellow hemosiderin granules in the cytoplasm of periportal hepatocytes, which stain blue with the Prussian blue stain (Fig. 18-26). With increasing iron load, there is progressive involvement of the rest of the lobule, along with bile duct epithelium and Kupffer cell pigmentation. Iron is a direct hepatotoxin, and inflammation is characteristically absent. At this stage, the liver is typically slightly larger than normal, dense, and chocolate brown. Fibrous septa develop slowly, leading ultimately to a micronodular pattern of cirrhosis in an intensely pigmented liver.

Biochemical determination of hepatic tissue iron concentration is the standard for quantitating hepatic iron content. In normal individuals, the iron content of liver tissue is less than 1000 μg per gram dry weight of liver. Adult patients with hereditary hemochromatosis exhibit over 10,000 μg iron per gram dry weight; hepatic iron concentrations in excess of 22,000 μg per gram dry weight are associated with the development of fibrosis and cirrhosis.

The **pancreas** becomes intensely pigmented, has diffuse interstitial fibrosis, and may exhibit some parenchymal atrophy. Hemosiderin is found in both the acinar and the islet cells, and sometimes in the interstitial fibrous stroma. The **heart** is often enlarged and has hemosiderin granules within the myocardial fibers, producing a striking brown coloration to the myocardium. A delicate interstitial fibrosis may appear. Although **skin** pigmentation is partially attributable to hemosiderin deposition in dermal macrophages and fibroblasts, most of the pigmentation results from increased epidermal melanin production. The combination of these pigments imparts a characteristic slate-gray color to the skin. With hemosiderin deposition in the **joint synovial linings**, an acute synovitis may develop. Excessive deposition of calcium pyrophosphate damages the articular cartilage, producing a disabling polyarthritis referred to as **pseudo-gout**. The **testes** may be small and atrophic but are not usually significantly pigmented. It is thought that the atrophy is secondary to a derangement in the hypothalamic-pituitary axis resulting in reduced gonadotropin and testosterone levels.

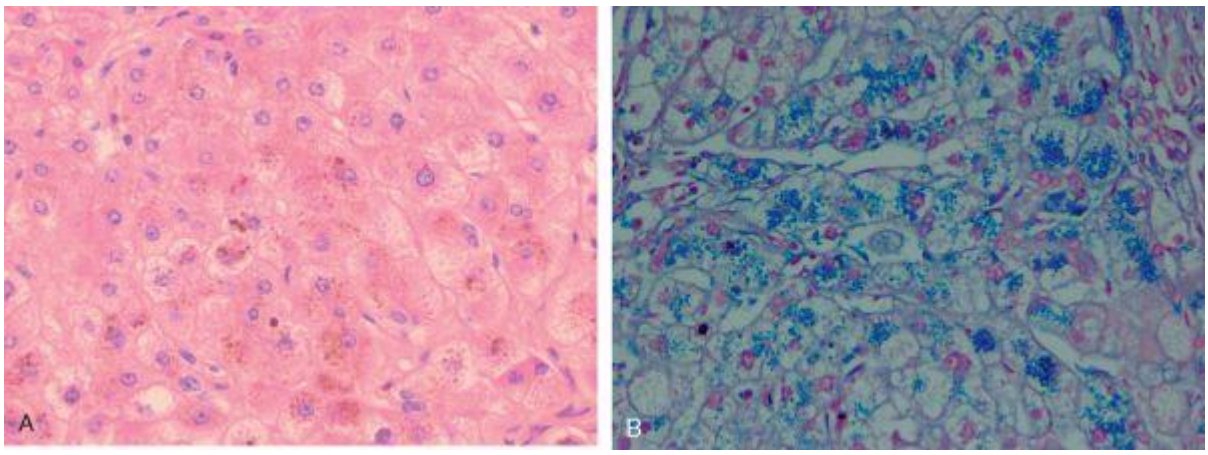

FIGURE 18-26 Histologic appearance of hereditary hemochromatosis. Hepatocellular iron deposition is dark-brown in H&E stain (**A**) and blue in Prussian blue–stained section (**B**). This is a section from an early stage of the disease, in which parenchymal architecture is normal.

Clinical Features.

Classical hemochromatosis is more often a disease of males and rarely becomes evident before age 40. The principal manifestations include hepatomegaly, abdominal pain, skin pigmentation (particularly in sun-exposed areas), deranged glucose homeostasis or frank diabetes mellitus due to destruction of pancreatic islets, cardiac dysfunction (arrhythmias, cardiomyopathy), and atypical arthritis. In some patients, the presenting complaint is hypogonadism (e.g., amenorrhea in the female, impotence and loss of libido in the male). *The classic triad of pigment cirrhosis with hepatomegaly, skin pigmentation, and diabetes mellitus might not develop until late in the course of the disease*. Death may result from cirrhosis or cardiac disease. A significant cause of death is hepatocellular carcinoma; the risk is 200-fold greater than in the general population, and treatment for iron overload does not remove the risk for this tumor.

Fortunately, hemochromatosis can be diagnosed long before irreversible tissue damage has occurred. Screening involves demonstration of very high levels of serum iron and ferritin, exclusion of secondary causes of iron overload, and liver biopsy if indicated. *Screening of family members of probands is important*. Heterozygotes also accumulate excessive iron, but not to a level that causes significant tissue damage. Currently most patients with hemochromatosis are diagnosed in the subclinical, precirrhotic

stage due to routine serum iron measurements (as part of other diagnostic workup). They are treated by regular phlebotomy and have a normal life expectancy.

Neonatal hemochromatosis (also called congenital hemochromatosis) is a disease of unknown origin manifested by severe liver disease and extrahepatic hemosiderin deposition.[49] Neonatal hemochromatosis is not an inherited disease; liver injury, leading to hemosiderin accumulation, occurs in utero, and might be related to maternal alloimmune injury to the fetal liver. Extrahepatic hemosiderin deposition, detected by buccal biopsy, needs to be documented for the correct diagnosis. There is no specific treatment, except for supportive care, and liver transplantation in severe cases.

The most common causes of *hemosiderosis* (secondary or acquired hemochromatosis) are disorders associated with ineffective erythropoiesis, such as severe forms of thalassemia (Chapter 14) and myelodysplastic syndromes (Chapter 13). In these disorders, the excess iron results not only from transfusions, but also from increased absorption. Transfusions alone, when given repeatedly over a period of years (such as in patients with chronic hemolytic anemias), can also lead to systemic hemosiderosis and parenchymal organ injury. *Alcoholic cirrhosis* is often associated with a modest increase in stainable iron within liver cells. However, this represents alcohol-induced redistribution of iron, since total body iron is not significantly increased. A rather unusual form of iron overload resembling hereditary hemochromatosis occurs in sub-Saharan Africa, the result of ingesting large quantities of alcoholic beverages fermented in iron utensils (Bantu siderosis). Home brewing in steel drums continues to this day, and genetic susceptibility to this disease, such as mutations of ferroportin has been proposed in these populations.[50] Lastly, chronic HBV and HCV infection may increase iron storage within hepatocytes.

WILSON DISEASE

Wilson disease is an autosomal recessive disorder caused by mutation of the *ATP7B* gene, resulting in impaired copper excretion into bile and a failure to incorporate copper into *ceruloplasmin*.[51] This disorder is marked by *the accumulation of toxic levels of copper in many tissues and organs, principally the liver, brain, and eye*. Normally, 40% to 60% of ingested copper (2 to 5 mg/day) is absorbed in the duodenum and proximal small intestine, and is transported to the portal circulation complexed with albumin and histidine. Free copper dissociates and is taken up by hepatocytes. Copper is incorporated into enzymes and also binds to a α_2-globulin (apoceruloplasmin) to form ceruloplasmin, which is secreted into the blood. Excess copper is transported into the bile. Ceruloplasmin accounts for 90% to 95% of plasma copper. Circulating ceruloplasmin is eventually desialylated, endocytosed by the liver, and degraded within lysosomes, after which the released copper is excreted into bile. This degradation/excretion pathway is the primary route for copper elimination. The estimated total body copper is only 50 to 150 mg.

The *ATP7B* gene, located on chromosome 13, encodes a transmembrane copper-transporting ATPase, expressed on the hepatocyte canalicular membrane. More than 300 mutations in the *ATP7B* gene have been identified, but not all genes cause the disease. *The overwhelming majority of patients are compound heterozygotes containing different mutations on each ATP7B allele*. The overall frequency of mutated alleles is 1 : 100, and the prevalence of the disease of approximately 1 : 30,000 to 1 : 50,000 (approximately 9000 patients in the United States). *Deficiency in the ATP7B protein causes a decrease in copper transport into bile, impairs its incorporation into ceruloplasmin, and inhibits ceruloplasmin secretion into the blood*. These changes cause copper accumulation in the liver and a decrease in circulating ceruloplasmin. The copper causes toxic liver injury, through the production of ROS by the Fenton reaction (Chapter 1). Although there is a latent period of variable duration for the disease, once the hepatic capacity for incorporating copper into ceruloplasmin is exceeded, there may be sudden onset of critical systemic illness. Specifically, non-ceruloplasmin–bound copper spills over from the liver into

the circulation, causing hemolysis and pathologic changes at other sites such as the brain, corneas, kidneys, bones, joints, and parathyroids. Concomitantly, urinary excretion of copper markedly increases from its normal minuscule levels.

Morphology. The liver often bears the brunt of injury, but the disease may also present as a neurologic disorder. The hepatic changes are variable, ranging from relatively minor to massive damage. **Fatty change (steatosis)** may be mild to moderate, with vacuolated nuclei (glycogen or water) and occasionally, focal hepatocyte necrosis. An **acute hepatitis** can show features mimicking acute viral hepatitis, except possibly for the accompanying fatty change. The **chronic hepatitis** of Wilson disease exhibits moderate to severe inflammation and hepatocyte necrosis, with the particular features of macrovesicular steatosis, vacuolated hepatocellular nuclei, and Mallory bodies. With progression of chronic hepatitis, **cirrhosis** will develop. **Massive liver necrosis** is a rare manifestation that is indistinguishable from that caused by viruses or drugs. Excess copper deposition can often be demonstrated by special stains (rhodamine stain for copper, orcein stain for copper-associated protein). Because copper also accumulates in chronic obstructive cholestasis and because histology cannot reliably distinguish Wilson disease from viral- and drug-induced hepatitis, demonstration of hepatic copper content in excess of 250 μg per gram dry weight is most helpful for making a diagnosis.

In the **brain**, toxic injury primarily affects the basal ganglia, particularly the putamen, which shows atrophy and even cavitation. Nearly all patients with neurologic involvement develop **eye lesions** called **Kayser-Fleischer rings**, green to brown deposits of copper in Desçemet's membrane in the limbus of the cornea.

Clinical Features.

The age at onset and the clinical presentation of Wilson disease are extremely variable (average age is 11.4 years), but the disorder usually manifests in affected individuals between 6 and 40 years of age. The most common presentation is *acute or chronic liver disease*. Neuropsychiatric manifestations, including mild behavioral changes, frank psychosis, or a *Parkinson disease–like syndrome* (such as tremor), are the initial features in most of the remaining cases. The biochemical diagnosis of Wilson disease is based on *a decrease in serum ceruloplasmin, an increase in hepatic copper content (the most sensitive and accurate test), and increased urinary excretion of copper (the most specific screening test)*. Serum copper levels are of no diagnostic value, since they may be low, normal, or elevated, depending on the stage of evolution of the disease. Demonstration of Kayser-Fleischer rings further favors the diagnosis. Early recognition and long-term copper chelation therapy (as with D-penicillamine, or Trientine) or zinc-based therapy has dramatically altered the usual progressive downhill course. Individuals with hepatitis or unmanageable cirrhosis require liver transplantation for survival, which can also lead to eventual cure.

α_1-ANTITRYPSIN DEFICIENCY

α_1-Antitrypsin deficiency is an autosomal recessive disorder marked by very low levels of α_1-antitrypsin. The major function of this protein is the inhibition of proteases, particularly neutrophil elastase, cathepsin G, and proteinase 3, which are normally released from neutrophils at sites of inflammation. α_1-Antitrypsin deficiency leads to the development of pulmonary emphysema, because the activity of destructive proteases is not inhibited (discussed in Chapter 15). It also causes liver disease, as a consequence of the accumulation of this protein in hepatocytes.[52] In addition, cutaneous panniculitis, arterial aneurysm, bronchiectasis, and Wegener's granulomatosis can occur in α_1-antitrypsin deficiency.

α_1-Antitrypsin is a small 394–amino acid plasma glycoprotein synthesized predominantly by hepatocytes. It is a member of the serine protease inhibitor (serpin) family. The gene, located on chromosome 14, is very polymorphic, and at least 75 α_1-antitrypsin forms have been identified, denoted alphabetically by their relative migration on an isoelectric gel. The general notation is "Pi" for "protease inhibitor" and an alphabetic letter for the position on the gel; two letters denote the genotype of the two alleles. The most common genotype is PiMM, occurring in 90% of individuals (in the traditional sense, this would be the wild-type genotype). Most allelic variants show substitutions in the polypeptide chain but produce normal levels of functional α_1-antitrypsin. Some *deficiency variants*, including the PiS variant, result in a moderate reduction in serum concentrations of α_1-antitrypsin without clinical manifestations. Rare variants termed *Pi-null* have no detectable serum α_1-antitrypsin. The most common clinically significant mutation is PiZ; homozygotes for the PiZZ protein have circulating α_1-antitrypsin levels that are only 10% of normal. These individuals are at high risk for developing clinical disease. Expression of alleles is autosomal codominant, and consequently, PiMZ heterozygotes have intermediate plasma levels of α_1-antitrypsin. Among people of northern European descent the PiS frequency is 6% and the PiZ frequency is 4%; the PiZZ state affects 1 in 1800 live births. Because of its occasionally early presentation for liver disease, α_1-antitrypsin deficiency is the most commonly diagnosed genetic hepatic disorder in infants and children.

Pathogenesis.

With most allelic variants, the mRNA is transcribed, and the protein is synthesized and secreted normally. Deficiency variants show a selective defect in migration of this secretory protein from the endoplasmic reticulum to Golgi apparatus; this is most marked for the PiZ polypeptide, attributable to a single amino acid substitution of Glu342 to Lys342. *The mutant polypeptide (α_1AT-Z) is abnormally folded and polymerizes,* creating endoplasmic reticulum stress and leading to apoptosis (Chapter 1 ; see Fig. 1-27). The precise mechanisms of liver disease with α_1AT-Z are not well defined. The accumulated α_1AT-Z in the endoplasmic reticulum triggers a series of events, including an autophagocytic response, mitochondrial dysfunction, and possible activation of pro-inflammatory NF-κB, causing hepatocyte damage.[53] All individuals with the PiZZ genotype accumulate α_1AT-Z in the endoplasmic reticulum of hepatocytes, but only 10% to 15% of PiZZ individuals develop overt clinical liver disease. Other genetic factors or environmental factors are thus posited to play a role in the development of liver disease.

Morphology. α_1-Antitrypsin deficiency is characterized by the presence of round-to-oval cytoplasmic globular inclusions in hepatocytes, which in routine H&E stains are acidophilic and indistinctly demarcated from the surrounding cytoplasm. They are strongly periodic acid–Schiff (PAS)-positive and diastase-resistant (Fig. 18-27). The globules are also present but in diminished size and number in the PiMZ and PiSZ genotypes. For unknown reasons most of the globules are in hepatocytes surrounding the portal tracts. Moreover, the number of globule-containing hepatocytes in a patient's liver is not correlated with the severity of pathologic findings. The hepatic pathology associated with PiZZ homozygosity is extremely varied, ranging from neonatal hepatitis (Fig. 18-28) without or with cholestasis and fibrosis (discussed below), to childhood cirrhosis, to a smoldering chronic inflammatory hepatitis or cirrhosis that becomes apparent only late in life. For the most part the only distinctive feature of the hepatic disease is the PAS-positive globules; infrequently, fatty change and Mallory bodies are present. The diagnostic α_1-antitrypsin globules may be absent in the young infant; steatosis may be present as a tip-off to the possibility of α_1-antitrypsin deficiency.

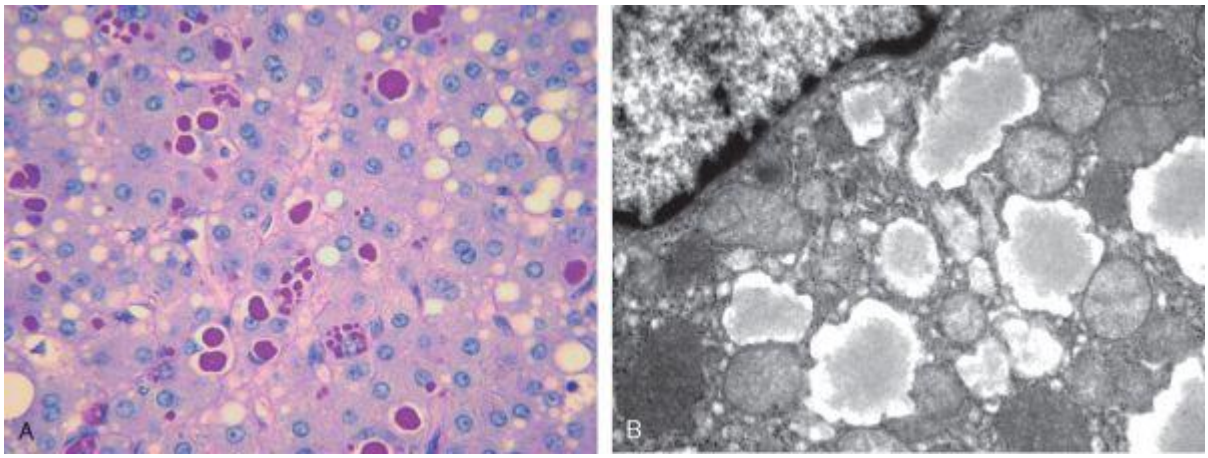

FIGURE 18-27 α_1-Antitrypsin deficiency. **A**, Periodic acid–Schiff (PAS) stain of the liver, highlighting the characteristic red cytoplasmic granules. **B**, Electron micrograph showing the dilatation of the endoplasmic reticulum.

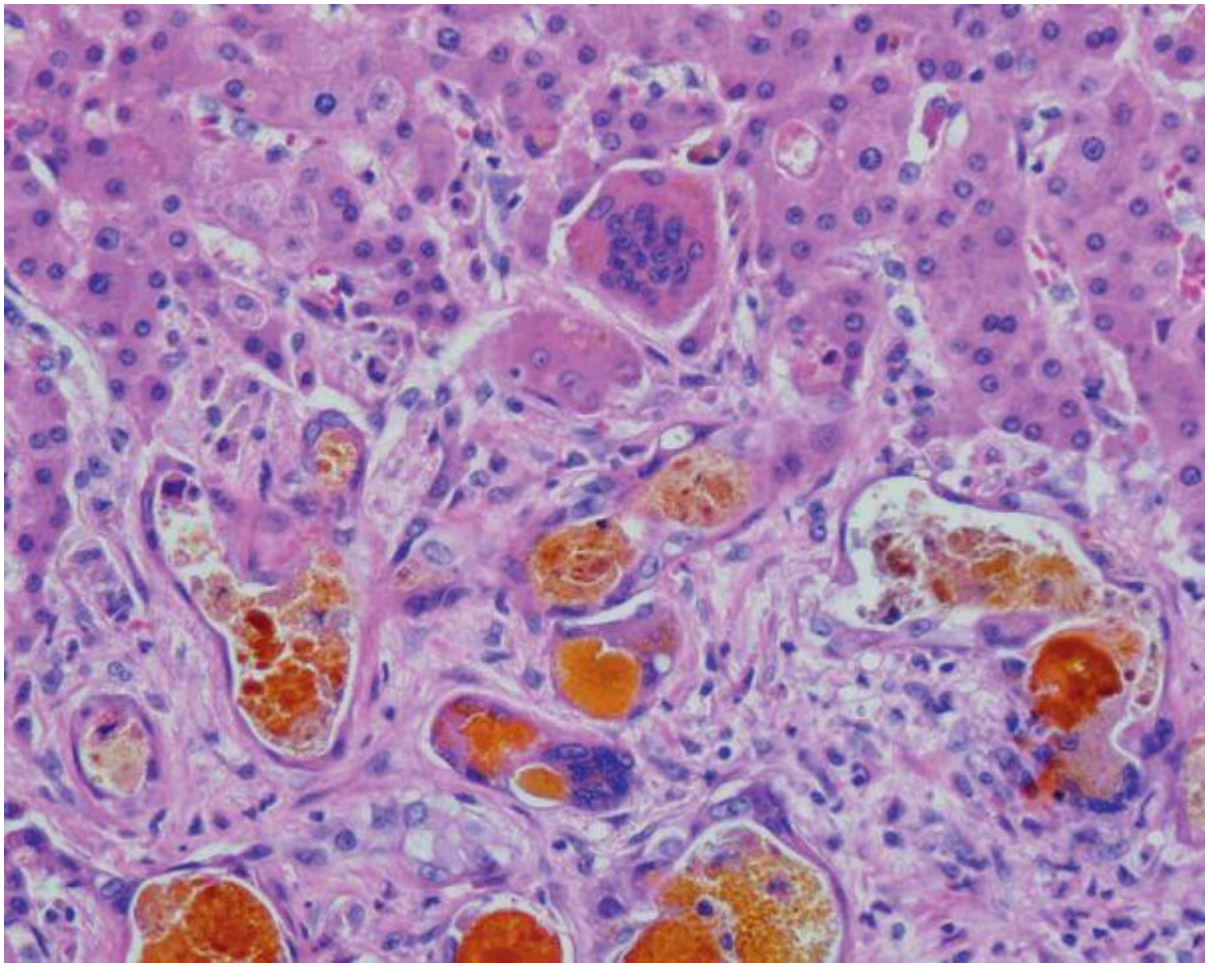

FIGURE 18-28 Neonatal hepatitis caused by α_1-antitrypsin deficiency. Note the severe cholestasis.

Clinical Features.

Neonatal hepatitis with cholestatic jaundice appears in 10% to 20% of newborns with the deficiency. In adolescence, presenting symptoms may be related to hepatitis or cirrhosis. Attacks of hepatitis may subside with apparent complete recovery, or they may become chronic and lead progressively to cirrhosis. Finally, the disease may remain silent until cirrhosis appears in middle to later life. HCC develops in 2% to 3% of PiZZ adults, usually but not always in the setting of cirrhosis. The treatment, and the cure, for severe hepatic disease is orthotopic liver transplantation. In patients with pulmonary disease the single most important treatment is avoidance of cigarette smoking, because smoking markedly accelerates emphysema and the destructive lung disease associated with α_1-antitrypsin deficiency.

NEONATAL CHOLESTASIS

Prolonged conjugated hyperbilirubinemia in the neonate, termed *neonatal cholestasis*, affects approximately 1 in 2500 live births. The major conditions causing it are (1) cholangiopathies, primarily *biliary atresia* (discussed later), and (2) a variety of disorders causing conjugated hyperbilirubinemia in the neonate, collectively referred to as *neonatal hepatitis*. *Neonatal cholestasis and hepatitis are not specific entities, nor are the disorders necessarily inflammatory*. Instead, the finding of "neonatal cholestasis" should evoke a diligent search for recognizable toxic, metabolic, and infectious liver diseases, the more common of which are listed in Table 18-7 . Once identifiable causes have been excluded, one is left with the syndrome of "idiopathic" neonatal hepatitis, which shows considerable clinical overlap with biliary atresia. Despite the long list of disorders associated with neonatal cholestasis, most are quite rare. "Idiopathic" neonatal hepatitis represents as many as 50% of cases, biliary atresia represents another 20%, and α_1-antitrypsin deficiency represents 15%. Differentiation of biliary atresia from nonobstructive neonatal cholestasis assumes great importance, since definitive treatment of biliary atresia requires surgical intervention (Kasai procedure), whereas surgery may adversely affect the clinical course of a child with other disorders. Fortunately, discrimination can be made with clinical data in about 90% of cases, with or without liver biopsy. Affected infants have jaundice, dark urine, light or acholic stools, and hepatomegaly. Variable degrees of hepatic synthetic dysfunction may be identified, such as hypoprothrombinemia. Thus, liver biopsy is critical in distinguishing neonatal hepatitis from an identifiable cholangiopathy.

TABLE 18-7 -- Major Causes of Neonatal Cholestasis

Bile duct obstruction
Extrahepatic biliary atresia
Neonatal infection
Cytomegalovirus
Bacterial sepsis
Urinary tract infection

- α_1-Antitrypsin deficiency
- Cystic fibrosis

Miscellaneous

- Shock/hypoperfusion
- Indian childhood cirrhosis
- Alagille syndrome (paucity of bile ducts)

Idiopathic neonatal hepatitis

Morphology. The morphologic features of neonatal hepatitis include lobular disarray with focal liver cell apoptosis and necrosis, panlobular giant-cell transformation of hepatocytes (Fig. 18-29), prominent hepatocellular and canalicular cholestasis, mild mononuclear infiltration of the portal areas, reactive changes in Kupffer cells, and extramedullary hematopoiesis. This predominantly parenchymal pattern of injury may blend imperceptibly into a ductal pattern of injury, with bile ductular proliferation and fibrosis of portal tracts. In these cases distinction from an obstructive biliary atresia may therefore be difficult.

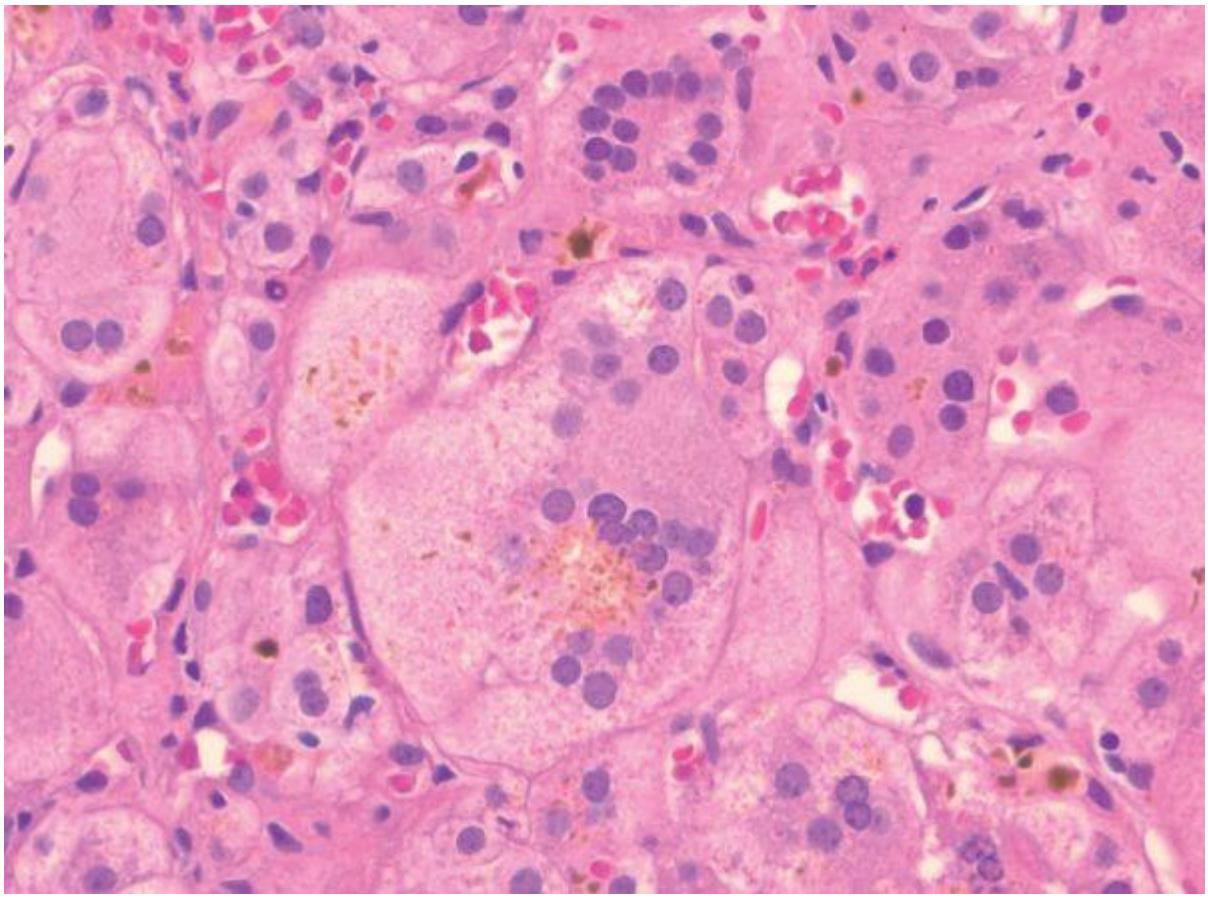

FIGURE 18-29 Neonatal hepatitis. Note the multinucleated giant hepatocytes.

3.8.1.6 Intrahepatic Biliary Tract Disease

In this section we discuss three disorders of intrahepatic bile ducts: *secondary biliary cirrhosis*, *primary biliary cirrhosis*, and *primary sclerosing cholangitis* (summarized in Table 18-8). Secondary biliary cirrhosis is a condition resulting most often from uncorrected obstruction of the extrahepatic biliary tree. Primary biliary cirrhosis is a destructive disorder of the intrahepatic biliary tree. Primary selerosing cholangitis involves both the extrahepatic and intrahepatic biliary tree. It should also be noted that intrahepatic bile ducts are frequently damaged as part of more general liver diseases as in drug toxicity, viral hepatitis, liver transplantation, and graft-versus-host disease after bone marrow transplantation.

TABLE 18-8 -- Distinguishing Features of the Major Intrahepatic Bile Duct Disorders

	Secondary Biliary Cirrhosis	Primary Billiary Cirrhosis	Primary Sclerosing Cholangitis
Etiology	Extrahepatic bile duct obstruction: biliary atresia, gallstones, stricture, carcinoma of pancreatic head	Possibly autoimmune	Unknown, possibly autoimmune; 50% to 70% associated with inflammatory bowel disease
Sex predilection	None	Female to male, 6 : 1	Female to male, 1 : 2
Symptoms and signs	Pruritus, jaundice, malaise, dark urine, light stools, hepatosplenomegaly	Same as secondary biliary cirrhosis; insidious onset	Same as secondary biliary cirrhosis; insidious onset
Laboratory findings	Conjugated hyperbilirubinemia, increased serum alkaline phosphatase, bile acids, cholesterol	Same as secondary biliary cirrhosis, plus elevated serum IgM autoantibodies (especially M2 form of anti-mitochondrial antibody)	Same as secondary biliary cirrhosis, plus elevated serum IgM, hypergammaglobulinemia
Important pathologic findings before cirrhosis develops	Prominent bile stasis in bile ducts, bile ductular proliferation with surrounding neutrophils, portal tract edema	Dense lymphocytic infiltrate in portal tracts with granulomatous destruction of bile ducts	Periductal portal tracts fibrosis, segmental stenosis of extrahepatic and intrahepatic bile ducts

SECONDARY BILIARY CIRRHOSIS

Prolonged obstruction of the extrahepatic biliary tree results in profound hepatic alterations. The most common cause of obstruction in adults is *extrahepatic cholelithiasis* (gallstones, described later), followed by *malignancies* of the biliary tree or head of the pancreas, and strictures resulting from previous *surgical procedures*. Obstructive conditions in children include biliary atresia, cystic fibrosis, choledochal cysts (a cystic anomaly of the extrahepatic biliary tree, discussed later), and syndromes in which there are insufficient intrahepatic bile ducts (paucity of bile duct syndromes). The initial morphologic features of *cholestasis* were described earlier and are entirely reversible with correction of the obstruction. However, secondary inflammation resulting from biliary obstruction initiates periportal fibrosis, which eventually leads to hepatic scarring and nodule formation, generating secondary biliary cirrhosis. Subtotal obstruction may promote secondary bacterial infection of the biliary tree *(ascending cholangitis)*, which aggravates the inflammatory injury. Enteric organisms such as coliforms and enterococci are common culprits.

Morphology. The end-stage obstructed liver shows yellow-green pigmentation that is accompanied by marked icteric discoloration of body tissues and fluids. On cut surface the liver is hard, with a finely granular appearance (Fig. 18-30). The histology is characterized by coarse fibrous septa that subdivide the liver in a jigsaw-like pattern. Embedded in the septa are distended small and large bile ducts, which frequently contain inspissated pigmented material. There is extensive **proliferation of smaller bile ductules**, particularly at the interface between septa in former portal tracts and the parenchyma. Cholestatic features in the parenchyma may be severe, with extensive **feathery degeneration** and formation of **bile lakes**. However, once regenerative nodules have formed, bile stasis may become less conspicuous. Ascending bacterial infection incites a robust neutrophilic infiltration of bile ducts; severe pylephlebitis and cholangitic abscesses may develop.

FIGURE 18-30 Biliary cirrhosis. Sagittal section through the liver demonstrates the fine nodularity and bile staining of end-stage biliary cirrhosis.

PRIMARY BILIARY CIRRHOSIS (PBC)

PBC is an inflammatory autoimmune disease mainly affecting the intrahepatic bile ducts. *The primary feature of this disease is a nonsuppurative, inflammatory destruction of medium-sized intrahepatic bile ducts*. It is accompanied by portal inflammation, scarring, and eventual development of cirrhosis and liver failure.[54] Because cirrhosis develops only after many years, the disease name is somewhat misleading for patients diagnosed early at a pre-cirrhotic stage.

This is primarily a disease of middle-aged women, with a female predominance over males in excess of 6 : 1. It may occur between the ages of 20 and 80 years, with peak incidence between 40 and 50 years of age. The incidence of this disease in the United States is approximately 27 per million people (7 and 45 per million in males and females, respectively). Both the incidence and prevalence of PBC are increasing and geographic clustering has been reported, suggesting that genetic and environmental factors are important in the pathogenesis of the disease. Family members of PBC patients have an increased risk of developing the disease. The onset is insidious, usually presenting with fatigue and pruritus. Hepatomegaly is a typical finding, and eyelid xanthelasmas arise as a result of infiltration of the nasal area of the eyelid by cholesterol-rich macrophages. Hyperpigmentation due to melanin deposition and an inflammatory arthropathy are seen in 25% to 40% of cases. Signs and symptoms of chronic liver disease, such as spider nevi, are late features. Over a period of two or more decades, patients develop cirrhosis and complications that include portal hypertension with variceal bleeding, and hepatic encephalopathy.

Serum *alkaline phosphatase and cholesterol are almost always elevated*, even at onset; hyperbilirubinemia is a late development and usually signifies incipient hepatic decompensation. *Antimitochondrial* antibodies are present in 90% to 95% of patients. They are highly characteristic of PBC and an essential element for diagnosis, together with the elevation of alkaline phosphatase and γ-glutamyltransferase, which are markers of cholestasis.

Pathogenesis.

PBC is thought to be an autoimmune disorder, but its pathogenesis is still unknown. Many potential mechanisms have been proposed, including aberrant expression of MHC class II molecules on bile duct epithelial cells, accumulation of autoreactive T cells around bile ducts, reaction of antimitochondrial antibodies to hepatocytes, or of other antibodies against cellular components (nuclear pore proteins, and centromeric proteins, among others).[55] The antimitochondrial antibodies, the characteristic autoantibodies in PBC, target the E2 component of the pyrurate dehydrogenase complex (PDC-E2). PDC-E2–specific T cells are also present in these patients, supporting the notion of immune-mediated pathogenesis.[56]

Morphology. PBC is the prototype of conditions leading to **small-duct biliary fibrosis and cirrhosis**. PBC is a focal and variable disease, showing different degrees of severity in different portions of the liver. During the pre-cirrhotic stage portal tracts are **infiltrated by a dense accumulation of lymphocytes, macrophages, plasma cells, and occasional eosinophils**. Interlobular bile ducts are infiltrated by lymphocytes and may show noncaseating granulomatous inflammation (Fig. 18-31) and undergo progressive destruction. With time the obstruction to intrahepatic bile flow leads to progressive secondary hepatic damage. Portal tracts upstream from damaged bile ducts show bile ductular proliferation, inflammation, and necrosis of the adjacent periportal hepatic parenchyma. The parenchyma develops generalized cholestasis. Over years to decades, relentless portal tract scarring and bridging fibrosis lead to cirrhosis.

Macroscopically, the liver does not at first appear abnormal, but as the disease progresses bile stasis stains the liver green. The capsule remains smooth and glistening until a fine granularity appears, representing deposition of fibrous septa. This process culminates in a well-developed, uniform micronodular cirrhosis. Liver weight is at first normal to increased (because of inflammation) but is ultimately decreased. **In most cases the end-stage picture is indistinguishable from secondary biliary cirrhosis or the cirrhosis that follows chronic hepatitis from other causes**.

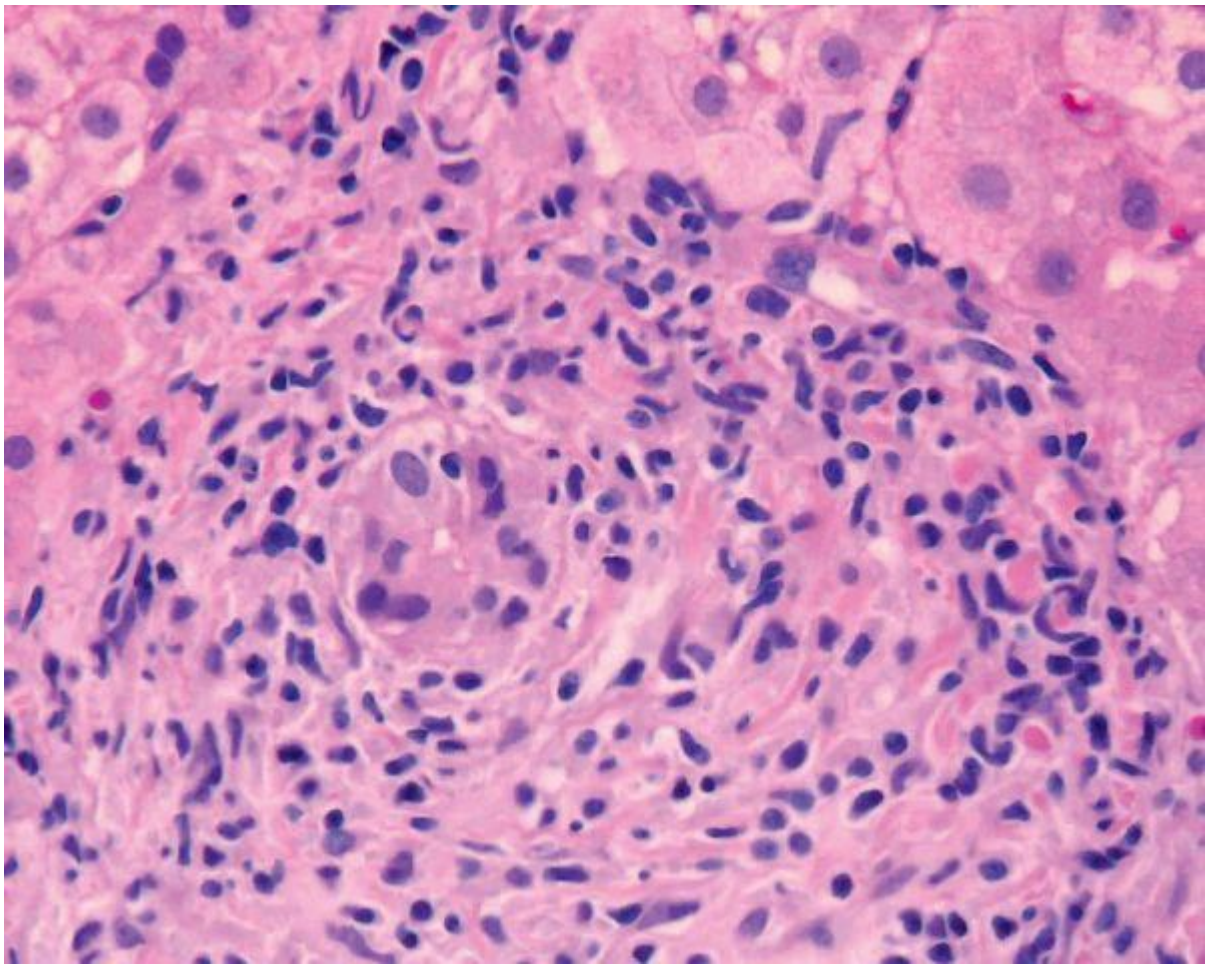

FIGURE 18-31 Primary biliary cirrhosis. A portal tract is markedly expanded by an infiltrate of lymphocytes and plasma cells. There is a granulomatous reaction to a bile duct undergoing destruction (florid duct lesion).

Clinical Features.

The onset is extremely insidious, and patients may be symptom-free for many years. Eventually, *pruritus*, *fatigue*, and abdominal discomfort develop, followed in time by secondary features: skin pigmentation, xanthelasmas, steatorrhea, and vitamin D malabsorption–related osteomalacia and/or osteoporosis. More general features of jaundice and hepatic decompensation, including portal hypertension and variceal bleeding, mark entry into the end stages of the disease. PBC patients have an *increased risk to develop hepatocellular carcinomas*. The major cause of death is liver failure, followed in order by massive variceal hemorrhage and intercurrent infection. Individuals with PBC may also have extrahepatic manifestations of autoimmunity, including the sicca complex of dry eyes and mouth (Sjögren syndrome; from the Latin *sicca*, meaning dryness), systemic sclerosis, thyroiditis, rheumatoid arthritis, Raynaud phenomenon, membranous glomerulonephritis, and celiac disease. There is no specific therapy for PBC but treatment with ursodeoxycholic acid, if started early, can provide complete remission and prolong survival is 25% to 30% of cases. Its mechanism of action is not well understood. Liver transplantation is the best form of treatment for persons with end-stage liver disease.

PRIMARY SCLEROSING CHOLANGITIS (PSC)

PSC is characterized by inflammation and obliterative fibrosis of intrahepatic and extrahepatic bile ducts, with dilation of preserved segments. Characteristic "beading" of a contrast medium in radiographs of the intrahepatic and extrahepatic biliary tree is attributable to the irregular strictures and dilations of affected bile ducts. *PSC is commonly seen in association with inflammatory bowel disease* (see Chapter 17), particularly chronic ulcerative colitis, which coexists in approximately 70% of individuals with primary sclerosing cholangitis. Conversely, the prevalence of PSC in persons with ulcerative colitis is about 4%. PSC tends to occur in the third through fifth decades of life, and males predominate 2 : 1. (See Table 18-8 for comparisons with primary and secondary biliary cirrhosis.)

Pathogenesis.

Primary sclerosing cholangitis is a chronic cholestatic disorder characterized by non-specific inflammation, fibrosis and strictures of intra- and extrahepatic bile ducts.[57] Several features of the disease suggest that it results from immunologically mediated injury to bile ducts. These include the detection of T cells in the periductal stroma, the presence of a plethora of circulating autoantibodies, and the association with ulcerative colitis. It has been proposed that T cells activated in the gut mucosa travel to the liver where they recognize a bile duct antigen that cross-reacts with gut antigens. Another proposed etiology is that the bile duct lesions are a consequence of cross-reaction of bile duct antigens with enteric bacteria or bacterial products. Antibodies commonly found in patients with primary sclerosing cholangitis include anti-smooth muscle antibodies, anti-nuclear antibodies (ANAs), rheumatoid factor, and an atypical p-ANCA which shows a perinuclear staining pattern but is directed against a nuclear envelope protein, instead of myeloperoxidase as is typical of p-ANCA antibodies. The atypical p-ANCA is found in up to 80% of patients, but its relationship with the pathogenesis of the disease is unknown. First degree relatives of patients with primary sclerosing cholangitis have an increased risk of developing the disease. As with many other immunologically mediated diseases, primary sclerosing cholangitis is associated with an increased prevalence of certain MHC class I and class II haplotypes.[58]

Morphology. PSC is a fibrosing cholangitis of bile ducts, with a lymphocytic infiltrate, progressive atrophy of the bile duct epithelium, and obliteration of the lumen (Fig. 18-32). The concentric periductal fibrosis around affected ducts ("onion-skin fibrosis") is followed by their disappearance, leaving behind a solid, cordlike fibrous scar. In between areas of progressive stricture, bile ducts become ectatic and inflamed, presumably the result of downstream obstruction. As the disease progresses the liver becomes markedly cholestatic, culminating in biliary cirrhosis much like that seen with primary and secondary biliary cirrhosis.

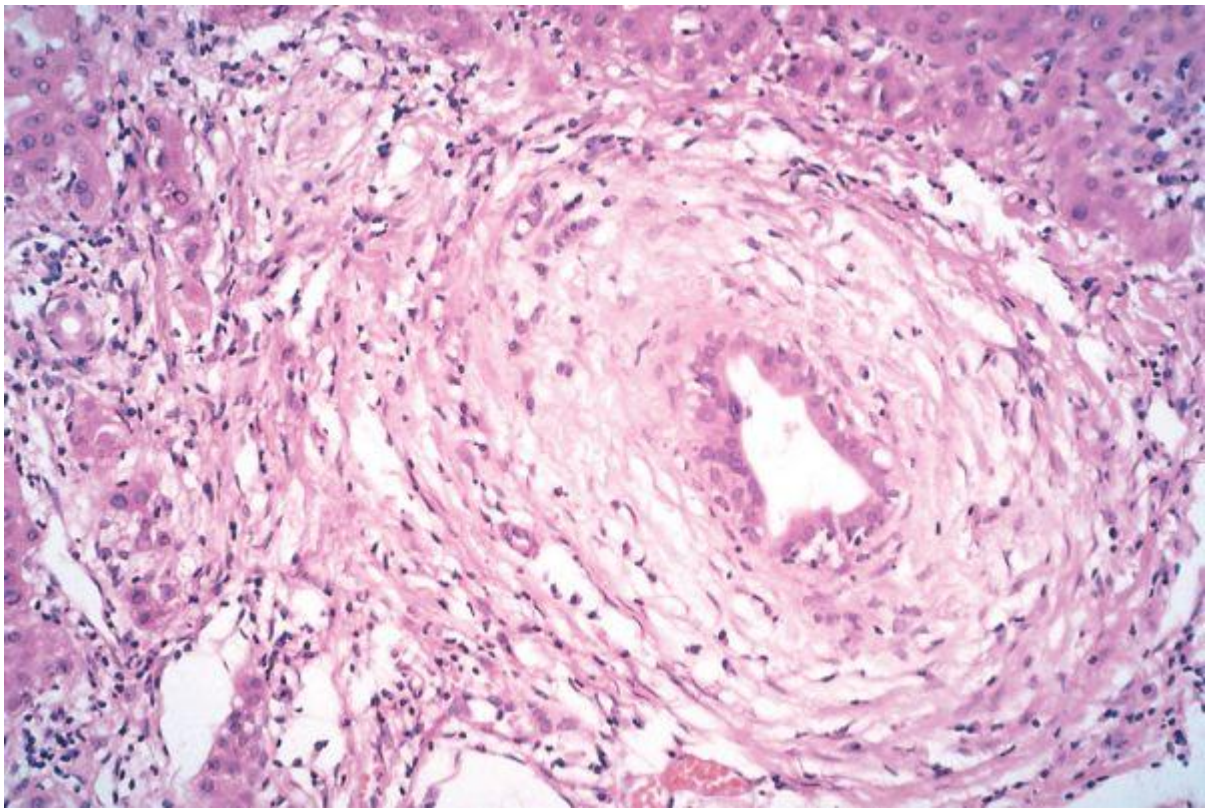

FIGURE 18-32 Primary sclerosing cholangitis. A bile duct undergoing degeneration is entrapped in a dense, "onion-skin" concentric scar.

Clinical Features.

Asymptomatic patients may come to attention only because of persistent elevation of serum alkaline phosphatase. Alternatively, progressive fatigue, pruritus, and jaundice may develop. The disease follows a protracted course of 5 to 17 years, and the severely afflicted patients have the usual symptoms of chronic liver disease, including weight loss, ascites, variceal bleeding, and encephalopathy. Approximately 7% of individuals with PSC develop *cholangiocarcinoma*, a very high frequency relative to that of the general population. The incidence of *chronic pancreatitis* and *hepatocellular carcinoma* also seems to be increased in PSC patients. A distinctive type of sclerosing cholangitis, with elevated IgG4 and associated with autoimmune pancreatitis, has been recognized recently.[59] There is no specific medical therapy for PSC. Cholestyramine has been used for pruritus, and endoscopic dilation with sphincterotomy or stenting is used for relieving symptoms. *Liver transplantation* is the definitive treatment for persons with end-stage liver disease.

ANOMALIES OF THE BILIARY TREES (INCLUDING LIVER CYSTS)

A heterogeneous group of lesions exist in which the primary abnormality is altered architecture or paucity of the intrahepatic biliary tree. Lesions may be found incidentally during radiographic studies, surgery, or at autopsy. Such conditions may become manifest as hepatosplenomegaly and portal hypertension in the absence of hepatic dysfunction, starting in late childhood or adolescence. There are five distinct conditions: von Meyenburg complexes, polycystic liver disease, congenital hepatic fibrosis, Caroli disease, and Alagille syndrome.

Von Meyenburg Complexes.

These are small clusters of modestly dilated bile ducts embedded in a fibrous, sometimes hyalinized, stroma located close to or within portal tracts. These lesions are often referred to as “bile duct hamartomas” (Fig. 18-33). Von Meyenburg complexes are common and without clinical significance except in the differential diagnosis of metastases to the liver.

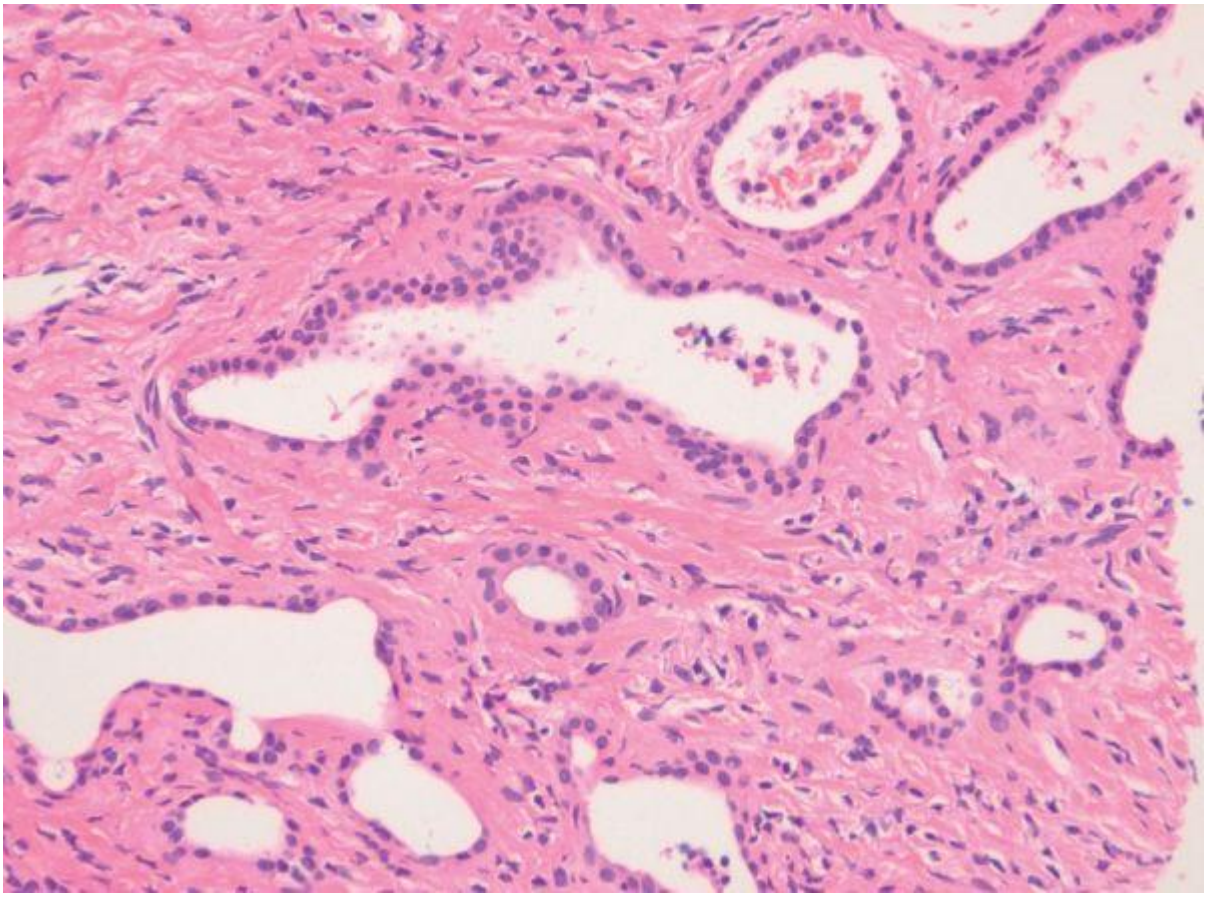

FIGURE 18-33 Bile duct hamartoma (von Meyenburg complexes). Note the dilated and irregularly shaped bile ducts.

Polycystic Liver Disease.

In this disease there are multiple diffuse cystic lesions in the liver, varying in number from a scattered few to hundreds (Fig. 18-34). The cysts, lined by cuboidal or flattened biliary epithelium, contain straw-colored fluid.

FIGURE 18-34 Polycystic liver disease.

Congenital Hepatic Fibrosis.

In this condition portal tracts are enlarged by irregular, broad bands of collagenous tissue, forming septa that divide the liver into irregular islands. Variable numbers of abnormally shaped bile ducts are embedded in the fibrous tissue, and are in continuity with the biliary tree. This anomaly arises because of persistence of the embryonic form of the biliary tree, with ensuing portal tract fibrosis over the individual's lifetime. Although individuals with congenital hepatic fibrosis rarely develop cirrhosis, they may still face complications of portal hypertension, particularly bleeding varices.

Caroli Disease.

In this disease the larger ducts of the intrahepatic biliary tree are segmentally dilated and may contain inspissated bile. Pure forms are rare; this disease is usually associated with portal tract fibrosis of the congenital hepatic fibrosis type. The disease is frequently complicated by intrahepatic cholelithiasis (described later), cholangitis, hepatic abscesses, and portal hypertension. Persons with Caroli disease and congenital hepatic fibrosis have an increased risk of developing cholangiocarcinomas.

Each of the four conditions discussed above can be associated with polycystic kidney disease. Single or multiple liver cysts are the most frequent extrarenal manifestation of autosomal-dominant polycystic kidney disease caused by a mutation in *PKD1* (Chapter 20), and occur in 75% to 90% of patients with this type of kidney disease.[60] A form of polycystic liver disease caused by mutations of the *PRKCSH* gene (which encodes a protein kinase C substrate 80K-H) does not coexist with polycystic kidney disease.[61] Congenital hepatic fibrosis is strongly associated with the autosomal recessive form of polycystic kidney disease, which is caused by mutations of the *PKHD1* (polycystic kidney and hepatic disease) gene.[62] The exact pathogenesis of these biliary lesions and the basis of their association with polycystic kidney disorders remain unclear.

Alagille Syndrome (Syndromatic Paucity of Bile Ducts; Arteriohepatic Dysplasia).

This is a rare autosomal dominant multi-organ disorder, in which *the liver pathology is characterized by absence of bile ducts in portal tracts*. The syndrome is caused by mutations or deletion of the gene encoding *Jagged1*, which is located on chromosome 20p. Jagged1 is a cell surface protein that functions as a ligand for Notch receptors (Chapter 3). Mutations in Jagged can be detected in as many as 94% of individuals with a clinical diagnosis of Alagille syndrome, and some of the remaining patients have mutations in the Notch 2 receptor.[63] The Jagged1-Notch signaling pathway regulates cell fate and is involved in the development of the organ systems affected in Alagille syndrome. Affected patients have five major clinical features: chronic cholestasis, peripheral stenosis of the pulmonary artery, butterfly-like vertebral arch defects, an eye defect known as posterior embryotoxon, and a peculiar hypertelic facies. Patients can survive into adulthood but are at risk for hepatic failure and hepatocellular carcinoma.

3.8.1.7 Circulatory Disorders

Given the enormous flow of blood through the liver, it is not surprising that circulatory disturbances have considerable impact on the liver. In most instances, however, clinically significant abnormalities of liver function do not develop, but hepatic morphology may be strikingly affected. These disorders can be grouped according to whether blood flow into, through, or from the liver is impaired (Fig. 18-35).

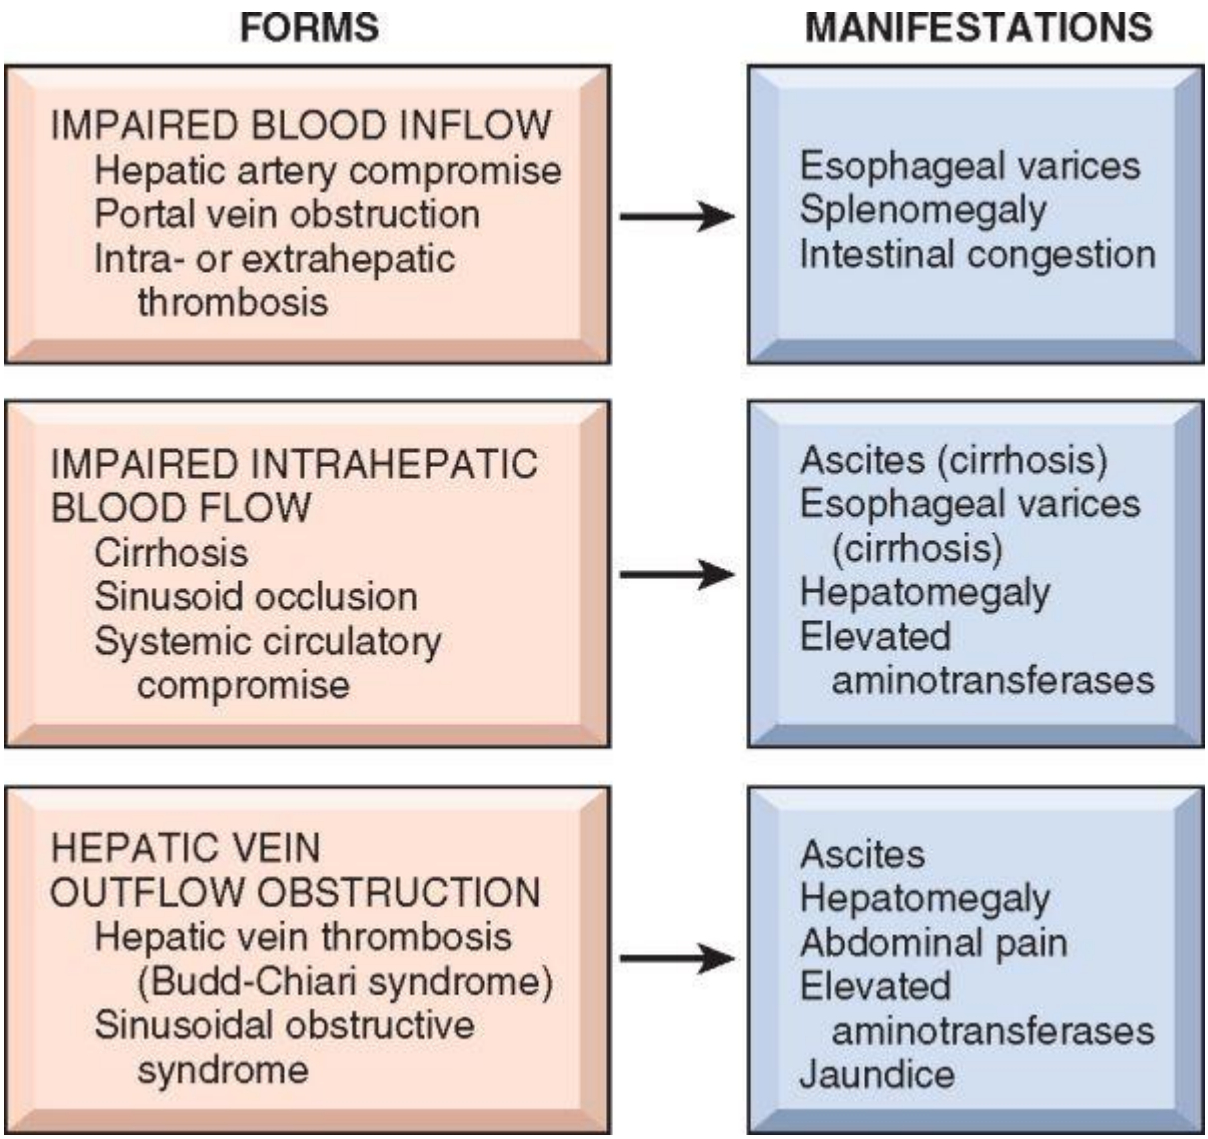

FIGURE 18-35 Hepatic circulatory disorders. Forms and clinical manifestations of compromised hepatic blood flow.

IMPAIRED BLOOD FLOW INTO THE LIVER

Hepatic Artery Compromise

Liver infarcts are rare, thanks to the double blood supply to the liver. Nonetheless, thrombosis or compression of an intrahepatic branch of the hepatic artery by embolism (Fig. 18-36), neoplasia, polyarteritis nodosa (Chapter 11), or sepsis may result in a localized infarct that is usually anemic and pale tan, or sometimes hemorrhagic, as a result of suffusion of portal blood. Interruption of the main hepatic artery does not always produce ischemic necrosis of the organ, particularly if the liver is otherwise normal. Retrograde arterial flow through accessory vessels, when coupled with the portal venous supply, is usually sufficient to sustain the liver parenchyma. The one exception is hepatic artery thrombosis in a transplanted liver, which generally leads to infarction of the major ducts of the biliary tree and loss of the organ.

FIGURE 18-36 Liver infarct. A thrombus is lodged in a peripheral branch of the hepatic artery and compresses the adjacent portal vein; the distal hepatic tissue is pale, with a hemorrhagic margin.

Portal Vein Obstruction and Thrombosis

Blockage of the extrahepatic portal vein may be insidious and well tolerated, or may be a catastrophic and potentially lethal event; most cases fall somewhere in between. Occlusive disease of the portal vein or its major radicles typically produces abdominal pain and, in most instances, other manifestations of portal hypertension, principally esophageal varices that are prone to rupture. Ascites is not common (because the block is presinusoidal), but when present, is often massive and intractable. As discussed earlier, ascites is common in cirrhosis due to sinusoidal block and hyperdynamic circulation. Acute impairment of visceral blood flow leads to profound congestion and bowel infarction.

Extrahepatic portal vein obstruction may arise from the following conditions, but in about one third of cases no cause can be implicated:

- Subclinical occlusion of the portal vein, from neonatal umbilical sepsis or umbilical vein catheterization, presents as variceal bleeding and ascites years later
- Intra-abdominal sepsis, caused by acute diverticulitis or appendicitis leading to *pylephlebitis* in the splanchnic circulation
- Inherited or acquired hypercoagulable disorders, including postsurgical thromboses and myeloproliferative syndromes
- Trauma

- Pancreatitis and pancreatic cancer that initiate splenic vein thrombosis, which propagates into the portal vein
- Invasion of the portal vein by hepatocellular carcinoma
- Cirrhosis, which is associated with portal vein thrombosis in about 25% of patients with thrombosis

Intrahepatic portal vein radicles may be obstructed by acute thrombosis. The thrombosis does not cause ischemic infarction but instead results in a sharply demarcated area of red-blue discoloration called *infarct of Zahn*. There is no necrosis, only severe hepatocellular atrophy and marked hemostasis in distended sinusoids. Invasion of the portal vein system by primary or secondary cancer in the liver can progressively occlude portal inflow to the liver; tongues of HCC can even occlude the extrahepatic portal vein.

Noncirrhotic Portal Fibrosis and Idiopathic Portal Hypertension.

These conditions are similar and characterized by portal hypertension and a moderate degree of portal fibrosis without cirrhosis.[64] Noncirrhotic portal fibrosis is common in India and generally presents with upper gastrointestinal bleeding. Idiopathic portal hypertension, described in Japan, has a female predominance, and usually presents with splenomegaly. The pathogenesis of these conditions is unknown. It has been proposed that they may result from bacterial infection of the gut causing septic embolization of the portal vein. Another proposed mechanism is the fibrosis of portal vein branches associated with the increased expression of vascular cell adhesion molecule-1 (VCAM-1). Histologically there is a variable involvement of portal tracts, only some of which have increased connective tissue deposition and fibrosis. In addition, there is obliteration of small branches of the portal veins. This histological picture is sometimes referred to as *hepatic sclerosis* or obliterative portal venopathy.

IMPAIRED BLOOD FLOW THROUGH THE LIVER

The most common *intrahepatic cause* of blood flow obstruction is *cirrhosis*, as described earlier. In addition, physical occlusion of the *sinusoids* occurs in a small but striking group of diseases. In *sickle cell disease* the hepatic sinusoids may become packed with sickled erythrocytes, free in the sinusoids or phagocytosed by Kupffer cells (Fig. 18-37), leading to panlobular parenchymal necrosis. *Disseminated intravascular coagulation* may occlude sinusoids. This is usually inconsequential except for the periportal sinusoidal occlusion and parenchymal necrosis that may arise in pregnancy as part of *eclampsia* (discussed later). Finally, metastatic tumor cells (e.g., breast carcinoma, lymphoma, malignant melanoma) may fill the hepatic sinusoids in the absence of a mass lesion. The attendant obstruction to blood flow and massive necrosis of hepatocytes can lead to fulminant hepatic failure.

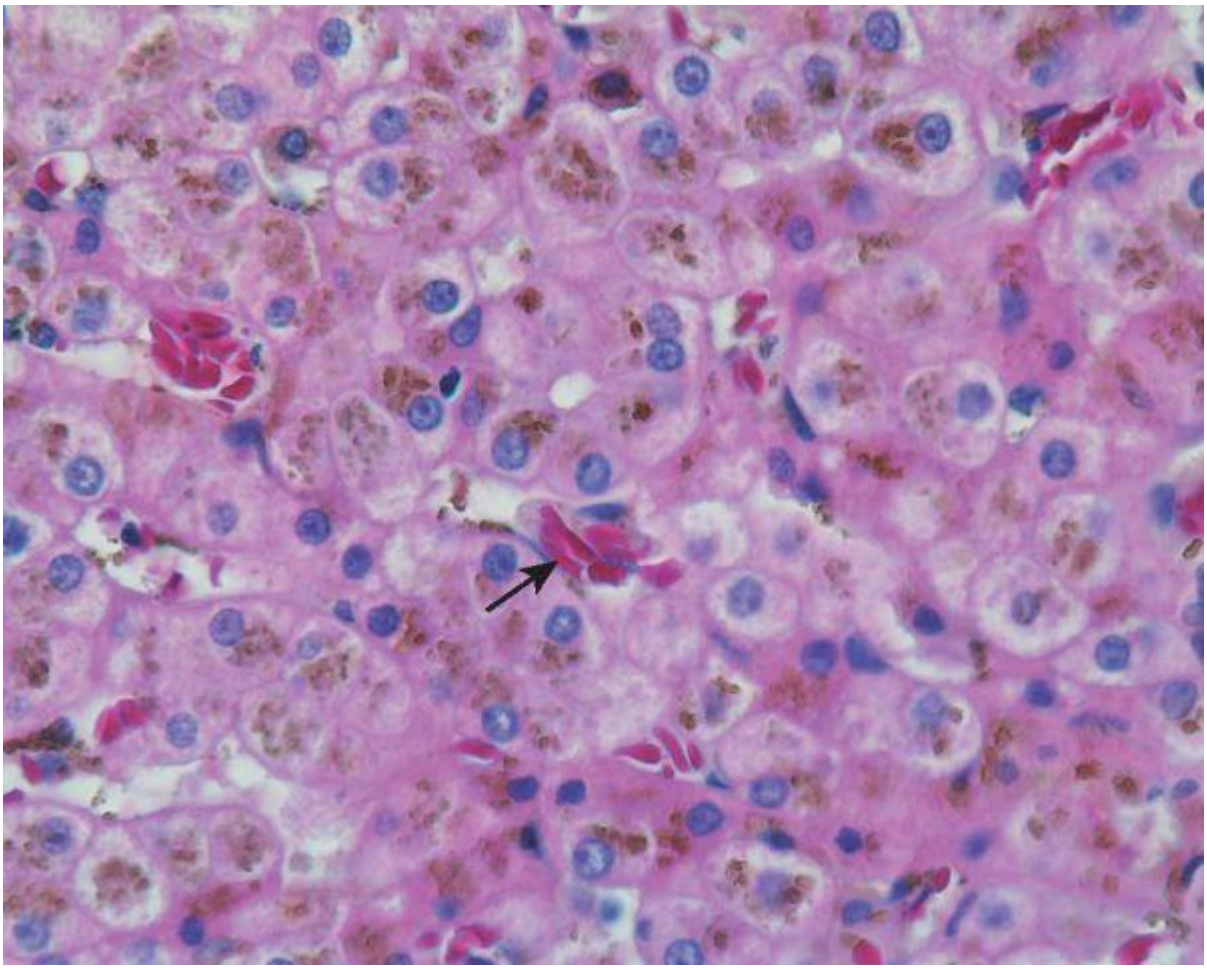

FIGURE 18-37 Sickle cell crisis in liver. The photomicrograph shows several aggregates of red blood cells, with some of them showing "sickle cell" appearance *(arrow).*

Passive Congestion and Centrilobular Necrosis

These hepatic manifestations of systemic circulatory compromise are considered together because they represent a morphologic continuum. Both changes are commonly seen at autopsy because there is an element of preterminal circulatory failure with virtually every nontraumatic death.

Right-sided cardiac decompensation leads to passive congestion of the liver. The liver is slightly enlarged, tense, and cyanotic, with rounded edges. Microscopically there is congestion of centrilobular sinusoids. With time, centrilobular hepatocytes become atrophic, resulting in markedly attenuated liver cell plates. *Left-sided cardiac failure* or *shock* may lead to hepatic hypoperfusion and hypoxia, causing ischemic coagulative necrosis of hepatocytes in the central region of the lobule *(centrilobular necrosis).* In most instances the only clinical evidence of centrilobular necrosis or its variants is transient elevation of serum aminotransferases, but the parenchymal damage may be sufficient to induce mild to moderate jaundice.

The combination of hypoperfusion and retrograde congestion acts synergistically to cause *centrilobular hemorrhagic necrosis*. The liver takes on a variegated mottled appearance, reflecting hemorrhage and necrosis in the centrilobular regions, known as the *nutmeg liver* (Fig. 18-38). By microscopy there is a sharp demarcation of viable periportal and necrotic pericentral hepatocytes, with suffusion of blood

through the centrilobular region. An uncommon complication of sustained chronic severe congestive heart failure is so-called *cardiac sclerosis*. The pattern of liver fibrosis is distinctive, inasmuch as it is mostly centrilobular. The damage rarely fulfills the criteria for the diagnosis of cirrhosis, but the historically sanctified term *cardiac cirrhosis* cannot easily be dislodged.

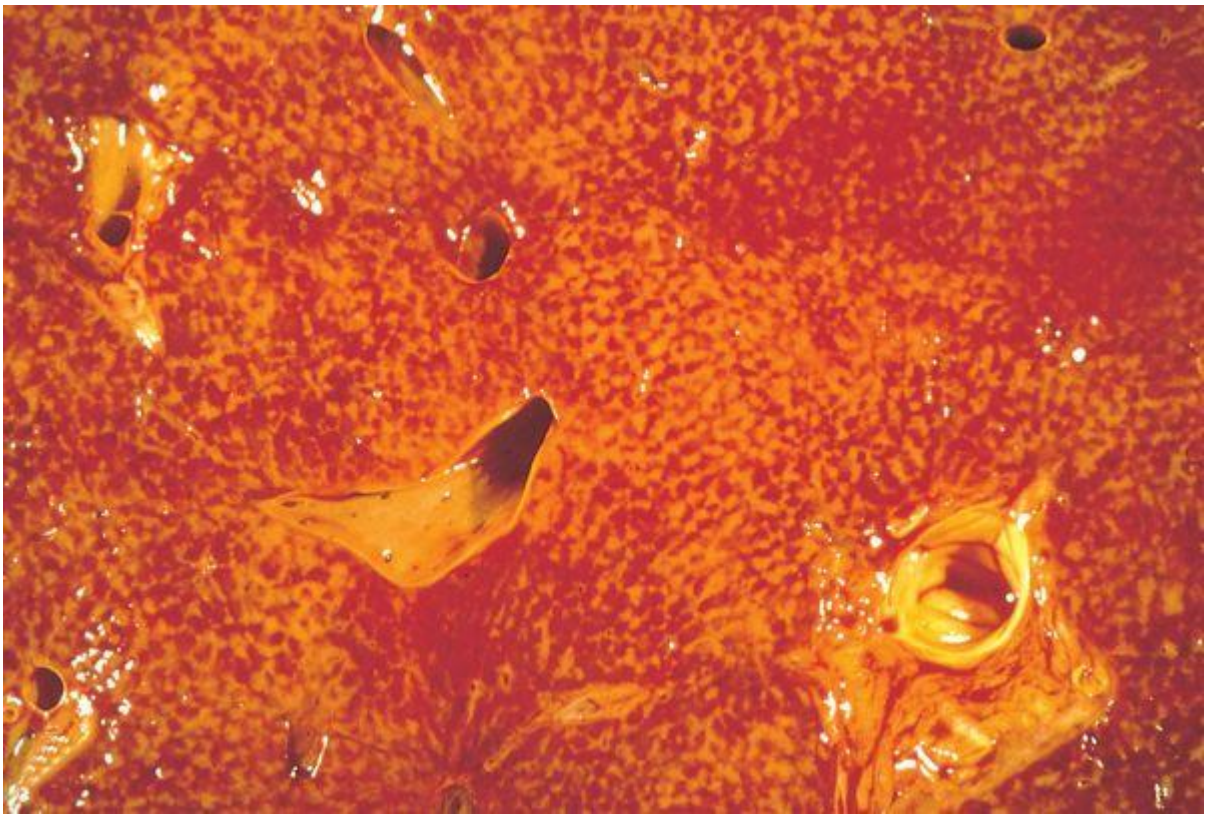

FIGURE 18-38 Centrilobular hemorrhagic necrosis. The cut liver section, in which major blood vessels are visible, is notable for a variegated, mottled, red appearance (nutmeg liver).

Peliosis Hepatis

Sinusoidal dilation occurs in any condition in which efflux of hepatic blood is impeded. *Peliosis hepatis* is a rare condition in which the dilation is primary. The liver contains blood-filled cystic spaces, either unlined or lined with sinusoidal endothelial cells. The pathogenesis of peliosis hepatis is unknown. Focal apoptosis of hepatocytes or sinusoidal endothelial cells, and disruption of liver extracellular matrix seem to play a role in the pathogenesis. *Bartonella* species have been seen in the sinusoidal endothelial cells in AIDS-associated peliosis.[65] Clinically, peliosis hepatis is associated with many diseases, including cancer, tuberculosis, AIDS, or post-transplantation immunodeficiency. It is also associated with exposure to anabolic steroids and, rarely, oral contraceptives and danazol. Clinical signs are generally absent even in advanced peliosis, but potentially fatal intra-abdominal hemorrhage or hepatic failure may occur. Peliotic lesions usually disappear after correction of the underlying causes.

HEPATIC VENOUS OUTFLOW OBSTRUCTION

Hepatic Vein Thrombosis and Inferior Vena Cava Thrombosis

Obstruction of a single main hepatic vein by thrombosis is clinically silent. The obstruction of two or more major hepatic veins produces liver enlargement, pain, and ascites, a condition known as *Budd-*

Chiari syndrome. Hepatic damage is the consequence of increased intrahepatic blood pressure, and an inability of the massive hepatic blood flow to shunt around the blocked outflow tract. *Hepatic vein thrombosis* is associated with primary myeloproliferative disorders (including polycythemia vera), inherited disorders of coagulation (e.g., deficiencies in antithrombin, protein S, or protein C, or mutations of factor V; see Chapter 4), antiphospholipid syndrome, paroxysmal nocturnal hemoglobinuria, and intra-abdominal cancers, particularly HCC. The occurrence of hepatic vein thrombosis in the setting of pregnancy or oral contraceptive use is usually through interaction with an underlying thrombogenic disorder. About 10% of cases are idiopathic in origin, presumably unrecognized thrombogenic disorders.

A separate distinction is made for *inferior vena cava obstruction at its hepatic portion (obliterative hepatocavopathy*). This disorder is caused by inferior vena cava thrombosis or membranous obstruction of the inferior vena cava. It is endemic in Nepal, with a suspected association with infections.

Morphology. In the Budd-Chiari syndrome, acutely developing thrombosis of the major hepatic veins or the hepatic portion of the inferior vena cava, the liver is swollen and red-purple and has a tense capsule (Fig. 18-39). Microscopically the affected hepatic parenchyma reveals severe centrilobular congestion and necrosis. Centrilobular fibrosis develops in instances in which the thrombosis is more slowly developing. The major veins may contain totally occlusive fresh thrombi, subtotal occlusion, or, in chronic cases, organized adherent thrombi.

FIGURE 18-39 Budd-Chiari syndrome. Thrombosis of the major hepatic veins has caused extreme blood retention in the liver.

The mortality of untreated acute hepatic vein thrombosis is high. Prompt surgical creation of a portosystemic venous shunt permits reverse flow through the portal vein and considerably improves the prognosis. In the case of vena caval thrombosis, direct dilation of caval obstruction may be possible during angiography. The chronic forms of these thrombotic syndromes are far less lethal, and more than two thirds of patients are alive after 5 years.

Sinusoidal Obstruction Syndrome (Veno-Occlusive Disease)

Originally described in Jamaican drinkers of pyrrolizidine alkaloid–containing bush tea and named veno-occlusive disease, the disease is now called sinusoidal obstruction syndrome, and occurs primarily following allogeneic bone marrow transplantation, usually within the first 3 weeks. The incidence approaches 25% in recipients of allogeneic marrow transplants. Sinusoidal obstruction syndrome can occur in cancer patients receiving chemotherapy, especially with agents such as gemtuzumad and ozagamicin, used in the treatment of acute myeloid leukemia, actinomycin D in the treatment of Wilms' tumors, dacarbazine (a drug activated by sinusoidal endothelial cells), and in patients who receive cytotoxic agents such as cyclophosphamide before bone marrow transplantation (discussed below). The mortality rates can be higher than 30%. Although histology is the gold standard for the diagnosis, a diagnosis of sinusoidal obstruction syndrome is frequently made on clinical grounds only (tender hepatomegaly, ascites, weight gain, and jaundice), because of the high risk of liver biopsy in these patients.

Morphology. Sinusoidal obstruction syndrome is characterized by obliteration of hepatic vein radicles by varying amounts of subendothelial swelling and finely reticulated collagen. In acute disease there is striking centrilobular congestion with hepatocellular necrosis and accumulation of hemosiderin-laden macrophages. As the disease progresses, obliteration of the lumen of the venule is easily identified with special stains for connective tissue (Fig. 18-40). In chronic or healed sinusoidal obstruction syndrome, dense perivenular fibrosis radiating out into the parenchyma may be present, frequently with total obliteration of the venule; hemosiderin deposition is evident in the scar tissue, and congestion is minimal.

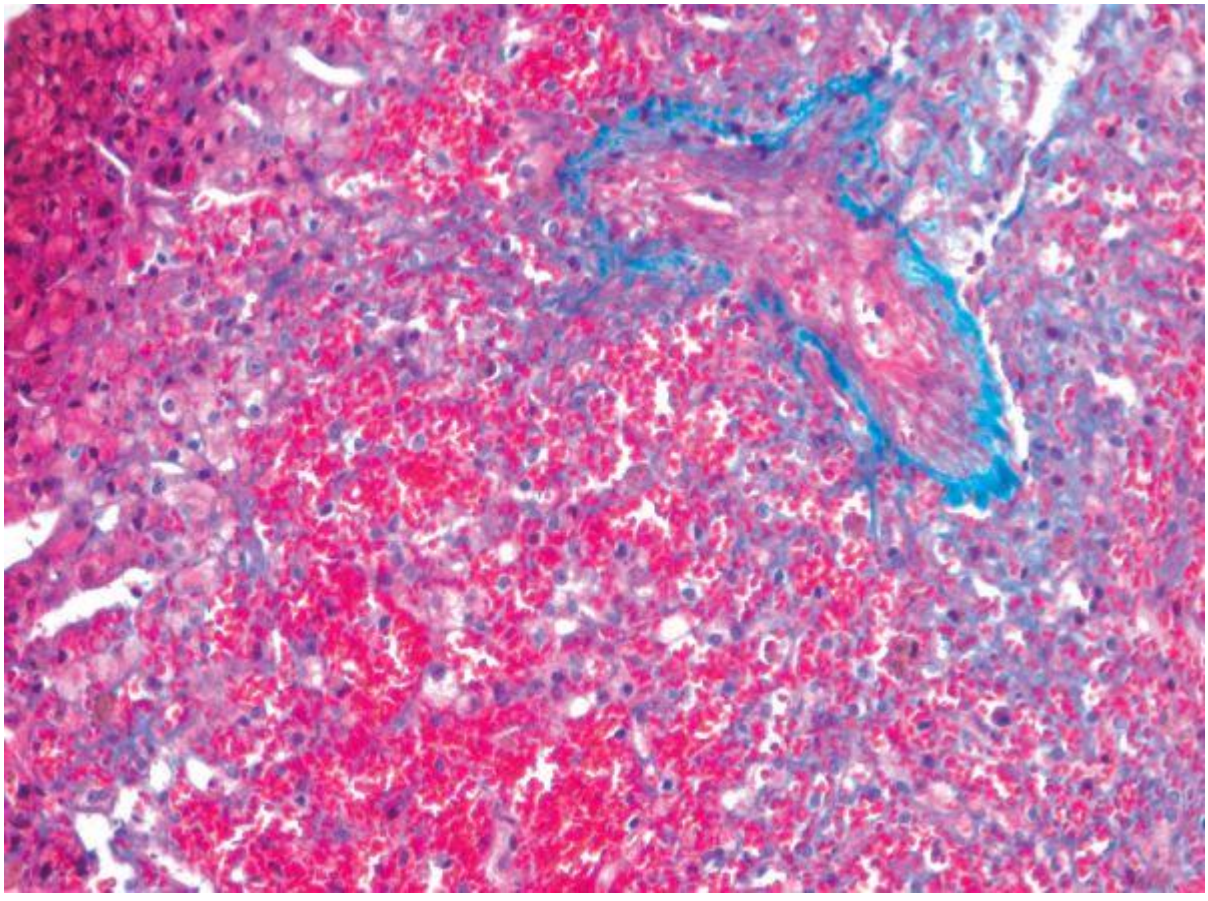

FIGURE 18-40 Sinusoidal obstruction syndrome (previously known as veno-occlusive disease). Reticulin stain reveals the parenchyma framework of the lobule and the marked deposition of collagen within the lumen of the central vein.

Sinusoidal obstruction syndrome arises from toxic injury to the sinusoidal endothelium.[66] Endothelial lining cells round up and slough off the sinusoidal wall, embolizing downstream and obstructing sinusoidal blood flow. This is accompanied by entry of erythrocytes into the space of Disse, necrosis of perivenular hepatocytes, and downstream accumulation of cellular debris in the terminal hepatic vein. Proliferation of perisinusoidal stellate cells and subendothelial fibroblasts in the terminal hepatic vein follows, with fibrosis and deposition of extracellular matrix in the sinusoids.

3.8.1.8 Hepatic Complications of Organ or Bone Marrow Transplantation

The use of transplantation for bone marrow, renal, hepatic and other organ disorders has generated a challenging group of hepatic complications. The liver may be damaged by toxic drugs or graft-versus-host disease in patients undergoing bone marrow transplantation, whereas patients receiving a liver transplant may have graft failure or rejection, and may develop sinusoidal obstruction syndrome, as already discussed. Although the clinical settings are obviously different for each patient population, the common themes of toxic or immunologically mediated liver damage, infection of immunosuppressed hosts, recurrent disease, and post-transplant lymphoproliferative disorder are readily apparent. The following focuses on post-transplant graft-versus-host disease and liver rejection.

GRAFT-VERSUS-HOST DISEASE AND LIVER REJECTION

The liver has the unenviable position of being attacked by graft-versus-host and host-versus-graft mechanisms, in the setting of bone marrow transplantation and liver transplantation, respectively. These processes are discussed in detail in Chapter 6 . More than other solid organs, liver transplants are reasonably well tolerated by recipients. That being said, the hepatic morphologic features that are peculiar to immunological attack after transplantation deserve comment.

Morphology. Liver damage after bone marrow transplantation is the consequence of acute or chronic **graft-versus-host disease. In acute graft-versus-host disease**, which occurs 10 to 50 days after bone marrow transplantation, donor lymphocytes attack the epithelial cells of the liver. This results in hepatitis with necrosis of hepatocytes and bile duct epithelial cells, and inflammation of the parenchyma and portal tracts. In **chronic hepatic graft-versus-host disease** (usually more than 100 days after transplantation), there is portal tract inflammation, selective bile duct destruction, and eventual fibrosis. Portal vein and hepatic vein radicles may show endothelitis, a process in which a subendothelial lymphocytic infiltrate lifts the endothelium from its basement membrane. Cholestasis may be observed in both acute and chronic graft-versus-host disease.

In **transplanted livers, acute rejection** is characterized by infiltration of a mixed population of inflammatory cells that include eosinophils into portal tracts, bile duct and hepatocyte injury, and endothelitis (Fig. 18-41). The severity of the rejection is graded according to the BANFF scheme, which is important for clinical management.[67] With **chronic rejection** a severe obliterative arteritis of small and larger arterial vessels (arteriopathy) results in ischemic changes in the liver parenchyma. Alternatively, bile ducts are progressively destroyed, because of either direct immunological attack or obliteration of their arterial supply, resulting in loss of the graft.

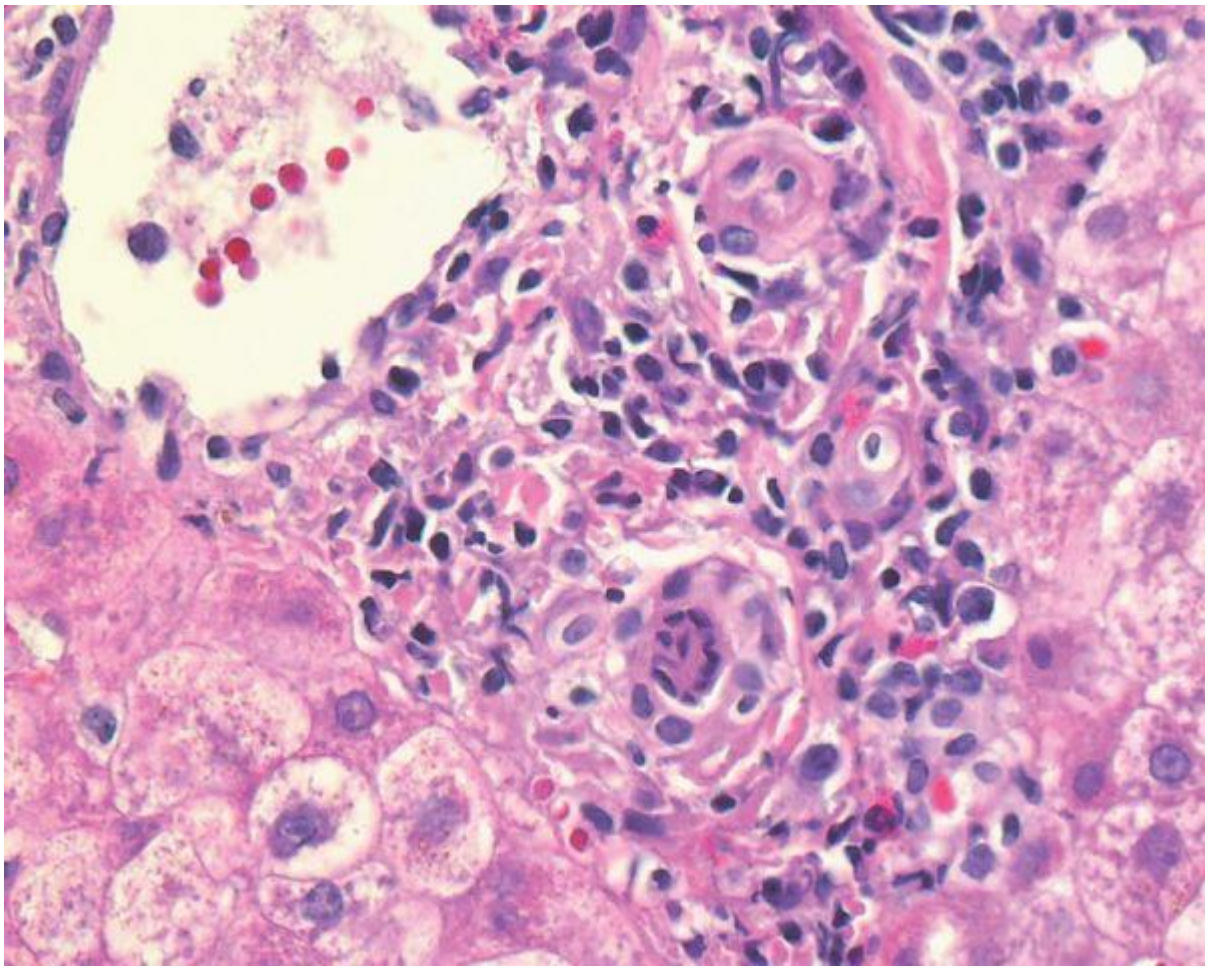

FIGURE 18-41 Transplanted liver with acute cellular rejection. Note the mixed inflammatory cell infiltration including eosinophils in portal tracts, bile duct damage, and endotheliitis.

3.8.1.9 Hepatic Disease Associated with Pregnancy

Hepatic diseases may occur in women with chronic liver disease who become pregnant, or they may develop during pregnancy in women who were not affected by liver disease. Abnormal liver tests occur in 3% to 5% of pregnancies.[68] Viral hepatitis (HAV, HBV, HCV, and even HBV + HDV) is the most common cause of jaundice in pregnancy. While these women require careful clinical management, pregnancy does not specifically alter the course of the liver disease. The one exception is HEV infection, which, for unknown reasons, runs a more severe course in pregnant patients, with fatality rates of 10% to 20%.

A very small subgroup of pregnant women (0.1%) develops hepatic complications directly attributable to pregnancy: preeclampsia and eclampsia, acute fatty liver of pregnancy, and intrahepatic cholestasis of pregnancy. In extreme cases of the first two conditions, the outcome is fatal.

PREECLAMPSIA AND ECLAMPSIA

Preeclampsia affects 3% to 5% of pregnancies and is characterized by maternal hypertension, proteinuria, peripheral edema, coagulation abnormalities, and varying degrees of disseminated intravascular coagulation (Chapter 22). When hyper-reflexia and convulsions occur the condition is

called *eclampsia* and may be life-threatening. Alternatively, subclinical hepatic disease may be the primary manifestation of preeclampsia, as part of a syndrome of hemolysis, elevated liver enzymes, and low platelets, dubbed the *HELLP syndrome*.[69]

Morphology. The affected liver in preeclampsia is normal in size, firm, and pale, with small red patches due to hemorrhage. Occasionally, yellow or white patches of ischemic infarction can be seen. Microscopically, **the periportal sinusoids contain fibrin deposits with hemorrhage into the space of Disse**, leading to periportal hepatocellular coagulative necrosis. Blood under pressure may coalesce and expand to form a **hepatic hematoma**; **dissection of blood under Glisson's capsule may lead to catastrophic hepatic rupture** (Fig. 18-42). Patients with hepatic involvement in preeclampsia may show modest to severe elevation of serum aminotransferases and mild elevation of serum bilirubin. Hepatic dysfunction sufficient to cause a coagulopathy signifies far-advanced and potentially lethal disease. **Definitive treatment in severe cases requires termination of the pregnancy**. In mild cases patients may be managed conservatively. Women who survive mild or severe preeclampsia recover without sequelae.

ACUTE FATTY LIVER OF PREGNANCY (AFLP)

AFLP presents with a spectrum ranging from modest or even subclinical hepatic dysfunction (evidenced by elevated serum aminotransferase levels) to hepatic failure, coma, and death. It is a rare disease affecting 1 in 13,000 deliveries. Affected women present in the latter half of pregnancy, usually in the third trimester. Symptoms are directly attributable to incipient hepatic failure, including bleeding, nausea and vomiting, jaundice, and coma. In 20% to 40% of cases the presenting symptoms may be those of coexistent preeclampsia.

Morphology. The diagnosis of acute fatty liver rests on biopsy identification of the characteristic microvesicular fatty transformation of hepatocytes. In severe cases there may be lobular disarray with hepatocyte dropout, reticulin collapse, and portal tract inflammation, making distinction from viral hepatitis difficult. Diagnosis depends on (1) a high index of suspicion and (2) confirmation of microvesicular steatosis using special stains for fat (oil-red-O or Sudan black) on frozen tissue sections; electron microscopy may also be used to demonstrate the steatosis.

While this condition most commonly runs a mild course, women with AFLP can progress within days to hepatic failure and death. *The primary treatment for AFLP is termination of the pregnancy*. The pathogenesis of this disease is unknown, but mitochondrial dysfunction has been implicated. In a subset of patients, both mother and father carry a heterozygous deficiency in mitochondrial long-chain 3-hydroxyacyl coenzyme A (CoA) dehydrogenase. The homozygous-deficient fetuses fare well during pregnancy but cause hepatic dysfunction in the mother, because long-chain 3-hydroxylacyl metabolites produced by the fetus or placenta are washed away into the maternal circulation and cause hepatic toxicity. This is a rare instance of the fetus causing metabolic disease in the mother.[70]

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

The onset of pruritus in the third trimester, followed by darkening of the urine and occasionally light stools and jaundice, heralds the development of this enigmatic syndrome. Serum bilirubin (mostly conjugated) rarely exceeds 5 mg/dL; alkaline phosphatase may be slightly elevated. Liver biopsy reveals mild cholestasis without necrosis. The altered hormonal state of pregnancy seems to combine with biliary defects in the secretion of bile salts or sulfated progesterone metabolites to engender cholestasis. Although this is generally a benign condition, the mother is at risk for gallstones and malabsorption, and the incidence of fetal distress, stillbirths, and prematurity is modestly increased. Perhaps most importantly, the pruritus can be extremely distressing for the pregnant mother.

3.8.1.10 Nodules & Tumors

Hepatic masses may come to attention for a variety of reasons. They may generate epigastric fullness and discomfort or be detected by routine physical examination or radiographic studies for other indications. Nodular hyperplasias are not neoplasms; the remaining lesions discussed in this section are true neoplasms.

NODULAR HYPERPLASIAS

Solitary or multiple hyperplastic hepatocellular nodules may develop in the noncirrhotic liver. Two such conditions, having confusingly overlapping names, are *focal nodular hyperplasia* and *nodular regenerative hyperplasia*. The common factor in both types of nodules seems to be either focal or

diffuse alterations in hepatic blood supply, arising from obliteration of portal vein radicles and compensatory augmentation of arterial blood supply.

Morphology. Focal nodular hyperplasia appears as a well-demarcated but poorly encapsulated nodule, ranging up to many centimeters in diameter (Fig. 18-43A). It presents as a spontaneous mass lesion in an otherwise normal liver, most frequently in young to middle-aged adults. The lesion is generally lighter than the surrounding liver and is sometimes yellow. Typically, there is a central gray-white, depressed stellate scar from which fibrous septa radiate to the periphery (Fig. 18-43B). The central scar contains large vessels, usually arterial, that typically show fibromuscular hyperplasia with eccentric or concentric narrowing of the lumen. The radiating septa show foci of intense lymphocytic infiltrates and exuberant bile duct proliferation along septal margins. The parenchyma between the septa shows essentially normal hepatocytes but with a thickened plate architecture characteristic of regeneration. Long-term use of anabolic hormones or of contraceptives have been implicated in the development of focal nodular hyperplasia.

Nodular regenerative hyperplasia denotes a liver entirely transformed into roughly spherical nodules, in the absence of fibrosis. Microscopically, plump hepatocytes are surrounded by rims of atrophic hepatocytes. The variation in parenchymal architecture may be missed on an H&E stain, and reticulin staining is required to appreciate the changes in hepatocellular architecture. Nodular regenerative hyperplasia can lead to the development of portal hypertension and occurs in association with conditions affecting intrahepatic blood flow, including solid-organ (particularly renal) transplantation, bone marrow transplantation, and vasculitis. It also occurs in HIV-infected persons.[71]

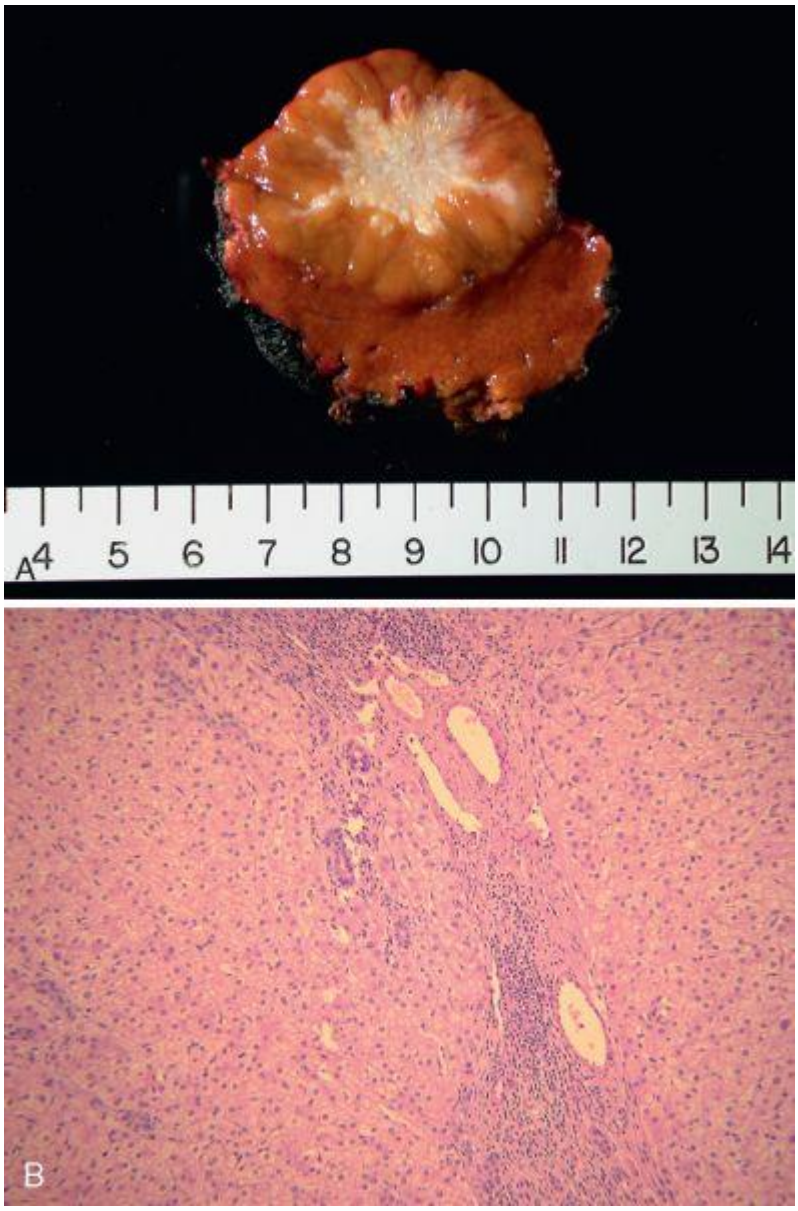

FIGURE 18-43 Focal nodular hyperplasia. **A**, Resected specimen showing lobulated contours and a central stellate scar. **B**, Low-power photomicrograph showing a broad fibrous scar with hepatic arterial and bile duct elements and chronic inflammation, present within hepatic parenchyma that lacks the normal sinusoidal plate architecture.

BENIGN NEOPLASMS

Cavernous hemangiomas, blood vessel tumors identical to those occurring elsewhere (see Chapter 11), are the most common benign liver tumors. They appear as discrete red-blue, soft nodules, usually less than 2 cm in diameter, generally located directly beneath the capsule. Histologically, the tumor consists of vascular channels in a bed of fibrous connective tissue (Fig. 18-44). Their chief clinical significance is that they should not be mistaken for metastatic tumors, and that blind percutaneous biopsies not be performed on them.

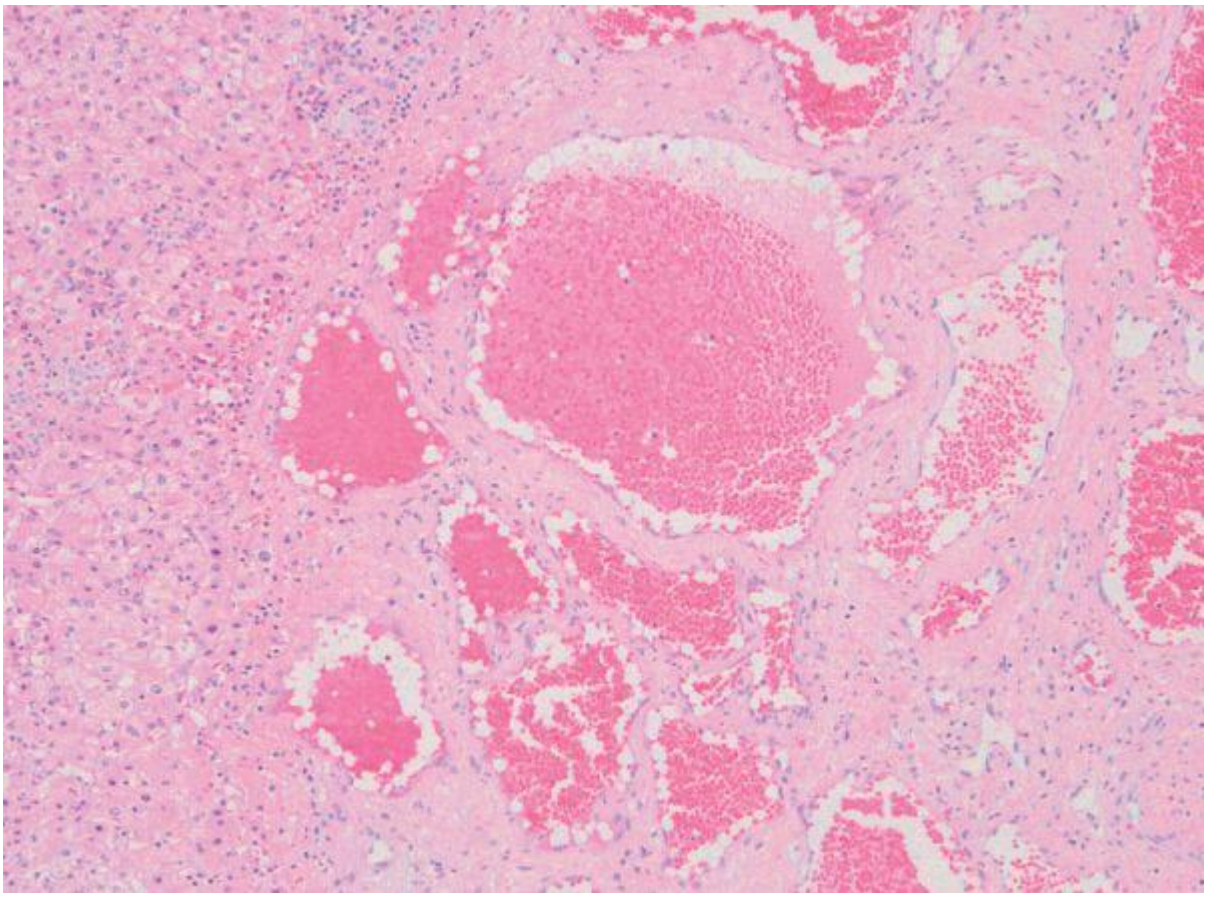

FIGURE 18-44 Hemangioma. The photomicrograph shows the vesicular channels embedded in fibrous stroma.

Hepatic Adenoma

Benign neoplasms developing from hepatocytes are called *hepatic adenomas* or *liver cell adenomas*. Although they may occur in men, hepatic adenomas most frequently occur in young women who have used oral contraceptives; tumors generally regress if contraceptive use is terminated. The incidence of adenoma is approximately 1 in 100,000. Hepatic adenomas have clinical significance for three reasons: (1) when they present as an intrahepatic mass they may be mistaken for the more ominous hepatocellular carcinomas; (2) subcapsular adenomas have a tendency to rupture, particularly during pregnancy (under estrogen stimulation), causing life-threatening intraperitoneal hemorrhage; (3) rarely, they may transform into carcinomas, particularly, when the adenoma arises in an individual with glycogen storage disease, and adenomas in which mutations of the β-catenin gene are present.

Pathogenesis.

Although hormonal stimulation is clearly associated with the development of solitary hepatic adenoma, the causal events are unknown. Mutations in the genes encoding the transcription factor HNF1α and β-catenin have been identified in 50% and 15% of the hepatic adenomas, respectively.[72] Multiple hepatic adenoma (adenomatosis) syndromes can occur in individuals with maturity-onset diabetes of young (MODY3), with *HNF1* mutations.[73]

Morphology. Liver cell adenomas are pale, yellowtan, and frequently bile-stained nodules, found anywhere in the hepatic substance but often beneath the capsule (Fig. 18-45A). They may reach 30 cm in diameter. Although they are usually well demarcated, encapsulation might not be present. The tumor commonly presents as a solitary lesion, but multiple lesions (adenomatosis) can occur. Histologically, liver cell adenomas are composed of sheets and cords of cells that may resemble normal hepatocytes or have some variation in cell and nuclear size (Fig. 18-45B). Abundant glycogen may generate large hepatocytes with a clear cytoplasm. Steatosis is commonly present. Portal tracts are absent; instead, prominent solitary arterial vessels and draining veins are distributed through the substance of the tumor.

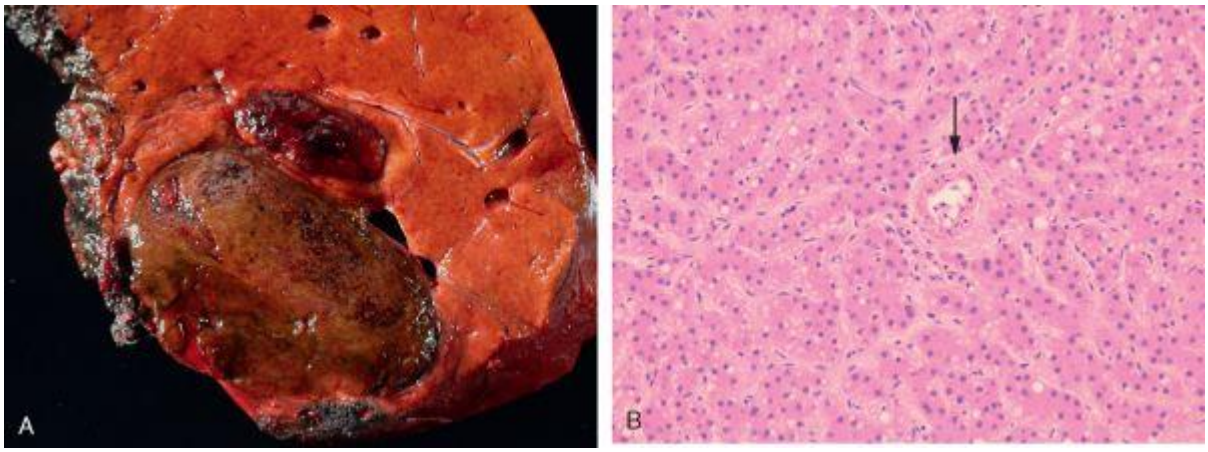

FIGURE 18-45 Liver cell adenoma. **A**, Resected specimen presenting as a pendulous mass arising from the liver. **B**, Microscopic view showing cords of hepatocytes, with an arterial vascular supply *(arrow)* and no portal tracts.

MALIGNANT TUMORS

Malignant tumors occurring in the liver can be primary or metastatic. Most of the discussion in this section deals with primary hepatic tumors. Primary carcinomas of the liver are relatively uncommon in North America and western Europe (0.5% to 2% of all cancers) but represent 20% to 40% of cancers in many other countries. Most primary liver cancers arise from hepatocytes and are termed *hepatocellular carcinoma* (HCC). Much less common are carcinomas of bile duct origin, *cholangiocarcinomas*. The incidence of these two cancers is increasing in the United States.

Before embarking on a discussion of the major forms of malignancy affecting the liver, two rare forms of primary liver cancer deserve brief mention: hepatoblastomas and angiosarcomas. *Angiosarcoma* of the liver resembles those occurring elsewhere. The primary liver form is of interest because of its association with exposure to vinyl chloride, arsenic, or Thorotrast (Chapters 9 and 11 . The latency period after exposure to the putative carcinogen may be several decades. These highly aggressive neoplasms metastasize widely and generally kill within a year. The major features of hepatoblastoma are discussed next.

Hepatoblastoma

Hepatoblastoma is the most common liver tumor of young childhood. Its incidence, which is increasing, is approximately 1 to 2 in 1 million births.[74] The tumor is usually fatal within a few years if not treated. This tumor has two anatomic variants:

- The *epithelial type*, composed of small polygonal fetal cells or smaller embryonal cells forming acini, tubules, or papillary structures vaguely recapitulating liver development (Fig. 18-46)
- The *mixed epithelial and mesenchymal type*, which contains foci of mesenchymal differentiation that may consist of primitive mesenchyme, osteoid, cartilage, or striated muscle

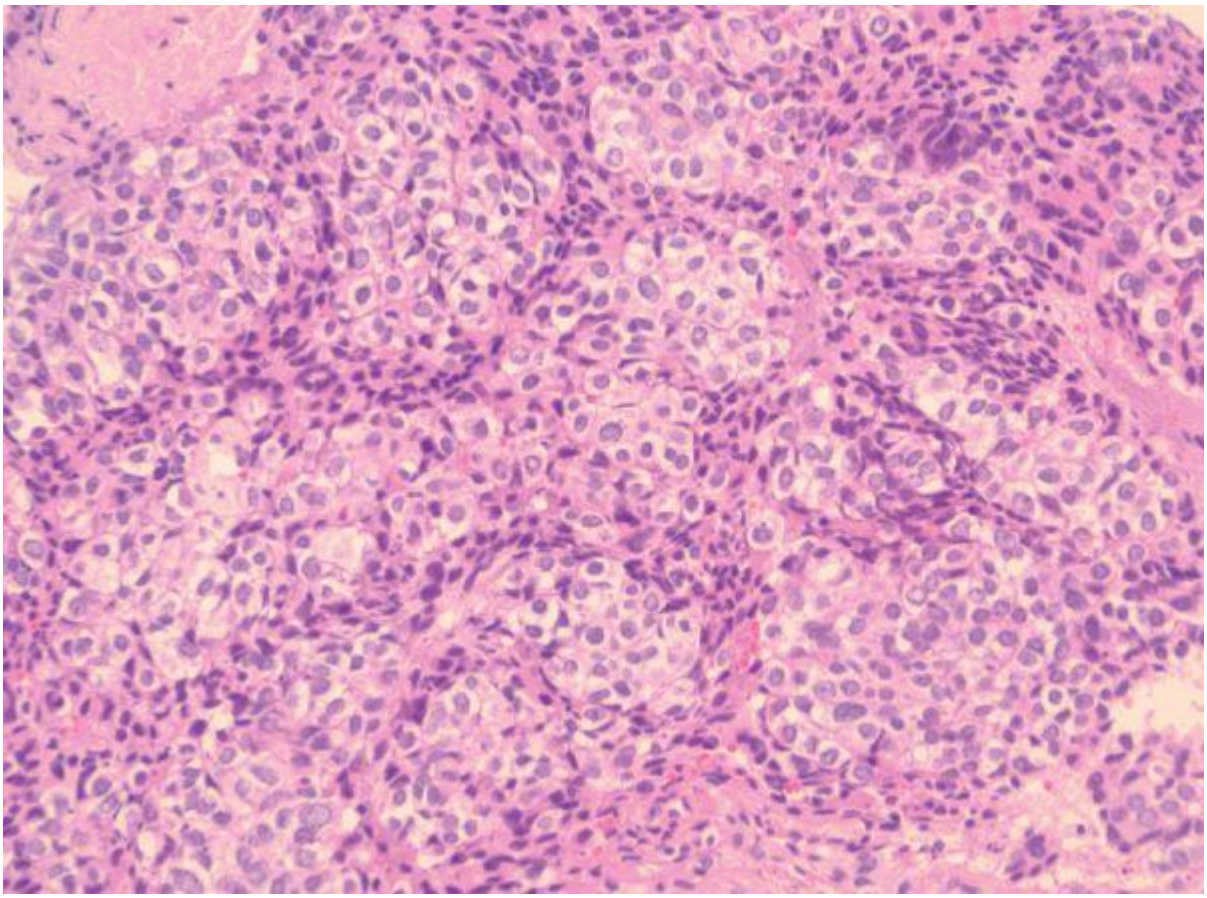

FIGURE 18-46 Hepatoblastoma. The photograph shows proliferating hepatoblasts.

A characteristic feature of hepatoblastomas is the frequent activation of the WNT/β-catenin signaling pathway.[75] Chromosomal abnormalities are common in hepatoblastomas, and FOXG1, a regulator of the TGF-β pathway, is highly expressed in some subsets of the tumor.[76] Hepatoblastoma may be associated with familial adenomatous polyposis syndrome and Beckwith-Wiedmann syndrome. The treatment is chemotherapy and complete surgical resection. The therapy has raised the 5-year survival to 80%.

Hepatocellular Carcinoma (HCC)

On a global basis, there are more than 626,000 new cases per year of primary liver cancer, almost all being HCC, and approximately 598,000 patients die from this cancer every year,[77] the third most frequent cause of cancer deaths. About 82% of HCC cases occur in developing countries with high rates of chronic HBV infection, such as in southeast Asian and African countries; 52% of all HCC cases occur in China. In the United States the incidence of liver cancer increased by 25% between 1993 and 1998, mainly due to HCV and HBV chronic infection. There is a clear predominance of males with a ratio of 2.4 : 1.

Pathogenesis.

Several general factors relevant to the pathogenesis of HCC were discussed in Chapter 7 . Some issues specifically related to HCC deserve emphasis here.

Four major etiologic factors associated with HCC have been established: chronic viral infection (HBV, HCV), chronic alcoholism, non-alcoholic steatohepatitis (NASH), and food contaminants (primarily aflatoxins). Other conditions include tyrosinemia, glycogen storage disease, hereditary hemochromatosis, non-alcoholic fatty liver disease, and α_1-antitrypsin deficiency. Many factors, including genetic factors, age, gender, chemicals, hormones, and nutrition, interact in the development of HCC. The disease that is most likely to give rise to HCC is the extremely rare hereditary tyrosinemia, in which almost 40% of patients develop the tumor despite adequate dietary control.

The pathogenesis of HCC may be different in high-incidence, HBV-prevalent populations versus low-incidence Western populations, in which other chronic liver diseases such as alcoholism, non-alcoholic steatohepatitis, chronic HCV infection, and hemochromatosis are more common. In high-prevalence regions the HBV infection begins in infancy by the vertical transmission of virus from infected mothers, which confers a 200-fold increased risk for HCC development by adulthood. Cirrhosis may be absent in as many as half of these patients, and the cancer often occurs between 20 and 40 years of age. In the Western world where HBV is not prevalent, cirrhosis is present in 75% to 90% of cases of HCC, usually in the setting of other chronic liver diseases. Thus, cirrhosis seems to be a prerequisite contributor to the emergence of HCC in Western countries but may have a different role in HCC that develops in endemic areas. In China and southern Africa, where HBV is endemic, there may also be exposure to aflatoxin, a toxin produced by the fungus *Aspergillus flavus*, which contaminates peanuts and grains. Aflatoxin can bind covalently with cellular DNA and cause a specific mutation in codon 249 of *p53* (Chapter 9).

Although the precise mechanisms of carcinogenesis are unknown, several events have been implicated. Repeated cycles of cell death and regeneration, as occurs in chronic hepatitis from any cause, are important in the pathogenesis of HCCs (Chapter 7). It is thought that the accumulation of mutations during continuous cycles of cell division may damage DNA repair mechanisms and eventually transform hepatocytes. Preneoplastic changes can be recognized morphologically by the occurrence of hepatocyte dysplasia. Progression to HCC might result from point mutations in selected cellular genes such as *KRAS* and *p53*, and constitutive expression of c-MYC, c-MET (the receptor for hepatocyte growth factor), TGF-α, and insulin-like growth factor 2. Recent global gene expression studies revealed that approximately 50% of HCC cases are associated with activation of WNT or AKT pathways. A subgroup of tumors expresses a high proportion of genes present in fetal liver and liver progenitor cells, suggesting that at least some HCCs may be generated from liver stem cells (Chapter 3).

Molecular analysis of tumor cells in HBV-infected individuals showed that most nodules are clonal with respect to the HBV DNA integration pattern, suggesting that viral integration precedes or accompanies a transforming event. In HBV-induced carcinogenesis not only the disruption of cell genome caused by virus integration but also the site of integration can be important. Depending on the integration site, HBV integration may activate proto-oncogenes that contribute to tumorigenicity. Alternatively, it has been proposed that the HBV X-protein, a transcriptional activator of multiple genes, might be the main cause of cell transformation. The situation is even more uncertain regarding the mechanisms of HCV carcinogenesis. HCV is a RNA virus that does not disrupt DNA, and it does not produce oncogenic proteins. However, there are indications that the HCV core and NS5A proteins may participate in the development of HCC.[78]

Universal vaccination of children against HBV in endemic areas can dramatically decrease the incidence of HBV infection, and most likely, the incidence of HCC. Such a program, started in Taiwan in 1984, has reduced HBV infection rates from 10% to less than 1% in 20 years.[79]

Morphology. HCC may appear grossly as (1) a **unifocal** (usually large) mass (Fig. 18-47A); (2) **multifocal**, widely distributed nodules of variable size; or (3) a **diffusely infiltrative** cancer, permeating widely and sometimes involving the entire liver. All three patterns may cause liver enlargement, particularly the large unifocal and multinodular patterns. The diffusely infiltrative tumor may blend imperceptibly into a cirrhotic liver background.

HCCs are usually paler than the surrounding liver, and sometimes take on a green hue when composed of well-differentiated hepatocytes capable of secreting bile. **All patterns of HCCs have a strong propensity for invasion of vascular structures**. Extensive intrahepatic metastases ensue, and occasionally, long, snakelike masses of tumor invade the portal vein (with occlusion of the portal circulation) or inferior vena cava, extending even into the right side of the heart. HCC spreads extensively within the liver by obvious contiguous growth and by the development of satellite nodules, which can be shown by molecular methods to be derived from the parent tumor. Metastasis outside the liver is primarily via vascular invasion, especially into the hepatic vein system, but hematogenous metastases, especially to the lung, tend to occur late in the disease. Lymph node metastases to the perihilar, peripancreatic, and para-aortic nodes above and below the diaphragm are found in fewer than half of HCCs that spread beyond the liver. If HCC with venous invasion is identified in explanted livers at the time of liver transplantation, tumor recurrence is likely to occur in the transplanted donor liver.

HCCs range from well-differentiated to highly anaplastic undifferentiated lesions. In well-differentiated and moderately differentiated tumors, cells that are recognizable as hepatocytic in origin are disposed either in a trabecular pattern (recapitulating liver cell plates) (Fig. 18-47B) or in an acinar, pseudoglandular pattern. In poorly differentiated forms, tumor cells can take on a pleomorphic appearance with numerous anaplastic giant cells, can be small and completely undifferentiated, or may even resemble a spindle cell sarcoma.

A distinctive variant of HCC is the **fibrolamellar carcinoma**, which was first described in 1956. This variant constitutes 5% of HCCs. It occurs in young male and female adults (20 to 40 years of age) with equal incidence. Patients usually do not have underlying chronic liver diseases, and so the prognosis is better than the conventional HCC.[80] The etiology of fibrolamellar carcinoma is unknown. It usually presents as single large, hard “scirrhous” tumor with fibrous bands coursing through it. On microscopic examination it is composed of well-differentiated polygonal cells growing in nests or cords, and separated by parallel lamellae of dense collagen bundles. The tumor cells have abundant eosinophilic cytoplasm and prominent nucleoli (Fig. 18-48).

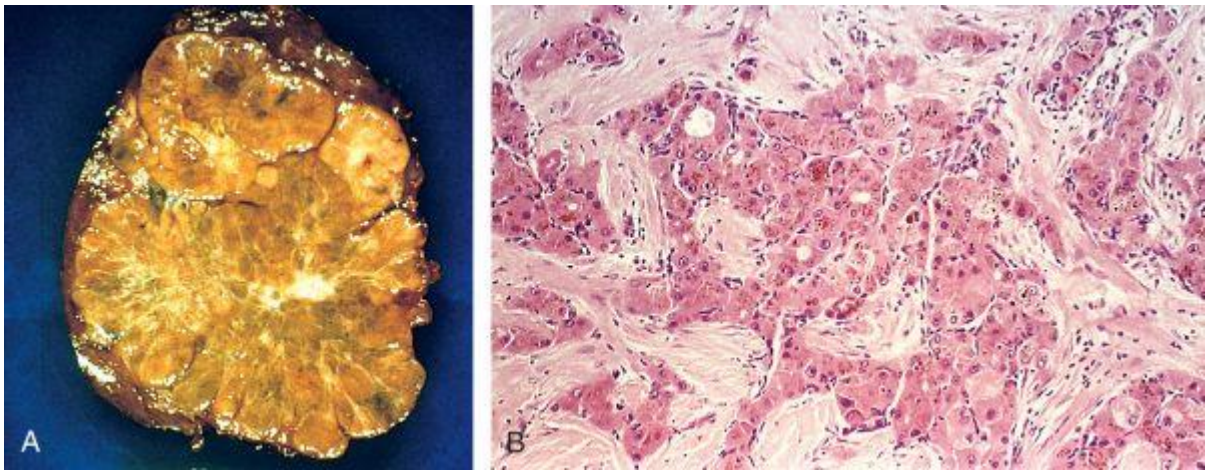

FIGURE 18-48 Fibrolamellar carcinoma. **A**, Resected specimen showing a demarcated nodule in an otherwise normal liver. **B**, Microscopic view showing nests and cords of malignant-appearing hepatocytes separated by dense bundles of collagen.

Clinical Features.

The clinical manifestations of HCC are seldom characteristic and, in the Western population, often are masked by those related to the underlying cirrhosis or chronic hepatitis. In areas of high incidence such as tropical Africa, patients usually have no clinical history of liver disease, although cirrhosis may be detected at autopsy. In both populations most patients have ill-defined upper abdominal pain, malaise, fatigue, weight loss, and sometimes awareness of an abdominal mass or abdominal fullness. In many cases the enlarged liver can be felt on palpation, with sufficient irregularity or nodularity to permit differentiation from cirrhosis. Jaundice, fever, and gastrointestinal or esophageal variceal bleeding are inconstant findings.

Laboratory studies may be helpful but are rarely conclusive. Elevated levels of *serum α-fetoprotein* are found in 50% of persons with HCC. However, false-positive results are encountered with yolk-sac tumors and many non-neoplastic conditions, including cirrhosis, massive liver necrosis (with compensatory liver cell regeneration), chronic hepatitis (especially HCV infection), normal pregnancy, fetal distress or death, and fetal neural tube defects such as anencephaly and spina bifida. Laboratory testing for α-fetoprotein and other proteins (such as serum carcinoembryonic antigen levels) often fails to detect small HCC lesions. Recently, staining for Glypican-3 has been used to distinguish early HCC from dysplastic nodules. Most valuable for detection of small tumors are imaging studies: ultrasonography, hepatic angiography, computed tomography, and magnetic resonance imaging. Molecular analysis of HCC is actively being pursued and will most likely lead to new HCC classifications that can help determine treatment options. As already mentioned, some molecular signatures of HCC have already been identified.[81]

The natural course of HCC involves the progressive enlargement of the primary mass until it seriously disturbs hepatic function, or metastasizes, generally first to the lungs and then to other sites. Overall, death usually occurs from (1) cachexia, (2) gastrointestinal or esophageal variceal bleeding, (3) liver failure with hepatic coma, or, rarely, (4) rupture of the tumor with fatal hemorrhage. The 5-year survival of large tumors is dismal, with the majority of patients dying within the first 2 years. With implementation of screening procedures and advances in imaging, the detection of HCCs less than 2 cm in diameter has increased in countries where such facilities are available. These small tumors can be

removed surgically with good prognostic outcomes. Radiofrequency ablation is used for local control of large tumors, and chemoembolization can also be used, according to a clinical algorithm that has been widely adopted.[82] Recent findings show that the kinase inhibitor sorafenib can prolong the life of individuals with advanced-stage HCC.[83]

Cholangiocarcinoma (CCA)

Cholangiocarcinoma, the second most common hepatic malignant tumor after HCC, is a malignancy of the biliary tree, arising from bile ducts within and outside of the liver.[84] It accounts for 7.6% of cancer deaths worldwide and 3% of cancer deaths in the United States. The prevalence of the disease in the United States is variable, the highest being in Hispanics (1.22 per 100,000 population), and the lowest in African-Americans (0.17–0.5 per 100,000). The risk factors for development of CCA include primary sclerosing cholangitis (PSC), congenital fibropolycystic diseases of the biliary system (particularly Caroli disease and choledochal cysts that will be discussed later), HCV infection, and previous exposure to Thorotrast (formerly used in radiography of the biliary tract). Most cholangiocarcinomas in the Western world, however, arise without evidence of such antecedent conditions. In southeast Asia, where the incidence rates are higher, a major risk factor is chronic infection of the biliary tract by the liver fluke *Opisthorchis sinensis* and its close relatives. *According to their localization, CCAs are classified into intrahepatic and extrahepatic forms*. Eighty to 90% of the tumors are extrahepatic. However, the incidence of intrahepatic tumors has increased during the last two decades in the United States, western Europe, and Japan, while the incidence of extrahepatic CCA has remained constant. The extrahepatic forms include perihilar tumors known as *Klatskin tumors*, which are located at the junction of the right and left hepatic ducts forming the common hepatic duct, and distal bile duct tumors. A subgroup of distal tumors arise in the immediate vicinity of the ampulla of Vater. Tumors of this region also include adenocarcinoma of the duodenal mucosa and pancreatic carcinoma (discussed in Chapters 17 and 19 , respectively) and are collectively referred to as *periampullary carcinomas*.

Fifty to 60% of all CCAs are perihilar (Klatskin) tumors, 20% to 30% are distal tumors, and about 10% are intrahepatic. In any case the prognosis is dismal, with survival rates of about 15% at 2 years after diagnosis. The median time from diagnosis to death for intrahepatic CCAs is 6 months, even after surgery. Intrahepatic CCAs are not usually detected until late in their course, and come to the attention because of obstruction of bile flow, or as a symptomatic liver mass. In contrast, hilar and distal tumors present with symptoms of biliary obstruction, cholangitis, and right upper quadrant pain.

Morphology. Extrahepatic CCAs are generally small lesions at the time of diagnosis. Most tumors appear as firm, gray nodules within the bile duct wall; some may be diffusely infiltrative lesions; others are papillary, polypoid lesions. Most are adenocarcinomas that may or may not secrete mucin. Uncommonly, squamous features are present. For the most part, an abundant fibrous stroma accompanies the epithelial proliferation. Klatskin tumors generally have slower growth than other CCAs, show prominent fibrosis, and infrequently involve distal metastases.

Intrahepatic CCAs occur in the noncirrhotic liver and may track along the intrahepatic portal tract system to create a treelike tumorous mass within a portion of the liver. Alternatively, a massive tumor nodule may develop. In either instance, vascular invasion and propagation along portal lymphatics may be prominent features, giving rise to extensive intrahepatic metastasis (Fig. 18-49A). By microscopy, CCAs resemble adenocarcinomas arising in other parts of the body, and they may show the full range of morphologic variation. Most are well- to moderately differentiated sclerosing adenocarcinomas with clearly defined glandular and tubular structures lined by cuboidal to low columnar epithelial cells (Fig. 18-49B). These neoplasms are usually markedly desmoplastic, with dense collagenous stroma separating the glandular elements. As a result, the tumor substance is

extremely firm and gritty. Lymph node metastasis and hematogenous metastases to the lungs, bones (mainly vertebrae), adrenals, brain, or elsewhere are present at autopsy in about 50% of cases. Mixed variants occur, in which elements of both HCC and CCA are present. Three forms are recognized: (1) separate tumor masses of HCC and CCA within the same liver; (2) “collision tumors,” in which tumorous masses of HCC and CCA commingle at an identifiable interface; and (3) tumors in which elements of HCC and CCA are intimately mixed at the microscopic level. These “mixed tumors” are infrequent, but careful microscopic examination of CCAs can often reveal small foci of hepatocellular differentiation. The HCC-CCA may be generated from a common bipotential precursor cell (oval cells, Chapter 3), capable of producing both hepatocytes and bile duct epithelial cells (cholangiocytes).

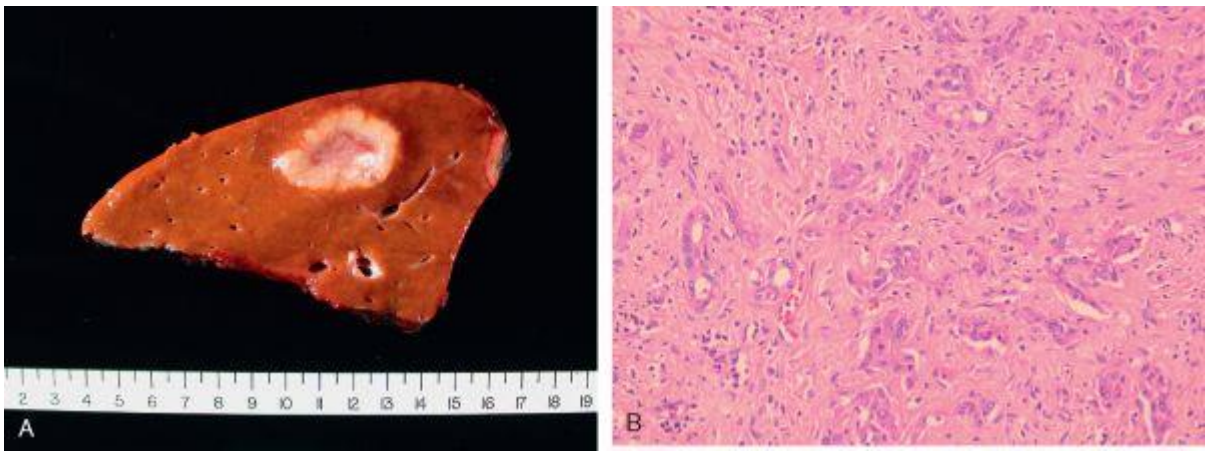

FIGURE 18-49 Cholangiocarcinoma. **A**, Liver removed at autopsy showing a massive neoplasm in the right hepatic lobe and innumerable metastases permeating the entire liver. **B**, Microscopic view showing tubular glandular structures embedded in a dense sclerotic stroma.

Pathogenesis.

Several signaling pathways, some listed here, are involved in the pathogenesis of CCA. Among these is IL-6 overexpression that leads to activation of AKT and the anti-apoptotic protein MCL-1. Also increased in CCAs is the expression of COX-2, ERB-2, and c-MET. *KRAS* expression is increased in 20% to 100% of cases in different studies, and *p53* expression is decreased in about 40% of cases. Other alterations involve amplification of epidermal growth factor receptors, and decreases in the expression of the cell cycle regulator and tumor suppressor p16/ink4A. In addition to cytologic diagnosis, fluorescence in situ hybridization using specific probes for epidermal growth factor receptors and digital image analysis to determine ploidy are now being used to improve diagnostic accuracy. Surgery, when possible, is the only treatment that is potentially curative.

METASTATIC TUMORS

Involvement of the liver by metastatic malignancy is far more common than primary hepatic neoplasia. The liver and lungs share the dubious distinction of being the visceral organs that are most often involved in the metastatic spread of cancers. Although the most common primary sources producing hepatic metastases are those of the colon, breast, lung, and pancreas, any cancer in any site of the body may spread to the liver, including leukemias, melanomas, and lymphomas. Typically, multiple nodular metastases are found that often cause striking hepatomegaly and may replace over 80% of existent hepatic parenchyma. The liver weight can exceed several kilograms. Metastasis may also appear as a

single nodule, in which case it may be resected surgically. There is a tendency for metastatic nodules to outgrow their blood supply, producing central necrosis and umbilication when viewed from the surface of the liver. Always surprising is the amount of metastatic involvement that may be present in the absence of clinical or laboratory evidence of hepatic functional insufficiency. Often the only telltale clinical sign is hepatomegaly, sometimes with nodularity of the free edge. However, with massive destruction of liver substance or direct obstruction of major bile ducts, jaundice and abnormal elevations of liver enzymes may appear.

3.8.2 The Biliary Tract

Disorders of the biliary tract affect a significant portion of the world's population. Over 95% of biliary tract disease is attributable to cholelithiasis (gallstones). In the United States, gallstones affect 20 million people, and more than 700,000 cholecystectomies are performed annually at a cost of approximately $6 billion.

As much as 1 L of bile is secreted by the liver per day. Between meals bile is stored in the gallbladder, where it is concentrated. The adult gallbladder has a capacity of about 50 mL. The organ is not essential for biliary function, since humans do not suffer from indigestion or malabsorption of fat after cholecystectomy.

3.8.2.1 Congenital Anomalies

The gallbladder may be *congenitally absent*, or there may be gallbladder *duplication* with conjoined or independent cystic ducts. A longitudinal or transverse septum may create a *bilobed gallbladder*. *Aberrant locations* of the gallbladder occur in 5% to 10% of the population, most commonly partial or complete embedding in the liver substance. A *folded fundus* is the most common anomaly, creating a *phrygian cap* (Fig. 18-50). *Agenesis* of all or any portion of the hepatic or common bile ducts and *hypoplastic* narrowing of biliary channels (true “biliary atresia”) may also occur.

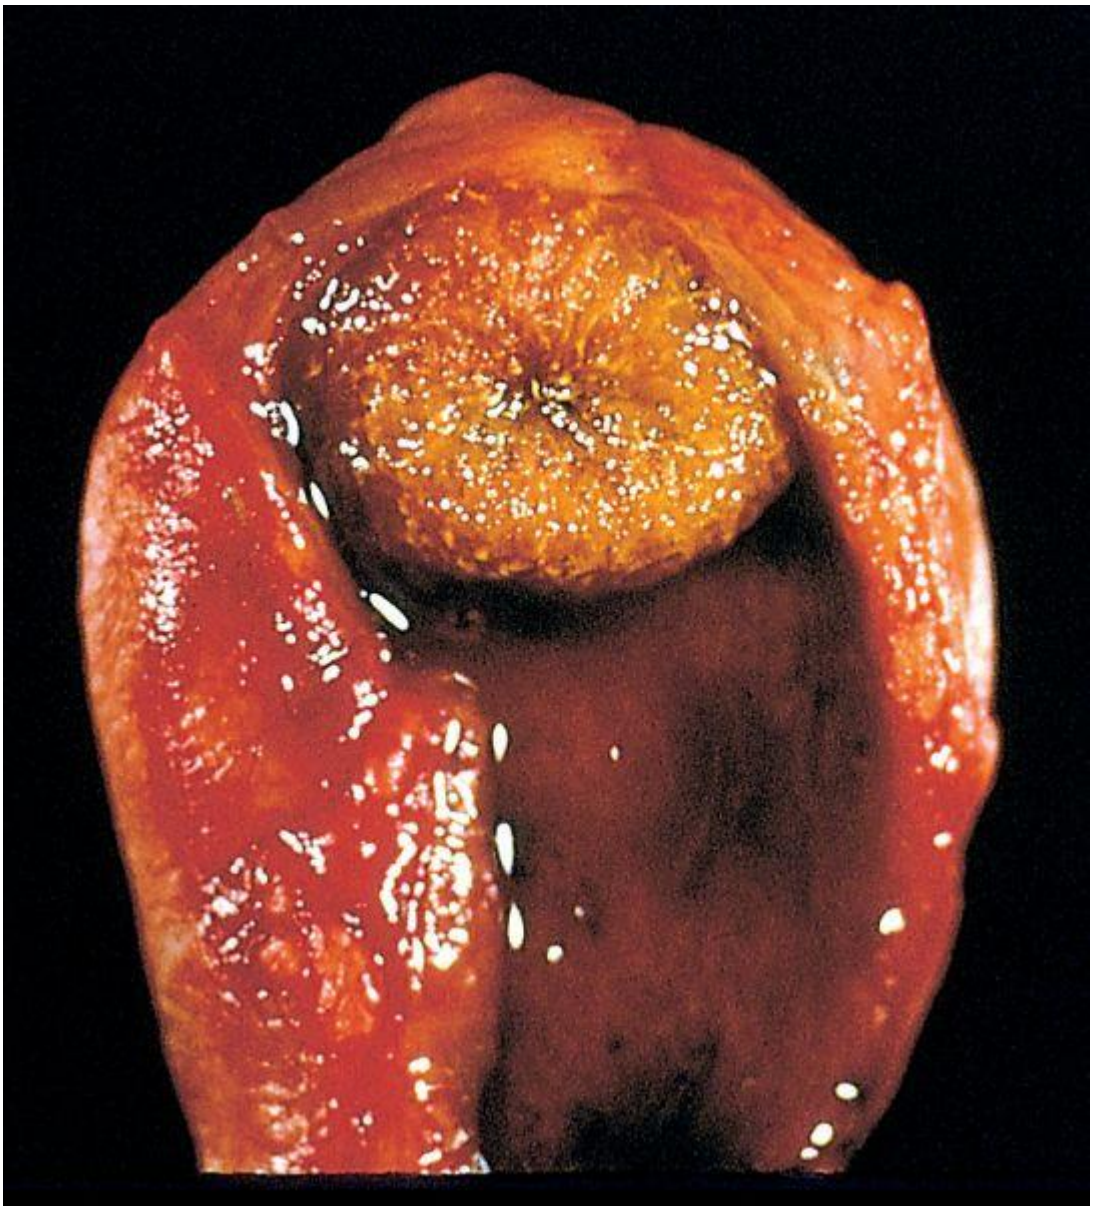

FIGURE 18-50 Phrygian cap of the gallbladder; the fundus is folded inward.

3.8.2.2 Disorders of the Gallbladder
CHOLELITHIASIS (GALLSTONES)

Gallstones afflict 10% to 20% of adult populations in developed countries. It is estimated that more than 20 million persons in the United States have gallstones, totaling some 25 to 50 tons in weight! The vast majority of gallstones (>80%) are "silent," and most individuals remain free of biliary pain or other complications for decades. There are two main types of gallstones. In the West, about 90% are *cholesterol stones*, containing more than 50% of crystalline cholesterol monohydrate. The rest are *pigment stones* composed predominantly of bilirubin calcium salts.[85]

Prevalence and Risk Factors.

Certain populations are far more prone than others to develop gallstones. The major risk factors are listed in Table 18-9 and discussed below.

TABLE 18-9 -- Risk Factors for Gallstones

CHOLESTEROL STONES
Demography: northern Europeans, North and South Americans, Native Americans, Mexican-Americans
Advancing age
Female sex hormones
Female gender
Oral contraceptives
Pregnancy
Obesity and metabolic syndrome
Rapid weight reduction
Gallbladder stasis
Inborn disorders of bile acid metabolism
Hyperlipidemia syndromes
PIGMENT STONES
Demography: Asians more than Westerners, rural more than urban
Chronic hemolytic syndromes
Biliary infection
Gastrointestinal disorders: ileal disease (e.g., Crohn disease), ileal resection or bypass, cystic fibrosis with pancreatic insufficiency

Cholesterol gallstones are more prevalent in the United States and western Europe and uncommon in developing countries. The prevalence rates of cholesterol gallstones approach 75% in Native Americans of the Pima, Hopi, and Navajo groups; pigment stones are rare in these populations. Pigment gallstones, the predominant type of gallstone in non-Western populations, arise primarily in the setting of bacterial infections of the biliary tree and parasitic infestations.

The risk factors most commonly associated with the *development of cholesterol stones* are:

- ***Age and Sex*.** The prevalence of cholesterol gallstones increases throughout life. In the United States, fewer than 5% to 6% of people under age 40 have stones, in contrast to 25% to 30% of those older than age 80. The prevalence in Caucasian women is about twice as high as in men. With both aging and gender, hypersecretion of biliary cholesterol seems to play the major role. In aging populations there is an increase in patients with gallstone disease associated with the metabolic syndrome and obesity.
- ***Environmental Factors*.** Estrogenic influence, including oral contraceptives and pregnancy, increases the expression of hepatic lipoprotein receptors and stimulates hepatic HMG-CoA reductase activity, enhancing both cholesterol uptake and biosynthesis, respectively. Clofibrate, used to lower blood cholesterol, increases hepatic HMG-CoA reductase and decreases conversion of cholesterol to bile acids by reducing cholesterol 7-α-hydroxylase activity. The net result of these influences is excess biliary secretion of cholesterol. Obesity and rapid weight loss also are strongly associated with increased biliary cholesterol secretion.
- ***Acquired Disorders*.** Gallbladder stasis, either neurogenic or hormonal, fosters a local environment that is favorable for both cholesterol and pigment gallstone formation.
- ***Hereditary Factors*.** Much progress has been made recently in identifying susceptibility factors for cholesterol gallstones. These investigations have focused on genes encoding hepatocyte proteins that transport biliary lipids, known as ATP-binding cassette (ABC) transporters. In particular, a common variant of

the protein heterodimer encoded by the *ABCG5* and *ABG2* genes that participates in biliary cholesterol secretion, confers a genetic risk for the development of cholesterol gallstones. The variant is known as D19H, and it is estimated that it may contribute 8% to 11% of the risk for the formation of cholesterol gallstones. (The odds ratios are 2–3 for heterozygous carriers of D19H, and 7 for homozygous carriers). Individuals with the D19H variant absorb less, but synthesize more, cholesterol, suggesting that HMG-CoA inhibitors (statins) may decrease the risk of gallstone formation in these individuals.

Pathogenesis of Cholesterol Stones.

Cholesterol is rendered soluble in bile by aggregation with water-soluble bile salts and water-insoluble lecithins, both of which act as detergents. *When cholesterol concentrations exceed the solubilizing capacity of bile (supersaturation), cholesterol can no longer remain dispersed and nucleates into solid cholesterol monohydrate crystals*. Cholesterol gallstone formation involves four simultaneous conditions (Fig. 18-51): (1) The bile must be supersaturated with cholesterol; (2) hypomotility of the gallbladder promotes nucleation; (3) cholesterol nucleation in the bile is accelerated; (4) hypersecretion of mucus in the gallbladder traps the nucleated crystals, leading to their aggregation into stones.

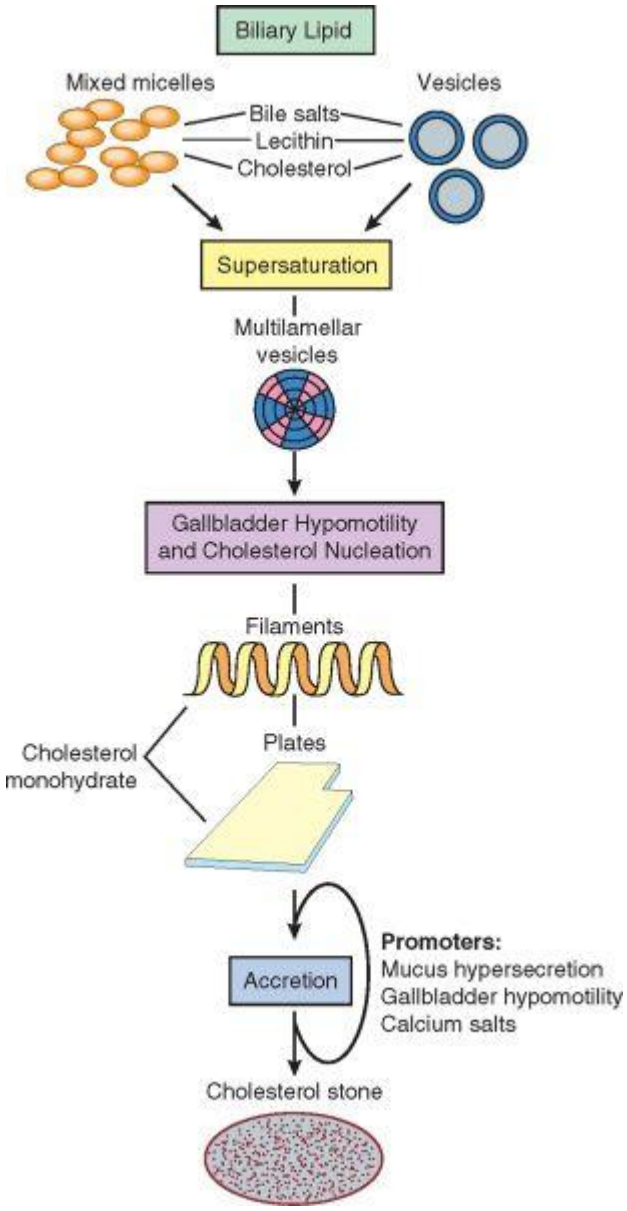

FIGURE 18-51 The four contributing factors for cholelithiasis: supersaturation, gallbladder hypomotility, crystal nucleation, and accretion

within the gallbladder mucous layer.

Pathogenesis of Pigment Stones.

Pigment gallstones are complex mixtures of abnormal insoluble calcium salts of unconjugated bilirubin along with inorganic calcium salts. Disorders that are associated with elevated levels of unconjugated bilirubin in bile such as hemolytic syndromes, severe ileal dysfunction (or bypass), and bacterial contamination of the biliary tree, increase the risk of developing pigment stones. Unconjugated bilirubin is normally a minor component of bile, but it increases when infection of the biliary tract leads to release of microbial β-glucuronidases, which hydrolyze bilirubin glucuronides. Thus, infection of the biliary tract with *Escherichia coli*, *Ascaris lumbricoides*, or the liver fluke *O. sinensis*, increases the likelihood of pigment stone formation. In hemolytic syndromes the secretion of conjugated bilirubin into the bile increases. However, because about 1% of bilirubin glucuronides are deconjugated in the biliary tree, the large amounts of unconjugated bilirubin produced may exceed its solubility.

Morphology. Cholesterol stones arise exclusively in the gallbladder and are composed of cholesterol, ranging from 100% pure (which is rare) down to around 50%. **Pure cholesterol stones** are pale yellow, round to ovoid, and have a finely granular, hard external surface (Fig. 18-52), which on transection reveals a glistening radiating crystalline palisade. With increasing proportions of calcium carbonate, phosphates, and bilirubin, the stones show discoloration and may be lamellated and gray-white to black. Most often, multiple stones are present that range up to several centimeters in diameter. Rarely, there is a single much larger stone that may virtually fill the fundus. Surfaces of multiple stones may be rounded or faceted, because of tight apposition. **Stones composed largely of cholesterol are radiolucent; sufficient calcium carbonate is found in 10% to 20% of cholesterol stones to render them radiopaque**.

Pigment gallstones are trivially classified as “black” and “brown.” In general, black pigment stones are found in sterile gallbladder bile, and brown stones are found in infected intrahepatic or extrahepatic ducts. “Black” pigment stones contain oxidized polymers of the calcium salts of unconjugated bilirubin, small amounts of calcium carbonate, calcium phosphate, and mucin glycoprotein, and some cholesterol monohydrate crystals. “Brown” pigment stones contain pure calcium salts of unconjugated bilirubin, mucin glycoprotein, a substantial cholesterol fraction, and calcium salts of palmitate and stearate. The black stones are rarely greater than 1.5 cm in diameter, are almost invariably present in great number (with an inverse relationship between size and number; Fig. 18-53), and may crumble to the touch. Their contours are usually spiculated and molded. Brown stones tend to be laminated and soft and may have a soaplike or greasy consistency. Because of calcium carbonates and phosphates, **approximately 50% to 75% of black stones are radiopaque**. Brown stones, which contain calcium soaps, are radiolucent. Mucin glycoproteins constitute the scaffolding and interparticle cement of all stones, whether pigment or cholesterol.

FIGURE 18-52 Cholesterol gallstones. Mechanical manipulation during laparoscopic cholecystectomy has caused fragmentation of several cholesterol gallstones, revealing interiors that are pigmented because of entrapped bile pigments. The gallbladder mucosa is reddened and irregular as a result of coexistent chronic cholecystitis.

FIGURE 18-53 Pigment gallstones. Several faceted black gallstones are present in this otherwise unremarkable gallbladder from a patient with a mechanical mitral valve prosthesis, leading to chronic intravascular hemolysis.

Clinical Features.

Gallstones may be present for decades before symptoms develop, and 70% to 80% of patients remain asymptomatic throughout their lives. It has been estimated that asymptomatic patients convert to symptomatic ones at the rate of 1% to 4% per year, and the risk diminishes with time. Prominent among symptoms is *biliary pain*, which tends to be excruciating and constant or "colicky" (spasmodic), as a result of the obstructive nature of gallstones in the biliary tree and perhaps in the gallbladder itself. Inflammation of the gallbladder (cholecystitis, discussed below), in association with stones, also generates pain. More severe complications include empyema, perforation, fistulas, inflammation of the biliary tree (cholangitis), and obstructive cholestasis or pancreatitis with ensuing problems. The larger the calculi, the less likely they are to enter the cystic or common ducts to produce obstruction; it is the very small stones, or "gravel," that are the more dangerous. Occasionally a large stone may erode directly into an adjacent loop of small bowel, generating intestinal obstruction ("gallstone ileus" or Bouveret's syndrome). Most notable is the *increased risk for carcinoma* of the gallbladder, discussed later.

CHOLECYSTITIS

Inflammation of the gallbladder may be acute, chronic, or acute superimposed on chronic. It almost always occurs in association with gallstones. In the United States cholecystitis is one of the most

common indications for abdominal surgery. Its epidemiologic distribution closely parallels that of gallstones.

Acute Cholecystitis

Acute calculous cholecystitis is an acute inflammation of the gallbladder, precipitated 90% of the time by obstruction of the neck or cystic duct.[86] It is the primary complication of gallstones and the most common reason for emergency cholecystectomy. Cholecystitis without gallstones called acalculous cholecystitis may occur in severely ill patients and accounts for about 10% of patients with cholecystitis.[87]

Pathogenesis.

Acute *calculous cholecystitis* results from chemical irritation and inflammation of the obstructed gallbladder. The action of mucosal phospholipases hydrolyzes luminal lecithins to toxic lysolecithins. The normally protective glycoprotein mucus layer is disrupted, exposing the mucosal epithelium to the direct detergent action of bile salts. Prostaglandins released within the wall of the distended gallbladder contribute to mucosal and mural inflammation. Gallbladder dysmotility develops; distention and increased intraluminal pressure compromise blood flow to the mucosa. *These events occur in the absence of bacterial infection*; only later in the course may bacterial contamination develop. Acute calculous cholecystitis frequently develops in diabetic patients who have symptomatic gallstones.

Acute *acalculous cholecystitis* is thought to result from ischemia. The cystic artery is an end artery with essentially no collateral circulation. Contributing factors may include inflammation and edema of the wall compromising blood flow, gallbladder stasis, and accumulation of microcrystals of cholesterol (biliary sludge), viscous bile, and gallbladder mucus, causing cystic duct obstruction in the absence of frank stone formation. It occurs in patients who are hospitalized for unrelated conditions. Risk factors for acute acalculous cholecytitis include: (1) sepsis with hypotension and multisystem organ failure; (2) immunosuppression; (3) major trauma and burns; (4) diabetes mellitus; and (5) infections.

Morphology. In **acute cholecystitis** the gallbladder is usually enlarged and tense, and it may assume a bright red or blotchy, violaceous to green-black discoloration, imparted by subserosal hemorrhages. The serosal covering is frequently layered by fibrin and, in severe cases, by a definite suppurative, coagulated exudate. There are no specific morphologic differences between acute acalculous and calculous cholecystitis, except for the absence of macroscopic stones in the acalculous form. In calculous cholecystitis, an obstructing stone is usually present in the neck of the gallbladder or the cystic duct. The gallbladder lumen may contain one or more stones and is filled with a cloudy or turbid bile that may contain large amounts of fibrin, pus, and hemorrhage. When the contained exudate is virtually pure pus, the condition is referred to as **empyema of the gallbladder**. In mild cases the gallbladder wall is thickened, edematous, and hyperemic. In more severe cases it is transformed into a green-black necrotic organ, termed **gangrenous cholecystitis**, with small-to-large perforations. The invasion of gas-forming organisms, notably clostridia and coliforms, may cause an acute “emphysematous” cholecystitis. The inflammatory reactions are not histologically distinctive and consist of the usual patterns of acute inflammation.

Clinical Features.

An attack of acute cholecystitis begins with progressive right upper quadrant or epigastric pain, frequently associated with mild fever, anorexia, tachycardia, sweating, nausea, and vomiting. Most patients are free of jaundice; the presence of hyperbilirubinemia suggests obstruction of the common

bile duct. Mild to moderate leukocytosis may be accompanied by mild elevations in serum alkaline phosphatase values.

Individuals with acute calculous cholecystitis usually, but not always, have experienced previous episodes of pain. *Acute calculous cholecystitis may appear with remarkable suddenness and constitute an acute surgical emergency or may present with mild symptoms that resolve without medical intervention*. In the absence of medical attention, the attack usually subsides in 7 to 10 days and frequently within 24 hours. However, as many as 25% of patients progressively develop more severe symptoms, requiring immediate surgical intervention. Recurrence is common in patients who recover.

Clinical symptoms of acute acalculous cholecystitis tend to be more insidious, since symptoms are obscured by the underlying conditions precipitating the attacks. A higher proportion of patients have no symptoms referable to the gallbladder; diagnosis therefore rests on a high index of suspicion. In the severely ill patient, early recognition of the condition is crucial, since failure to do so almost ensures a fatal outcome. As a result of either delay in diagnosis or the disease itself, the incidence of gangrene and perforation is much higher in acalculous than in calculous cholecystitis. In rare instances, primary bacterial infection can give rise to acute acalculous cholecystitis, including agents such as *Salmonella typhi* and staphylococci. A more indolent form of acute acalculous cholecystitis may occur in the outpatient population in the setting of systemic vasculitis, severe atherosclerotic ischemic disease in the elderly, in patients with AIDS, and with biliary tract infection.

Chronic Cholecystitis

Chronic cholecystitis may be a sequel to repeated bouts of mild to severe acute cholecystitis, but in many instances it develops in the apparent absence of antecedent attacks. Since it is associated with *cholelithiasis in more than 90% of cases*, the patient populations are the same as those for gallstones. The evolution of chronic cholecystitis is obscure, in that it is not clear that gallstones play a direct role in the initiation of inflammation or the development of pain, particularly since chronic acalculous cholecystitis shows symptoms and histology similar to those of the calculous form. Rather, supersaturation of bile predisposes to both chronic inflammation and, in most instances, stone formation. Microorganisms, usually *E. coli* and enterococci, can be cultured from the bile in about one third of cases. Unlike acute calculous cholecystitis, obstruction of gallbladder outflow is not a requisite. Nevertheless, the symptoms of calculous chronic cholecystitis are similar to those of the acute form and range from *biliary colic* to indolent *right upper quadrant pain* and *epigastric distress*. Since most gallbladders that are removed at elective surgery for gallstones show features of chronic cholecystitis, one must conclude that biliary symptoms often emerge following long-term coexistence of gallstones and low-grade inflammation.

Morphology. The morphologic changes in chronic cholecystitis are extremely variable and sometimes minimal. The serosa is usually smooth and glistening but may be dulled by subserosal fibrosis. Dense fibrous adhesions may remain as sequelae of preexistent acute inflammation. On sectioning, the wall is variably thickened, and has an opaque gray-white appearance. In the uncomplicated case the lumen contains fairly clear, green-yellow, mucoid bile and usually stones (Fig. 18-54). The mucosa itself is generally preserved.

On histologic examination the degree of inflammation is variable. In the mildest cases, only scattered lymphocytes, plasma cells, and macrophages are found in the mucosa and in the subserosal fibrous tissue. In more advanced cases there is marked subepithelial and subserosal fibrosis, accompanied by mononuclear cell infiltration. Reactive proliferation of the mucosa and fusion of the mucosal folds may give rise to buried crypts of epithelium within the gallbladder wall. Outpouchings of the mucosal

epithelium through the wall (**Rokitansky-Aschoff sinuses**) may be quite prominent. Superimposition of acute inflammatory changes implies acute exacerbation of an already chronically injured gallbladder.

In rare instances extensive dystrophic calcification within the gallbladder wall may yield a **porcelain gallbladder**, notable for a markedly increased incidence of associated cancer.
Xanthogranulomatous cholecystitis is also a rare condition in which the gallbladder has a massively thickened wall, is shrunken, nodular, and chronically inflamed with foci of necrosis and hemorrhage. Finally, an atrophic, chronically obstructed gallbladder may contain only clear secretions, a condition known as **hydrops of the gallbladder**.

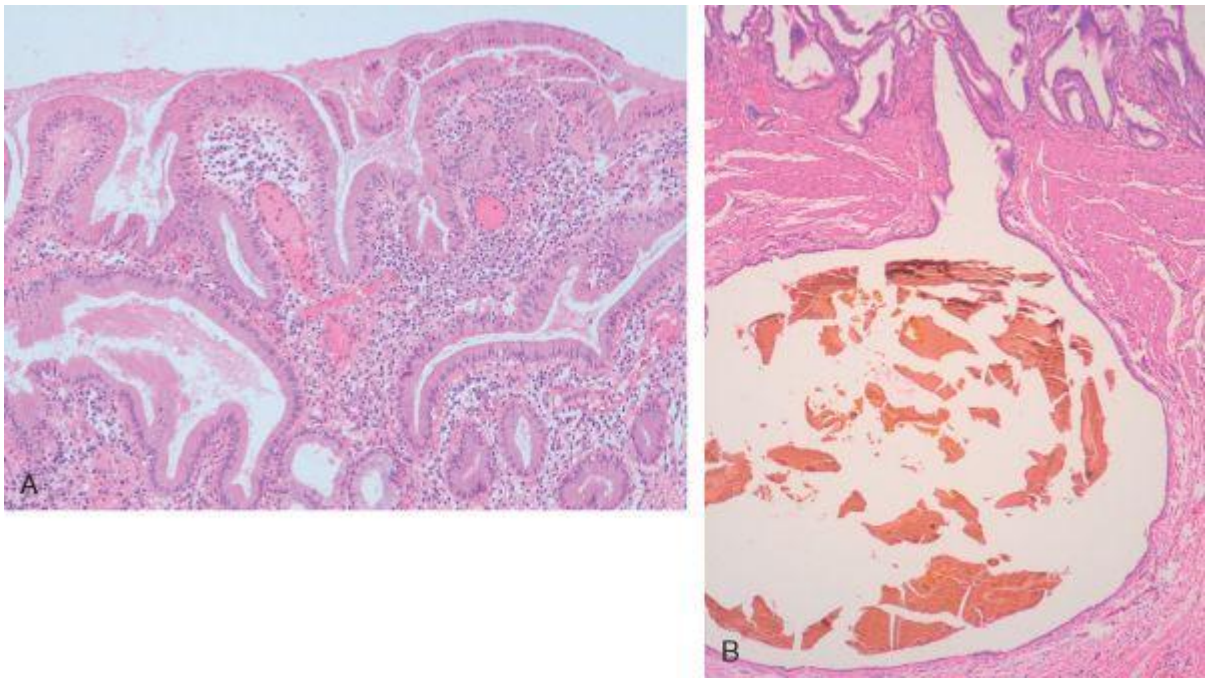

FIGURE 18-54 Chronic cholecystitis with Rokitansky-Aschoff sinus. **A**, The gallbladder mucosa is infiltrated by inflammatory cells. **B**, Outpouching of the mucosa through the wall forms Rokitansky-Aschoff sinus (contains bile).

Clinical Features.

Chronic cholecystitis does not have the striking manifestations of the acute forms and is usually characterized by recurrent attacks of either steady or colicky epigastric or right upper quadrant pain. Nausea, vomiting, and intolerance for fatty foods are frequent accompaniments.

Diagnosis of both acute and chronic cholecystitis is important because of the following complications:

- Bacterial superinfection with cholangitis or sepsis
- Gallbladder perforation and local abscess formation
- Gallbladder rupture with diffuse peritonitis
- Biliary enteric (cholecystenteric) fistula, with drainage of bile into adjacent organs, entry of air and bacteria into the biliary tree, and potentially, gallstone-induced intestinal obstruction (ileus)
- Aggravation of preexisting medical illness, with cardiac, pulmonary, renal, or liver decompensation

- Porcelain gallbladder, with increased risk of cancer, although surveys of this risk have yielded widely discrepant frequencies.

3.8.2.3 Disorders of the Extrahepatic Bile Ducts

CHOLEDOCHOLITHIASIS AND ASCENDING CHOLANGITIS

These conditions are considered together, since they frequently go hand in hand. *Choledocholithiasis is defined as the presence of stones within the bile ducts of the biliary tree*, as opposed to cholelithiasis (stones in the gallbladder). In Asia, there is a much higher incidence of primary stone formation within the biliary tree than in Western countries. The stones are usually pigmented and associated with biliary tract infections, as noted earlier in the discussion of gallstones. Choledocholithiasis may be asymptomatic or may cause symptoms from (1) obstruction, (2) pancreatitis, (3) cholangitis, (4) hepatic abscess, (5) secondary biliary cirrhosis, and (6) acute calculous cholecystitis.

Cholangitis is the term used for bacterial infection of the bile ducts. Cholangitis can result from any lesion that creates obstruction to bile flow, most commonly choledocholithiasis and biliary strictures. Less common causes include indwelling stents or catheters, tumors, acute pancreatitis, and rarely, fungi, viruses, or parasites. Bacteria most likely enter the biliary tract through the sphincter of Oddi; infection of intrahepatic biliary radicles is termed *ascending cholangitis*. The bacteria are usually enteric gram-negative aerobes such as *E. coli*, *Klebsiella*, *Interococcus*, or *Enterobacter*. *Clostridium* and *Bacteroides* are usually present as a mixed infection. Cholangitis usually presents with fever, chills, abdominal pain, and jaundice, accompanied by acute inflammation of the wall of the bile ducts with entry of neutrophils into the luminal space. The most severe form of cholangitis is suppurative cholangitis, in which purulent bile fills and distends bile ducts. Since sepsis rather than cholestasis tends to dominate the picture, prompt diagnostic evaluation and intervention are imperative in these seriously ill patients.

BILIARY ATRESIA

The infant presenting with neonatal cholestasis has been discussed already in the context of intrahepatic disorders. A major contributor to neonatal cholestasis is *biliary atresia*, representing one third of infants with neonatal cholestasis and occurring in approximately 1 : 12,000 live births. *Biliary atresia is defined as a complete or partial obstruction of the lumen of the extrahepatic biliary tree within the first 3 months of life*. It is characterized by progressive inflammation and fibrosis of intrahepatic or extrahepatic bile ducts.[88] Biliary atresia is the single most frequent cause of death from liver disease in early childhood and accounts for 50% to 60% of children referred for liver transplantation, as a result of the rapidly progressing secondary biliary cirrhosis.

Pathogenesis.

Two major forms of biliary atresia are recognized; they are based on the presumed timing of luminal obliteration. The *fetal form* accounts for as many as 20% of cases and is commonly associated with other anomalies resulting from ineffective establishment of laterality of thoracic and abdominal organ development. These include malrotation of abdominal viscera, interrupted inferior vena cava, polysplenia, and congenital heart disease. The presumed cause is aberrant intrauterine development of the extrahepatic biliary tree. Much more common is the *perinatal form* of biliary atresia, in which a presumed normally developed biliary tree is destroyed following birth. Although the etiology of perinatal biliary atresia remains unknown, viral infection and autoimmunity presumably play a critical role in the pathogenesis. Reovirus, rotavirus, and cytomegalovirus have been implicated in different cases.[89]

Morphology. The salient features of biliary atresia include inflammation and fibrosing stricture of the hepatic or common bile ducts, periductular inflammation of intrahepatic bile ducts, and progressive destruction of the intrahepatic biliary tree. On liver biopsy, florid features of extrahepatic biliary obstruction are evident in about two thirds of cases, that is, marked bile ductular proliferation, portal tract edema and fibrosis, and parenchymal cholestasis. In the remainder, inflammatory destruction of intrahepatic ducts leads to paucity of bile ducts and absence of edema or bile ductular proliferation on liver biopsy. When biliary atresia is unrecognized or uncorrected, cirrhosis develops within 3 to 6 months of birth.

There is considerable variability in the anatomy of biliary atresia. When the disease is limited to the common duct (type I) or hepatic bile ducts (type II) with patent proximal branches, the disease is surgically correctable (Kasai procedure). Unfortunately, 90% of patients have type III biliary atresia, in which there also is obstruction of bile ducts at or above the porta hepatis. These cases are noncorrectable, since there are no patent bile ducts amenable to surgical anastomosis. Moreover, in most patients, bile ducts within the liver are initially patent but are progressively destroyed.

Clinical Features.

Infants with biliary atresia present with neonatal cholestasis, discussed earlier. These infants exhibit normal birth weight and postnatal weight gain, a slight female preponderance, and the progression of initially normal stools to acholic stools as the disease evolves. At the time of presentation, serum bilirubin values are usually in the range of 6 to 12 mg/dL, with only moderately elevated aminotransferase and alkaline phosphatase levels. The success of surgical resection and bypass of the biliary tree is limited by subsequent bacterial contamination of the intrahepatic biliary tree and intrahepatic progression of the disease. Liver transplantation with accompanying donor bile ducts remains the primary hope for salvage of these young patients. Without surgical intervention, death usually occurs within 2 years of birth.

CHOLEDOCHAL CYSTS

Choledochal cysts are congenital dilations of the common bile duct, presenting most often in children before age 10 with the nonspecific symptoms of jaundice and/or recurrent abdominal pain that are typical of biliary colic.[90] Approximately 20% of cases become symptomatic only in adulthood; these sometimes occur in conjunction with cystic dilation of the intrahepatic biliary tree (Caroli disease, discussed earlier). The female-to-male ratio is 3 : 1 to 4 : 1. These uncommon cysts may take the form of segmental or cylindric dilation of the common bile duct, diverticuli of the extrahepatic ducts, or choledochoceles, which are cystic lesions that protrude into the duodenal lumen. Choledochal cysts predispose to stone formation, stenosis and stricture, pancreatitis, and obstructive biliary complications within the liver. In the older patient the risk of bile duct carcinoma is elevated.

3.8.2.4 Tumors

Although heterotopic tissues and carcinoids, fibromas, myomas, neuromas, hemangiomas, and their malignant counterparts have been described in the biliary tract, the neoplasms of primary clinical importance are those derived from the epithelium lining the biliary tree. Adenomas are benign epithelial tumors, representing localized neoplastic growth of the lining epithelium. Adenomas are classified as tubular, papillary, and tubulopapillary and are similar to adenomas found elsewhere in the alimentary tract. *Inflammatory polyps* are sessile mucosal projections with a surface stroma infiltrated with chronic inflammatory cells and lipid-laden macrophages. These lesions may be difficult to differentiate from neoplasms on imaging studies. *Adenomyosis* of the gallbladder is characterized by hyperplasia of the muscle layer, containing intramural hyperplastic glands.

Malignant tumors of the extrahepatic bile ducts have already been discussed under "Cholangiocarcinomas."

CARCINOMA OF THE GALLBLADDER

Carcinoma of the gallbladder is the most common malignancy of the extrahepatic biliary tract. It is slightly more common in women and occurs most frequently in the seventh decade of life. The incidence in the United States is 1 in 50,000. Only rarely is it discovered at a resectable stage, and the mean 5-year survival rate has remained for many years at about 5% to 12% despite surgical intervention. The most important risk factor associated with gallbladder carcinoma is gallstones (cholelithiasis), which are present in 95% of cases.[91] However, it should be noted that only 0.5% of patients with gallstones develop gallbladder cancer after twenty or more years. In Asia, where pyogenic and parasitic diseases of the biliary tree are common, the coexistence of gallstones in gallbladder cancer is much lower. Presumably, gallbladders containing stones or infectious agents develop cancer as a result of irritative trauma and chronic inflammation. Carcinogenic derivatives of bile acids are believed to play a role.

Morphology. Carcinomas of the gallbladder show two patterns of growth: **infiltrating** and **exophytic**. The infiltrating pattern is more common and usually appears as a poorly defined area of diffuse thickening and induration of the gallbladder wall that may cover several square centimeters or may involve the entire gallbladder. Deep ulceration can cause direct penetration of the gallbladder wall or fistula formation to adjacent viscera into which the neoplasm has grown. These tumors are scirrhous and have a very firm consistency. The exophytic pattern grows into the lumen as an irregular, cauliflower mass but at the same time invades the underlying wall. The luminal portion may be necrotic, hemorrhagic, and ulcerated (Fig. 18-55A). The most common sites of involvement are the fundus and the neck; about 20% involve the lateral walls.

Most carcinomas of the gallbladder are adenocarcinomas. They may be derived from adenomas, which are present in 1% of cholecystectomy specimens. Some of the carcinomas are papillary in architecture and are well to moderately differentiated; others are infiltrative and poorly differentiated to undifferentiated (Fig. 18-55B). About 5% are squamous cell carcinomas or have adenosquamous differentiation. A minority may show carcinoid or a variety of mesenchymal features (carcinosarcoma). Papillary tumors generally have a better prognosis than other tumors. By the time these neoplasms are discovered, **most have invaded the liver centrifugally**, and many have extended to the cystic duct and adjacent bile ducts and portal-hepatic lymph nodes. The peritoneum, gastrointestinal tract, and lungs are common sites of seeding.

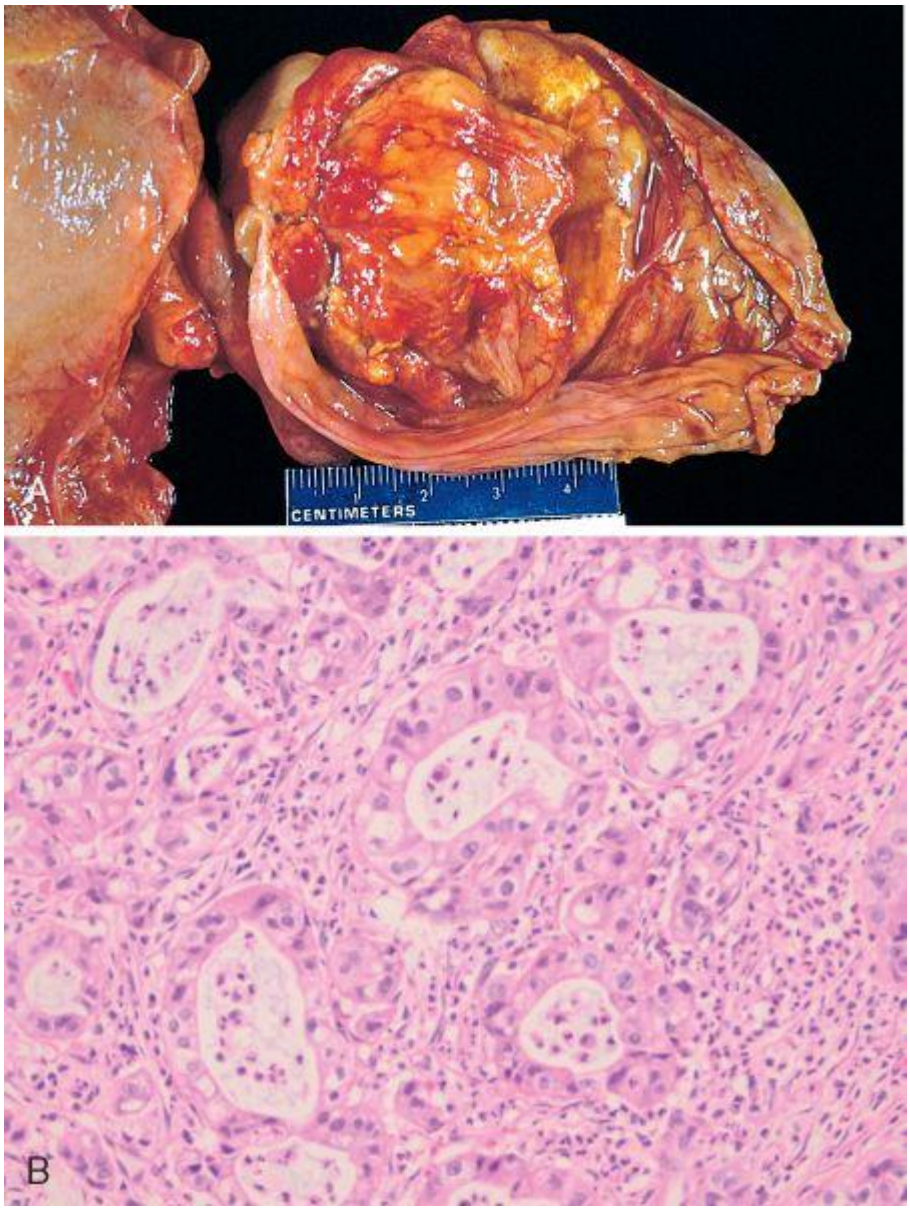

FIGURE 18-55 Gallbladder adenocarcinoma. **A**, The opened gallbladder contains a large, exophytic tumor that virtually fills the lumen. **B**, Malignant glandular structures are present within a densely fibrotic gallbladder wall.

Clinical Features.

Preoperative diagnosis of carcinoma of the gallbladder is the exception rather than the rule, occurring in fewer than 20% of patients. Presenting symptoms are insidious and typically indistinguishable from those associated with cholelithiasis: abdominal pain, jaundice, anorexia, and nausea and vomiting. Early detection of the tumor may be possible in patients who develop a palpable gallbladder and acute cholecystitis before extension of the tumor into adjacent structures, or when the carcinoma is an incidental finding during a cholecystectomy for symptomatic gallstones. Surgical resection, often including adjacent liver, is the only effective treatment, when possible, but chemotherapy regimens are also used.

3.9 19. The Pancreas

3.9.1 Congenital Anomalies

RALPH H. HRUBAN,
CHRISTINE IACOBUZIO-DONAHUE

The adult pancreas is a transversely oriented retroperitoneal organ extending from the "C" loop of the duodenum to the hilum of the spleen (Fig. 19-1). On average, the pancreas measures 20 cm in length and weighs 90 gm in men and 85 gm in women.[1] The vasculature adjacent to the pancreas can be used to separate the pancreas into four parts: the head, neck, body, and tail.

The pancreatic duct system is highly variable. The main pancreatic duct, also known as the duct of Wirsung, most commonly drains into the duodenum at the papilla of Vater, whereas the accessory pancreatic duct, also known as the duct of Santorini, most often drains into the duodenum through a separate minor papilla approximately 2 cm cephalad (proximal) to the major papilla of Vater (Fig. 19-1A). In most adults the main pancreatic duct joins the common bile duct proximal to the papilla of Vater, thus creating the ampulla of Vater, a common channel for biliary and pancreatic drainage. This ductal architecture can differ significantly from person to person.

The pancreas arises from the fusion of dorsal and ventral outpouchings of the foregut, which fuse to form a single organ.[2,][3] The majority of the gland, including the body, the tail, the superior/anterior aspect of the head, and the accessory duct of Santorini, is derived from the dorsal primordium. The ventral primordium gives rise to the posterior/inferior part of the head of the pancreas, and drains into the papilla of Vater.

Although the organ gets its name from the Greek *pankreas*, meaning "all flesh," the pancreas is, in fact, a complex lobulated organ with distinct exocrine and endocrine components. The exocrine portion, which produces digestive enzymes, constitutes 80% to 85% of the pancreas. The endocrine portion is composed of about 1 million clusters of cells, the islets of Langerhans. The islet cells secrete insulin, glucagon, and somatostatin and constitute only 1% to 2% of the organ. Diseases of the endocrine pancreas are described in detail in Chapter 24 .

The exocrine pancreas is composed of acinar cells, which produce the enzymes needed for digestion, and a series of ductules and ducts that convey secretions to the duodenum.[1] Acinar cells are pyramidally shaped epithelial cells that are radially oriented around a central lumen (Fig. 19-2). Acinar cells contain membrane-bound zymogen granules rich in digestive enzymes.

The pancreas secretes its exocrine products as enzymatically inert proenzymes. They include trypsinogen, chymotrypsinogen, procarboxypeptidase, proelastase, kallikreinogen, and prophospholipase A and B.[1] Self-digestion of pancreatic tissue is prevented by several mechanisms:

- The majority of the enzymes are synthesized as inactive proenzymes (with the exception of amylase and lipase).
- The enzymes are sequestered in membrane-bound zymogen granules in the acinar cells.
- Activation of proenzymes requires conversion of inactive trypsinogen to active trypsin by duodenal

enteropeptidase (enterokinase). Trypsin cleaves proenzymes to yield products such as chymotrypsin, elastases, and phospholipases.

- Trypsin inhibitors including serine protease inhibitor Kazal type l (SPINK1, also known as pancreatic secretory trypsin inhibitor, PSTI) are present within acinar and ductal secretions.
- Acinar cells are remarkably resistant to the action of trypsin, chymotrypsin, and phospholipase A_2.

The most significant disorders of the *exocrine* pancreas include cystic fibrosis, congenital anomalies, acute and chronic pancreatitis, pseudocysts, and neoplasms. Cystic fibrosis is discussed in detail in Chapter 10 .

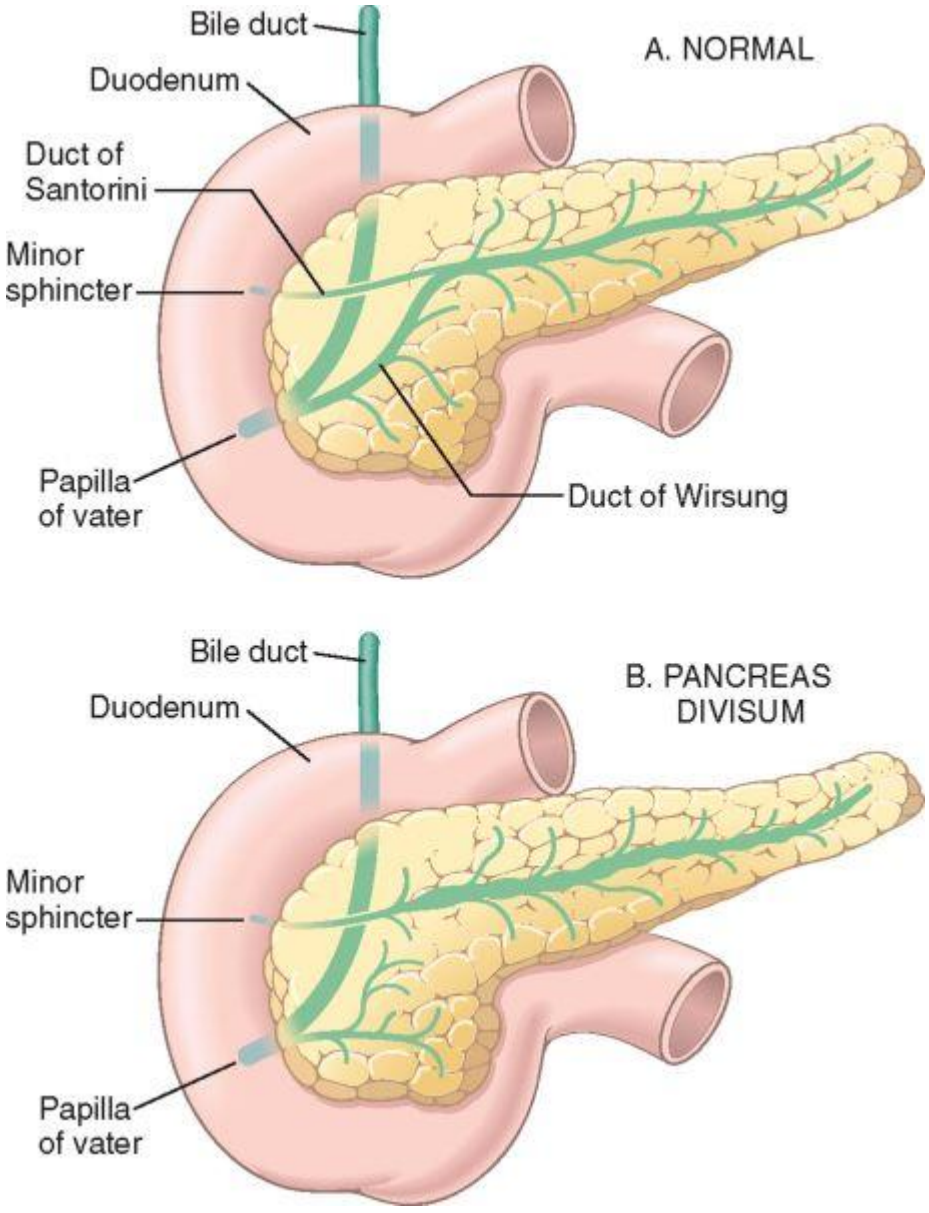

FIGURE 19-1 Pancreatic ductal anatomy. **A**, The normal ductal anatomy. **B**, The ductal anatomy in pancreatic divisum. *(Adapted from Gregg JA et al.: Pancreas divisum: results of surgical intervention. Am J Surg 145:488–492, 1983.)*

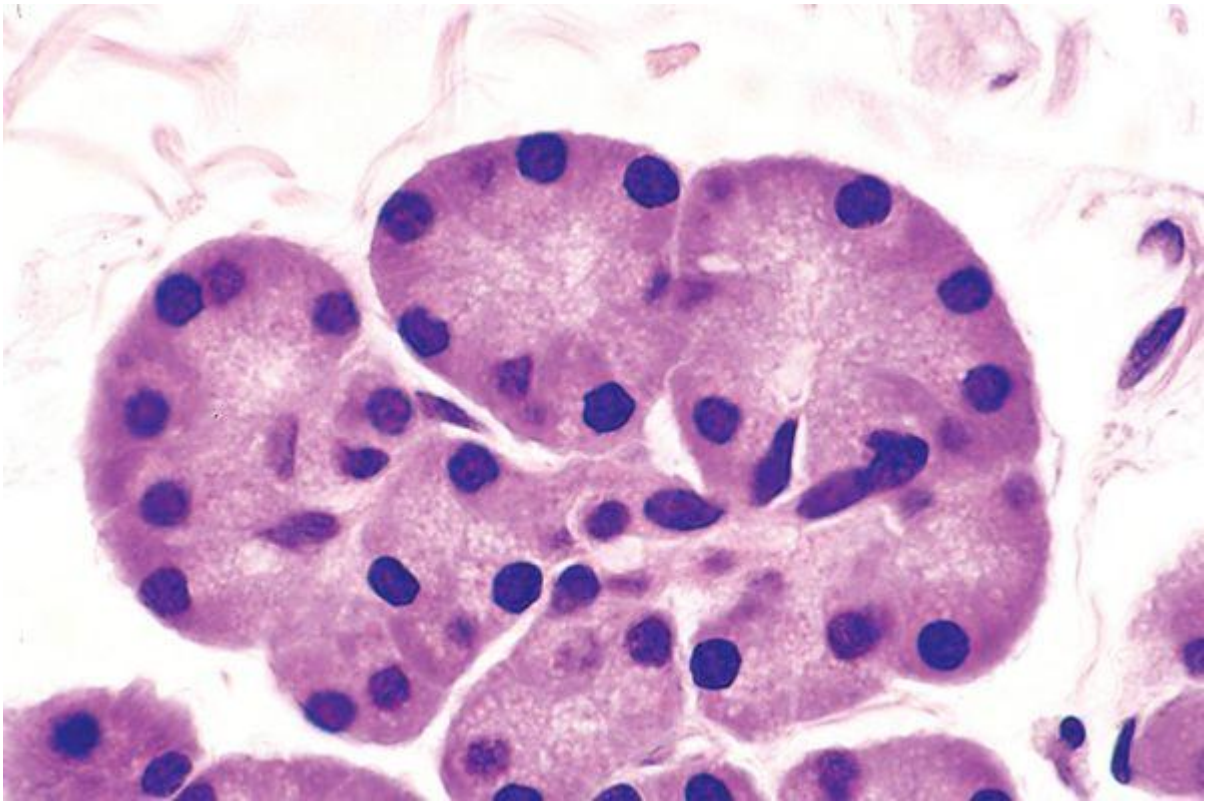

FIGURE 19-2 Pancreatic acini, showing the radial orientation of the pyramidal exocrine acinar cells. The cytoplasm is devoted to the synthesis and packaging of digestive enzymes for secretion into a central lumen.

Congenital Anomalies

The complex process by which the dorsal and ventral pancreatic primordia fuse during pancreatic development frequently gives rise to congenital variations in pancreatic anatomy.[3] Most of these do not directly cause disease; however, such variations, especially in ductal anatomy, may present particular problems to endoscopists and surgeons. For example, failure to recognize aberrant ductal anatomy may lead to the inadvertent ligation of a pancreatic duct during surgery, causing serious sequelae such as pancreatitis.

AGENESIS

Very rarely the pancreas may be totally absent (agenesis), a condition associated with other severe malformations that are usually incompatible with life. *PDX1* (pancreatic and duodenal homeobox-1 gene) encodes a transcription factor critical for the development of the pancreas.[3] Homozygous *PDX1* mutations on chromosome 13q12.1 have been reported in a person with pancreatic agenesis.[3,][4]

PANCREAS DIVISUM

Pancreas divisum is the most common congenital anomaly of the pancreas, with an incidence of 3% to 10%.[4] This anomaly is caused by a failure of fusion of the fetal duct systems of the dorsal and ventral pancreatic primordia.[4] As a result, the bulk of the pancreas (formed by the dorsal pancreatic primordium) drains through the dorsal pancreatic duct and the *small-caliber minor papilla* (see Fig. 19-1B).[4] The duct of Wirsung in persons with divisum, normally the main pancreatic duct, is very short (1 to 2 cm) and drains only a small portion of the head of the gland through the larger caliber major papilla

of Vater. Although controversy exists about the clinical significance of pancreatic divisum, it has been suggested that the relative stenosis caused by the bulk of the pancreatic secretions passing through the minor papilla predisposes individuals to the development of chronic pancreatitis.[4,][5]

ANNULAR PANCREAS

Annular pancreas is a band-like ring of normal pancreatic tissue that completely encircles the second portion of the duodenum. Annular pancreas is often associated with other congenital anomalies and may present early in life or in adults with signs and symptoms of duodenal obstruction such as gastric distention and vomiting.[4,][6]

ECTOPIC PANCREAS

Aberrantly situated, or *ectopic*, pancreatic tissue is found in about 2% of careful routine postmortem examinations. The favored sites for ectopia are the stomach and duodenum, followed by the jejunum, Meckel diverticula, and ileum.[4] These embryologic rests are a few millimeters to centimeters in size and are located in the submucosa. Histologic examination reveals that they are composed of normal-appearing pancreatic acini, glands, and sometimes islets of Langerhans. Though usually incidental, ectopic pancreas may cause pain from localized inflammation, or, rarely, may incite mucosal bleeding. Approximately 2% of islet cell neoplasms (Chapter 24) arise in ectopic pancreatic tissue. The pathogenesis of ectopic pancreas has not been established.

3.9.2 Pancreatitis

Pancreatitis is inflammation in the pancreas associated with injury to the exocrine parenchyma. The clinical manifestations range in severity from a mild, self-limited disease to a life-threatening acute inflammatory process, and the duration of the disease can range from a transient attack to a permanent loss of function.[7,][8] In *acute pancreatitis* the gland can return to normal if the underlying cause of the pancreatitis is removed.[9,][10] By contrast, *chronic pancreatitis* is defined by the irreversible loss of exocrine pancreatic parenchyma.[7,][11]

ACUTE PANCREATITIS

Acute pancreatitis is reversible pancreatic parenchymal injury associated with inflammation. Acute pancreatitis is relatively common, with an annual incidence rate in Western countries of 10 to 20 cases per 100,000 people. Biliary tract disease and alcoholism account for approximately 80% of cases in Western countries (Table 19-1).[8] [9] [10][12] Gallstones are present in 35% to 60% of cases of acute pancreatitis, and about 5% of patients with gallstones develop pancreatitis. The proportion of cases of acute pancreatitis caused by excessive alcohol intake varies from 65% in the United States to 20% in Sweden to 5% or less in southern France and the United Kingdom.[13] The male-to-female ratio is 1 : 3 in the group with biliary tract disease and 6 : 1 in those with alcoholism.

TABLE 19-1 -- Etiologic Factors in Acute Pancreatitis

METABOLIC
Alcoholism
Hyperlipoproteinemia
Hypercalcemia
Drugs (e.g., azathioprine)
GENETIC

Mutations in the cationic trypsinogen (*PRSS1*) and trypsin inhibitor (*SPINK1*) genes
MECHANICAL
Gallstones Trauma Iatrogenic injury Operative injury Endoscopic procedures with dye injection
VASCULAR
Shock Atheroembolism Vasculitis
INFECTIOUS
Mumps

Less common causes of acute pancreatitis include the following:

- Obstruction of the pancreatic duct system. Reasons for obstruction other than gallstones include periampullary neoplasms (such as pancreatic cancer), pancreas divisum (although its role is controversial), choledochoceles (congenital cystic dilatation of the common bile duct), biliary "sludge," and parasites (particularly the *Ascaris lumbricoides* and *Clonorchis sinensis* organisms).[10,][14]
- Medications. More than 85 drugs have been implicated. These include furosemide, azathioprine, 2′,3′-dideoxyinosine, estrogens, and many others.[10,][15]
- Infections, including mumps, can lead to acute pancreatitis.
- Metabolic disorders, such as hypertriglyceridemia, hyperparathyroidism, and other hypercalcemic states.
- Ischemic injury from shock, vascular thrombosis, embolism, and vasculitis.
- Trauma. Both blunt abdominal trauma and iatrogenic injury during surgery or endoscopic retrograde cholangiopancreatography.
- Inherited alterations in genes encoding pancreatic enzymes and their inhibitors, including germline mutations in the cationic trypsinogen (*PRSS1*) and trypsin inhibitor (*SPINK1*) genes. [16] [17] [18] [19] These are discussed below.

Hereditary Pancreatitis.

Notably, 10% to 20% of individuals with acute pancreatitis have no known associated processes. Although this condition is currently termed *idiopathic*, a growing body of evidence suggests that some of these cases actually have a genetic basis. The genetic alterations associated with the development of pancreatitis therefore deserve special note.[17] Hereditary pancreatitis is characterized by recurrent attacks of severe pancreatitis usually beginning in childhood.[16,][17] Most cases are caused by germline (inherited) mutations in the *cationic trypsinogen* gene (also known as *PRSS1*).[16] These mutations abrogate a critical fail-safe mechanism by altering a site on the cationic trypsinogen molecule that is essential for the cleavage (inactivation) of trypsin by trypsin itself.[17] When this site is mutated, trypsin becomes resistant to cleavage by another trypsin molecule, and if a small amount of this tryspin is inappropriately activated in the pancreas, it can activate other digestive proenzymes, resulting in the development of pancreatitis. Only one mutated allele is required for cleavage-resistant trypsin to be produced; thus, this form of hereditary pancreatitis has an autosomal dominant mode of inheritance.

The *serine protease inhibitor Kazal type 1 (SPINK1)* gene codes for a pancreatic secretory trypsin inhibitor that, as the name suggests, inhibits trypsin activity, helping to prevent the autodigestion of the pancreas by activated trypsin.[17] As one might suspect, inherited inactivating mutations in the *SPINK1* gene can also lead to the development of pancreatitis. This form of hereditary pancreatitis has an autosomal recessive mode of inheritance, as both alleles must be inactivated.

Morphology. The morphology of acute pancreatitis ranges from trivial inflammation and edema to severe extensive necrosis and hemorrhage. The basic alterations are **(1) microvascular leakage causing edema, (2) necrosis of fat by lipolytic enzymes, (3) acute inflammation, (4) proteolytic destruction of pancreatic parenchyma, and (5) destruction of blood vessels and subsequent interstitial hemorrhage**. The extent of each of these alterations depends on the duration and severity of the process.

In the milder form, acute interstitial pancreatitis, histologic alterations are limited to mild inflammation, interstitial edema, and focal areas of fat necrosis in the substance of the pancreas and in peripancreatic fat (Fig. 19-3). Fat necrosis, as we have seen, results from enzymatic activity of lipase. The released fatty acids combine with calcium to form insoluble salts that impart a granular blue microscopic appearance to the fat cells (Chapter 1).

In the more severe form, **acute necrotizing pancreatitis**, the acinar and ductal tissues as well as the islets of Langerhans are necrotic. Vascular injury can lead to hemorrhage into the parenchyma of the pancreas. Macroscopically, the pancreatic substance shows areas of red-black hemorrhage interspersed with foci of yellow-white, chalky fat necrosis (Fig. 19-4). Foci of fat necrosis may also be found in extra-pancreatic collections of fat, such as the omentum and the mesentery of the bowel, and even outside the abdominal cavity, such as in the subcutaneous fat. In the majority of cases the peritoneal cavity contains a serous, slightly turbid, brown-tinged fluid in which globules of fat (derived from the action of enzymes on adipose tissue) can be identified. In its most severe form, **hemorrhagic pancreatitis**, extensive parenchymal necrosis is accompanied by dramatic hemorrhage within the substance of the gland.[20,][21]

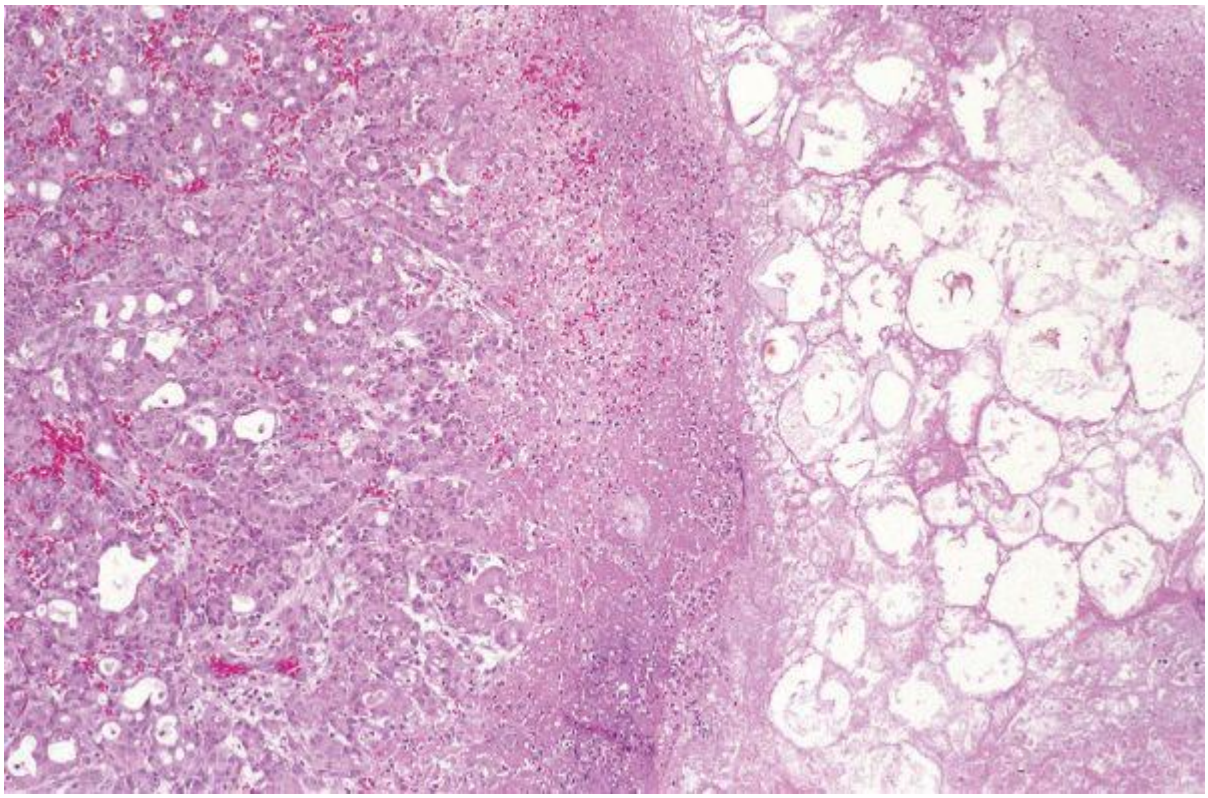

FIGURE 19-3 Acute pancreatitis. The microscopic field shows a region of fat necrosis on the right and focal pancreatic parenchymal necrosis *(center)*.

FIGURE 19-4 Acute pancreatitis. The pancreas has been sectioned longitudinally to reveal dark areas of hemorrhage in the head of the

pancreas and a focal area of pale fat necrosis in the peripancreatic fat *(upper left)*.

Pathogenesis.

The anatomic changes of acute pancreatitis strongly suggest *autodigestion of the pancreatic substance by inappropriately activated pancreatic enzymes*. This hypothesis is supported by the hereditary forms of pancreatitis described above. Here we focus on the more common, acquired forms of acute pancreatitis.

As has been discussed, pancreatic enzymes, including trypsin, are synthesized in an inactive proenzyme form. If trypsin is inappropriately activated it can in turn activate other proenzymes such as prophospholipase and proelastase, which then degrade fat cells and damage the elastic fibers of blood vessels, respectively. [8] [9] [10][12] Trypsin also converts prekallikrein to its activated form, thus bringing into play the kinin system and, by activation of Hageman factor (factor XII), the clotting and complement systems as well (Chapters 2 and 4 . In this way inflammation and small-vessel thromboses (which may lead to congestion and rupture of already weakened vessels) are amplified. Thus, the *inappropriate activation of trypsinogen is an important triggering event in acute pancreatitis*.

The mechanisms by which the activation of pancreatic enzymes is initiated are not entirely clear, but there is evidence for three possible events (Fig. 19-5):

1. *Pancreatic duct obstruction*. Gallstones or biliary sludge impacted in the region of the ampulla of Vater can raise intrapancreatic ductal pressure and lead to the accumulation of enzyme-rich fluid in the interstitium. Since lipase is one of the few enzymes secreted in an active form, this can cause local fat necrosis. Injured tissues, periacinar myofibroblasts, and leukocytes then release proinflammatory cytokines including IL-1β, IL-6, tumor necrosis factor, platelet-activating factor, and substance P, initiating local inflammation and promoting the development of interstitial edema through a leaky microvasculature (see Fig. 19-5). [22] [23] [24] [25] Edema may further compromise local blood flow, causing vascular insufficiency and ischemic injury to acinar cells.[26]
2. *Primary acinar cell injury*. This mechanism is most clearly involved in the pathogenesis of acute pancreatitis caused by certain viruses (e.g., mumps), drugs, and direct trauma to the pancreas, as well as pancreatitis following ischemia or shock.
3. *Defective intracellular transport of proenzymes within acinar cells*.[27] In normal acinar cells, digestive enzymes and lysosomal hydrolases are transported in separate pathways. In animal models of acinar injury, the pancreatic proenzymes are inappropriately delivered to the intracellular compartment containing lysosomal hydrolases. Proenzymes are then activated, the lysosomes disrupted, and activated enzymes released. The role of this mechanism in human acute pancreatitis is not clear.[28]

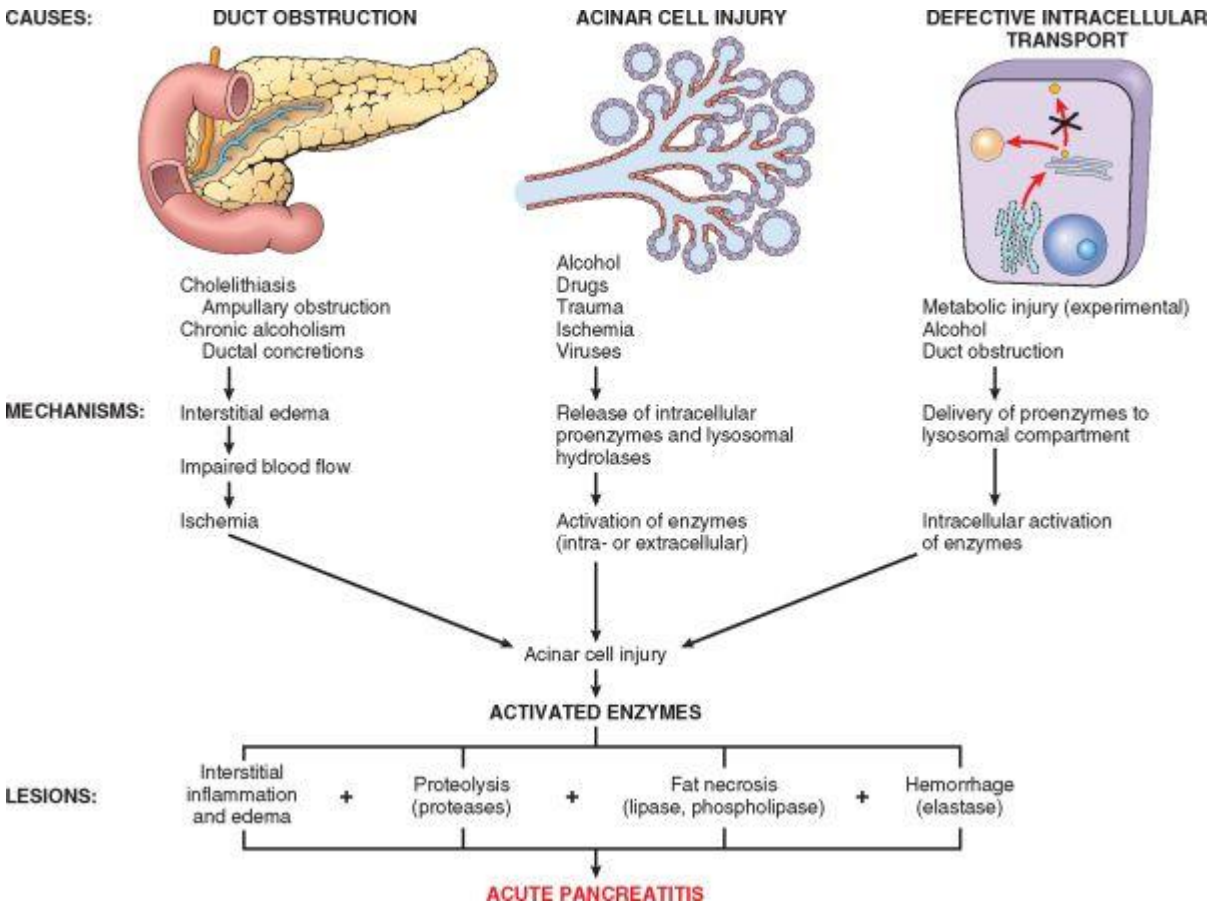

FIGURE 19-5 Three proposed pathways in the pathogenesis of acute pancreatitis.

Alcohol consumption may cause pancreatitis by several mechanisms. Chronic alcohol ingestion results in the secretion of protein-rich pancreatic fluid, which leads to the deposition of inspissated protein plugs and obstruction of small pancreatic ducts. Alcohol also transiently increases pancreatic exocrine secretion and contraction of the sphincter of Oddi (the muscle at the ampulla of Vater), and it has direct toxic effects on acinar cells.[29]

Clinical Features.

Abdominal pain is the cardinal manifestation of acute pancreatitis. [8] [9] [10][12] Characteristically, the pain is constant and intense and is often referred to the upper back and occasionally can be associated with referred pain to the left shoulder. Its severity varies from mild and uncomfortable to severe and incapacitating. Anorexia, nausea, and vomiting frequently accompany the pain. Suspected acute pancreatitis is primarily diagnosed by the presence of elevated plasma levels of amylase and lipase and the exclusion of other causes of abdominal pain.

Full-blown acute pancreatitis is a medical emergency. These patients usually have the sudden calamitous onset of an "acute abdomen." Many of the systemic features of severe acute pancreatitis can be attributed to release of toxic enzymes, cytokines, and other mediators into the circulation and explosive activation of the systemic inflammatory response, resulting in *leukocytosis, hemolysis, disseminated intravascular coagulation, fluid sequestration, acute respiratory distress syndrome, and*

diffuse fat necrosis. *Peripheral vascular collapse and shock with acute renal tubular necrosis may occur*. [8] [9] [10][12]

Laboratory findings include marked elevation of serum amylase levels during the first 24 hours, followed within 72 to 96 hours by a rising serum lipase level. Glycosuria occurs in 10% of cases. Hypocalcemia may result from precipitation of calcium soaps in necrotic fat; if persistent, it is a poor prognostic sign. Direct visualization of the enlarged inflamed pancreas by radiography is useful in the diagnosis of pancreatitis.

The key to the management of acute pancreatitis is "resting" the pancreas by total restriction of oral intake and by supportive therapy with intravenous fluids and analgesia. Although most individuals with acute pancreatitis recover fully, about 5% with severe acute pancreatitis die from shock during the first week of illness. Acute respiratory distress syndrome and acute renal failure are ominous complications. [8] [9] [10][12] Sequelae can include a sterile *pancreatic abscess* and a *pancreatic pseudocyst* (discussed later). In 40% to 60% of patients with acute necrotizing pancreatitis the necrotic debris becomes infected, usually by gram-negative organisms from the alimentary tract, further complicating the clinical course.

CHRONIC PANCREATITIS

Chronic pancreatitis is defined as inflammation of the pancreas with irreversible destruction of exocrine parenchyma, fibrosis, and, in the late stages, the destruction of endocrine parenchyma.[11,][30] Although chronic pancreatitis may present as repeated bouts of acute pancreatitis, the chief distinction between acute and chronic pancreatitis is the irreversible impairment in pancreatic function that is characteristic of chronic pancreatitis. The prevalence of chronic pancreatitis ranges between 0.04% and 5%.[7] There is significant overlap in the causes of acute and chronic pancreatitis. By far *the most common cause of chronic pancreatitis is long-term alcohol abuse*, and these patients are usually middle-aged males.

Less common causes of chronic pancreatitis include the following:

- Long-standing *obstruction* of the pancreatic duct by pseudocysts, calculi, trauma, neoplasms, or pancreas divisum. There is often dilation of the pancreatic duct.
- *Tropical pancreatitis*, which is a poorly characterized heterogeneous disease seen in Africa and Asia.[31] Some cases have a genetic basis.
- *Hereditary pancreatitis*, which is caused by germline mutations in *PRSS1* (cationic trypsinogen gene) or *SPINK1* (serine protease inhibitor Kazal type 1 gene), and is associated with the development of both acute and chronic pancreatitis.[16,][17]
- *CFTR gene mutations*. As was discussed in detail in Chapter 10 , cystic fibrosis is caused by bi-allelic inherited mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. Mutations in *CFTR* decrease bicarbonate secretion by pancreatic ductal cells, thereby promoting protein plugging and the development of chronic pancreatitis.[19] Mutations in the *CFTR* gene occur in 25% to 30% of patients with idiopathic pancreatitis, a rate that is approximately 5 times higher than that of the general population.

As many as 40% of individuals with chronic pancreatitis have no recognizable predisposing factor, but as is true for acute pancreatitis, a growing number of these "idiopathic" cases can now be shown to be caused by inherited mutations in pancreatitis-associated genes.[19]

Pathogenesis.

The pathogenesis of chronic pancreatitis is not well understood. Almost all individuals with repeated episodes of acute pancreatitis later develop chronic pancreatitis. It has been proposed that acute

pancreatitis initiates a sequence of perilobular fibrosis, duct distortion, and altered pancreatic secretions. Over time and with multiple episodes, this can lead to loss of pancreatic parenchyma and fibrosis.[32] The events that have been proposed to account for the development of chronic pancreatitis include:[32,][33]

1. *Ductal obstruction by concretions*. Some of the agents responsible for the development of chronic pancreatitis are believed to increase protein concentrations in the pancreatic juice. These proteins form ductal plugs. Such plugs are particularly prominent in alcoholic chronic pancreatitis.[34] The ductal plugs may calcify, forming calculi composed of calcium carbonate precipitates that can further obstruct the pancreatic ducts and contribute to the development of chronic pancreatitis.
2. *Toxic effects*. Toxins, including alcohol and its metabolites, can exert a direct toxic effect on acinar cells.
3. *Oxidative stress*. Alcohol-induced oxidative stress may generate free radicals in acinar cells, leading to membrane lipid oxidation and the activation of transcription factors, including AP1 and NF-κB, which in turn induce the expression of chemokines that attract mononuclear cells.[32,][33] Oxidative stress may promote the fusion of lysosomes and zymogen granules, acinar cell necrosis, inflammation, and fibrosis.

A variety of chemokines have been identified in chronic pancreatitis, including IL-8 and monocyte chemoattractant protein.[35] In addition, transforming growth factor β (TGF-β) and platelet-derived growth factor induce the activation and proliferation of periacinar myofibroblasts (pancreatic stellate cells), resulting in the deposition of collagen and ultimately fibrosis (Fig. 19-6).[36] [37] [38] While the chemokines produced during chronic pancreatitis are similar to those produced in acute pancreatitis, the profibrogenic chemokines tend to predominate in chronic pancreatitis.[39]

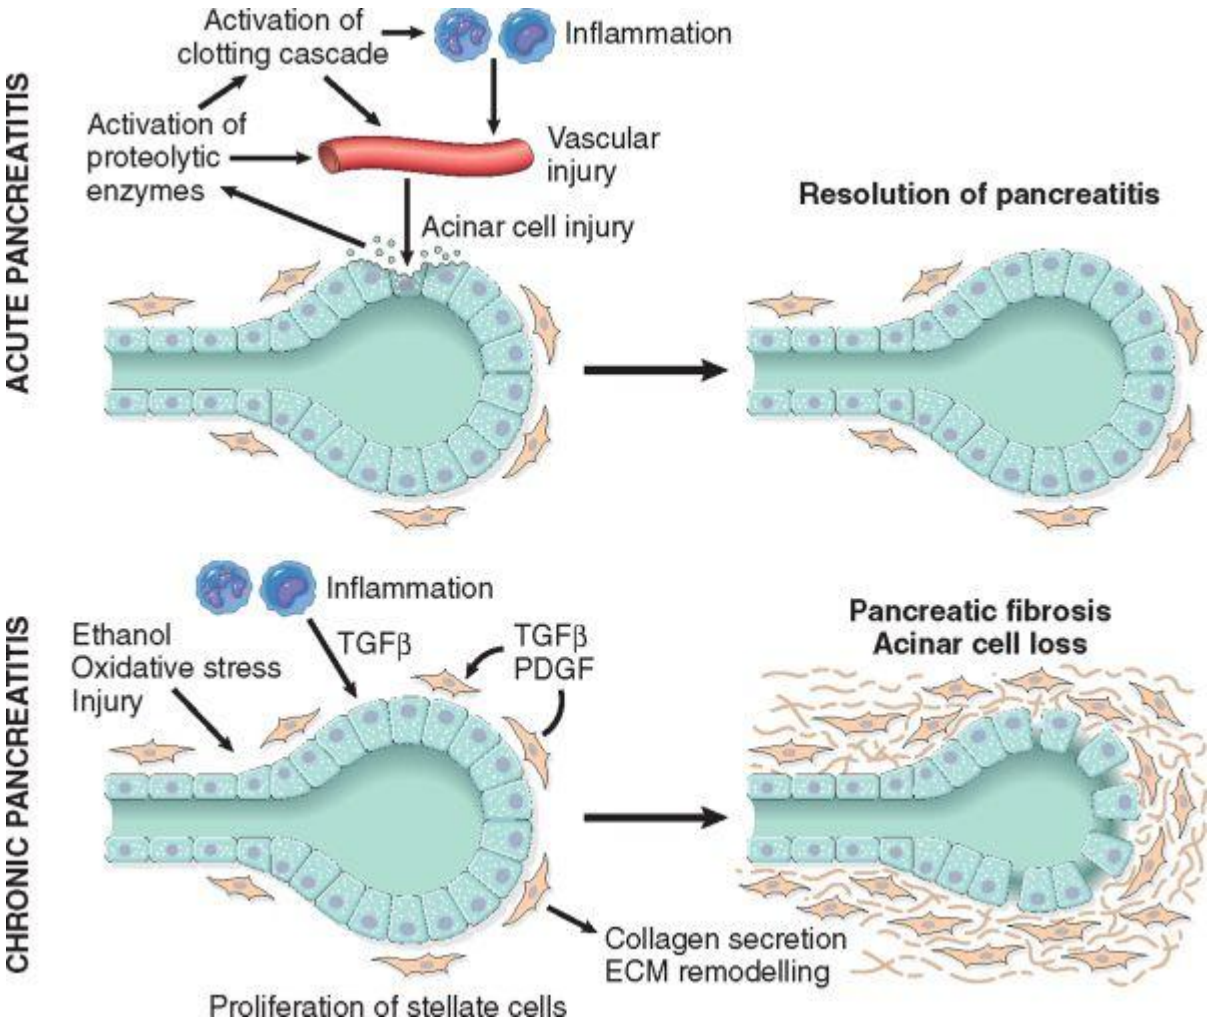

FIGURE 19-6 Comparison of the mediators in acute and chronic pancreatitis. In acute pancreatitis acinar injury results in release of proteolytic enzymes, leading to a cascade of events including activation of the clotting cascade, acute and chronic inflammation, vascular injury, and edema. In most patients, complete resolution of the acute injury occurs with restoration of acinar cell mass. In chronic pancreatitis, repeated episodes of acinar cell injury lead to the production of profibrogenic cytokines such as transforming growth factor β (TGF-β) and platelet-derived growth factor (PDGF), resulting in the proliferation of myofibroblasts, the secretion of collagen, and remodeling of the extracellular matrix (ECM). Repeated injury produces irreversible loss of acinar cell mass, fibrosis, and pancreatic insufficiency.

Morphology. Chronic pancreatitis is characterized by parenchymal fibrosis, reduced number and size of acini with relative sparing of the islets of Langerhans, and variable dilation of the pancreatic ducts (Fig. 19-7A). These changes are usually accompanied by a chronic inflammatory infiltrate around lobules and ducts. The interlobular and intralobular ducts are frequently dilated and contain protein plugs in their lumens. The ductal epithelium may be atrophied or hyperplastic or may show squamous metaplasia, and ductal concretions may be evident (Fig. 19-7B). Acinar loss is a constant feature. The remaining islets of Langerhans become embedded in the sclerotic tissue and may fuse and appear enlarged. Eventually, they too disappear. Grossly, the gland is hard, sometimes with extremely dilated ducts and visible calcified concretions. **Lymphoplasmacytic sclerosing pancreatitis** (autoimmune pancreatitis) is a distinct form of chronic pancreatitis characterized by a duct-centric mixed inflammatory cell infiltrate, venulitis, and increased numbers of IgG4-producing plasma cells.[40] It is important to recognize lymphoplasmacytic sclerosing pancreatitis, since it can clinically mimic pancreatic cancer and also because it responds to steroid therapy.

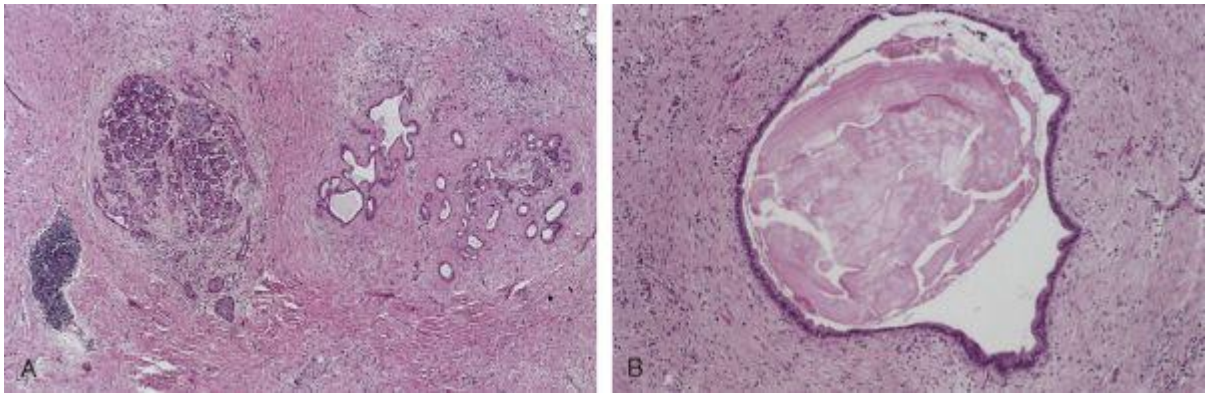

FIGURE 19-7 Chronic pancreatitis. **A**, Extensive fibrosis and atrophy has left only residual islets *(left)* and ducts *(right)*, with a sprinkling of chronic inflammatory cells and acinar tissue. **B**, A higher power view demonstrating dilated ducts with inspissated eosinophilic ductal concretions in a person with alcoholic chronic pancreatitis.

Clinical Features.

Chronic pancreatitis may present in many different forms. It may be associated with repeated attacks of moderately severe abdominal pain, recurrent attacks of mild pain, or persistent abdominal and back pain. The disease may be entirely silent until pancreatic insufficiency and diabetes mellitus develop, the latter from associated destruction of islets of Langerhans. In still other instances, recurrent attacks of jaundice or vague attacks of indigestion may hint at pancreatic disease. Attacks may be precipitated by alcohol abuse, overeating (which increases demand on the pancreas), or the use of opiates and other drugs that increase the tone of the sphincter of Oddi.

The diagnosis of chronic pancreatitis requires a high degree of suspicion. During an attack of abdominal pain there may be mild fever and mild-to-moderate elevations of serum amylase. When the disease has been present for a long time, however, the destruction of acinar cells may preclude such diagnostic clues. Gallstone-induced obstruction may be evident as jaundice or elevations in serum levels of alkaline phosphatase. A very helpful finding is visualization of calcifications within the pancreas by computed tomography and ultrasonography. Weight loss and hypoalbuminemic edema from malabsorption caused by pancreatic exocrine insufficiency may point toward the disease.

Although chronic pancreatitis is usually not an immediately life-threatening condition, the long-term outlook for individuals with chronic pancreatitis is poor, with a 20- to 25-year mortality rate of 50%. Severe *pancreatic exocrine insufficiency* and chronic malabsorption may develop, as can *diabetes mellitus*. In other patients *severe chronic pain* may become the dominant problem. *Pancreatic pseudocysts* (described below) develop in about 10% of patients. While patients with hereditary pancreatitis have a 40% lifetime risk of developing pancreatic cancer, the degree to which other forms of chronic pancreatitis predispose to the development of pancreatic cancer is unclear.[41,][42]

3.9.3 Non-Neoplastic Cysts

A variety of cysts can arise in the pancreas. Most are non-neoplastic pseudocysts (discussed later), but congenital cysts and neoplastic cysts also occur.

CONGENITAL CYSTS

Congenital cysts are believed to result from anomalous development of the pancreatic ducts. Cysts in the kidney, liver, and pancreas frequently coexist in *polycystic disease* (discussed in Chapter 20). Congenital cysts are usually unilocular, thin-walled, and range from microscopic lesions to 5 cm in diameter. They are lined by a glistening, uniform cuboidal epithelium or, if the intracystic pressure is high, by a flattened and attenuated cell layer; they are enclosed in a thin, fibrous capsule and are filled with a clear serous fluid. Congenital cysts may be sporadic, or part of *autosomal-dominant polycystic kidney disease* and *von Hippel-Lindau disease*.[4] In von Hippel-Lindau disease (Chapter 20) vascular neoplasms are found in the retina and cerebellum or brain stem in association with congenital cysts (and also neoplasms) in the pancreas, liver, and kidney.

PSEUDOCYSTS

Pseudocysts are localized collections of necrotic-hemorrhagic material rich in pancreatic enzymes.[43] Such cysts lack an epithelial lining (hence the prefix “pseudo”), and account for approximately 75% of cysts in the pancreas.[43] Pseudocysts usually arise after an episode of acute pancreatitis, often in the setting of chronic alcoholic pancreatitis. Traumatic injury to the pancreas can also give rise to pseudocysts.

Morphology. Pseudocysts are usually solitary and may be situated within the substance of the pancreas, or, more commonly, involve the lesser omental sac or lie in the retroperitoneum between the stomach and transverse colon or between the stomach and liver. They can even be subdiaphragmatic[43] (Fig. 19-8A). Pseudocysts are formed by the walling off of areas of peripancreatic hemorrhagic fat necrosis with fibrous tissue. As such, they usually are composed of central necrotic-hemorrhagic material rich in pancreatic enzymes surrounded by non-epithelial-lined fibrous walls of granulation tissue (Fig. 19-8B).[43] They can range in size from 2 to 30 cm in diameter.

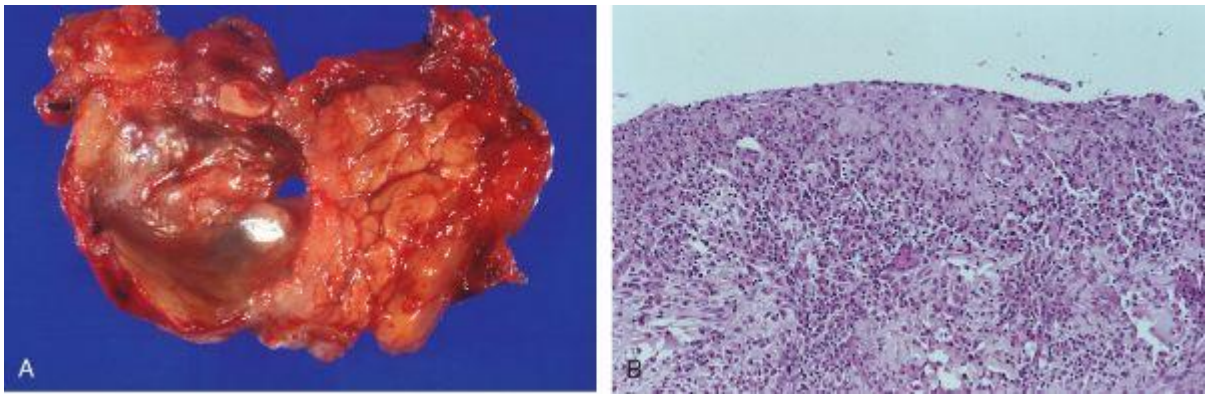

FIGURE 19-8 Pancreatic pseudocyst. **A**, Cross-section through this previously bisected lesion revealing a poorly defined cyst with a necrotic brown-black wall. **B**, Histologically, the cyst lacks a true epithelial lining and instead is lined by fibrin and granulation tissue.

While many pseudocysts spontaneously resolve, they may become secondarily infected, and larger pseudocysts may compress or even perforate into adjacent structures.

3.9.4 Neoplasms

A broad spectrum of exocrine neoplasms can arise in the pancreas. They may be cystic or solid; some are benign, while others are among the most lethal of all malignancies.

CYSTIC NEOPLASMS

Only 5% to 15% of all pancreatic cysts are neoplastic (most cysts are pseudocysts; see the previous section), and cystic neoplasms make up fewer than 5% of all pancreatic neoplasms. While some, such as the serous cystadenoma, are entirely benign, others, such as mucinous cystic neoplasms, can be benign or malignant.

Serous cystadenomas are benign cystic neoplasms composed of glycogen-rich cuboidal cells surrounding small (1- to 3-mm) cysts containing clear, thin, straw-colored fluid (Fig. 19-9).[1] They account for about 25% of all cystic neoplasms of the pancreas. These neoplasms arise twice as often in women as in men and typically present in the seventh decade of life with nonspecific symptoms such as abdominal pain. They may also present as palpable abdominal masses. Serous cystadenomas are almost always benign, and surgical resection is curative in the vast majority of patients.[44]

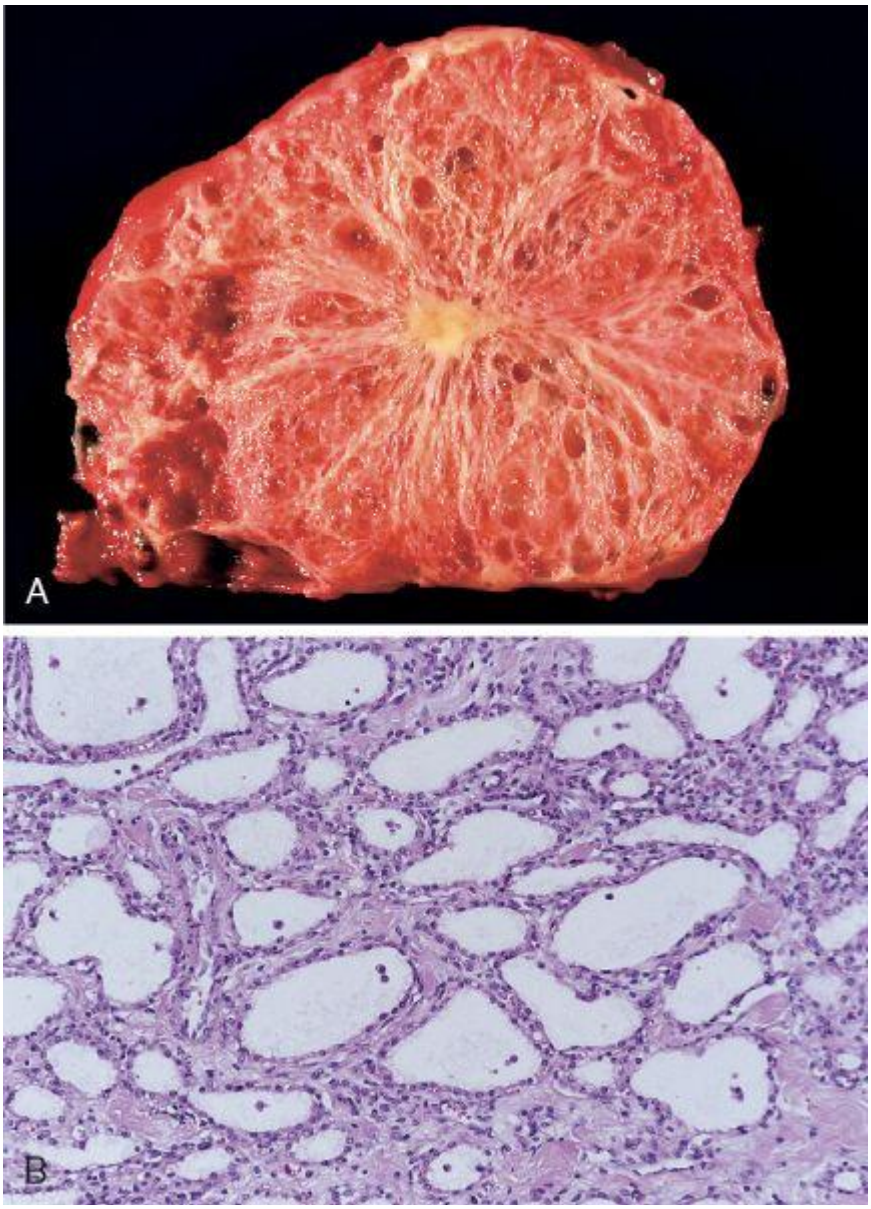

FIGURE 19-9 Serous cystadenoma. **A**, Cross-section through a serous cystadenoma. Only a thin rim of normal pancreatic parenchyma remains. The cysts are relatively small and contain clear, straw-colored fluid. **B**, The cysts are lined by cuboidal epithelium without atypia.

Close to 95% of *mucinous cystic neoplasms* arise in women, and, in contrast to serous cystadenomas, they can be associated with an invasive carcinoma.[1,][45,][46] Mucinous cystic neoplasms usually arise in the body or tail of the pancreas and present as painless, slow-growing masses. The cysts are larger than those formed in serous cystadenomas; they are filled with thick, tenacious mucin and lined by a columnar mucin-producing epithelium with an associated dense stroma similar to ovarian stroma (Fig. 19-10).[1] One third of surgically resected mucinous cystic neoplasms harbor an associated invasive adenocarcinoma. The best way to distinguish the entirely benign form (mucinous cystadenoma) from its malignant counterpart (invasive adenocarcinoma arising in association with a mucinous cystic neoplasm) is pathologic assessment after complete surgical removal, usually by distal pancreatectomy.[45]

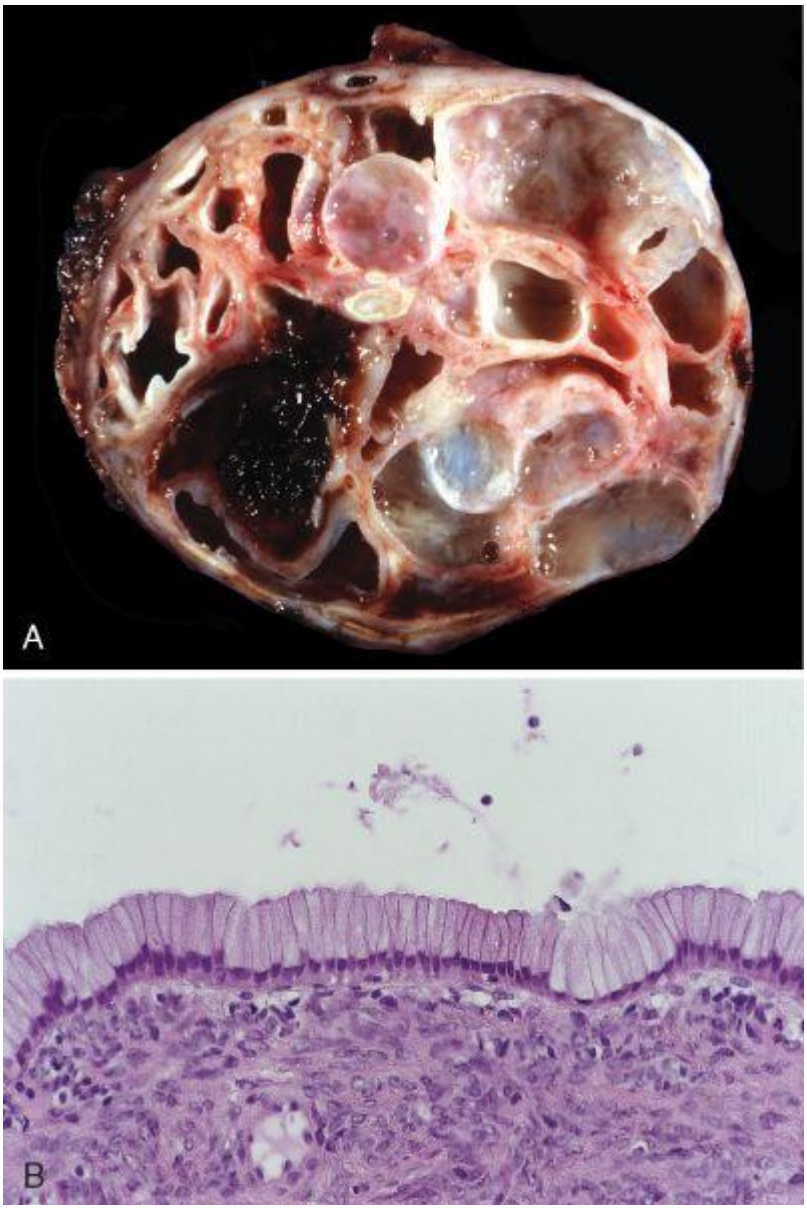

FIGURE 19-10 Pancreatic mucinous cystadenoma. **A**, Cross-section through a mucinous multiloculated cyst in the tail of the pancreas. The cysts are large and filled with tenacious mucin. **B**, The cysts are lined by columnar mucinous epithelium, and a dense "ovarian" stroma is noted.

Intraductal papillary mucinous neoplasms (IPMNs) are mucin-producing intraductal neoplasms.[1,][47,][48] In contrast to mucinous cystic neoplasms, IPMNs arise more frequently in men than in women, and they involve the head of the pancreas more often than the tail. Ten to twenty percent are multifocal. Two features are useful in distinguishing IPMNs from mucinous cystic neoplasms: IPMNs lack the dense "ovarian" stroma seen in mucinous cystic neoplasms, and involve a larger pancreatic duct (Fig. 19-11), while mucinous cystic neoplasms do not connect to the pancreatic duct system. Just as with mucinous cystic neoplasms, benign IPMNs are distinguished from malignant IPMNs by the lack of tissue invasion.

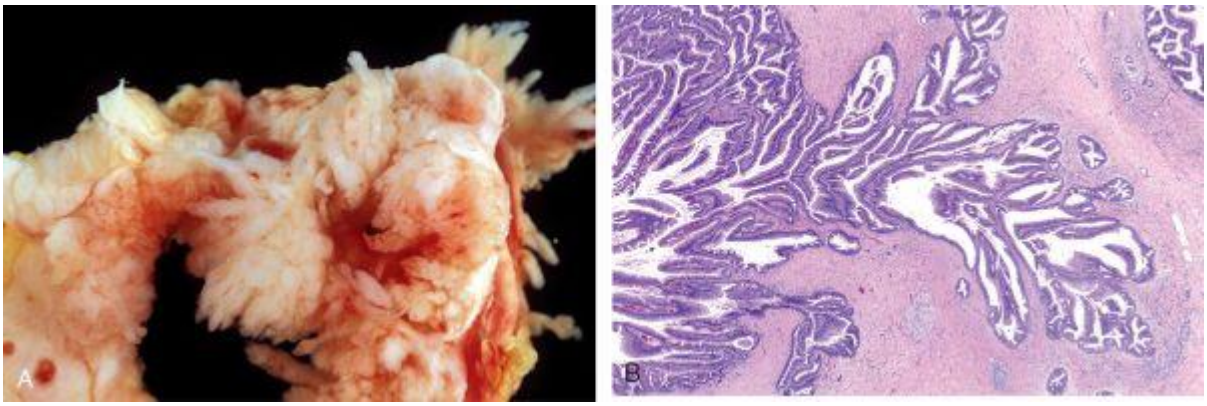

FIGURE 19-11 Intraductal papillary mucinous neoplasm. **A**, Cross-section through the head of the pancreas showing a prominent papillary neoplasm distending the main pancreatic duct. **B**, The papillary mucinous neoplasm involved the main pancreatic duct *(left)* and extending down into the smaller ducts and ductules *(right)*.

The unusual *solid-pseudopapillary neoplasm* is seen mainly in young women.[1,][49] These large, well-circumscribed masses have solid and cystic components. The cystic areas are filled with hemorrhagic debris, and on histologic examination the neoplastic cells can be seen to grow in solid sheets or, as the name suggests, as papillary projections. These neoplasms often cause abdominal discomfort because of their large size. Of note, the β-catenin/adenomatous polyposis coli genetic pathway (Chapter 7) seems to be almost universally altered in these neoplasms often due to the presence of activating mutations of β-catenin.[49] Surgical resection is the treatment of choice. Although some solid-pseudopapillary neoplasms are locally aggressive, most patients are cured following complete surgical resection of the neoplasm.

PANCREATIC CARCINOMA

Infiltrating ductal adenocarcinoma of the pancreas, more commonly known as "pancreatic cancer," is the fourth leading cause of cancer deaths in the United States, preceded only by lung, colon, and breast cancers.[50] Pancreatic cancer has one of the highest mortality rates of any cancer. It is estimated that in 2008 approximately 37,000 Americans were diagnosed with pancreatic cancer, and that virtually all of them will die from their disease. The 5-year survival rate is dismal, less than 5%.

Precursors to Pancreatic Cancer

Just as there is a progression in the colorectum from non-neoplastic epithelium to adenoma to invasive carcinoma (Chapters 7 and 17 , there is a progression in the pancreas from non-neoplastic epithelium to histologically well-defined noninvasive lesions in small ducts and ductules to invasive carcinoma.[51] These precursor lesions are called "pancreatic intraepithelial neoplasias" (PanINs). The PanIN-invasive carcinoma sequence is supported by the following observations:

- The distribution of PanINs within the pancreas parallels that of invasive cancer.
- PanINs are often found in pancreatic parenchyma adjacent to infiltrating carcinomas.
- Isolated case reports have documented individuals with PanINs who later developed an invasive pancreatic cancer.

The genetic and epigenetic alterations identified in PanINs are similar to those present in invasive cancers. The epithelial cells in PanINs show dramatic telomere shortening. A critical shortening of telomere length in PanINs may predispose these lesions to accumulate progressive chromosomal abnormalities and to develop invasive carcinoma.[52]

Based on these observations, a model for progression of PanINs has been proposed (Fig. 19-12).[51]

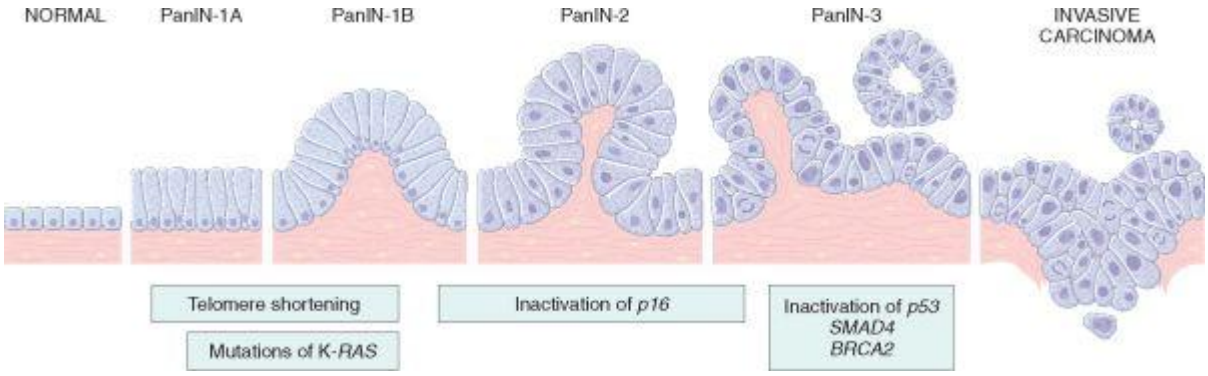

FIGURE 19-12 Progression model for the development of pancreatic cancer. It is postulated that telomere shortening and mutations of the oncogene *KRAS* occur at early stages, that inactivation of the *p16* tumor suppressor gene occurs at intermediate stages, and the inactivation of the *TP53*, *SMAD4* (*DPC4*), and *BRCA2* tumor suppressor genes occur at late stages. It is important to note that while there is a general temporal sequence of changes, the accumulation of multiple mutations is more important than their occurrence in a specific order. *(Adapted from Wilentz RE et al.: Loss of expression of DPC4 in pancreatic intraepithelial neoplasia: evidence that DPC4 inactivation occurs late in neoplastic progression. Cancer Res 60:2002, 2000.)*

Molecular Carcinogenesis

Multiple genes are often altered in a single pancreatic cancer, and the patterns of genetic alterations differ from those seen in other malignancies.[53] Molecular alterations in pancreatic carcinogenesis are summarized in Table 19-2 and include the following:

TABLE 19-2 -- Molecular Alterations in Invasive Pancreatic Adenocarcinoma

Gene	Chromosomal Region	Percentage of Carcinoma with Genetic Alteration
KRAS	12p	90
p16/CDKN2A	9p	95
TP53	17p	50–70
SMAD4	18q	55
AKT2	19q	10–20
MYB	6q	10
NCOA3/AIB1	20q	10
BRCA2	13q	7–10
GATA-6	18q	10
STK11	19p	5
MAP2K4/MKK4	17p	5
TGFβ-R1	9q	2

Gene	Chromosomal Region	Percentage of Carcinoma with Genetic Alteration
TGFβ-R2	3p	2
RB1	13q	5

KRAS.

The *KRAS* gene (chromosome 12p) is the most frequently altered oncogene in pancreatic cancer. This oncogene is activated by point mutation in 80% to 90% of cases. These point mutations impair the intrinsic guanosine triphosphatase activity of the K-ras protein, resulting in a protein that is constitutively active. Ras in turn activates several intracellular signal transduction pathways that, among other effects, culminate in the activation of the transcription factors Fos and Jun.

CDKN2A (p16).

The *p16/CDKN2A* gene (chromosome 9p) is inactivated in 95% of the cases, making *p16/CDKN2A* the most frequently inactivated tumor suppressor gene in pancreatic cancer.[54] The p16 protein plays a critical role in the control of the cell cycle, and inactivation of *p16* abrogates an important cell cycle checkpoint.

SMAD4.

The *SMAD4* tumor suppressor gene (chromosome 18q) is inactivated in 55% of pancreatic cancers.[55] *SMAD4* encodes a protein that plays an important role in signal transduction from the TGF-β family of cell surface receptors. *SMAD4* is only rarely inactivated in other cancer types.

p53.

Inactivation of the *p53* tumor suppressor gene (chromosome 17p) is seen in 50% to 70% of pancreatic cancers.[56] As you recall, the p53 protein is a nuclear DNA-binding protein that acts both as a cell cycle checkpoint, as an inducer of cell death (apoptosis), and cellular senescence (Chapter 7).

Other Genes.

A growing number of less common, but nonetheless important, genetic loci have been reported to be damaged in pancreatic cancer (see Table 19-2). For example, the *AKT2* gene (chromosome 19q) is amplified in 10% to 20%, the *MYB* gene (6q) in 10%, the *GATA-6* gene (chromosome 18q) in 10%, and the *NCOA3/AIB1* gene (chromosome 20q) in 10%.[58] The *BRCA2* (chromosome 13q), *LKB1/STK11* (chromosome 19p), *MAP2K4/MKK4* (chromosome 17p), *TGFβ-R1* (chromosome 9q), *TGFβ-R2* (chromosome 3p), and *RB1* (chromosome 13q) tumor suppressor genes are inactivated in fewer than 10% of pancreatic cancers.

Methylation Abnormalities.

Several methylation abnormalities also occur in pancreatic cancer. Hypermethylation of the promoter of several tumor suppressor genes is associated with transcriptional silencing of the genes.

Gene Expression.

In addition to DNA alterations, global analyses of gene expression have identified several genes that are highly expressed in pancreatic cancers.[54,][59] These genes are potential targets for novel therapeutics and may form the basis of future screening tests. For example, the hedgehog signaling pathway has been shown to be activated in pancreatic cancer, and inhibition of this pathway with the drug cyclopamine blocks growth of pancreatic cancers in experimental systems.[60]

Epidemiology, Etiology, and Pathogenesis.

Pancreatic cancer is primarily a disease in the elderly, 80% of cases occurring between the ages of 60 and 80 years.[61] It is more common in blacks than in whites, and it is slightly more common in individuals of Ashkenazi Jewish descent.

The strongest environmental influence is *cigarette smoking*, which is believed to double the risk of pancreatic cancer.[59] Even though the magnitude of this increased risk is not great, the impact of smoking on pancreatic cancer is significant because of the large number of people who smoke. Consumption of a diet rich in fats has also been implicated, but less consistently. Chronic pancreatitis and diabetes mellitus have both been associated with an increased risk of pancreatic cancer. Pancreatic cancer arises with greater frequency in patients with chronic pancreatitis,[42] but a causal role for pancreatitis, with the exception of hereditary pancreatitis, is not well established. Smoking and alcohol use in individuals with chronic pancreatitis may underlie some of the association.[42] In an individual patient it can be difficult to sort out whether chronic pancreatitis is the cause of pancreatic cancer or an effect of the disease, since small pancreatic cancers may block the pancreatic duct and produce chronic pancreatitis. A similar argument applies to the association of diabetes mellitus with pancreatic cancer, since diabetes may develop as a consequence of pancreatic cancer. New-onset diabetes mellitus in an elderly patient may be the first sign that the patient has pancreatic cancer.[62]

Familial clustering of pancreatic cancer has been reported, and a growing number of inherited genetic defects are recognized to increase pancreatic cancer risk (Table 19-3).[63] BRCA2 mutations account for approximately 10% of pancreatic cancer cases in Ashkenazi Jews. Patients with these mutations may not have a family history of breast or ovarian cancers. Mutations in CDKN2A (p16) in pancreatic cancer almost always occur in individuals from melanoma-prone families.

TABLE 19-3 -- Inherited Predisposition to Pancreatic Cancer

Disorder	Gene (Chromosome Location)	Increased Risk of Pancreatic Cancer fold	Risk of Pancreatic Cancer by Age 70 (%)
Hereditary breast and ovarian cancer	*BRCA2* (13q12–q13)	4–10	5
Familial atypical multiple-mole melanoma syndrome	*p16/CDKN2A* (9p21)	20–35	10–17
Strong family history (3 or more relatives with pancreatic cancer)	Unknown	14–32	8–16
Hereditary pancreatitis	*PRSS1* (7q35) and *SPINK1*	50–80	25–40
Peutz-Jeghers syndrome	*LKB1* (19p13)	130	30–60

A mutation in the *PALLD* gene, which encodes the extracellular matrix protein palladin, was reported in one family with high incidence of pancreatic cancer. The mutation was not found in other families, but palladin is highly expressed in the surrounding stroma of pancreatic cancers.

Morphology. Approximately 60% of cancers of the pancreas arise in the head of the gland, 15% in the body, and 5% in the tail; in 20% the neoplasm diffusely involves the entire gland. Carcinomas of the pancreas are usually hard, stellate, gray-white, poorly defined masses (Fig. 19-13A).

The vast majority of carcinomas are ductal adenocarcinomas that recapitulate to some degree normal

ductal epithelium by forming glands and secreting mucin. Two features are characteristic of pancreatic cancer: It is highly invasive (even "early" invasive pancreatic cancers extensively invade peripancreatic tissues), and elicits an intense non-neoplastic host reaction composed of fibroblasts, lymphocytes, and extracellular matrix (called a "desmoplastic response").

Most carcinomas of the head of the pancreas obstruct the distal common bile duct as it courses through the head of the pancreas. As a consequence there is marked distention of the biliary tree in about 50% of patients with carcinoma of the head of the pancreas, and most develop jaundice. In marked contrast, **carcinomas of the body and tail of the pancreas do not impinge on the biliary tract and hence remain silent for some time. They may be quite large and most are widely disseminated by the time they are discovered**. Pancreatic cancers often grow along nerves and invade into the retroperitoneum. They can directly invade the spleen, adrenals, vertebral column, transverse colon, and stomach. Peripancreatic, gastric, mesenteric, omental, and portahepatic lymph nodes are frequently involved. Distant metastases occur, principally to the liver, lungs, and bones.

Microscopically, there is no difference between carcinomas of the head of the pancreas and those of the body and tail of the pancreas. The appearance is usually that of a **moderately to poorly differentiated adenocarcinoma forming abortive tubular structures or cell clusters and showing an aggressive, deeply infiltrative growth pattern** (Fig. 19-13B). Dense stromal fibrosis accompanies the invasive cancer, and there is a proclivity for perineural invasion within and beyond the organ. Lymphatic and large vessel invasion are also commonly seen. The malignant glands are poorly formed and are usually lined by pleomorphic cuboidal-to-columnar epithelial cells. Well-differentiated carcinomas are the exception.

Less common variants of pancreatic cancer include **adenosquamous carcinomas, colloid carcinoma, hepatoid carcinoma, medullary carcinoma, signet-ring cell carcinoma, undifferentiated carcinoma, and undifferentiated carcinomas with osteoclast-like giant cells**.[1] Adenosquamous carcinomas have focal squamous differentiation in addition to glandular differentiation, and undifferentiated carcinomas may contain large multinucleated osteoclast-like giant cells.

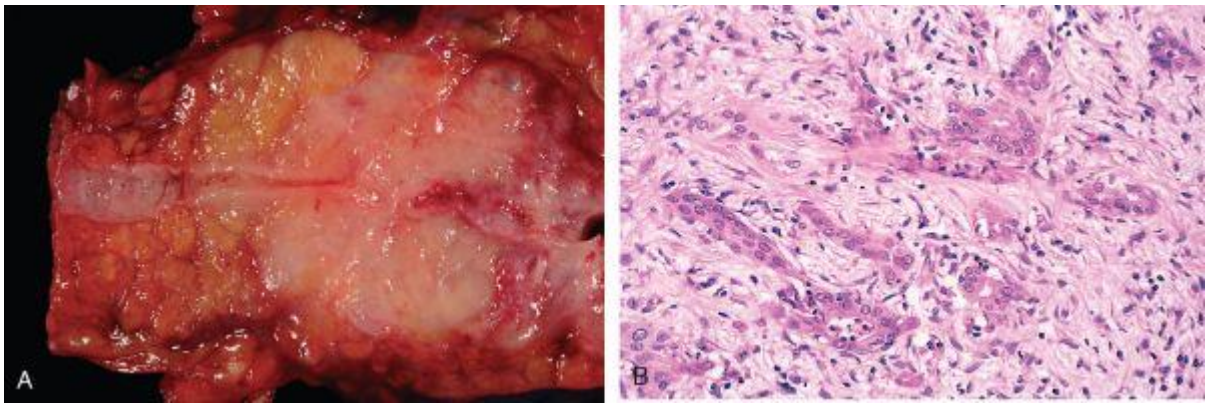

FIGURE 19-13 Carcinoma of the pancreas. **A**, A cross-section through the tail of the pancreas showing normal pancreatic parenchyma and a normal pancreatic duct *(left)*, an ill-defined mass in the pancreatic substance *(center)* with narrowing of the pancreatic duct, and dilatation of the pancreatic duct upstream *(right)* from the mass. **B**, Poorly formed glands are present in densely fibrotic stroma within the pancreatic substance; there are some inflammatory cells.

Clinical Features.

From the preceding discussion it should be evident that *carcinomas of the pancreas remain silent until they invade into adjacent structures*. Pain is usually the first symptom, but by the time pain appears these cancers are usually beyond cure. *Obstructive jaundice* is associated with most cases of carcinoma of the head of the pancreas, but it rarely draws attention to the invasive cancer soon enough. Weight loss, anorexia, and generalized malaise and weakness tend to be signs of advanced disease. *Migratory thrombophlebitis*, known as the *Trousseau sign*, occurs in about 10% of patients and is attributable to the elaboration of platelet-aggregating factors and procoagulants from the carcinoma or its necrotic products (Chapter 4). On a sad note, Armand Trousseau (1801–1867, physician at Hotel Dieu, Paris) suspected that he had cancer when he developed spontaneously appearing and disappearing (migratory) thrombosis, and his autopsy revealed that he had pancreatic cancer.

The course of pancreatic carcinoma is typically brief and progressive. Despite the tendency of lesions of the head of the pancreas to obstruct the biliary system, fewer than 20% of pancreatic cancers overall are resectable at the time of diagnosis. There has long been a search for tests that could be useful in the early detection of pancreatic cancer. Serum levels of many enzymes and antigens (e.g., carcinoembryonic antigen and CA19–9 antigen) are often elevated in individuals with pancreatic cancer. These markers, while useful in following a patient's response to treatment, are too nonspecific and lack the sensitivity needed to be used as screening tests. Several imaging techniques, such as endoscopic ultrasonography and computed tomography, have proved of great value in establishing the diagnosis once it is suspected, but are not useful as screening tests.

ACINAR CELL CARCINOMA

Acinar cell carcinomas, by definition, show prominent acinar cell differentiation, including the formation of zymogen granules and the production of exocrine enzymes including trypsin and lipase.[64] Fifteen percent of individuals with acinar cell carcinoma develop the syndrome of metastatic fat necrosis caused by the release of lipase into the circulation.

PANCREATOBLASTOMA

Pancreatoblastomas are rare neoplasms that occur primarily in children aged 1 to 15 years.[65] They have a distinct microscopic appearance with squamous islands admixed with acinar cells. These are fully malignant neoplasms, although survival may be better than that for pancreatic ductal adenocarcinomas.

3.10 20. The Kidney

3.10.1 Clinical Manifestations of Renal Diseases

CHARLES E. ALPERS

What is a human but an ingenious machine designed to turn, with “infinite artfulness, the red wine of Shiraz into urine”? So said the storyteller in Isak Dinesen's *Seven Gothic Tales*.[1] More accurately but less poetically, human kidneys serve to convert more than 1700 liters of blood per day into about 1 liter of a highly specialized concentrated fluid called urine. In so doing the kidney excretes the waste products of metabolism, precisely regulates the body's concentration of water and salt, maintains the appropriate acid balance of plasma, and serves as an endocrine organ, secreting such hormones as erythropoietin, renin, and prostaglandins. The physiologic mechanisms that the kidney has developed to carry out these functions require a high degree of structural complexity.

Renal diseases are responsible for a great deal of morbidity but, fortunately, are not equally major causes of mortality. To place the problem in some perspective, approximately 45,000 deaths are attributed yearly to renal disease in the United States, in contrast to about 650,000 to heart disease, 560,000 to cancer, and 145,000 to stroke.[2] Morbidity, however, is by no means insignificant. Millions of people are affected annually by nonfatal kidney diseases, most notably infections of the kidney or lower urinary tract, kidney stones, and urinary obstruction. Twenty percent of all women suffer from infection of the urinary tract or kidney at some time in their lives, and as many as 5% of the U.S. population develops renal stones. Similarly, modern treatments, notably dialysis and transplantation, keep many patients alive who earlier would have died of renal failure, adding to the pool of renal morbidity. Further, people with even mild chronic kidney disease have greatly enhanced risk for cardiovascular disease.

The study of kidney diseases is facilitated by dividing them into those that affect the four basic morphologic components: glomeruli, tubules, interstitium, and blood vessels. This traditional approach is useful, since the early manifestations of disease affecting each of these components tend to be distinct. Further, some components seem to be more vulnerable to specific forms of renal injury; for example, *most glomerular diseases are immunologically mediated, whereas tubular and interstitial disorders are*

frequently caused by toxic or infectious agents. Nevertheless, some agents affect more than one structure. In addition, the anatomic and functional interdependence of the components of the kidney implies that damage to one almost always secondarily affects the others. Disease primarily in the blood vessels, for example, inevitably affects all the structures that depend on this blood supply. Severe glomerular damage impairs the flow through the peritubular vascular system and also delivers potentially toxic products to tubules; conversely, tubular destruction, by increasing intraglomerular pressure, may induce glomerular injury. Thus, whatever the origin, there is a tendency for all forms of chronic kidney disease ultimately to destroy all four components of the kidney, culminating in chronic renal failure and what has been called end-stage kidneys. The functional reserve of the kidney is large, and much damage may occur before there is evident functional impairment. For these reasons the early signs and symptoms are particularly important clinically.

Clinical Manifestations of Renal Diseases

The clinical manifestations of renal disease can be grouped into reasonably well-defined syndromes. Some are peculiar to glomerular diseases, and others are present in diseases that affect any one of the components. Before we list the syndromes, a few terms must be clarified.

Azotemia is a biochemical abnormality that refers to an elevation of the blood urea nitrogen (BUN) and creatinine levels, and is related largely to a decreased glomerular filtration rate (GFR). Azotemia is a consequence of many renal disorders, but it also arises from extrarenal disorders. *Prerenal azotemia* is encountered when there is hypoperfusion of the kidneys (e.g., in hemorrhage, shock, volume depletion, and congestive heart failure) that impairs renal function in the absence of parenchymal damage. *Postrenal azotemia* is seen whenever urine flow is obstructed beyond the level of the kidney. Relief of the obstruction is followed by correction of the azotemia.

When azotemia becomes associated with a constellation of clinical signs and symptoms and biochemical abnormalities, it is termed *uremia*. Uremia is characterized not only by failure of renal excretory function but also by a host of metabolic and endocrine alterations resulting from renal damage. Uremic patients frequently manifest secondary involvement of the gastrointestinal system (e.g., uremic gastroenteritis), peripheral nerves (e.g., peripheral neuropathy), and heart (e.g., uremic fibrinous pericarditis).

We can now turn to a brief description of the clinical presentations of renal disease:

- *Nephritic syndrome* is due to glomerular disease and is dominated by the acute onset of usually grossly visible hematuria (red blood cells in urine), mild to moderate proteinuria, and hypertension; it is the classic presentation of acute poststreptococcal glomerulonephritis.
- *Rapidly progressive glomerulonephritis* is characterized as a nephritic syndrome with rapid decline (hours to days) in GFR.
- The *nephrotic syndrome*, also due to glomerular disease, is characterized by heavy proteinuria (more than 3.5 gm/day), hypoalbuminemia, severe edema, hyperlipidemia, and lipiduria (lipid in the urine).
- *Asymptomatic hematuria or proteinuria*, or a combination of these two, is usually a manifestation of subtle or mild glomerular abnormalities.
- *Acute renal failure* is dominated by oliguria or anuria (reduced or no urine flow), and recent onset of azotemia. It can result from glomerular, interstitial, or vascular injury or acute tubular injury.
- *Chronic renal failure*, characterized by prolonged symptoms and signs of uremia, is the end result of all chronic renal parenchymal diseases.
- Renal tubular defects are dominated by polyuria (excessive urine formation), nocturia, and electrolyte disorders (e.g., metabolic acidosis). They are the result of diseases that either directly affect tubular structure (e.g., medullary cystic disease) or cause defects in specific tubular functions. The latter can be

inherited (e.g., familial nephrogenic diabetes, cystinuria, renal tubular acidosis) or acquired (e.g., lead nephropathy).

- Urinary tract infection is characterized by bacteriuria and pyuria (bacteria and leukocytes in the urine). The infection may be symptomatic or asymptomatic, and it may affect the kidney (pyelonephritis) or the bladder (cystitis).
- Nephrolithiasis (renal stones) is manifested by severe spasms of pain (renal colic) and hematuria, often with recurrent stone formation.
- Urinary tract obstruction and renal tumors have varied clinical manifestations based on the specific anatomic location and nature of the lesion.

Renal Failure.

Acute renal failure implies a rapid and frequently reversible deterioration of renal function. It is discussed in the section on "Acute Kidney Injury (Acute Tubular Necrosis)," because it commonly occurs in this disorder. Here, the discussion is limited to chronic renal failure, which is the end result of a variety of renal diseases and the major cause of death from renal disease.

Although exceptions abound, the evolution from normal renal function to symptomatic *chronic renal failure* broadly progresses through a series of four stages that merge into one another.

1. In *diminished renal reserve* the GFR is about 50% of normal. Serum BUN and creatinine values are normal, and the patients are asymptomatic. However, they are more susceptible to developing azotemia with an additional renal insult.
2. In *renal insufficiency* the GFR is 20% to 50% of normal. Azotemia appears, usually associated with anemia and hypertension. Polyuria and nocturia can occur as a result of decreased concentrating ability. Sudden stress (e.g., with nephrotoxins) may precipitate uremia.
3. In *chronic renal failure* the GFR is less than 20% to 25% of normal. The kidneys cannot regulate volume and solute composition, and patients develop edema, metabolic acidosis, and hyperkalemia. Overt uremia may ensue, with neurologic, gastrointestinal, and cardiovascular complications.
4. In *end-stage renal disease* the GFR is less than 5% of normal; this is the terminal stage of uremia. Recent clinical classifications of chronic kidney disease, adopted in part to better stratify patients in clinical trials, adhere to this schema of progressive injury but divide patients into five classes based on levels of GFR.

The details of the pathophysiology of chronic renal failure are beyond the scope of this book and are well covered in various nephrology texts. Table 20-1 lists the major systemic abnormalities in chronic kidney failure.

3.10.2 Glomerular Diseases

Glomerular diseases constitute some of the major problems in nephrology; indeed, chronic glomerulonephritis is one of the most common causes of chronic kidney disease in humans. Glomeruli may be injured by a variety of factors and in the course of several systemic diseases. Systemic immunological diseases such as systemic lupus erythematosus (SLE), vascular disorders such as hypertension, metabolic diseases such as diabetes mellitus, and some hereditary conditions such as Fabry disease often affect the glomerulus. These are termed *secondary glomerular diseases* to differentiate them from disorders in which the kidney is the only or predominant organ involved. The latter constitute the various types of *primary glomerulonephritis* or, because some do not have a cellular inflammatory component, *glomerulopathy*. *However, both the clinical manifestations and glomerular histologic changes in primary and secondary forms can be similar*.

Here we discuss the various types of primary glomerulopathies and briefly review the secondary forms covered in other parts of this book. Table 20-2 lists the most common forms of glomerulonephritis that have reasonably well defined morphologic and clinical characteristics.

TABLE 20-2 -- Glomerular Diseases

PRIMARY GLOMERULOPATHIES
Acute proliferative glomerulonephritis
Post-infectious
Other
Rapidly progressive (crescentic) glomerulonephritis
Membranous glomerulopathy
Minimal-change disease
Focal segmental glomerulosclerosis
Membranoproliferative glomerulonephritis
IgA nephropathy
Chronic glomerulonephritis
SYSTEMIC DISEASES WITH GLOMERULAR INVOLVEMENT
Systemic lupus erythematosus
Diabetes mellitus
Amyloidosis
Goodpasture syndrome
Microscopic polyarteritis/polyangiitis
Wegener granulomatosis
Henoch-Schönlein purpura
Bacterial endocarditis
HEREDITARY DISORDERS
Alport syndrome
Thin basement membrane disease
Fabry disease

CLINICAL MANIFESTATIONS

The clinical manifestations of glomerular disease are clustered into the five major glomerular syndromes summarized in Table 20-3 . Both the primary glomerulopathies and the systemic diseases affecting the glomerulus can result in these syndromes. Because glomerular diseases are often associated with systemic disorders, mainly *diabetes mellitus*, *SLE*, *vasculitis*, and *amyloidosis*, in any patient with manifestations of glomerular disease it is essential to consider these systemic conditions.

TABLE 20-3 -- The Glomerular Syndromes

Syndrome	Manifestations
Nephritic syndrome	Hematuria, azotemia, variable proteinuria, oliguria, edema, and hypertension
Rapidly progressive glomerulonephritis	Acute nephritis, proteinuria, and acute renal failure
Nephrotic syndrome	>3.5 gm/day proteinuria, hypoalbuminemia, hyperlipidemia, lipiduria

Syndrome	Manifestations
Chronic renal failure	Azotemia → uremia progressing for months to years
Isolated urinary abnormalities	Glomerular hematuria and/or subnephrotic proteinuria

Many clinical manifestations of glomerular disease result from perturbations of specific components of the glomerular tuft, so we present key anatomic structures that are subject to alteration in disease. The glomerulus consists of an anastomosing network of capillaries lined by fenestrated endothelium invested by two layers of epithelium (Fig. 20-1). The visceral epithelium is incorporated into and becomes an intrinsic part of the capillary wall, separated from endothelial cells by a basement membrane. The parietal epithelium, situated on the Bowman capsule, lines the urinary space, the cavity in which plasma filtrate first collects.

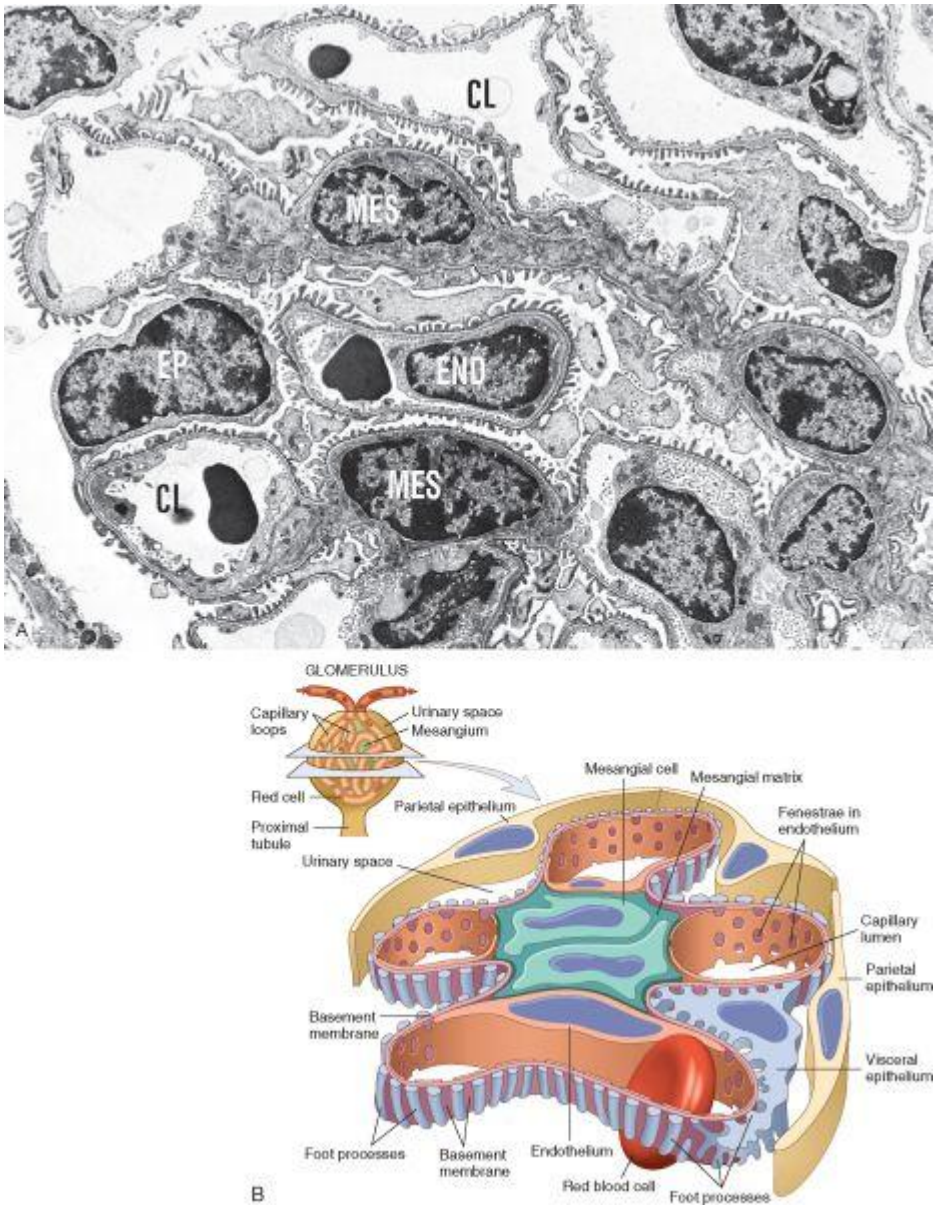

FIGURE 20-1 **A**, Low-power electron micrograph of renal glomerulus. CL, capillary lumen; EP, visceral epithelial cells with foot processes; END, endothelium; MES, mesangium. **B**, Schematic representation of a glomerular lobe. *(**A**, Courtesy of Dr. Vicki Kelley, Brigham and*

Women's Hospital, Boston, MA.)

The glomerular capillary wall is the filtering membrane and consists of the following structures[3,][4] (Fig. 20-2):

- There is a thin layer of fenestrated *endothelial cells*, each fenestrum being about 70 to 100 nm in diameter.
- A *glomerular basement membrane* (GBM) with a thick electron-dense central layer, the *lamina densa*, and thinner electron-lucent peripheral layers, the *lamina rara interna* and *lamina rara externa*. The GBM consists of collagen (mostly type IV), laminin, polyanionic proteoglycans (mostly heparan sulfate), fibronectin, entactin, and several other glycoproteins. Type IV collagen forms a network suprastructure to which other glycoproteins attach. The building block (monomer) of this network is a triple-helical molecule made up of three α chains, composed of one or more of six types of α chains (α_1 to α_6 or COL4A1 to COL4A6), the most common consisting of α_1, α_2, α_1.[3,][5] Each molecule consists of a 7S domain at the N terminus, a triple-helical domain in the middle, and a globular noncollagenous domain (NC1) at the C terminus. The NC1 domain is important for helix formation and for assembly of collagen monomers into the basement membrane suprastructure. Glycoproteins (laminin, entactin) and proteoglycans (heparan sulfate, perlecan) attach to the collagenous suprastructure. These biochemical determinants are critical to understanding glomerular diseases. For example, as we shall see, the antigens in the NC1 domain are the targets of antibodies in anti-GBM nephritis; genetic defects in the α-chains underlie some forms of hereditary nephritis; and the proteoglycan content of the GBM may contribute to its permeability characteristics.
- The *visceral epithelial cells* (podocytes) are structurally complex cells that possess interdigitating processes embedded in and adherent to the lamina rara externa of the basement membrane. Adjacent *foot processes* (pedicels) are separated by 20- to 30-nm-wide *filtration slits*, which are bridged by a thin diaphragm (see Fig. 20-2).
- The entire glomerular tuft is supported by *mesangial cells* lying between the capillaries. Basement membrane–like *mesangial matrix* forms a meshwork through which the mesangial cells are centered (see Fig. 20-1). These cells, of mesenchymal origin, are contractile, phagocytic, and capable of proliferation, of laying down both matrix and collagen, and of secreting several biologically active mediators. Biologically, they are most akin to vascular smooth muscle cells and pericytes. They are, as we shall see, important players in many forms of human glomerulonephritis.

FIGURE 20-2 Glomerular filter consisting, from bottom to top, of fenestrated endothelium, basement membrane, and foot processes of epithelial cells. Note the filtration slits *(arrows)* and diaphragm situated between the foot processes. Note also that the basement membrane consists of a central lamina densa, sandwiched between two looser layers, the lamina rara interna and lamina rara externa. *(Courtesy of Dr. Helmut Rennke, Brigham and Women's Hospital, Boston, MA.)*

The major characteristics of normal glomerular filtration are an extraordinarily high permeability to water and small solutes, because of the highly fenestrated nature of the endothelium, and impermeability to proteins, such as molecules of the size of albumin (~3.6-nm radius; 70 kilodaltons [kD] molecular weight) or larger. The latter property of the *glomerular filtration barrier* allows discrimination among various protein molecules, depending on their size (the larger, the less permeable) and charge (the more cationic, the more permeable). This size- and charge-dependent barrier function is accounted for by the complex structure of the capillary wall, the collagenous porous and charged structure of the GBM, and the many anionic moieties present within the wall, including the acidic proteoglycans of the GBM and the sialoglycoproteins of epithelial and endothelial cell coats (also called glycocalyx). The charge-dependent restriction is important in the virtually complete exclusion of albumin from the filtrate, because albumin is an anionic molecule of a pI 4.5. The visceral epithelial cell,

also known as a podocyte, is important for the maintenance of glomerular barrier function; its slit diaphragm presents a size-selective distal diffusion barrier to the filtration of proteins, and it is the cell type that is largely responsible for synthesis of GBM components. Proteins located in the slit diaphragm control glomerular permeability. Three of the most important slit diaphragm proteins are depicted in Figure 20-3 . Nephrin is a transmembrane protein with a large extracellular portion made up of immunoglobulin (Ig)-like domains. Nephrin molecules extend toward each other from neighboring foot processes and dimerize across the slit diaphragm. Within the cytoplasm of the foot processes, nephrin forms molecular connections with podocin, CD2-associated protein, and ultimately the actin cytoskeleton. The number of identified slit diaphragm proteins continues to grow rapidly, and more comprehensive descriptions of their complex localization and interactions have been published.[6,][7] The importance of these proteins in maintaining glomerular permeability is demonstrated by the observation that mutations in the genes encoding them give rise to nephrotic syndrome (discussed later). This has resulted in renewed appreciation of the importance of the slit diaphragm in glomerular barrier function and its contribution to protein leakage in disease states.[8]

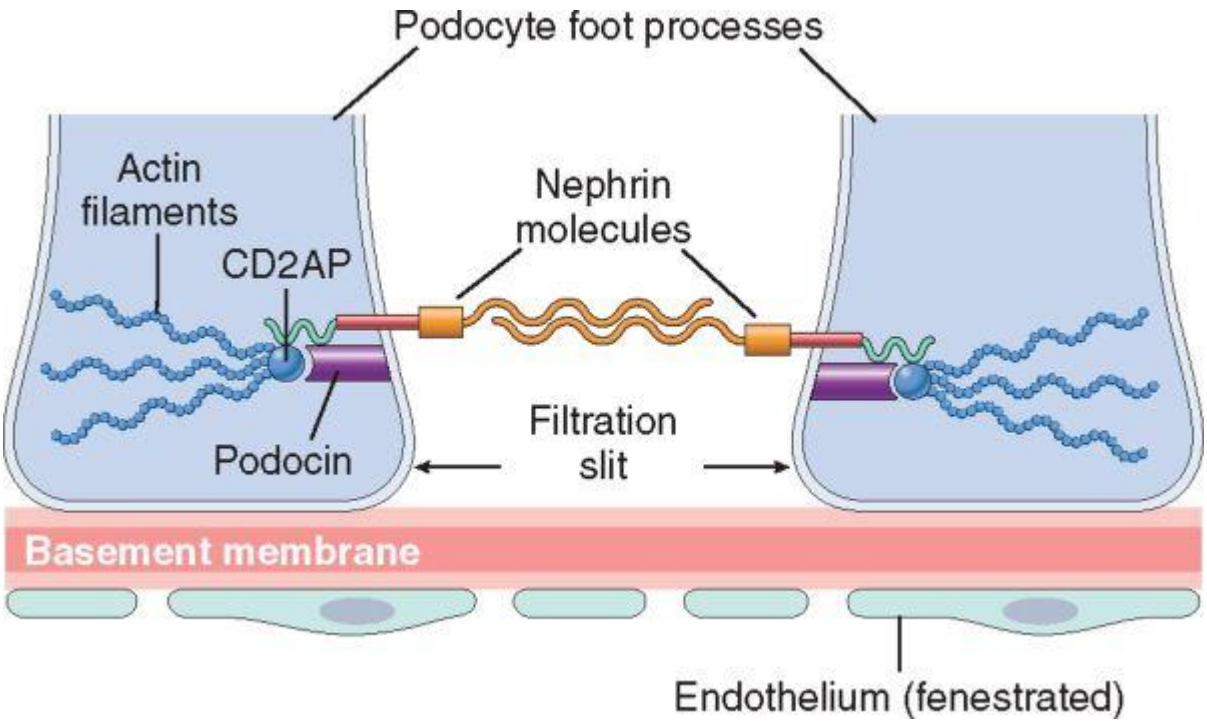

FIGURE 20-3 A simplified schematic diagram of some of the best-studied proteins of the glomerular slit diaphragm. CD2AP, CD2-associated protein.

HISTOLOGIC ALTERATIONS

Various types of glomerulopathies are characterized by one or more of four basic tissue reactions.

Hypercellularity.

Some *inflammatory diseases* of the glomerulus are characterized by an increase in the number of cells in the glomerular tufts. This hypercellularity is characterized by one or more combinations of the following:

- *Cellular proliferation* of mesangial or endothelial cells.

- *Leukocytic infiltration* consisting of neutrophils, monocytes, and, in some diseases, lymphocytes.
- *Formation of crescents*. These are accumulations of cells composed of proliferating parietal epithelial cells and infiltrating leukocytes. The epithelial cell proliferation that characterizes crescent formation occurs following an immune/inflammatory injury (see later). Fibrin, which leaks into the urinary space, often through ruptured basement membranes, has been long thought to be the molecule that elicits the crescentic response. In support of this, fibrin can be demonstrated immunohistochemically in the glomerular tufts and urinary spaces of glomeruli that contain crescents. Mice that are deficient in fibrinogen are protected to a degree from crescent formation, and mice that are deficient in molecules important in fibrinolysis (e.g., plasminogen activators) exhibit enhanced crescent formation in models of anti-GBM antibody–mediated crescentic glomerulonephritis.[9] Other molecules that have been implicated in crescent formation and recruitment of leukocytes into crescents include procoagulants such as tissue factor and cytokines such as interleukin-1 (IL-1), tumor necrosis factor (TNF), and interferon-γ.

Basement Membrane Thickening.

By light microscopy, this change appears as thickening of the capillary walls, best seen in sections stained with periodic acid–Schiff (PAS). By electron microscopy such thickening takes one of two forms:

- Deposition of amorphous electron-dense material, most often immune complexes, on the endothelial or epithelial side of the basement membrane or within the GBM itself. Fibrin, amyloid, cryoglobulins, and abnormal fibrillary proteins may also deposit in the GBM.
- Thickening of the basement membrane due to increased synthesis of its protein components, as occurs in diabetic glomerulosclerosis.

Hyalinosis and Sclerosis.

Hyalinosis, as applied to the glomerulus, denotes the accumulation of material that is homogeneous and eosinophilic by light microscopy. By electron microscopy the hyalin is extracellular and amorphous. It is made up of plasma proteins that have insudated from the circulation into glomerular structures. When extensive, this change contributes to obliteration of the capillary lumens of the glomerular tuft. Hyalinosis is usually a consequence of endothelial or capillary wall injury and typically the end result of various forms of glomerular damage. It is a common feature of focal segmental glomerulosclerosis.

Sclerosis is characterized by accumulations of extracellular collagenous matrix, either confined to mesangial areas as is often the case in diabetic glomerulosclerosis, or involving the capillary loops, or both. The sclerosing process may also result in obliteration of some or all of the capillary lumens in affected glomeruli, which in turn can result in formation of fibrous adhesions between the sclerotic portions of glomeruli and the nearby parietal epithelium and Bowman capsules.

Because many of the primary glomerulopathies are of unknown cause, they are often classified by their histology, as can be seen in Table 20-2 . The histologic changes can be further subdivided by their distribution into *diffuse*, involving all glomeruli; *global*, involving the entire glomerulus; *focal*, involving only a proportion of the glomeruli; *segmental*, affecting a part of each glomerulus; and by either *capillary loop* or *mesangial*, affecting predominantly capillary or mesangial regions. These terms are sometimes appended to the histologic classifications.

PATHOGENESIS OF GLOMERULAR INJURY

Although much is not known about etiologic agents and triggering events, it is clear that immune mechanisms underlie most forms of primary glomerulopathy and many of the secondary glomerular disorders[10,][11] (Table 20-4). Glomerulonephritis can be readily induced experimentally by antigen-antibody reactions. Furthermore, glomerular deposits of immunoglobulins, often with components of complement, are found in the majority of individuals with glomerulonephritis. Cell-mediated immune

reactions also may play a role, usually in concert with antibody-mediated events. We begin this discussion with a review of antibody-instigated injury.

TABLE 20-4 -- Immune Mechanisms of Glomerular Injury

ANTIBODY-MEDIATED INJURY
IN SITU IMMUNE COMPLEX DEPOSITION
Fixed intrinsic tissue antigens
NC1 domain of collagen type IV antigen (anti-GBM nephritis)
Heymann antigen (membranous glomerulopathy)
Mesangial antigens
Others
Planted antigens
Exogenous (infectious agents, drugs)
Endogenous (DNA, nuclear proteins, immunoglobulins, immune complexes, IgA)
CIRCULATING IMMUNE COMPLEX DEPOSITION
Endogenous antigens (e.g., DNA, tumor antigens)
Exogenous antigens (e.g., infectious products)
CYTOTOXIC ANTIBODIES
CELL-MEDIATED IMMUNE INJURY
ACTIVATION OF ALTERNATIVE COMPLEMENT PATHWAY

GBM, glomerular basement membrane.

Two forms of antibody-associated injury have been established: (1) injury by *antibodies reacting in situ within the glomerulus, either binding to insoluble fixed (intrinsic) glomerular antigens or to molecules planted within the glomerulus*, and (2) injury resulting from *deposition of circulating antigen-antibody complexes* in the glomerulus. In addition, there is experimental evidence that *cytotoxic antibodies* directed against glomerular cell components may cause glomerular injury. These pathways are not mutually exclusive, and in humans, all may contribute to injury.

Immune Complex Deposition Involving Intrinsic and in Situ Renal Antigens

In these forms of injury, antibodies react directly with intrinsic tissue antigen, or antigens “planted” in the glomerulus from the circulation. The best established experimental models for anti–glomerular antibody–mediated glomerular injury, for which there are counterparts in human disease, are anti–glomerular basement membrane (antiGBM) antibody–induced glomerulonephritis and Heymann nephritis.

Heymann Nephritis

The Heymann model of rat glomerulonephritis is induced by immunizing animals with an antigen contained within preparations of proximal tubular brush border (Fig. 20-4C). The rats develop

antibodies to this antigen, and a membranous nephropathy, resembling human membranous nephropathy, develops (discussed later; see also Fig. 20-13). On electron microscopy the glomerulopathy is characterized by the presence of numerous discrete electron-dense deposits (made up largely of immune reactants) along the *subepithelial aspect* of the basement membrane. The pattern of immune deposition by immunofluorescence microscopy is *granular* rather than linear. It is now clear that this type of disease results largely from the reaction of antibody with an antigen complex located on the basal surface of visceral epithelial cells and cross-reacting with the brush-border antigen used in the original experiments. This so-called Heymann antigen in rats is a large 330-kD protein called *megalin*, which has homology to the low-density lipoprotein receptor (Chapter 5); the corresponding antigen in human membranous nephropathy has not yet been identified.[12] Antibody binding to glomerular epithelial cell membrane is followed by complement activation and then shedding of the immune aggregates from the cell surface to form the characteristic subepithelial deposits (see Fig. 20-4C).

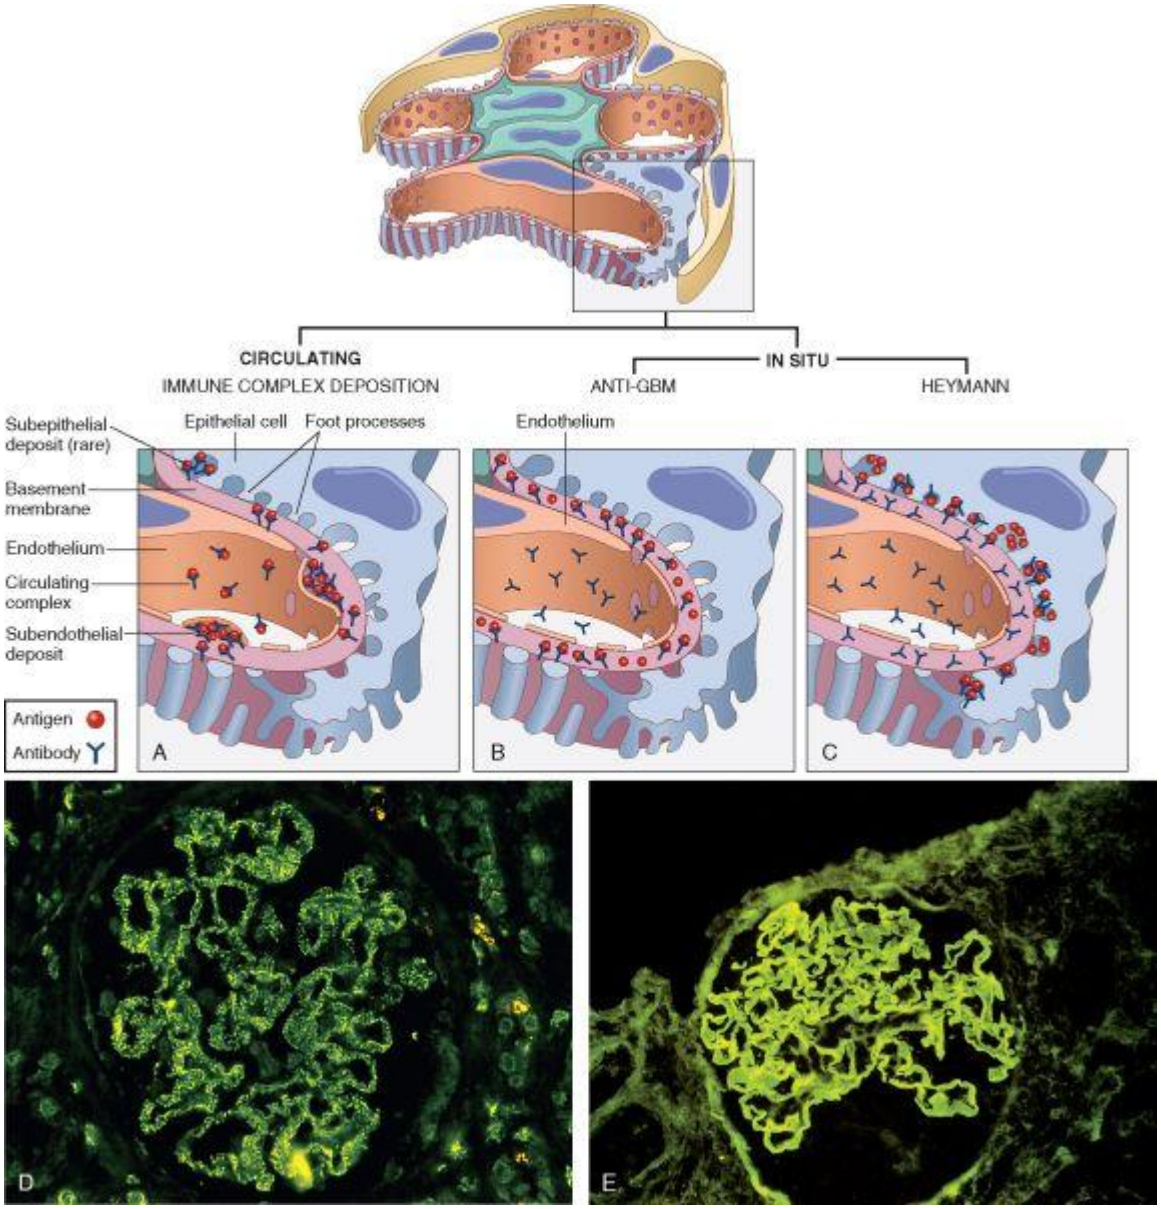

FIGURE 20-4 Antibody-mediated glomerular injury can result either from the deposition of circulating immune complexes (**A**) or, more commonly, from in situ formation of complexes exemplified by anti-GBM disease (**B**) or Heymann nephritis (**C**). **D** and **E**, Two patterns of deposition of immune complexes as seen by immunofluorescence microscopy: granular, characteristic of circulating and in situ immune

complex nephritis (**D**), and linear, characteristic of classic anti-GBM disease (**E**).

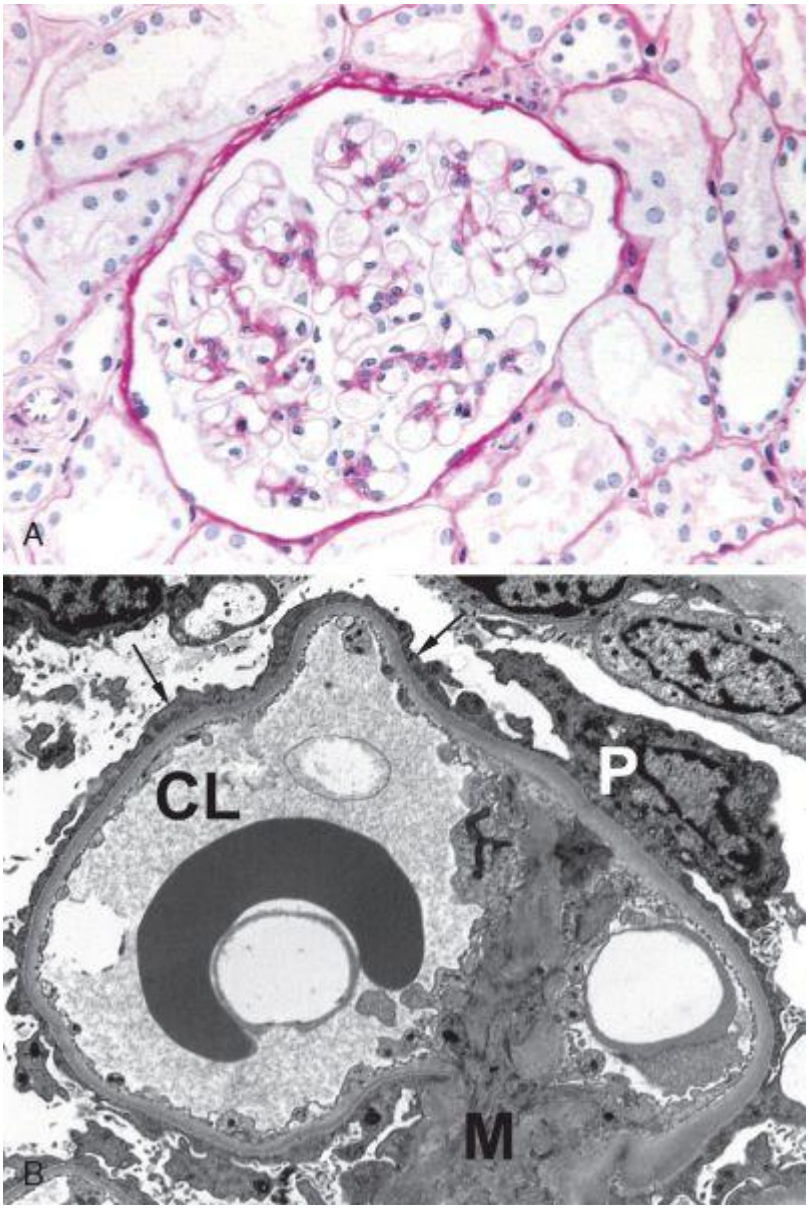

FIGURE 20-13 Minimal-change disease. **A**, Glomerulus stained with PAS. Note normal basement membranes and absence of proliferation. **B**, Ultrastructural characteristics of minimal-change disease include effacement of foot processes *(arrows)* and absence of deposits. CL, capillary lumen; M, mesangium; P, podocyte cell body.

In humans, anti-GBM antibody–induced disease and membranous nephropathy are autoimmune diseases, caused by antibodies to endogenous tissue components. What triggers these autoantibodies is unclear, but any one of the several mechanisms responsible for autoimmunity, discussed in Chapter 6 , may be involved. Several forms of autoimmune glomerulonephritis can be experimentally induced by drugs (e.g., mercuric chloride), infectious products (endotoxin), and the graft-versus-host reaction

(Chapter 6). In such models there is an alteration of immune regulation associated with B-cell activation and the induction of an array of autoantibodies that react with renal antigens.

Antibodies against Planted Antigens

Antibodies can react in situ with antigens that are not normally present in the glomerulus but are "planted" there. There is increasing experimental support for such a mechanism of glomerulonephritis. Such antigens may localize in the kidney by interacting with various intrinsic components of the glomerulus. Planted antigens include cationic molecules that bind to anionic components of the glomerulus; DNA, nucleosomes, and other nuclear proteins, which have an affinity for GBM components; bacterial products; large aggregated proteins (e.g., aggregated immunoglobulins, which deposit in the mesangium because of their size; and immune complexes themselves, since they continue to have reactive sites for further interactions with free antibody, free antigen, or complement. There is no dearth of other possible planted antigens, including viral, bacterial, and parasitic products and drugs. Antibodies that bind to most of these planted antigens induce a discrete pattern of Ig deposition detected as granular staining by immunofluorescence microscopy, similar to the pattern found in circulating immune complex nephritis.

Anti-GBM Antibody–Induced Glomerulonephritis

In this type of injury *antibodies are directed against intrinsic fixed antigens that are normal components of the GBM proper*. It has its experimental counterpart in so-called Masugi or nephrotoxic nephritis, produced in rats by injections of anti-rat kidney antibodies prepared in rabbits by immunization with rat kidney tissue. The injected antibodies bind along the entire length of the GBM, *resulting in a diffuse linear pattern of staining for the antibodies by immunofluorescent techniques* (see Fig. 20-4B and E). This is contrasted with the granular lumpy pattern of immunofluorescent staining seen in other in situ models, such as the Heymann model of membranous glomerulopathy, or after deposition of circulating immune complexes.

In the Masugi model the injected anti-GBM antibody is rabbit Ig, which is foreign to the host and thus acts as an antigen eliciting anti-Ig antibody in the rat. The rat antibodies then react with the rabbit Ig deposited in the basement membrane, leading to further glomerular injury. Often the anti-GBM antibodies cross-react with other basement membranes, especially those in the lung alveoli, resulting in simultaneous lung and kidney lesions *(Goodpasture syndrome). The GBM antigen that is responsible for classic anti-GBM antibody–induced glomerulonephritis and Goodpasture syndrome is a component of the noncollagenous domain (NC1) of the* α_3 *chain of collagen type IV* that is critical for maintenance of GBM suprastructure.[5] Anti-GBM antibody–induced glomerulonephritis accounts for fewer than 5% of cases of human glomerulonephritis. It is solidly established as the cause of injury in Goodpasture syndrome, discussed later. Most instances of anti-GBM antibody–induced glomerulonephritis are characterized by severe crescentic glomerular damage and the clinical syndrome of rapidly progressive glomerulonephritis.

Circulating Immune Complex Glomerulonephritis

In this type of nephritis glomerular injury is caused by the trapping of circulating antigen-antibody complexes within glomeruli. The antibodies have no immunological specificity for glomerular constituents, and the complexes localize within the glomeruli because of their physicochemical properties and the hemodynamic factors peculiar to the glomerulus (see Fig. 20-4A).

The pathogenesis of immune complex diseases was discussed in Chapter 6 . Here we briefly review the salient features that relate to glomerular injury.

The antigens that trigger the formation of circulating immune complexes may be of endogenous origin, as in the glomerulonephritis associated with SLE, or they may be exogenous, as is likely in the glomerulonephritis that follows certain infections. Microbial antigens that are implicated include bacterial products (streptococci), the surface antigen of hepatitis B virus, hepatitis C virus antigens, and antigens of *Treponema pallidum*, *Plasmodium falciparum*, and several viruses. Some tumor antigens are also thought to cause immune complex–mediated nephritis. In many cases the inciting antigen is unknown.

Whatever the antigen may be, antigen-antibody complexes are formed in the circulation and then trapped in the glomeruli, where they produce injury. It has long been thought that this injury is mediated and amplified by the binding of complement, but recent studies in knockout mice also point to the importance of engagement of Fc receptors on leukocytes and perhaps intrinsic renal cells as mediators of the injury process.[13] The glomerular lesions usually exhibit leukocytic infiltration and proliferation of mesangial and endothelial cells. Electron microscopy reveals the immune complexes as electron-dense deposits that lie in the mesangium, between the endothelial cells and the GBM (subendothelial deposits), or between the outer surface of the GBM and the podocytes (subepithelial deposits). Deposits may be located at more than one site in a given case. By immunofluorescence microscopy the immune complexes are seen as granular deposits along the basement membrane, in the mesangium, or in both locations (see Fig. 20-4D). Once deposited in the kidney, immune complexes may eventually be degraded, mostly by infiltrating neutrophils and monocytes/macrophages, mesangial cells, and endogenous proteases, and the inflammatory reaction may then subside. Such a course occurs when the exposure to the inciting antigen is short-lived and limited, as in most cases of poststreptococcal glomerulonephritis. However, if a continuous shower of antigens develops, as may be seen in SLE or viral hepatitis, repeated cycles of immune complex formation, deposition, and injury may occur, leading to a more chronic membranous or membranoproliferative type of glomerulonephritis.

Several factors affect glomerular localization of antigen, antibody, or complexes of both. The molecular charge and size of these reactants are clearly important. Highly cationic immunogens tend to cross the GBM, and the resultant complexes eventually reside in a subepithelial location. Highly anionic macromolecules are excluded from the GBM and either are trapped subendothelially or are not nephritogenic at all. Molecules of neutral charge and immune complexes containing these molecules tend to accumulate in the mesangium. Large circulating complexes are not usually nephritogenic, because they are cleared by the mononuclear phagocyte system and do not enter the GBM in sufficient quantities. The pattern of localization is also affected by changes in glomerular hemodynamics, mesangial function, and integrity of the charge-selective barrier in the glomerulus. These influences may underlie the variable pattern of immune reactant deposition in various forms of glomerulonephritis, as shown in Figure 20-5 . In turn, the distinct patterns of localization of immune complexes is a key determinant of the injury response and the histologic features that subsequently develop.

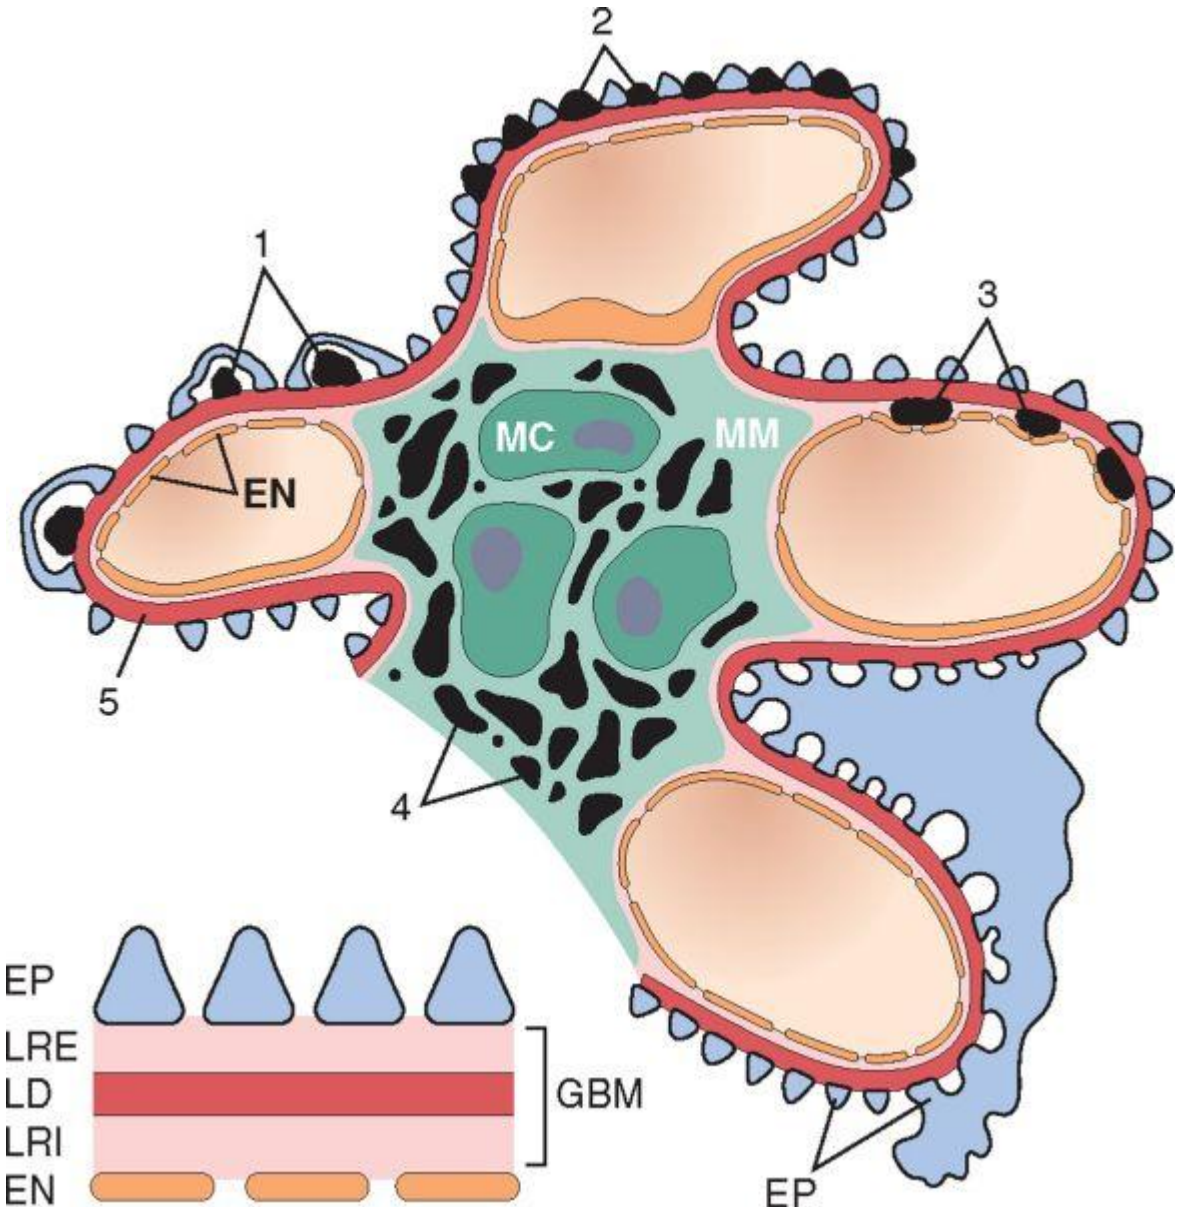

FIGURE 20-5 Localization of immune complexes in the glomerulus: (1) subepithelial humps, as in acute glomerulonephritis; (2) epimembranous deposits, as in membranous nephropathy and Heymann glomerulonephritis; (3) subendothelial deposits, as in lupus nephritis and membranoproliferative glomerulonephritis; (4) mesangial deposits, as in IgA nephropathy; (5) basement membrane. EN, endothelium; EP, epithelium; LD, lamina densa; LRE, lamina rara externa; LRI, lamina rara interna; MC, mesangial cell; MM, mesangial matrix. *(Modified from Couser WG: Mediation of immune glomerular injury. J Am Soc Nephrol 1:13, 1990.)*

Antibodies to Glomerular Cells

In addition to causing immune deposits, antibodies against glomerular cell antigens may react with cellular components and cause injury by cytotoxic or other mechanisms. Antibodies to mesangial cell antigens, for example, can cause mesangiolysis followed by mesangial cell proliferation; antibodies to endothelial cell antigens cause endothelial injury and intravascular thrombosis; and antibodies to certain visceral epithelial cell components cause proteinuria in experimental animals. This mechanism may play a role in certain human immune disorders that are without demonstrable immune deposits.

In summary, *most cases of human glomerulonephritis are a consequence of deposits of discrete immune complexes, which are visualized by granular immunofluorescence staining along the basement membranes or in the mesangium*. However, it may be difficult to determine whether the deposition has occurred in situ, by circulating complexes, or by both mechanisms because, as was discussed earlier, trapping of circulating immune complexes can initiate further in situ complex formation. Single etiologic agents, such as hepatitis B and C viruses, can cause either a membranous pattern of glomerulonephritis, suggesting in situ deposition, or a membranoproliferative pattern, more indicative of circulating complexes. It is best then to consider that *antigen-antibody deposition in the glomerulus is a major pathway of glomerular injury and that in situ immune reactions, trapping of circulating complexes, interactions between these two events, and local hemodynamic and structural determinants in the glomerulus all contribute to the diverse morphologic and functional alterations in glomerulonephritis*.

Cell-Mediated Immunity in Glomerulonephritis

Although antibody-mediated mechanisms may initiate many forms of glomerulonephritis, there is now considerable evidence that sensitized T cells cause some forms of glomerular injury and are involved in the progression of many glomerulonephritides.[14] Clues to the role of cellular immunity include the presence of activated macrophages and T cells and their products in the glomerulus in some forms of human and experimental glomerulonephritis;[15] in vitro and in vivo evidence of lymphocyte activation on exposure to antigen in human and experimental glomerulonephritis; abrogation of glomerular injury by lymphocyte depletion; and successful attempts to induce glomerular injury by transfer of T cells from nephritic animals to normal recipients. The evidence is most compelling for certain types of experimental crescentic glomerulonephritis in which antibodies to GBM may initiate glomerular injury but activated T lymphocytes may propogate the inflammation.[15]

Activation of Alternative Complement Pathway

Alternative complement pathway activation occurs in the clinicopathologic entity called dense-deposit disease, also referred to as *membranoproliferative glomerulonephritis (MPGN type II)*. It may also occur in some forms of proliferative glomerulonephritis. This mechanism is discussed later.

Epithelial Cell Injury

This can be induced by antibodies to visceral epithelial cell antigens; by toxins, as in an experimental model of proteinuria induced by puromycin aminonucleoside; conceivably by certain cytokines; or by still poorly characterized factors, as in the case of human minimal-change disease and focal segmental glomerulosclerosis, discussed later. Such injury is reflected morphologically by changes in the visceral epithelial cells, which include effacement of foot processes, vacuolization, retraction, and detachment of cells from the GBM, and functionally by proteinuria. It is hypothesized that the detachment of visceral epithelial cells is caused by loss of adhesive interactions with the basement membrane and that this detachment contributes to protein leakage (Fig. 20-6).

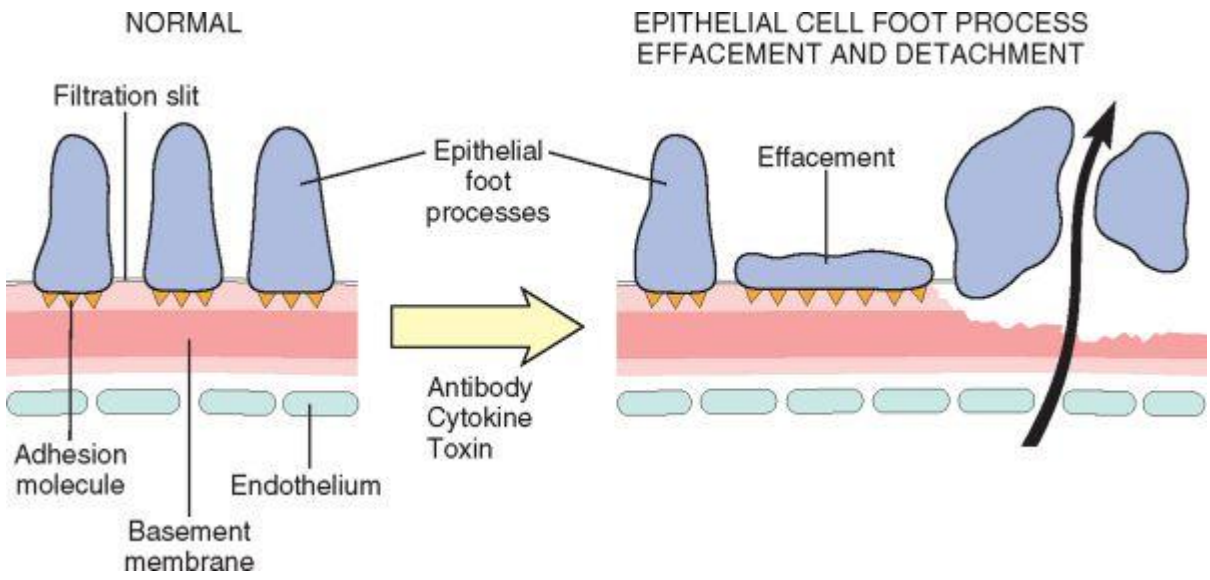

FIGURE 20-6 Epithelial cell injury. The postulated sequence is a consequence of antibodies specific to epithelial cell antigens, toxins, cytokines, or other factors causing injury; this results in foot process effacement and sometimes detachment of epithelial cells and protein leakage through defective GBM and filtration slits.

Mediators of Glomerular Injury

Once immune reactants or sensitized T cells have localized in the glomerulus, how does the glomerular damage ensue? The mediators—both cells and molecules—are the usual suspects involved in acute and chronic inflammation, described in Chapter 2 , and only a few are highlighted here (Fig. 20-7).

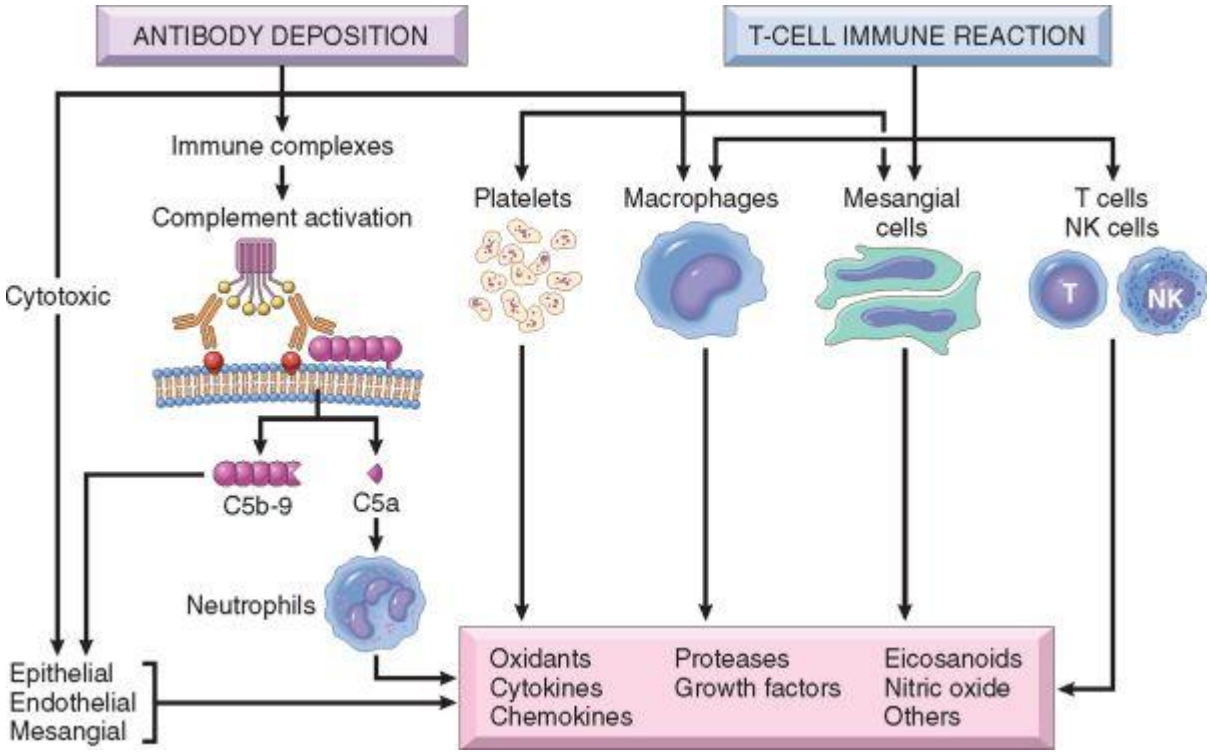

FIGURE 20-7 Mediators of immune glomerular injury including cells and soluble mediators (see text).

Cells

- *Neutrophils* and *monocytes* infiltrate the glomerulus in certain types of glomerulonephritis, largely as a result of activation of complement, resulting in generation of chemotactic agents (mainly C5a), but also by Fc-mediated adherence and activation. Neutrophils release proteases, which cause GBM degradation; oxygen-derived free radicals, which cause cell damage; and arachidonic acid metabolites, which contribute to the reductions in GFR.
- *Macrophages, T lymphocytes*, and *natural killer cells*, which infiltrate the glomerulus in antibody- and cell-mediated reactions, when activated release a vast number of biologically active molecules.
- *Platelets* aggregate in the glomerulus during immune-mediated injury. Their release of eicosanoids and growth factors may contribute to the manifestations of glomerulonephritis. Antiplatelet agents have beneficial effects in both human and experimental glomerulonephritis.
- *Resident glomerular cells*, particularly mesangial cells, can be stimulated to produce several inflammatory mediators, including reactive oxygen species (ROS), cytokines, chemokines, growth factors, eicosanoids, nitric oxide, and endothelin. In the absence of leukocytic infiltration, they may initiate inflammatory responses in the glomerulus.

Soluble Mediators

Virtually all the known inflammatory chemical mediators have been implicated in glomerular injury.

- The *chemotactic complement components* induce leukocyte influx (complement-neutrophil–dependent injury) and lead to formation of C5b-C9, the membrane attack complex. C5b-C9 causes cell lysis but, in addition, stimulates mesangial cells to produce oxidants, proteases, and other mediators. Thus, even in the absence of neutrophils, C5b-C9 can cause proteinuria, as has been postulated in membranous glomerulopathy.
- *Eicosanoids*, *nitric oxide*, *angiotensin*, and *endothelin* are involved in the hemodynamic changes.
- *Cytokines*, particularly IL-1 and TNF, which may be produced by infiltrating leukocytes and resident glomerular cells, induce leukocyte adhesion and a variety of other effects.
- *Chemokines* such as monocyte chemoattractant protein 1 and CCL5 promote monocyte and lymphocyte influx. *Growth factors* such as platelet-derived growth factor (PDGF) are involved in mesangial cell proliferation.[16] TGF-β, connective tissue growth factor, and fibroblast growth factor seem to be critical in the ECM deposition and hyalinization leading to glomerulosclerosis in chronic injury.[17] Vascular endothelial growth factor (VEGF) seems to maintain endothelial integrity and may help regulate capillary permeability.
- The *coagulation system* is also a mediator of glomerular damage. Fibrin is frequently present in the glomeruli in glomerulonephritis, and fibrin may leak into Bowman space, serving as a stimulus for parietal epithelial cell proliferation (crescent formation). Fibrin deposition is mediated largely by stimulation of macrophage procoagulant activity. Plasminogen activator inhibitor-1 is linked to increased thrombosis and fibrosis by inhibiting degradation of fibrin and matrix proteins.

MECHANISMS OF PROGRESSION IN GLOMERULAR DISEASES

Thus far we have discussed the immunological mechanisms and mediators that *initiate* glomerular injury. The outcome of such injury depends on several factors, including the initial severity of renal damage, the nature and persistence of the antigens, and the immune status, age, and genetic predisposition of the host.

It has long been known that once any renal disease, glomerular or otherwise, destroys functioning nephrons and reduces the GFR to about 30% to 50% of normal, progression to end-stage renal failure proceeds at a relatively constant rate, independent of the original stimulus or activity of the underlying

disease. The secondary factors that lead to progression are of great clinical interest, since they can be targets of therapy that delays or even prevents the inexorable journey to dialysis or transplantation.

The two major histologic characteristics of such progressive renal damage are *focal segmental glomerulosclerosis* and *tubulointerstitial fibrosis*; we discuss these separately. [18] [19] [20]

Focal Segmental Glomerulosclerosis (FSGS).

Patients with this secondary change develop proteinuria, even if the primary disease was nonglomerular. The glomerulosclerosis seems to be initiated by the *adaptive change* that occurs in the relatively unaffected glomeruli of diseased kidneys.[19,][21] Such a mechanism is suggested by experiments in rats subjected to ablation of renal mass by subtotal nephrectomy. *Compensatory hypertrophy* of the remaining glomeruli serves to maintain renal function in these animals, but proteinuria and segmental glomerulosclerosis soon develop, leading eventually to total glomerular sclerosis and uremia. The glomerular hypertrophy is associated with *hemodynamic changes*, including increases in glomerular blood flow, filtration, and transcapillary pressure (glomerular hypertension), and often with systemic hypertension. The sequence of events (Fig. 20-8) that is thought to lead to sclerosis in this setting entails endothelial and epithelial cell injury, increased glomerular permeability to proteins, and accumulation of proteins in the mesangial matrix. This is followed by proliferation of mesangial cells, infiltration by macrophages, increased accumulation of extracellular matrix (ECM), and segmental and eventually global sclerosis of glomeruli. This results in further reductions in nephron mass, ongoing activation of these compensatory changes, and a vicious circle of continuing glomerulosclerosis. Most of the mediators of chronic inflammation and fibrosis, particularly TGF-β, play a role in the induction of sclerosis. Currently, the most successful interventions to interrupt these mechanisms of progressive glomerulosclerosis involve treatment with inhibitors of the renin-angiotensin system, which not only reduce intraglomerular hypertension, but also have direct effects on each of the mechanisms identified above.[21] Importantly, these agents have been shown to ameliorate progression of sclerosis in both animal and human studies.[20]

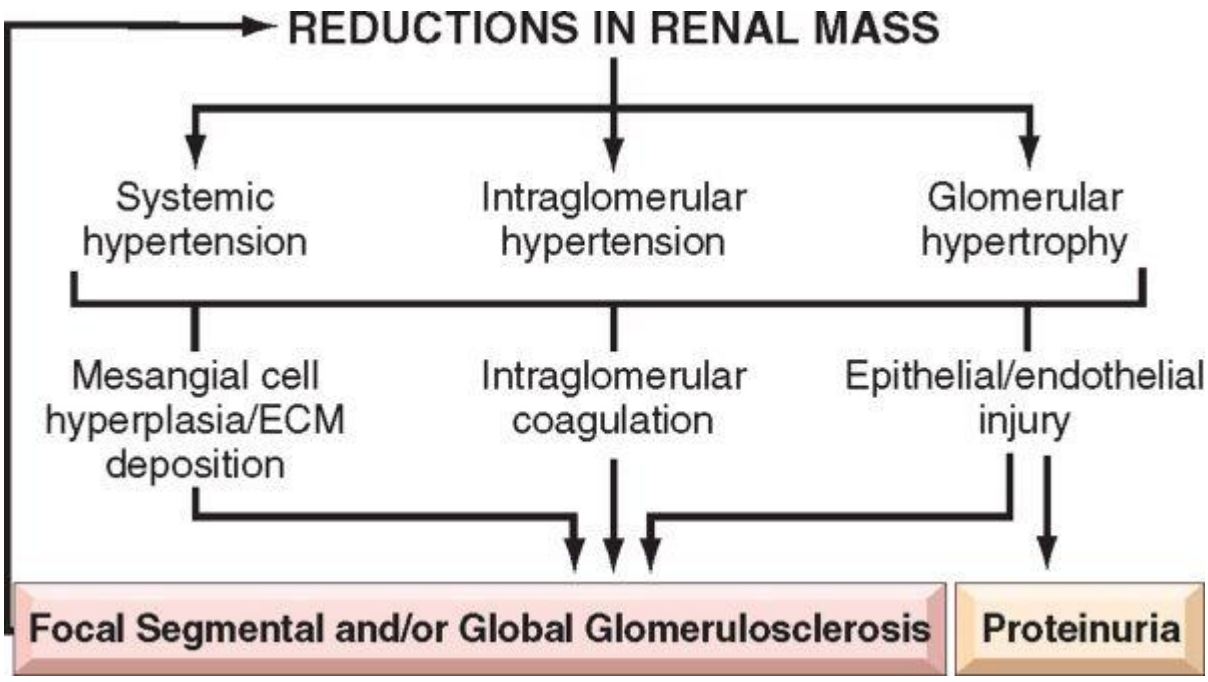

FIGURE 20-8 Focal segmental glomerulosclerosis associated with loss of renal mass. The adaptive changes in glomeruli (hypertrophy and glomerular capillary hypertension), as well as systemic hypertension, cause epithelial and endothelial injury and resultant proteinuria. The mesangial response, involving mesangial cell proliferation and ECM production together with intraglomerular coagulation, causes the

glomerulosclerosis. This results in further loss of functioning nephrons and a vicious circle of progressive glomerulosclerosis.

Contributing to the progressive injury of focal and segmental glomerulosclerosis is the inability of mature visceral epithelial cells (podocytes) to proliferate after injury. This can lead to a decrease in glomerular podocyte number after a severe injury resulting in loss of some of these cells, leading in turn to a process whereby remaining podocytes are either abnormally stretched to maintain an appropriate filtration barrier or unable to cover portions of the GBM, which become denuded of the overlying podocyte foot processes. These alterations lead to abnormal protein filtration as well as loss of structural support for the glomerular capillary walls. This latter alteration in turn may lead to segmental loop dilation because of now incompletely opposed intracapillary pressures, with subsequent formation of a fibrous attachment to Bowman capsule by the bulging capillary segment, and eventual sclerosis of this segment.[22]

Tubulointerstitial Fibrosis.

Tubulointerstitial injury, manifested by tubular damage and interstitial inflammation, is a component of many acute and chronic glomerulonephritides. Tubulointerstitial fibrosis contributes to progression in both immune and nonimmune glomerular diseases, for example, diabetic nephropathy. *Indeed, there is often a much better correlation of decline in renal function with the extent of tubulointerstitial damage than with the severity of glomerular injury*.[18] Many factors may lead to such tubulointerstitial injury, including ischemia of tubule segments downstream from sclerotic glomeruli, acute and chronic inflammation in the adjacent interstitium, and damage or loss of the peritubular capillary blood supply. Current work also points to the effects of *proteinuria* on tubular cell structure and function[23]. On the basis of in vitro and animal studies, proteinuria is thought to cause *direct injury to and activation of tubular cells*. Activated tubular cells in turn express adhesion molecules and elaborate pro-inflammatory cytokines, chemokines, and growth factors that contribute to interstitial fibrosis. Filtered proteins that may produce these tubular effects include cytokines, complement products, the iron in transferrin, immunoglobulins, lipid moieties, and oxidatively modified plasma proteins.

Having discussed factors in the initiation and progression of glomerular injury, we now turn to a discussion of individual glomerular diseases. Table 20-5 summarizes the main clinical and pathologic features of the major forms of primary glomerulopathies.

TABLE 20-5 -- Summary of Major Primary Glomerulonephritides

			Glomerular Pathology		
Disease	**Most Frequent Clinical Presentation**	**Pathogenesis**	***Light Microscopy***	***Fluorescence Microscopy***	***Electron Microscopy***
Postinfectious glomerulonephritis	Nephritic syndrome	Immune complex mediated; circulating or planted antigen	Diffuse endocapillary proliferation; leukocytic infiltration	Granular IgG and C3 in GBM and mesangium	Subepithelial humps
Goodpasture syndrome	Rapidly progressive glomerulonephritis	Anti-GBM COL4-A3 antigen	Extracapillary proliferation with crescents; necrosis	Linear IgG and C3; fibrin in crescents	No deposits; GBM disruptions; fibrin
Chronic glomerulonephritis	Chronic renal failure	Variable	Hyalinized glomeruli	Granular or negative	

			Glomerular Pathology		
Disease	**Most Frequent Clinical Presentation**	**Pathogenesis**	***Light Microscopy***	***Fluorescence Microscopy***	***Electron Microscopy***
Membranous glomerulopathy	Nephrotic syndrome	In situ immune complex formation; antigens mostly unknown	Diffuse capillary wall thickening	Granular IgG and C3; diffuse	Subepithelial deposits
Minimal-change disease	Nephrotic syndrome	Unknown; loss of glomerular polyanion; podocyte injury	Normal; lipid in tubules	Negative	Loss of foot processes; no deposits
Focal segmental glomerulosclerosis	Nephrotic syndrome; non-nephrotic proteinuria	Unknown Ablation nephropathy Plasma factor (?); podocyte injury	Focal and segmental sclerosis and hyalinosis	Focal; IgM + C3	Loss of foot processes; epithelial denudation
Membranoproliferative glomerulonephritis (MPGN) type I	Nephrotic/nephrotic syndrome	Immune complex		IgG + C3; C1q + C4	Subendothelial deposits
Dense-deposit disease (MPGN type II)	Hematuria Chronic renal failure	Autoantibody; alternative complement pathway	Mesangial and endocapillary proliferation; GBM thickening; splitting	C3±IgG; no C1q or C4	Dense deposits
IgA nephropathy	Recurrent hematuria or proteinuria	Unknown	Focal mesangial proliferative glomerulonephritis; mesangial widening	IgA±IgG, IgM, and C3 in mesangium	Mesangial and paramesangial dense deposits

GBM, glomerular basement membrane.

NEPHRITIC SYNDROME

Glomerular diseases presenting with a nephritic syndrome are often *characterized by inflammation in the glomeruli*. The nephritic patient usually presents with hematuria, red cell casts in the urine, azotemia, oliguria, and mild to moderate hypertension. Proteinuria and edema are common, but these are not as severe as those encountered in the nephrotic syndrome, discussed later. The acute nephritic syndrome may occur in such multisystem diseases as SLE and microscopic polyangiitis. Typically, however, it is characteristic of acute proliferative glomerulonephritis and is an important component of crescentic glomerulonephritis, which is described later.

Acute Proliferative (Poststreptococcal, Postinfectious) Glomerulonephritis

As the name implies, this cluster of diseases is characterized histologically by diffuse proliferation of glomerular cells, associated with influx of leukocytes. These lesions are typically caused by immune

complexes. The inciting antigen may be exogenous or endogenous. The prototypic exogenous antigen-induced disease pattern is postinfectious glomerulonephritis, whereas an example of an endogenous antigen-induced disease is the nephritis of SLE, described in Chapter 6 . The most common underlying infections are streptococcal, but the disorder also has been associated with other infections.

Poststreptococcal Glomerulonephritis

This glomerular disease is decreasing in frequency in the United States but continues to be a fairly common disorder worldwide.[24] It usually appears 1 to 4 weeks after a streptococcal infection of the pharynx or skin (impetigo). Skin infections are commonly associated with overcrowding and poor hygiene. Poststreptococcal glomerulonephritis occurs most frequently in children 6 to 10 years of age, but adults of any age can also be affected.

Etiology and Pathogenesis.

Only certain strains of group A β-hemolytic streptococci are nephritogenic, more than 90% of cases being traced to types 12, 4, and 1, which can be identified by typing of M protein of the cell wall.

Poststreptococcal glomerulonephritis is an immunologically mediated disease. The latent period between infection and onset of nephritis is compatible with the time required for the production of antibodies and the formation of immune complexes. Elevated titers of antibodies against one or more streptococcal antigens are present in a great majority of patients. Serum complement levels are low, compatible with activation of the complement system and consumption of complement components. There are granular immune deposits in the glomeruli, supporting an immune complex–mediated mechanism. The streptococcal antigenic com-ponent responsible for the immune reaction has eluded identification for years. Several *cationic antigens*, including a nephritis-associated streptococcal plasmin receptor (NAPlr), unique to nephritogenic strains of streptococci, can be found in affected glomeruli. Other evidence suggests that streptococcal pyogenic exotoxin B (SpeB) and its zymogen precursor (zSpeB), another protein that functions as a plasmin receptor, are the principal antigenic determinants in most cases of poststreptococcal glomerulonephritis.[25] It is not known if these represent antigens planted in the GBM, or parts of circulating immune complexes, or both. GBM proteins altered by streptococcal enzymes have also been implicated as antigens.

Morphology. The classic diagnostic picture is one of **enlarged, hypercellular glomeruli** (Fig. 20-9). The hypercellularity is caused by (1) infiltration by leukocytes, both neutrophils and monocytes; (2) proliferation of endothelial and mesangial cells; and (3) in severe cases by crescent formation. The proliferation and leukocyte infiltration are diffuse, that is, involving all lobules of all glomeruli. There is also swelling of endothelial cells, and the combination of proliferation, swelling, and leukocyte infiltration obliterates the capillary lumens. There may be interstitial edema and inflammation, and the tubules often contain red cell casts.

By **immunofluorescence microscopy**, there are granular deposits of IgG, IgM, and C3 in the mesangium and along the GBM (Fig. 20-9D). Although immune complex deposits are almost universally present, they are often focal and sparse. The characteristic **electron microscopic findings** are discrete, amorphous, electron-dense deposits on the epithelial side of the membrane, often having the appearance of “humps” (Fig. 20-9C), presumably representing the antigen-antibody complexes at the epithelial cell surface. Subendothelial and intramembranous deposits are also commonly seen, and mesangial deposits may be present.

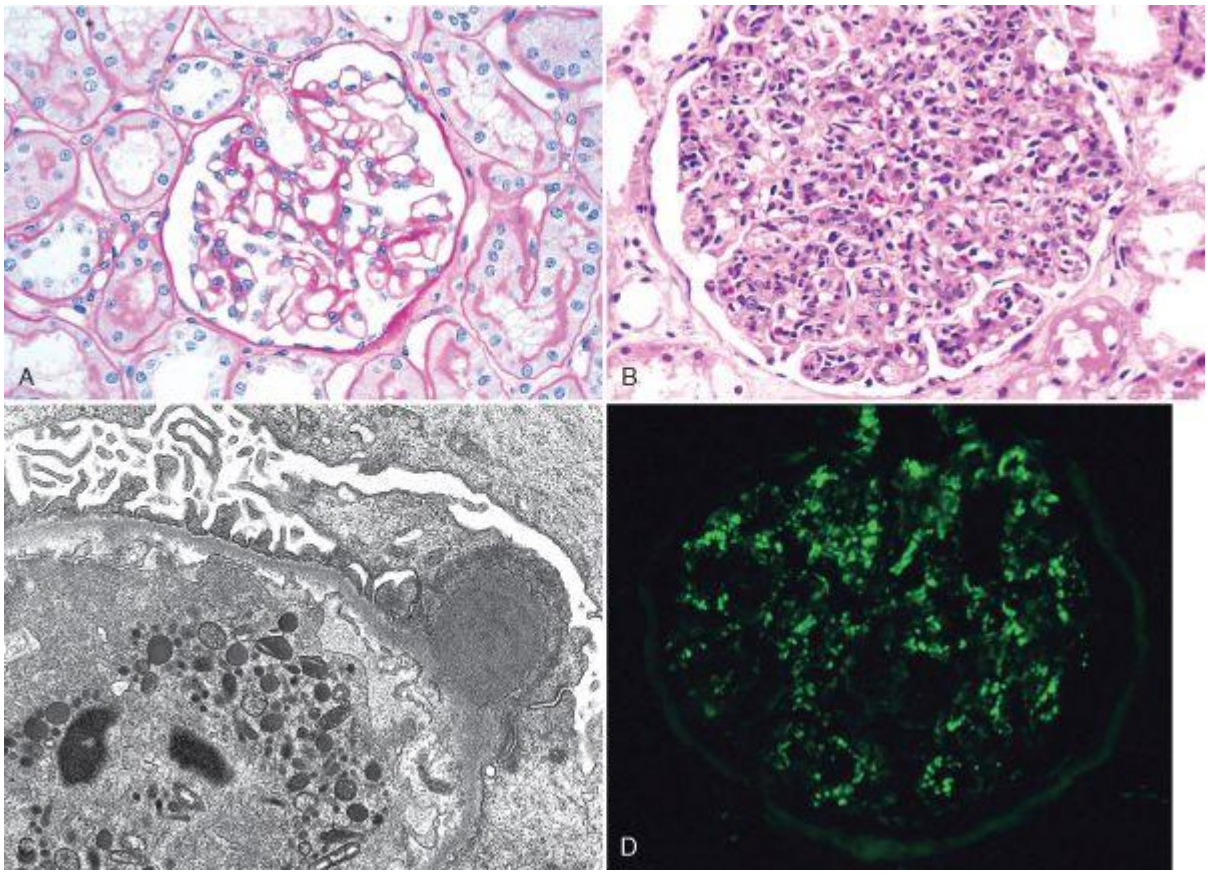

FIGURE 20-9 Acute proliferative glomerulonephritis. **A**, Normal glomerulus. **B**, Glomerular hypercellularity is due to intracapillary leukocytes and proliferation of intrinsic glomerular cells. **C**, Typical electron-dense subepithelial "hump" and a neutrophil in the lumen. **D**, Immunofluorescent stain demonstrates discrete, coarsly granular deposits of complement protein C3, corresponding to "humps" illustrated in part C. *(**A–C**, courtesy of Dr. H. Rennke, Brigham and Women's Hospital, Boston, MA. **D**, courtesy of D. J. Kowaleska, University of Washington, Seattle, WA.)*

Clinical Course.

In the classic case, a young child abruptly develops malaise, fever, nausea, oliguria, and hematuria (smoky or cola-colored urine) 1 to 2 weeks after recovery from a sore throat. The patients have red cell casts in the urine, mild proteinuria (usually less than 1 gm/day), periorbital edema, and mild to moderate hypertension. In adults the onset is more likely to be atypical, such as the sudden appearance of hypertension or edema, frequently with elevation of BUN. During epidemics caused by nephritogenic streptococcal infections, glomerulonephritis may be asymptomatic, discovered only on screening for microscopic hematuria. Important laboratory findings include elevations of antistreptococcal antibody titers and a decline in the serum concentration of C3 and other components of the complement cascade.

More than 95% of affected children eventually recover totally with conservative therapy aimed at maintaining sodium and water balance. A small minority of children (perhaps fewer than 1%) do not improve, become severely oliguric, and develop a rapidly progressive form of glomerulonephritis (described later). Some of the remaining patients may undergo slow progression to chronic glomerulonephritis with or without recurrence of an active nephritic picture. Prolonged and persistent heavy proteinuria and abnormal GFR mark patients with an unfavorable prognosis.

In adults the disease is less benign. Although the overall prognosis in epidemics is good, in only about 60% of *sporadic cases* do the patients recover promptly. In the remainder the glomerular lesions fail to resolve quickly, as manifested by persistent proteinuria, hematuria, and hypertension. In some of these patients, the lesions eventually clear totally, but others develop chronic glomerulonephritis. Some patients will develop a syndrome of rapidly progressive glomerulonephritis.

Nonstreptococcal Acute Glomerulonephritis (Postinfectious Glomerulonephritis)

A similar form of glomerulonephritis occurs sporadically in association with other infections, including bacterial (e.g., staphylococcal endocarditis, pneumococcal pneumonia, and meningococcemia), viral (e.g., hepatitis B, hepatitis C, mumps, human immunodeficiency virus [HIV] infection, varicella, and infectious mononucleosis), and parasitic (malaria, toxoplasmosis). In these settings, granular immunofluorescent deposits and subepithelial humps characteristic of immune complex nephritis are present.

RAPIDLY PROGRESSIVE (CRESCENTIC) GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis (RPGN) is a syndrome associated with severe glomerular injury and does not denote a specific etiologic form of glomerulonephritis. It is characterized clinically by rapid and progressive loss of renal function associated with severe oliguria and signs of nephritic syndrome; if untreated, death from renal failure occurs within weeks to months. *The most common histologic picture is the presence of crescents in most of the glomeruli* (crescentic glomerulonephritis). As discussed earlier, these are produced by the proliferation of the parietal epithelial cells lining Bowman capsule and by the infiltration of monocytes and macrophages.

Classification and Pathogenesis.

RPGN may be caused by a number of different diseases, some restricted to the kidney and others systemic. Although no single mechanism can explain all cases, there is little doubt that in most cases the glomerular injury is immunologically mediated. A practical classification divides RPGN into three groups on the basis of immunological findings (Table 20-6). In each group the disease may be associated with a known disorder, or it may be idiopathic.

TABLE 20-6 -- Rapidly Progressive Glomerulonephritides

TYPE I (ANTI-GBM ANTIBODY)
Renal limited
Goodpasture syndrome
TYPE II (IMMUNE COMPLEX)
Idiopathic
Post-infectious glomerulonephritis
Lupus nephritis
Henoch-Schönlein purpura (IgA nephropathy)
Others
TYPE III (PAUCI-IMMUNE)
ANCA-associated
Idiopathic

Wegener granulomatosis
Microscopic polyangiitis

ANCA, antineutrophil cytoplasmic antibodies; GBM, glomerular basement membrane.

The first type of RPGN is *anti-GBM antibody–induced disease*, characterized by linear deposits of IgG and, in many cases, C3 in the GBM that are visualized by immunofluorescence.[26] In some of these patients, the anti-GBM antibodies cross-react with pulmonary alveolar basement membranes to produce the clinical picture of pulmonary hemorrhage associated with renal failure *(Goodpasture syndrome)*. Plasmapheresis to remove the pathogenic circulating antibodies is usually part of the treatment, which also includes therapy to suppress the underlying immune response.

The Goodpasture antigen is a peptide within the noncollagenous portion of the α_3 chain of collagen type IV.[5] What triggers the formation of these antibodies is unclear in most patients. Exposure to viruses or hydrocarbon solvents (found in paints and dyes) has been implicated in some patients, as have various drugs and cancers. There is a high prevalence of certain HLA subtypes and haplotypes (e.g., HLA-DRB1) in affected patients, a finding consistent with the genetic predisposition to autoimmunity.[27]

The second type of RPGN is the result of *immune complex deposition*. It can be a complication of any of the immune complex nephritides, including postinfectious glomerulonephritis, lupus nephritis, IgA nephropathy, and HenochSchönlein purpura. In all these cases, immunofluorescence studies reveal the granular pattern of staining characteristic of immune complex deposition. This type of RPGN frequently demonstrates cellular proliferation within the glomerular tuft, in addition to crescent formation. These patients cannot usually be helped by plasmapheresis, and they require treatment for the underlying disease.

The third type of RPGN, also called *pauci-immune type*, is defined by the lack of anti-GBM antibodies or immune complexes by immunofluorescence and electron microscopy. Most patients with this type of RPGN have circulating *antineutrophil cytoplasmic antibodies* (ANCAs) that produce cytoplasmic (c) or perinuclear (p) staining patterns and, as we have seen (Chapter 11), play a role in some vasculitides. Hence, in some cases this type of RPGN is a component of a systemic vasculitis such as Wegener granulomatosis or microscopic polyangiitis. In many cases, however, pauci-immune crescentic glomerulonephritis is isolated and hence *idiopathic*. More than 90% of such idiopathic cases have c-ANCAs or p-ANCAs in the sera.[26] The presence of circulating ANCAs in both idiopathic crescentic glomerulonephritis and cases of crescentic glomerulonephritis that occur as a component of systemic vasculitis, and the similar pathologic features in either setting, have led to the idea that these disorders are pathogenetically related. According to this concept, all cases of crescentic glomerulonephritis of the pauci-immune type are manifestations of small-vessel vasculitis or polyangiitis, which is limited to glomerular and perhaps peritubular capillaries in cases of idiopathic crescentic glomerulonephritis. The clinical distinction between systemic vasculitis with pauci-immune renal involvement and idiopathic crescentic glomerulonephritis accordingly has become de-emphasized, since these entities are viewed as part of a spectrum of vasculitic disease. ANCAs have proved to be invaluable as a highly sensitive diagnostic marker for pauci-immune crescentic glomerulonephritis, but proof of their role as a direct cause of this glomerulonephritis has been elusive. Recent strong evidence of their pathogenic potential has been obtained by studies in mice showing that transferring antibodies against myeloperoxidase (the target antigen of most p-ANCAs) induces a form of RPGN.[28]

To summarize, all three types of RPGN may be associated with a well-defined renal or extrarenal disease, but in many cases (~50%), the disorder is idiopathic. Of the patients with this syndrome, about one fifth have anti–GBM antibody–mediated glomerulonephritis without lung involvement; another one fourth have immune complex–mediated crescentic glomerulonephritis; and the remainder are of the pauci-immune type. *The common denominator in all types of RPGN is severe glomerular injury*.

Morphology. The kidneys are enlarged and pale, often with petechial hemorrhages on the cortical surfaces. Depending on the underlying cause, the glomeruli may show focal necrosis, diffuse or focal endothelial proliferation, and mesangial proliferation. The histologic picture, however, is dominated by distinctive **crescents** (Fig. 20-10). Crescents are formed by proliferation of parietal cells and by migration of monocytes and macrophages into the urinary space. Neutrophils and lymphocytes may be present. The crescents eventually obliterate Bowman space and compress the glomerular tuft. **Fibrin strands are frequently prominent between the cellular layers in the crescents**; indeed, as discussed earlier, the escape of fibrinogen into Bowman space and its conversion to fibrin are an important contributor to crescent formation. By immunofluorescence microscopy, immune complex–mediated cases show granular immune deposits; Goodpasture syndrome cases show linear GBM fluorescence for Ig and complement, and pauci-immune cases have little or no deposition of immune reactants. Electron microscopy discloses deposits in those cases due to immune complex deposition (type II). Regardless of type, electron microscopy may show distinct **ruptures in the GBM**, the severe injury that allows leukocytes, proteins, and inflammatory mediators to reach the urinary space, where they trigger the crescent formation (Fig. 20-11). In time, most crescents undergo sclerosis, but restoration of normal glomerular architecture may be achieved with early aggressive therapy.

Texas Health Sciences Center, San Antonio, TX.)

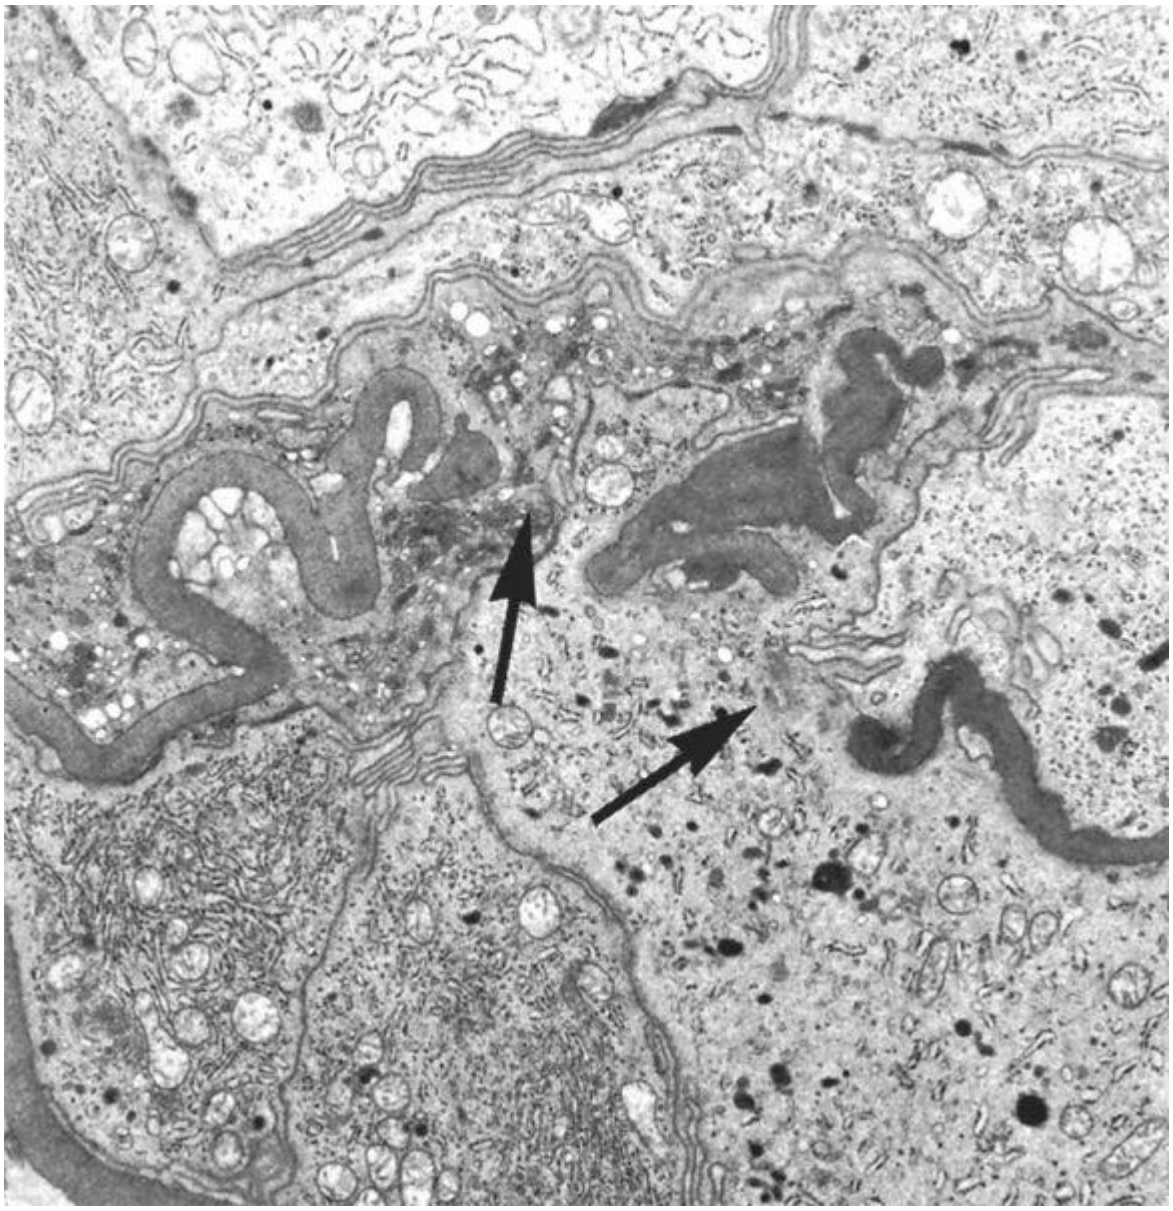

FIGURE 20-11 Crescentic glomerulonephritis. Electron micrograph showing characteristic wrinkling of GBM with focal disruptions *(arrows)*.

Clinical Course.

The renal manifestations of all forms of crescentic glomerulonephritis include hematuria with red blood cell casts in the urine, moderate proteinuria occasionally reaching the nephrotic range, and variable hypertension and edema. In Goodpasture syndrome the course may be dominated by recurrent hemoptysis or even life-threatening pulmonary hemorrhage. Serum analyses for anti-GBM antibodies, antinuclear antibodies, and ANCAs are helpful in the diagnosis of specific subtypes. Although milder

forms of glomerular injury may subside, the renal involvement is usually progressive over a matter of weeks and culminates in severe oliguria. Recovery of renal function may follow early intensive plasmapheresis (plasma exchange) combined with steroids and cytotoxic agents in Goodpasture syndrome. This therapy can reverse both pulmonary hemorrhage and renal failure. Other forms of RPGN also respond well to steroids and cytotoxic agents. However, despite therapy, some patients may eventually require chronic dialysis or transplantation, particularly if the disease is discovered at a late stage.

NEPHROTIC SYNDROME

Certain glomerular diseases virtually always produce the nephrotic syndrome. In addition, many other forms of primary and secondary glomerulopathies discussed in this chapter may underlie the syndrome. Before the major diseases associated with nephrotic syndrome are presented, the causes and pathophysiology of this clinical complex are briefly discussed.

Pathophysiology.

The manifestations of the nephrotic syndrome include:

1. *Massive proteinuria*, with the daily loss of 3.5 gm or more of protein (less in children)
2. *Hypoalbuminemia*, with plasma albumin levels less than 3 gm/dL
3. *Generalized edema*
4. *Hyperlipidemia and lipiduria*

The various components of nephrotic syndrome bear a logical relationship to one another. The initial event is a derangement in glomerular capillary walls resulting in *increased permeability to plasma proteins*. The glomerular capillary wall, with its endothelium, GBM, and visceral epithelial cells, acts as a size and charge barrier through which the plasma filtrate passes. Increased permeability resulting from either structural or physicochemical alterations allows protein to escape from the plasma into the urinary space. *Massive proteinuria results*.

The heavy proteinuria depletes serum albumin levels at a rate beyond the compensatory synthetic capacity of the liver, resulting in hypoalbuminemia and a reversed albumin-to-globulin ratio. Increased renal catabolism of filtered albumin also contributes to the hypoalbuminemia. The generalized edema is, in turn, the consequence of decreased colloid osmotic pressure of the blood with subsequent accumulation of fluid in the interstitial tissues. There is also *sodium and water retention*, which aggravates the edema (Chapter 4). This seems to be due to several factors, including compensatory secretion of aldosterone, mediated by the hypovolemia-enhanced renin secretion; stimulation of the sympathetic system; and a reduction in the secretion of natriuretic factors such as atrial peptides. Edema is characteristically soft and pitting, most marked in the periorbital regions and dependent portions of the body. It may be massive, with pleural effusions and ascites.

The largest proportion of protein lost in the urine is albumin, but globulins are also excreted in some diseases. The ratio of low- to high-molecular-weight proteins in the urine in various cases of nephrotic syndrome is a manifestation of the *selectivity* of proteinuria. A *highly selective proteinuria* consists mostly of low-molecular-weight proteins (albumin, 70 kD; transferrin, 76 kD molecular weight), whereas a *poorly selective proteinuria* consists of higher molecular-weight globulins in addition to albumin.

The genesis of the *hyperlipidemia* is complex. Most patients with nephritic syndrome have increased blood levels of cholesterol, triglyceride, very-low-density lipoprotein, low-density lipoprotein, Lp(a)

lipoprotein, and apoprotein, and there is a decrease in high-density lipoprotein concentration in some patients. These defects seem to be due in part to *increased synthesis of lipoproteins in the liver, abnormal transport of circulating lipid particles, and decreased catabolism. Lipiduria* follows the hyperlipidemia, because lipoproteins also leak across the glomerular capillary wall. The lipid appears in the urine either as free fat or as *oval fat bodies*, representing lipoprotein resorbed by tubular epithelial cells and then shed along with the degenerated cells.

Nephrotic patients are particularly vulnerable to *infection*, especially staphylococcal and pneumococcal, probably related to loss of immunoglobulins in the urine. *Thrombotic and thromboembolic complications* are also common in nephrotic syndrome, due in part to loss of endogenous anticoagulants (e.g., antithrombin III) and antiplasmins in the urine. *Renal vein thrombosis*, once thought to be a cause of nephrotic syndrome, is most often a *consequence* of this hypercoagulable state, particularly in patients with membranous nephropathy (see below).

Causes.

The relative frequencies of the several causes of the nephrotic syndrome vary according to age and geography. In children younger than 17 years in North America, for example, the nephrotic syndrome is almost always caused by a lesion primary to the kidney; among adults, in contrast, it may often be associated with a systemic disease. Table 20-7 represents a composite derived from several studies of the causes of the nephrotic syndrome and is therefore only approximate. The most frequent *systemic causes* of the nephrotic syndrome are diabetes, amyloidosis, and SLE. The most important of the *primary glomerular lesions* are *minimal-change disease*, *membranous glomerulopathy*, and *focal segmental glomerulosclerosis*. The first is most common in children in North America, the second is most common in older adults, and focal segmental glomerulosclerosis occurs at all ages.[29] These three lesions are discussed individually in the following sections. Other primary causes, the various proliferative glomerulonephritides including MPGN, frequently present as a mixed syndrome with nephrotic and nephritic features.

TABLE 20-7 -- Cause of Nephrotic Syndrome

	Prevalence (%)[*]	
Causes	***Children***	***Adults***
PRIMARY GLOMERULAR DISEASE		
Membranous glomerulopathy	5	30
Minimal-change disease	65	10
Focal segmental glomerulosclerosis	10	35
Membranoproliferative	10	10
glomerulonephritis[†]	10	15
Other proliferative glomerulonephritides (focal, “pure mesangial,” IgA nephropathy)[†]		
SYSTEMIC DISEASES		
Diabetes mellitus		
Amyloidosis		
Systemic lupus erythematosus		
Drugs (nonsteroidal anti-inflammatory, penicillamine, “street heroin”)		
Infections (malaria, syphilis, hepatitis B and C, HIV)		
Malignant disease (carcinoma, lymphoma)		

	Prevalence (%)[*]	
Causes	***Children***	***Adults***
Miscellaneous (bee-sting allergy, hereditary nephritis)		

[*] Approximate prevalence of primary disease = 95% of nephrotic syndrome in children, 60% in adults. Approximate prevalence of systemic disease = 5% in children, 40% in adults.

[†] Membranoproliferative and other proliferative glomerulonephritides may have mixed nephrotic/nephritic syndromes.

Membranous Nephropathy

Membranous nephropathy is a common cause of the nephrotic syndrome in adults. It is characterized by diffuse thickening of the glomerular capillary wall due to the accumulation of electron-dense, Ig-containing deposits along the subepithelial side of the basement membrane.[30]

Membranous glomerulopathy occurring in association with other systemic diseases and a variety of identifiable etiologic agents is referred to as secondary membranous glomerulopathy. The most notable such associations are as follows:

- *Drugs* (penicillamine, captopril, gold, nonsteroidal anti-inflammatory drugs [NSAIDs]): 1% to 7% of patients with rheumatoid arthritis treated with penicillamine or gold (drugs now used infrequently for this purpose) develop membranous glomerulopathy. NSAIDs, as we shall see, also cause minimal-change disease.
- *Underlying malignant tumors*, particularly carcinomas of the lung and colon, and melanoma. According to some investigators, these are present in as many as 5% to 10% of adults with membranous glomerulopathy.[31]
- *SLE*. About 10% to 15% of glomerulonephritis in SLE is of the membranous type.
- *Infections* (chronic hepatitis B, hepatitis C, syphilis, schistosomiasis, malaria).
- *Other autoimmune disorders* such as thyroiditis can underlie secondary membranous glomerulopathy.

In about 85% of patients no associated condition can be uncovered, and the disease is considered idiopathic.

Pathogenesis.

Membranous glomerulopathy is a form of chronic immune complex–mediated disease. In secondary membranous glomerulopathy, the inciting antigens can sometimes be identified in the immune complexes. For example, membranous glomerulopathy in SLE is associated with deposition of autoantigen-antibody complexes. Antigens that have been identified in the deposits in some patients include exogenous antigens (e.g., hepatitis B, *Treponema*), endogenous nonrenal antigens (e.g., thyroglobulin), and endogenous renal antigens (e.g., the membrane protein neutral endopeptidase recognized by placental transfer of maternal antibodies in cases of neonatal membranous nephropathy and possibly the phospholipase A_2 receptor in adult cases).[12]

The lesions bear a striking resemblance to those of experimental Heymann nephritis, which, as you might recall, is induced by antibodies to a *megalin* antigenic complex. It is still not known if a similar antigen is present in most cases of idiopathic membranous glomerulopathy in humans. Susceptibility to Heymann nephritis in rats and membranous glomerulopathy in humans is linked to the major histocompatibility complex locus, which can influence the ability to produce antibodies to the nephritogenic antigen. Thus, idiopathic membranous glomerulopathy, like Heymann nephritis, is considered *an autoimmune disease linked to susceptibility genes and caused most likely by antibodies to a renal autoantigen*.

How does the glomerular capillary wall become leaky in membranous glomerulopathy? There is a paucity of neutrophils, monocytes, or platelets in glomeruli. The virtually uniform presence of complement and corroborating experimental work suggest a direct action of C5b-C9, the pathway leading to the formation of the membrane attack complex. It is postulated that C5b-C9 activates glomerular epithelial and mesangial cells, inducing them to liberate proteases and oxidants, which cause capillary wall injury and increased protein leakage.[32]

Morphology. By light microscopy the glomeruli either appear normal in the early stages of the disease or exhibit **uniform, diffuse thickening of the glomerular capillary wall** (Fig. 20-12A). By electron microscopy the thickening is seen to be caused by irregular dense deposits of immune complexes between the basement membrane and the overlying epithelial cells, the latter having effaced foot processes (Fig. 20-12B and D). Basement membrane material is laid down between these deposits, appearing as irregular spikes protruding from the GBM. These spikes are best seen by silver stains, which color the basement membrane, but not the deposits, black. In time, these spikes thicken to produce domelike protrusions and eventually close over the immune deposits, burying them within a markedly thickened, irregular membrane. Immunofluorescence microscopy demonstrates that the granular deposits contain both immunoglobulins and complement (see Fig. 20-12C). As the disease advances sclerosis may occur; in the course of time glomeruli may become totally sclerosed. The epithelial cells of the proximal tubules contain protein reabsorption droplets, and there may be considerable interstitial mononuclear cell inflammation.

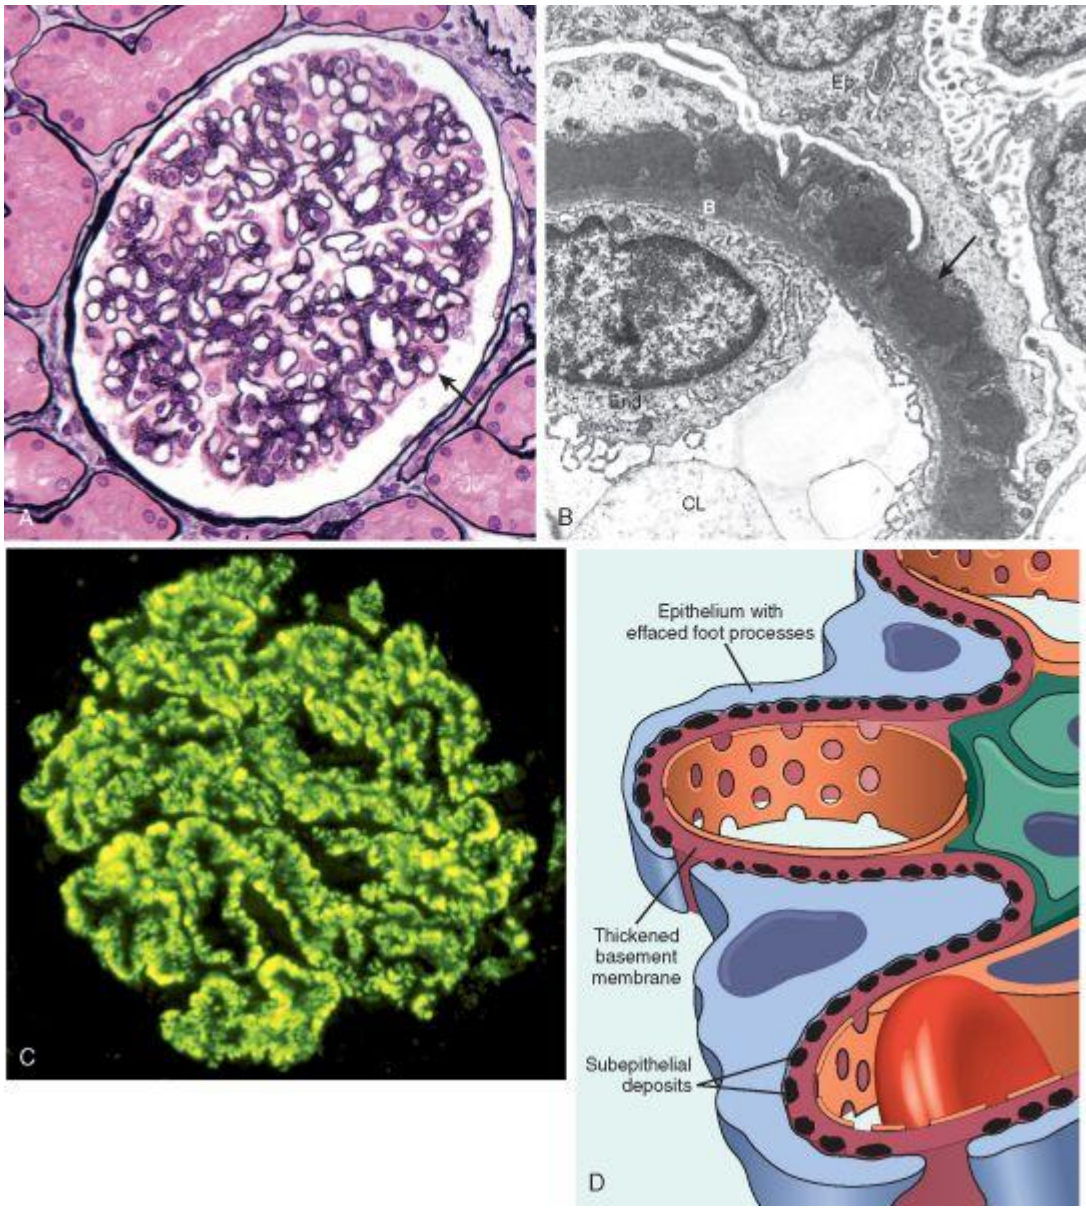

FIGURE 20-12 Membranous nephropathy. **A**, Silver methenamine stain. Note the marked diffuse thickening of the capillary walls without an increase in the number of cells. There are prominent "spikes" of silver-staining matrix *(arrow)* projecting from the basement membrane lamina densa toward the urinary space, which separate and surround deposited immune complexes that lack affinity for the silver stain. **B**, Electron micrograph showing electron-dense deposits *(arrow)* along the epithelial side of the basement membrane (B). Note the effacement of foot processes overlying deposits. CL, capillary lumen; End, endothelium; Ep, epithelium. **C**, Characteristic granular immunofluorescent deposits of IgG along GBM. **D**, Diagrammatic representation of membranous nephropathy. *(**A**, Courtesy of Dr. Charles Lassman, UCLA School of Medicine, Los Angeles, CA.)*

Clinical Features.

In a previously healthy individual, this disorder usually begins with the insidious onset of the nephrotic syndrome or, in 15% of patients, with non-nephrotic proteinuria. Hematuria and mild hypertension are present in 15% to 35% of cases. It is necessary in any patient to first rule out the secondary causes described earlier, since treatment of the underlying condition (malignant neoplasm, infection, or SLE) or discontinuance of the offending drug can reverse the injury.

The course of the disease is variable but generally indolent. In contrast to minimal-change disease, described later, the proteinuria is nonselective and usually does not respond well to corticosteroid therapy. Progression is associated with increasing sclerosis of glomeruli, rising serum creatinine reflecting renal insufficiency, and development of hypertension. Although proteinuria persists in more than 60% of patients, only about 10% die or progress to renal failure within 10 years, and no more than 40% eventually develop renal insufficiency. Concurrent sclerosis of glomeruli in the renal biopsy at the time of diagnosis is a predictor of poor prognosis. Spontaneous remissions and a relatively benign outcome occur more commonly in women and in those with proteinuria in the non-nephrotic range. Because of the variable course of the disease, it has been difficult to evaluate the overall effectiveness of corticosteroids or other immunosuppressive therapy in controlling the proteinuria or progression.

Minimal-Change Disease

This relatively benign disorder is the *most frequent cause of nephrotic syndrome in children*, but it is less common in adults (see Table 20-7). *It is characterized by diffuse effacement of foot processes of visceral epithelial cells (podocytes) in glomeruli that appear virtually normal by light microscopy*. The peak incidence is between 2 and 6 years of age. The disease sometimes follows a respiratory infection or routine prophylactic immunization. *Its most characteristic feature is its usually dramatic response to corticosteroid therapy*.[33]

Etiology and Pathogenesis.

Although the absence of immune deposits in the glomerulus excludes classic immune complex mechanisms, several features of the disease point to an immunological basis,[34] including (1) the clinical association with respiratory infections and prophylactic immunization; (2) the response to corticosteroids and/or other immunosuppressive therapy; (3) the association with other atopic disorders (e.g., eczema, rhinitis); (4) the increased prevalence of certain HLA haplotypes in patients with minimal-change disease associated with atopy (suggesting a genetic predisposition); (5) the increased incidence of minimal-change disease in patients with Hodgkin lymphoma, in whom defects in T cell–mediated immunity are well recognized; and (6) reports of proteinuria-inducing factors in the plasma or lymphocyte supernatants of patients with minimal-change disease.

The current leading hypothesis is that minimal-change disease involves some immune dysfunction, eventually resulting in the elaboration of a cytokine that damages visceral epithelial cells and causes proteinuria. The ultrastructural changes point to a primary *visceral epithelial cell injury*, and studies in animal models suggest the loss of glomerular polyanions. Thus, defects in the charge barrier may contribute to the proteinuria. The actual route by which protein traverses the epithelial cell portion of the capillary wall remains an enigma. Possibilities include transcellular passage through the epithelial cells, passage through residual spaces between remaining but damaged foot processes or through abnormal spaces developing underneath the portion of the foot process that directly abuts the basement membrane, or leakage through foci in which the epithelial cells have become detached from the basement membrane.

Additional insight into mechanisms by which epithelial cell injury results in proteinuria in minimal-change disease, focal segmental glomerulosclerosis, and related entities comes from the discovery of mutations in several podocyte proteins, including *nephrin and podocin*, discussed in the section on focal glomerulosclerosis below. These structural proteins are localized to the slit diaphragm, and nephrotic syndrome resulting from mutations in these proteins illustrates that structural defects of the podocyte are sufficient to cause marked proteinuria in the absence of an immune injury. A mutation in the nephrin gene causes a hereditary form of congenital nephrotic syndrome (Finnish type) with minimal-change glomerular morphology.[8]

Morphology. The glomeruli are normal by light microscopy (Fig. 20-13). By electron microscopy the GBM appears normal, and no electron-dense material is deposited. **The principal lesion is in the visceral epithelial cells, which show a uniform and diffuse effacement of foot processes**, these being replaced by a rim of cytoplasm often showing vacuolization, swelling, and hyperplasia of villi (see Fig. 20-13). This change, often incorrectly termed "fusion" of foot processes, actually represents simplification of the epithelial cell architecture with flattening, retraction, and swelling of foot processes. Foot process effacement is also present in other proteinuric states (e.g., membranous glomerulopathy, diabetic nephropathy); it is only when effacement is associated with normal glomeruli by light microscopy that the diagnosis of minimal-change disease can be made. The visceral epithelial changes are completely reversible after corticosteroid therapy, concomitant with remission of the proteinuria. The cells of the proximal tubules are often laden with lipid and protein, reflecting tubular reabsorption of lipoproteins passing through diseased glomeruli (thus, the historical name **lipoid nephrosis** for this disease). Immunofluorescence studies show no Ig or complement deposits.

Clinical Features.

Despite massive proteinuria, renal function remains good, and there is commonly no hypertension or hematuria. The proteinuria usually is highly selective, most of the protein being albumin. Most children (>90%) with minimal-change disease respond rapidly to corticosteroid therapy. However, proteinuria may recur, and some patients may become steroid-dependent or resistant. Nevertheless, the long-term prognosis for patients is excellent, and even steroid-dependent disease resolves when children reach puberty. Although adults are slower to respond, their long-term prognosis is also excellent.

As has been noted, minimal-change disease in adults can be associated with Hodgkin lymphoma and, less frequently, other lymphomas and leukemias. In addition, secondary minimal-change disease may follow NSAID therapy, usually in association with acute interstitial nephritis, to be described later in this chapter.

Focal Segmental Glomerulosclerosis

As the name implies, *this lesion is characterized by sclerosis of some, but not all, glomeruli (thus, it is focal); and in the affected glomeruli, only a portion of the capillary tuft is involved (thus, it is segmental)*. Focal segmental glomerulosclerosis is frequently manifest clinically by the nephrotic syndrome or heavy proteinuria.

Classification and Types.

Focal segmental glomerulosclerosis (FSGS) occurs in the following settings[35]:

- As a primary disease (idiopathic focal segmental glomerulosclerosis)
- In association with other known conditions, such as HIV infection (HIV-associated nephropathy), heroin addiction (heroin nephropathy), sickle-cell disease, and massive obesity
- As a secondary event, reflecting scarring of previously active necrotizing lesions, in cases of focal glomerulonephritis (e.g., IgA nephropathy)
- As a component of the adaptive response to loss of renal tissue (renal ablation, described earlier) in advanced stages of other renal disorders, such as reflux nephropathy, hypertensive nephropathy, or with unilateral renal agenesis
- In uncommon inherited forms of nephrotic syndrome where the disease, in some pedigrees, is caused by mutations in genes that encode proteins localized to the slit diaphragm, e.g., podocin, α-actinin 4, and

TRPC6 (transient receptor potential calcium channel-6)

Idiopathic focal segmental glomerulosclerosis accounts for as many as 10% and 35% of cases of nephrotic syndrome in children and adults in many series, respectively. FSGS (both primary and secondary forms) has increased in incidence and is now the most common cause of nephrotic syndrome in adults in the United States,[29] particularly in Hispanic and African-American patients. The clinical signs differ from those of minimal-change disease in the following respects: (1) there is a higher incidence of hematuria, reduced GFR, and hypertension; (2) proteinuria is more often nonselective; (3) there is poor response to corticosteroid therapy; and (4) there is progression to chronic kidney disease, with at least 50% developing end-stage renal disease within 10 years.

Pathogenesis.

Whether idiopathic FSGS represents a distinct disease or is simply a phase in the evolution of a subset of patients with minimal-change disease remains unresolved. The characteristic degeneration and focal disruption of visceral epithelial cells are thought to represent an accentuation of the diffuse epithelial cell change typical of minimal-change disease. *It is this epithelial damage that is the hallmark of FSGS*. Multiple different mechanisms can cause this epithelial damage, including circulating cytokines and genetically determined defects affecting components of the slit diaphragm complex. The hyalinosis and sclerosis stem from entrapment of plasma proteins in extremely hyperpermeable foci and increased ECM deposition. The recurrence of proteinuria, sometimes within 24 hours after transplantation, with subsequent progression to overt lesions of FSGS, suggests that a circulating factor, perhaps a cytokine, may be the cause of the epithelial damage in some patients. An approximately 50-kD non-Ig factor causing proteinuria has been isolated from sera of such patients, but more precise characterization of this factor has not been achieved.[36]

Morphology. By light microscopy the focal and segmental lesions may involve only a minority of the glomeruli and may be missed if the biopsy specimen contains an insufficient number of glomeruli (Fig. 20-14A). The lesions initially tend to involve the juxtamedullary glomeruli, although they subsequently become more generalized. In the sclerotic segments there is collapse of capillary loops, increase in matrix, and segmental deposition of plasma proteins along the capillary wall (hyalinosis), which may become so pronounced as to occlude capillary lumens. Lipid droplets and foam cells are often present (Fig. 20-14B). Glomeruli that do not show segmental lesions usually appear normal on light microscopy but may show increased mesangial matrix. On electron microscopy both sclerotic and nonsclerotic areas show diffuse effacement of foot processes, and there may also be focal detachment of the epithelial cells and denudation of the underlying GBM. By immunofluorescence microscopy IgM and C3 may be present in the sclerotic areas and/or in the mesangium. In addition to the focal sclerosis, there may be pronounced hyalinosis and thickening of afferent arterioles. With the progression of the disease, increased numbers of glomeruli become involved and sclerosis spreads within each glomerulus. In time, this leads to total (i.e., global) sclerosis of glomeruli, with pronounced tubular atrophy and interstitial fibrosis.

A morphologic variant of FSGS, called **collapsing glomerulopathy**, is characterized by retraction and/or collapse of the entire glomerular tuft, with or without additional FSGS lesions of the type described above (Fig. 20-15). A characteristic feature is proliferation and hypertrophy of glomerular visceral epithelial cells. This lesion may be idiopathic, but it is the most characteristic lesion of HIV-associated nephropathy. In both cases there is associated prominent tubular injury with formation of microcysts. It has a particularly poor prognosis.[37,][38]

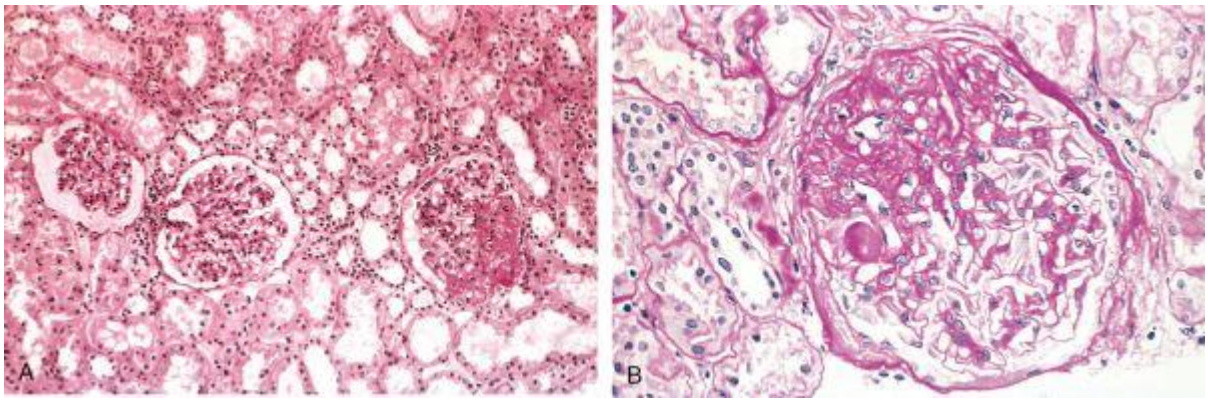

FIGURE 20-14 Focal segmental glomerulosclerosis, PAS stain. **A**, Low-power view showing segmental sclerosis in one of three glomeruli (at 3 o'clock). **B**, High-power view showing hyaline insudation and lipid (small vacuoles) in sclerotic area.

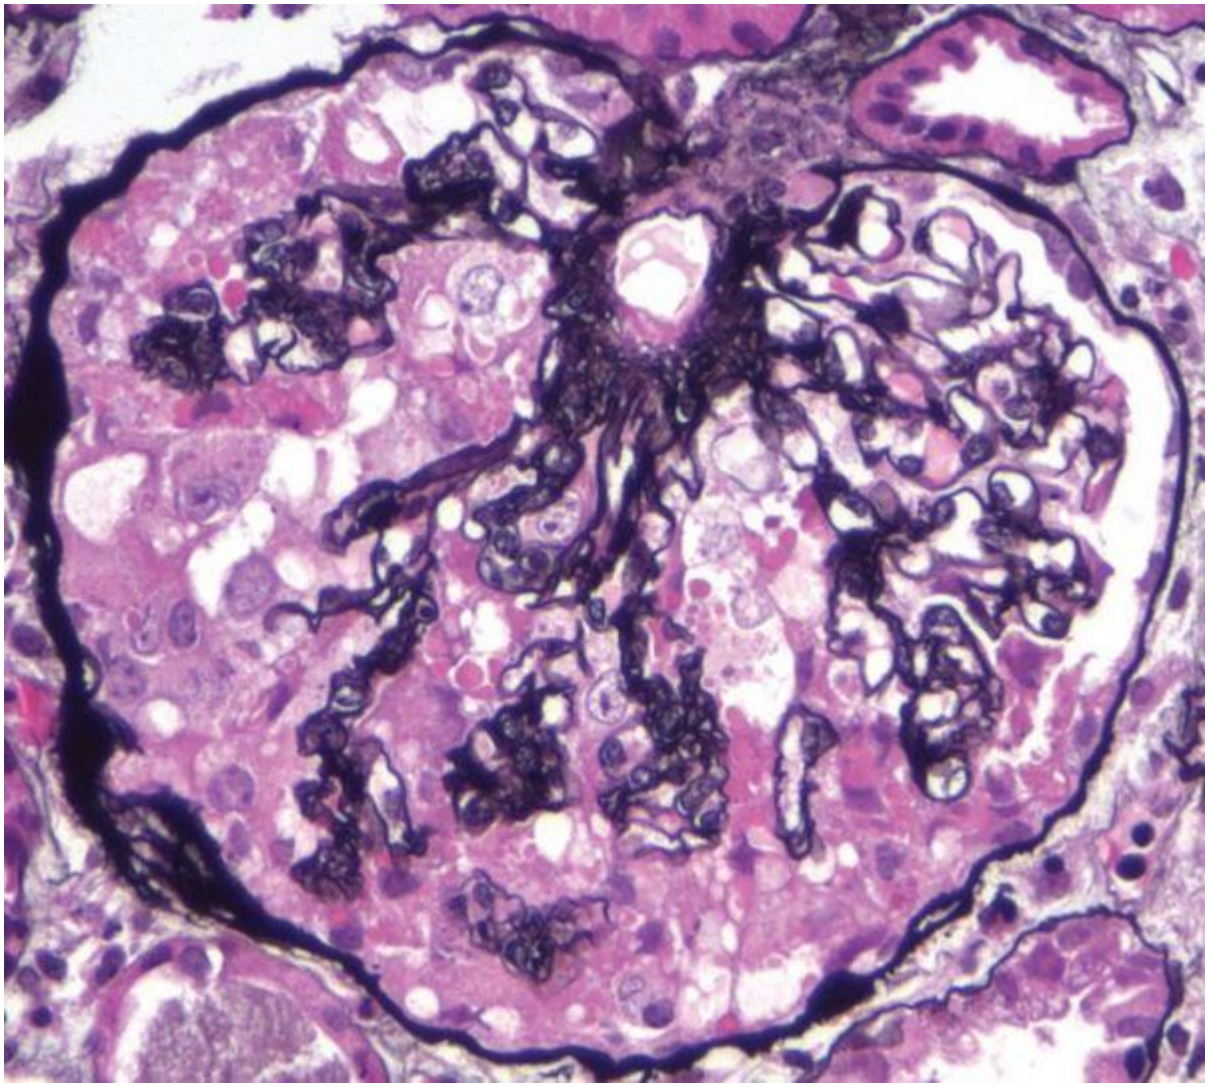

FIGURE 20-15 Collapsing glomerulopathy. Visible are retraction of the glomerular tuft, narrowing of capillary lumens, proliferation and swelling of visceral epithelial cells, and prominent accumulation of intracellular protein absorption droplets in the visceral epithelial cells.

The appearance is identical in cases wherein the etiology is idiopathic to cases associated with HIV infection. Silver methenamine stain. *(Courtesy of Dr. Jolanta Kowalewska, University of Washington, Seattle, WA.)*

The discovery of a genetic basis for some cases of FSGS and other causes of the nephrotic syndrome has improved the understanding of the pathogenesis of proteinuria in the nephrotic syndrome and has provided new methods for diagnosis and prognosis of affected patients. The first relevant gene to be identified, *NPHS1*, maps to chromosome 19q13 and encodes the protein *nephrin*.[8] Nephrin is a key component of the slit diaphragm (see Fig. 20-3), the zipper-like structure between podocyte foot processes that might control glomerular permeability. Several mutations of the *NPHS1* gene have been identified that give rise to *congenital nephrotic syndrome* of the Finnish type, producing a minimal-change disease–like glomerulopathy with extensive foot process effacement. Prenatal diagnosis of congenital nephrotic syndrome is possible by analysis of the *NPHS1* gene.

A distinctive pattern of autosomal recessive FSGS results from mutations in the *NPHS2* gene, which maps to chromosome 1q25–q31 and encodes the protein product *podocin*. Podocin has also been localized to the slit diaphragm. Mutations in *NPHS2* result in a syndrome of steroid-resistant nephrotic syndrome of childhood onset. Affected children usually show pathologic features of FSGS. Podocin mutations may account for as many as 30% of cases of steroid-resistant nephrotic syndrome in children.[8,][39] A third set of mutations in the gene encoding the podocyte actin-binding protein α-actinin 4 underlies some cases of autosomal dominant FSGS, which can be insidious in onset but has a high rate of progression to renal insufficiency.[39]

A fourth type of mutation was found in some kindreds with adult-onset FSGS, in the gene encoding TRPC6. This protein is widely expressed, including in podocytes, and the pathogenic mutations may perturb podocyte function by increasing calcium flux in these cells.

What these proteins have in common is their localization to the slit diaphragm and to adjacent podocyte cytoskeletal structures. Their specific functions and interactions are incompletely understood, but it is clear that the integrity of each is necessary to maintain the normal glomerular filtration barrier. Additional components of the podocyte/slit diaphragm apparatus, such as CD2-associated protein (CD2AP), have been identified that may also contribute to proteinuria, as has been suggested in studies of knockout mice (but only rarely demonstrated in humans).[6] While identification of these genetic defects has clarified the pathogenesis of some cases of the so-called idiopathic nephrotic syndrome, many other factors contribute to permeability defects. These include cell-cell and cell-matrix interactions, particularly those mediated by $\alpha_3\beta_1$ integrins, dystroglycans, and laminins. Defects in these interactions may also cause a loss of podocyte adhesion to the GBM.

Renal ablation FSGS, a secondary form of FSGS, occurs as a complication of glomerular and nonglomerular diseases causing reduction in functioning renal tissue, particularly reflux nephropathy and unilateral agenesis. These may lead to progressive glomerulosclerosis and renal failure. The pathogenesis of FSGS in this setting has been described earlier in this chapter.

Clinical Course.

There is little tendency for spontaneous remission in idiopathic FSGS, and responses to corticosteroid therapy are variable. In general, children have a better prognosis than adults do. Progression of renal failure occurs at variable rates. About 20% of patients follow an unusually rapid course, with intractable

massive proteinuria ending in renal failure within 2 years. Recurrences are seen in 25% to 50% of patients receiving allografts.

HIV-Associated Nephropathy

HIV infection can result directly or indirectly in several renal complications, including acute renal failure and/or acute interstitial nephritis induced by drugs or infection, thrombotic microangiopathies, postinfectious glomerulonephritis, and, *most commonly, a severe form of the collapsing variant of FSGS*.[40] The latter occurs in 5% to 10% of HIV-infected individuals in some series, more frequently in blacks than in whites. In rare cases the nephrotic syndrome may precede the development of acquired immunodeficiency syndrome. The morphologic features are characterized by

- A high frequency of the collapsing variant of FSGS (see Fig. 20-16)
- A striking focal cystic dilation of tubule segments, which are filled with proteinaceous material, and inflammation and fibrosis
- The presence of large numbers of tubuloreticular inclusions within endothelial cells, detected by electron microscopy. Such inclusions, also present in SLE, have been shown to be modifications of endoplasmic reticulum induced by circulating interferon-α. They are not present in idiopathic FSGS and therefore may have diagnostic value in a biopsy specimen.

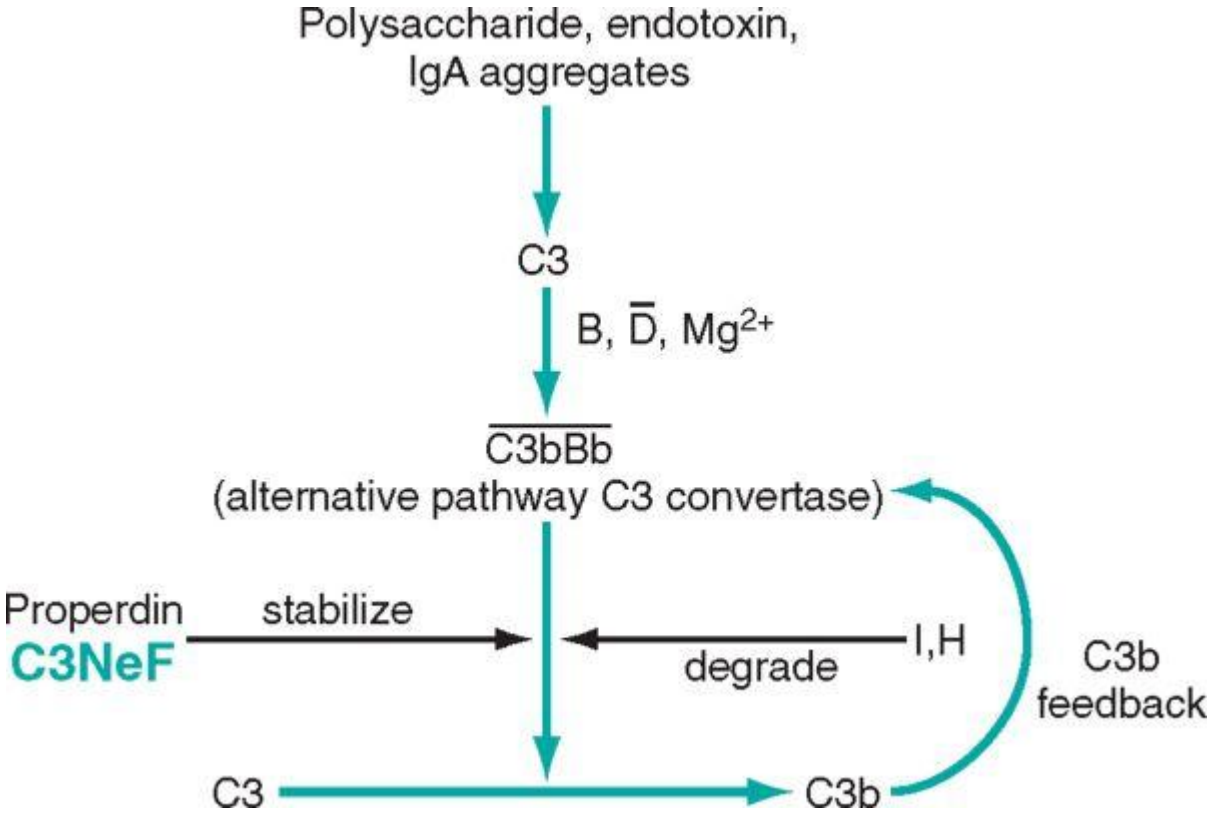

FIGURE 20-16 The alternative complement pathway in MPGN. Note that C3NeF, an antibody present in the serum of individuals with membranoproliferative glomerulonephritis, acts at the same step as properdin, serving to stabilize the alternative pathway C3 convertase, thus enhancing C3 activation and consumption, causing hypocomplementemia.

The pathogenesis of HIV-related FSGS and tubular injury is probably due to infection of glomerular and tubular cells by HIV, which has been detected in a few cases by very sensitive polymerase chain

reaction methods. Studies from animal models indicate that the glomerular lesion is most specifically the result of podocyte expression of the HIV gene products *vpr* and *nef*. Altered systemic or local release of cytokines may also modify and promote this particular renal injury.

Membranoproliferative Glomerulonephritis

MPGN is characterized histologically by *alterations in the glomerular basement membrane, proliferation of glomerular cells, and leukocyte infiltration*. Because the proliferation is predominantly in the mesangium but also may involve the capillary loops, a frequently used synonym is *mesangiocapillary glomerulonephritis*. MPGN accounts for 10% to 20% of cases of nephrotic syndrome in children and young adults. Some patients present only with hematuria or proteinuria in the non-nephrotic range, but many others have a combined nephrotic-nephritic picture. Like many other glomerulonephritides, MPGN either can be associated with other systemic disorders and known etiologic agents (secondary MPGN) or may be idiopathic (primary MPGN).[41]

Primary MPGN is divided into two major types on the basis of distinct ultrastructural, immunofluorescent, and pathologic findings: type I and type II MPGN (*dense-deposit disease*).

Pathogenesis.

In most cases of type I MPGN there is evidence of immune complexes in the glomerulus and activation of both classical and alternative complement pathways.[42] The antigens involved in idiopathic MPGN are unknown. In many cases they are believed to be proteins derived from infectious agents such as hepatitis C and B viruses, which presumably behave either as "planted" antigens after first binding to or becoming trapped within glomerular structures or are contained in preformed immune complexes deposited from the circulation.

Most patients with dense-deposit disease (type II MPGN) have abnormalities that suggest activation of the alternative complement pathway.[43] These patients have a consistently decreased serum C3 but normal C1 and C4, the immune complex–activated early components of complement. They also have diminished serum levels of factor B and properdin, components of the alternative complement pathway. In the glomeruli, C3 and properdin are deposited, but IgG is not. Recall that in the alternative complement pathway, C3 is directly cleaved to C3b (Fig. 20-16 ; see also Chapter 2 , Fig. 2-14). The reaction depends on the initial interaction of C3 with such substances as bacterial polysaccharides, endotoxin, and aggregates of IgA in the presence of factors B and D. This leads to the generation of C3bBb, the alternative pathway C3 convertase. This C3 convertase is labile, being degraded by factors I and H, but it can be stabilized by properdin. More than 70% of patients with dense-deposit disease have a circulating antibody termed *C3 nephritic factor (C3NeF)*, which is an autoantibody that binds to the alternative pathway C3 convertase (see Fig. 20-16). Binding of the antibody stabilizes the convertase, protecting it from enzymatic degradation and thus favoring persistent C3 activation and hypocomplementemia. There is also decreased C3 synthesis by the liver, further contributing to the profound hypocomplementemia. Precisely how C3NeF is related to glomerular injury and the nature of the dense deposits is unknown. C3NeF activity also occurs in some patients with a genetically determined disease, *partial lipodystrophy*, some of whom develop dense-deposit disease (type II MPGN).

Morphology. By light microscopy both types of MPGN are similar. The glomeruli are large and hypercellular. The hypercellularity is produced both by proliferation of cells in the mesangium and so-called endocapillary proliferation involving capillary endothelium and infiltrating leukocytes. Crescents are present in many cases. The glomeruli have an accentuated "lobular" appearance due to

the proliferating mesangial cells and increased mesangial matrix (Fig. 20-17). The GBM is thickened, often segmentally; this is most evident in the peripheral capillary loops. The glomerular capillary wall often shows a “double-contour” or “tram-track” appearance, especially evident in silver or PAS stains. This is caused by “duplication” of the basement membrane (also commonly referred to as splitting), usually as the result of new basement membrane synthesis in response to the subendothelial deposits of immune complexes. Within the duplicated basement membranes there is inclusion or interposition of cellular elements, which can be of mesangial, endothelial, or leukocytic origin. Such interposition also gives rise to the appearance of “split” basement membranes (Fig. 20-18A).

Types I and II MPGN differ in their ultrastructural and immunofluorescent features (Fig. 20-18).

Type I MPGN (the great majority of cases) is characterized by the presence of discrete **subendothelial electron-dense deposits**. Mesangial and occasional subepithelial deposits may also be present (see Fig. 20-18A). By immunofluorescence, C3 is deposited in a granular pattern, and IgG and early complement components (C1q and C4) are often also present, suggesting an immune complex pathogenesis.

In **dense-deposit disease (type II MPGN)** (Fig. 20-18B), a relatively rare entity, the lamina densa of the GBM is transformed into an irregular, ribbon-like, extremely electron-dense structure due to the **deposition of dense material** of unknown composition in the GBM proper. C3 is present in irregular granular or linear foci in the basement membranes on either side but not within the dense deposits. C3 is also present in the mesangium in characteristic circular aggregates (mesangial rings). IgG is usually absent, as are the early-acting complement components (C1q and C4).

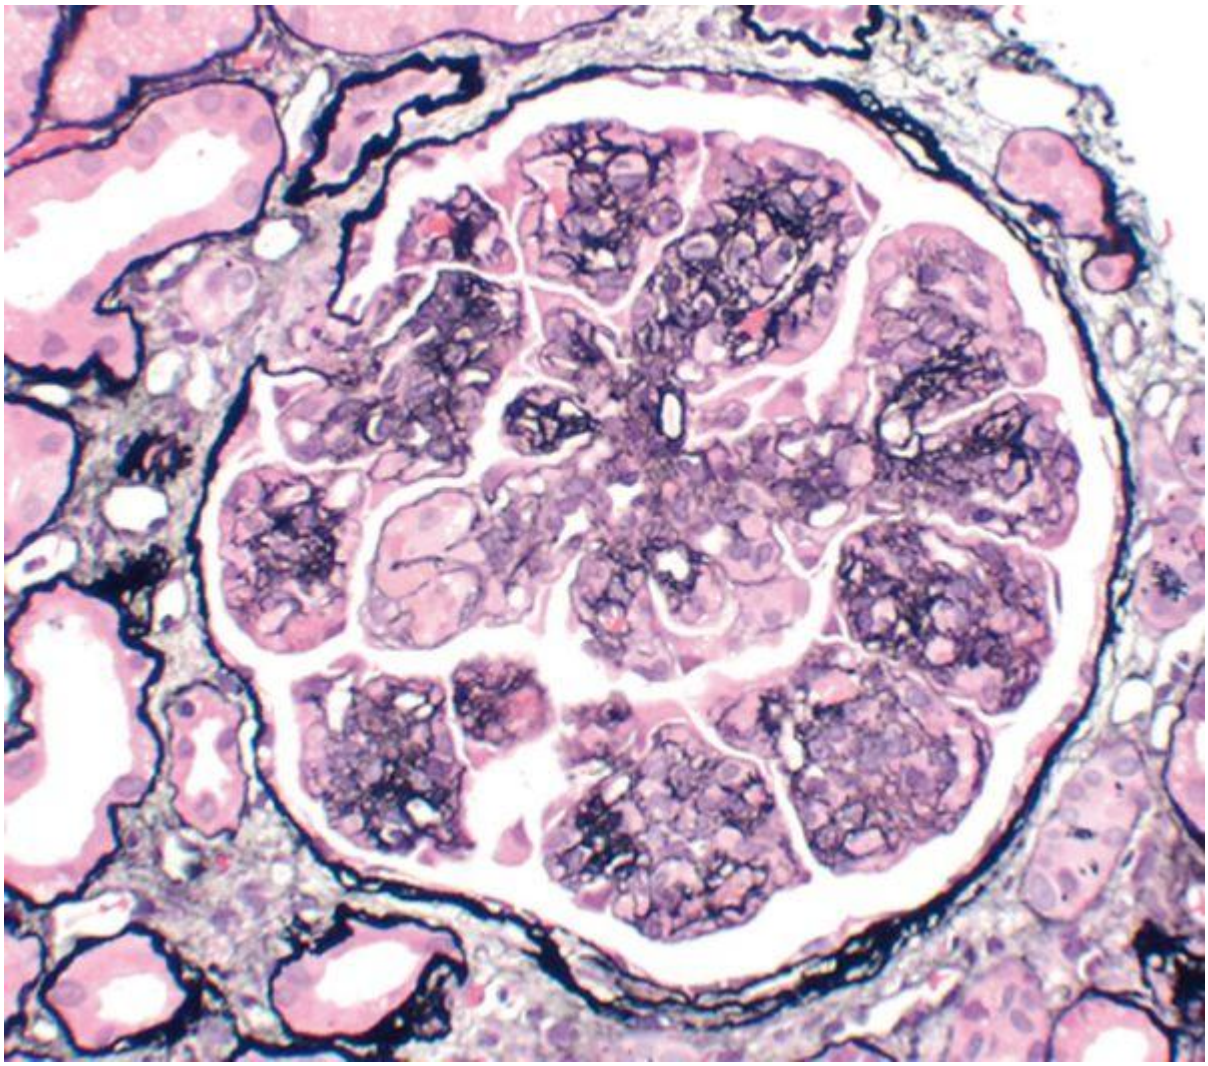

FIGURE 20-17 Membranoproliferative glomerulonephritis, showing mesangial cell proliferation, increased mesangial matrix (staining black with silver stain), basement membrane thickening with segmental splitting, accentuation of lobular architecture, swelling of cells lining peripheral capillaries, and influx of leukocytes (endocapillary proliferation).

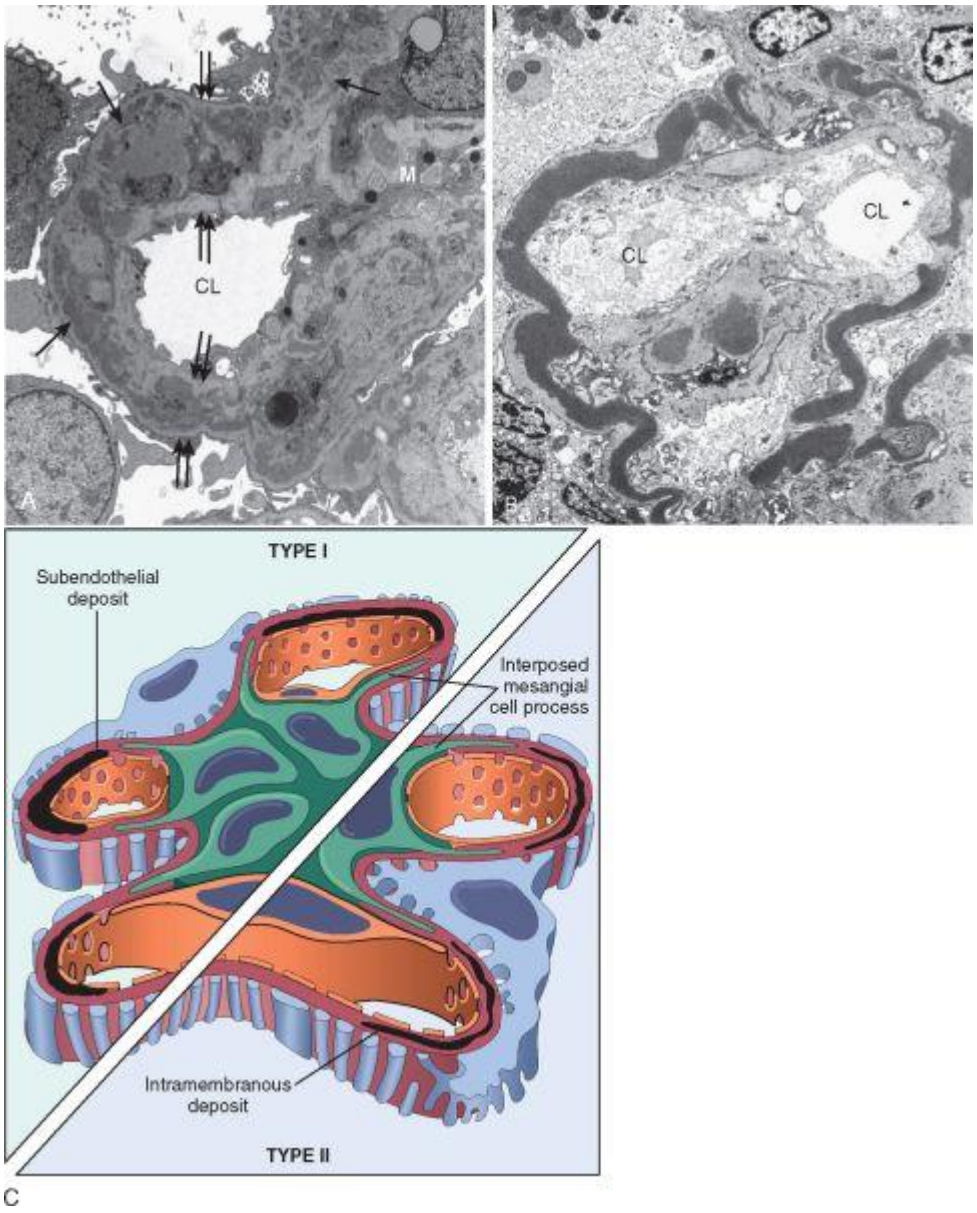

FIGURE 20-18 **A**, Membranoproliferative glomerulonephritis, type I. Note discrete electron-dense deposits *(arrows)* incorporated into the glomerular capillary wall between duplicated (split) basement membranes *(double arrows)*, and in mesangial regions (M); CL, capillary lumen. **B**, Dense-deposit disease (type II membranoproliferative glomerulonephritis). There are markedly dense homogeneous deposits within the basement membrane proper. CL, capillary lumen. In both, mesangial interposition gives the appearance of split basement membranes when viewed in the light microscope. **C**, Schematic representation of patterns in the two types of membranoproliferative GN. In type I there are subendothelial deposits; type II is characterized by intramembranous dense deposits (dense-deposit disease). In both, mesangial interposition gives the appearance of split basement membranes when viewed in the light microscope. *(**A**, Courtesy of Dr. Jolanta Kowalewska, University of Washington, Seattle, WA.)*

Clinical Features.

Most patients present in adolescence or as young adults with nephrotic syndrome and a nephritic component manifested by hematuria or, more insidiously, as mild proteinuria. Few remissions occur spontaneously in either type, and the disease follows a slowly progressive but unremitting course. Some patients develop numerous crescents and a clinical picture of RPGN. About 50% develop chronic renal

failure within 10 years. Treatments with steroids, immunosuppressive agents, and antiplatelet drugs have not been proved to be materially effective. There is a high incidence of recurrence in transplant recipients, particularly in dense-deposit disease; dense deposits may recur in 90% of such patients, although renal failure in the allograft is much less common.

Secondary MPGN

Secondary MPGN (invariably type I) is more common in adults and arises in the following settings[41]:

- Chronic immune complex disorders, such as SLE; hepatitis B infection; hepatitis C infection, usually with cryoglobulinemia; endocarditis; infected ventriculoatrial shunts; chronic visceral abscesses; HIV infection; and schistosomiasis
- α_1-Antitrypsin deficiency
- Malignant diseases (chronic lymphocytic leukemia and lymphoma)
- Hereditary deficiencies of complement regulatory proteins

The mechanisms underlying the process of immune complex deposition in the last three categories above remain unknown.

ISOLATED URINARY ABNORMALITIES

IgA Nephropathy (Berger Disease)

This form of glomerulonephritis is characterized by the presence of prominent IgA deposits in the mesangial regions, detected by immunofluorescence microscopy. The disease can be suspected by light microscopic examination, but the diagnosis is made only by immunocytochemical techniques (Fig. 20-19). *IgA nephropathy is a frequent cause of recurrent gross or microscopic hematuria and is probably the most common type of glomerulonephritis worldwide*.[44] Mild proteinuria is usually present, and the nephrotic syndrome may occasionally develop. Rarely, patients may present with cresentic RPGN.

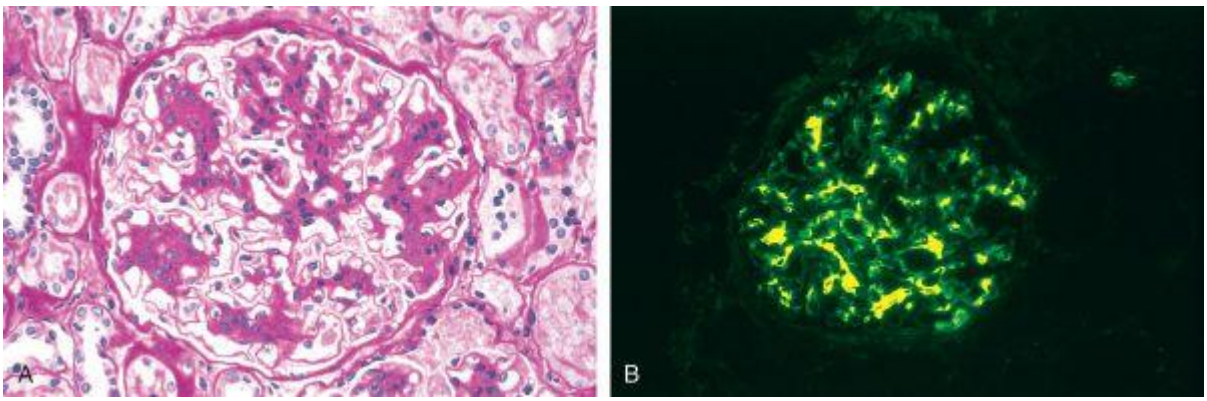

FIGURE 20-19 IgA nephropathy. **A**, Light microscopy showing mesangial proliferation and matrix increase. **B**, Characteristic deposition of IgA, principally in mesangial regions, detected by immunofluorescence.

Whereas IgA nephropathy is typically an isolated renal disease, similar IgA deposits are present in a systemic disorder of children, *Henoch-Schönlein purpura*, to be discussed later, which has many overlapping features with IgA nephropathy. In addition, *secondary IgA nephropathy* occurs in patients with liver and intestinal diseases, as discussed below.

Pathogenesis.

IgA, the main Ig in mucosal secretions, is present in plasma at low concentrations, mostly in monomeric form, the polymeric forms being catabolized in the liver. In patients with IgA nephropathy, plasma polymeric IgA is increased, and circulating IgA-containing immune complexes are present in some patients. However, it is clear that increased production of IgA cannot itself cause this disease. Although there are two subclasses of IgA molecules in humans (IgA1 and IgA2), only IgA1 forms the nephritogenic deposits of IgA nephropathy. The prominent mesangial deposition of IgA suggests entrapment of IgA immune complexes in the mesangium, and the presence of C3 combined with the absence of C1q and C4 in glomeruli points to activation of the alternative complement pathway. A genetic influence is suggested by the occurrence of this condition in families and in HLA-identical brothers and the increased frequency of certain HLA and complement genotypes in some populations.

Taken together, these clues suggest a genetic or acquired abnormality of immune regulation leading to increased IgA synthesis in response to respiratory or gastrointestinal exposure to environmental agents (e.g., viruses, bacteria, food proteins). IgA1 and IgA1-containing immune complexes are then trapped in the mesangium, where they activate the alternative complement pathway and initiate glomerular injury. In support of this scenario, IgA nephropathy occurs with increased frequency in individuals with *gluten enteropathy* (celiac disease), in whom intestinal mucosal defects are well defined, and in *liver disease*, in which there is defective hepatobiliary clearance of IgA complexes *(secondary IgA nephropathy)*.

The nature of the initiating antigens is unknown, and several infectious agents and food products have been implicated. The deposited IgA appears to be polyclonal, and it may be that a variety of antigens are involved in the course of the disease. Alternatively, there is evidence for qualitative alterations in the IgA1 molecule itself, specifically a defect in normal galactosylation that makes it immunogenic, giving rise to autoantibodies against the IgA1 that form immune complexes that deposit in the mesangium.[45]

Morphology. On histologic examination the lesions vary considerably. The glomeruli may be normal or may show mesangial widening and endocapillary proliferation (mesangioproliferative glomerulonephritis), segmental proliferation confined to some glomeruli (focal proliferative glomerulonephritis), or rarely, overt crescentic glomerulonephritis. The presence of leukocytes within glomerular capillaries is a variable feature. The mesangial widening may be the result of cell proliferation, accumulation of matrix, immune deposits, or some combination of these abnormalities. Healing of the focal proliferative lesion may lead to secondary focal segmental sclerosis. The characteristic immunofluorescent picture is of **mesangial deposition of IgA** (Fig. 20-19B), often with C3 and properdin and lesser amounts of IgG or IgM. Early complement components are usually absent. Electron microscopy confirms the presence of electron-dense deposits in the mesangium.

Clinical Features.

The disease affects people of any age, but older children and young adults are most commonly affected. Many patients present with gross hematuria after an infection of the respiratory or, less commonly, gastrointestinal or urinary tract; 30% to 40% have only microscopic hematuria, with or without proteinuria; and 5% to 10% develop a typical acute nephritic syndrome. The hematuria typically lasts for several days and then subsides, only to return every few months. The subsequent course is highly variable. Many patients maintain normal renal function for decades. Slow progression to chronic renal failure occurs in 15% to 40% of cases over a period of 20 years. Onset in old age, heavy proteinuria, hypertension, and the extent of glomerulosclerosis on biopsy are clues to an increased risk of progression. Recurrence of IgA deposits in transplanted kidneys is frequent. In approximately 15% of

those with recurrent IgA deposits, there is resulting clinical disease, which most frequently runs the same slowly progressive course as that of the primary IgA nephropathy.

Alport Syndrome

Hereditary nephritis refers to a group of heterogeneous familial renal diseases associated primarily with glomerular injury. Two deserve discussion: *Alport syndrome*, because the lesions and genetic defects have been well studied,[46] and *thin basement membrane lesion*, the most common cause of *benign familial hematuria*.[47]

Alport syndrome, when fully developed, is manifest by hematuria with progression to chronic renal failure, accompanied by nerve deafness and various eye disorders, including lens dislocation, posterior cataracts, and corneal dystrophy.[48] The disease is inherited as an X-linked trait in approximately 85% of cases. In this X-linked form, males express the full syndrome, and females are carriers in whom manifestations of disease are typically limited to hematuria. Autosomal recessive and autosomal dominant pedigrees also exist, in which males and females are equally susceptible to the full syndrome.

Pathogenesis.

The disease manifestations are due to abnormal α_3 (COL4A3), α_4 (COL4A4), or α_5 (COL4A5) chain of type IV collagen. This is due to mutation of COL4A5 in the classic X-linked form and COL4A3 or COL4A4 in the autosomal forms. In all cases, the result is defective assembly of type IV collagen, which is crucial for function of the GBM, the lens of the eye, and the cochlea. Because the GBM consists of networks of trimeric collagen molecules composed of α_3, α_4, and α_5 chains, mutations in COL4A5 also result in defective assembly of the collagen network.[46] The α_3 chain includes the Goodpasture antigen, and glomeruli from patients with Alport syndrome who lack the α_3 chain fail to react with anti-GBM antibodies from patients with Goodpasture syndrome.

Morphology. On histologic examination the glomeruli are always involved. The early lesion is detectable only by electron microscopy and consists of diffuse GBM thinning. Interstitial foam cells stuffed with neutral fats and mucopolysaccharides are a nonspecific finding consequent to proteinuria that for unknown reasons can be unusually prominent in this disorder. As the disease progresses there is development of focal segmental and global glomerulosclerosis and other changes of progressive renal injury, including vascular sclerosis, tubular atrophy, and interstitial fibrosis.

The characteristic electron microscopic findings of fully developed disease are found in most individuals with hereditary nephritis. The GBM shows irregular foci of thickening alternating with attenuation (thinning), and pronounced splitting and lamination of the lamina densa, often producing a distinctive basket-weave appearance (Fig. 20-20). Similar alterations can be found in the tubular basement membranes.

Immunohistochemistry can be helpful in cases with absent or borderline basement membrane lesions, because antibodies to α_3, α_4, and α_5 collagen fail to stain both glomerular and tubular basement membranes in the classic X-linked form. There is also absence of α_5 staining in skin biopsy specimens from these patients.

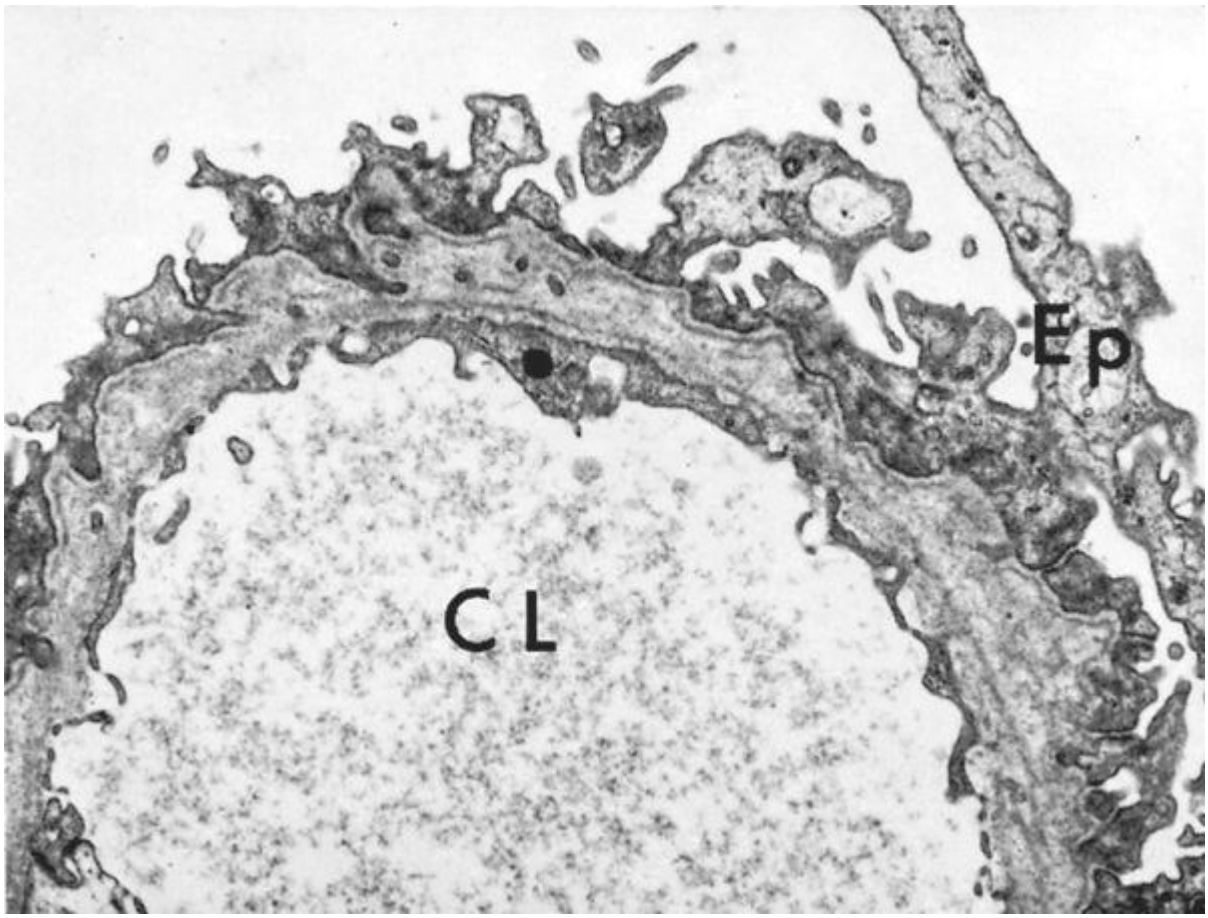

FIGURE 20-20 Hereditary nephritis (Alport syndrome). Electron micrograph of glomerulus with irregular thickening of the basement membrane, lamination of the lamina densa, and foci of rarefaction. Such changes may be present in other diseases but are most pronounced and widespread in hereditary nephritis. CL, capillary lumen; Ep, epithelium.

Clinical Features.

The most common presenting sign is gross or microscopic hematuria, frequently accompanied by red cell casts. Proteinuria may develop later, and rarely, the nephrotic syndrome develops. Symptoms appear at ages 5 to 20 years, and the onset of overt renal failure is between ages 20 and 50 years in men. The auditory defects may be subtle, requiring sensitive testing.

Thin Basement Membrane Lesion (Benign Familial Hematuria)

This is a fairly common hereditary entity manifested *clinically by familial asymptomatic hematuria*—usually uncovered on routine urinalysis—*and morphologically by diffuse thinning of the GBM* to between 150 and 250 nm (compared with 300–400 nm in normal adult individuals). Although mild or moderate proteinuria may also be present, renal function is normal and prognosis is excellent.

The disorder should be distinguished from IgA nephropathy, another common cause of hematuria, and X-linked Alport syndrome. In contrast to Alport syndrome, hearing loss, ocular abnormalities, and a family history of renal failure are absent.

The anomaly in thin basement membrane lesion has also been traced to mutations in genes encoding α_3 or α_4 chains of type IV collagen.[46,][47] Most patients are heterozygous for the defective gene and thus may be carriers. The disorder in homozygotes resembles autosomal recessive Alport syndrome. Homozygotes or compound heterozygotes may progress to renal failure. Thus, these diseases illustrate a continuum of changes resulting from mutations in collagen type IV genes.

CHRONIC GLOMERULONEPHRITIS

Chronic glomerulonephritis is best considered a pool of end-stage glomerular disease fed by several streams of specific types of glomerulonephritis (Fig. 20-21). Most of these diseases were described earlier in this chapter. Poststreptococcal glomerulonephritis is a rare antecedent of chronic glomerulonephritis, except in adults. Patients with crescentic glomerulonephritis, if they survive the acute episode, usually progress to chronic glomerulonephritis. Membranous nephropathy, MPGN, IgA nephropathy, and FSGS all may progress to chronic renal failure. *Nevertheless, in any series of individuals with chronic glomerulonephritis, a variable percentage of cases arise mysteriously with no antecedent history of any of the well-recognized forms of acute glomerulonephritis*. These cases must represent the end result of relatively asymptomatic forms of glomerulonephritis, either known or still unrecognized, that progress to uremia. Clearly, the proportion of such unexplained cases depends on the availability of renal biopsy material from patients early in their disease.

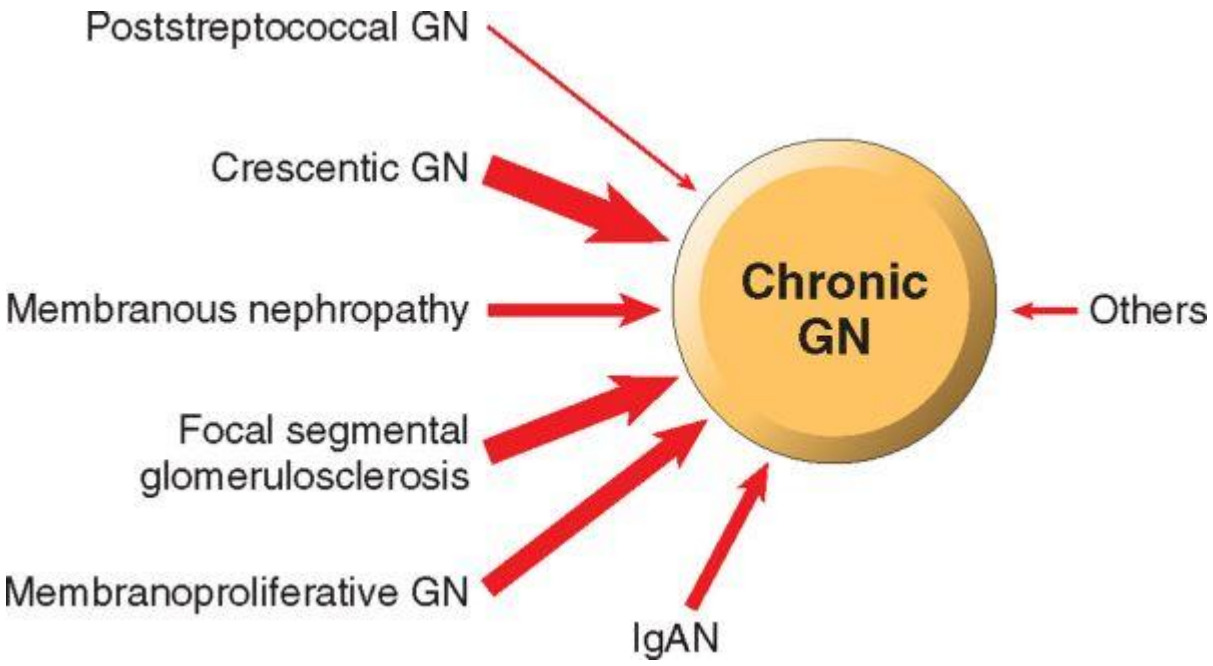

FIGURE 20-21 Primary glomerular diseases leading to chronic glomerulonephritis (GN). The thickness of the arrows reflects the approximate proportion of patients in each group who progress to chronic GN: poststreptococcal (1% to 2%); rapidly progressive (crescentic) (90%), membranous (30% to 50%), focal segmental glomerulosclerosis (50% to 80%), membranoproliferative GN (50%), IgA nephropathy (IgAN, 30% to 50%).

Morphology. The kidneys are symmetrically contracted and have diffusely granular cortical surfaces. On section, **the cortex is thinned**, and there is an increase in peripelvic fat. The glomerular histology depends on the stage of the disease. In early cases, the glomeruli may still show evidence of the primary disease (e.g., membranous nephropathy or MPGN). However, there eventually ensues

obliteration of glomeruli, transforming them into acellular eosinophilic masses, representing a combination of trapped plasma proteins, increased mesangial matrix, basement membrane–like material, and collagen (Fig. 20-22). Because hypertension is an accompaniment of chronic glomerulonephritis, **arterial and arteriolar sclerosis may be conspicuous**. **Marked atrophy of associated tubules**, irregular interstitial fibrosis, and mononuclear leukocytic infiltration of the interstitium also occur.

***Dialysis Changes*.** Kidneys from patients with end-stage disease on long-term dialysis show a variety of changes that are unrelated to the primary disease. These include **arterial intimal thickening** caused by accumulation of smooth muscle–like cells and a loose, proteoglycan-rich stroma; focal calcification, usually within residual tubular segments; **extensive deposition of calcium oxalate crystals** in tubules and interstitium; **acquired cystic disease**, discussed later; and increased numbers of renal adenomas and adenocarcinomas.

***Uremic Complications*.** Individuals dying with chronic glomerulonephritis also exhibit pathologic changes outside the kidney that are related to the uremic state and are also present in other forms of chronic renal failure. Often clinically important, these include uremic **pericarditis**, uremic gastroenteritis, **secondary hyperparathyroidism** with nephrocalcinosis and renal osteodystrophy, **left ventricular hypertrophy** due to hypertension, and pulmonary changes of diffuse alveolar damage often ascribed to uremia (uremic pneumonitis).

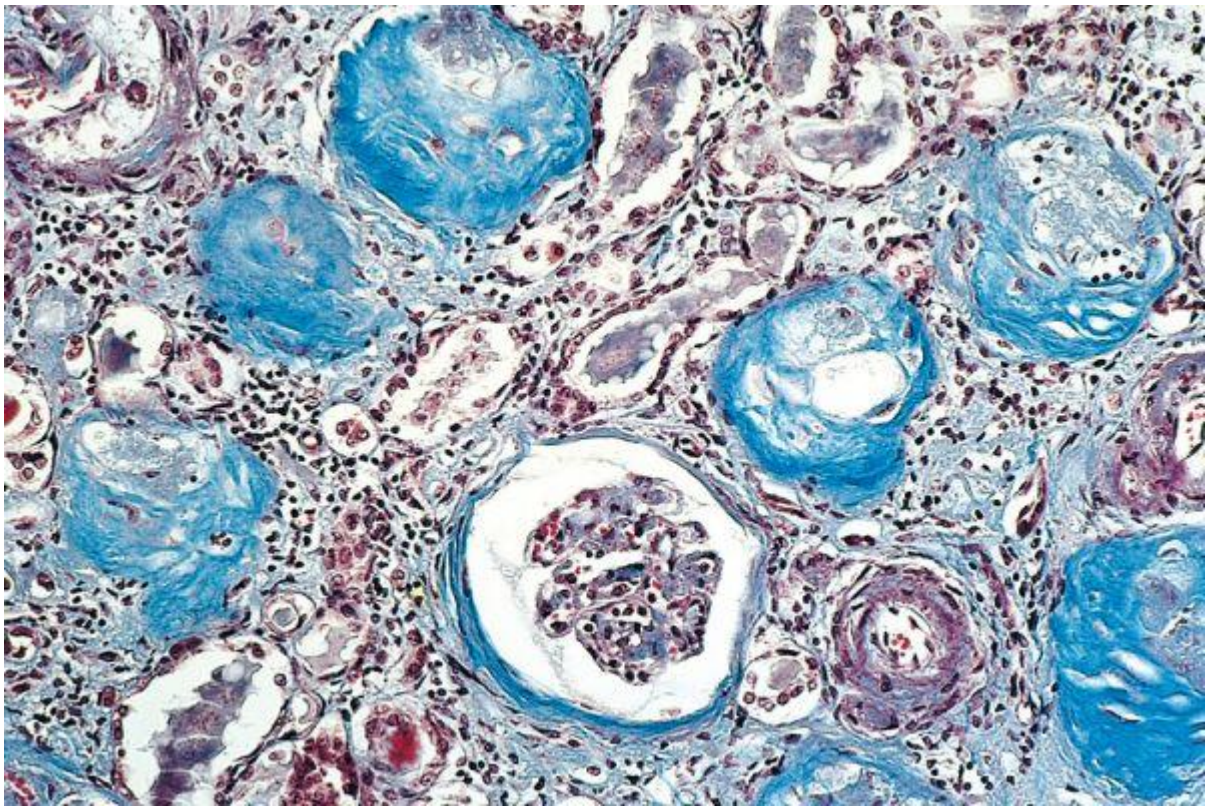

FIGURE 20-22 Chronic glomerulonephritis. A Masson trichrome preparation shows complete replacement of virtually all glomeruli by blue-staining collagen. *(Courtesy of Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, TX.)*

Clinical Course.

In most individuals, chronic glomerulonephritis develops insidiously and slowly progresses to renal insufficiency or death from uremia during a span of years or possibly decades (see the discussion of chronic renal failure). Not infrequently, patients present with such nonspecific complaints as loss of appetite, anemia, vomiting, or weakness. In some, the renal disease is suspected with the discovery of proteinuria, hypertension, or azotemia on routine medical examination. In others, the underlying renal disorder is discovered in the course of investigation of edema. *Most patients are hypertensive, and sometimes the dominant clinical manifestations are cerebral or cardiovascular*. In all, the disease is relentlessly progressive, though at widely varying rates. In nephrotic patients, as glomeruli become obliterated and therefore the GFR decreases, the protein loss in the urine diminishes. If patients with chronic glomerulonephritis do not recieve dialysis or if they do not receive a renal transplant, they invariably succumb to their disease.

GLOMERULAR LESIONS ASSOCIATED WITH SYSTEMIC DISEASES

Many immunologically mediated, metabolic, or hereditary systemic disorders are associated with glomerular injury; in some (e.g., SLE and diabetes mellitus), the glomerular involvement is a major clinical manifestation. Most of these diseases are discussed elsewhere in this book. Here we briefly recall some of the lesions and discuss only those not considered in other sections.

Lupus Nephritis

The various types of lupus nephritis were described and illustrated in Chapter 6 . As discussed, SLE gives rise to a heterogeneous group of lesions and clinical presentations. The clinical manifestations can include recurrent microscopic or gross hematuria, the nephritic syndrome, the nephrotic syndrome, chronic renal failure, and hypertension.

Henoch-Schönlein Purpura

This syndrome consists of *purpuric skin lesions characteristically involving the extensor surfaces of arms and legs as well as buttocks; abdominal manifestations including pain, vomiting, and intestinal bleeding; nonmigratory arthralgia; and renal abnormalities*. The renal manifestations occur in one third of patients and include gross or microscopic hematuria, nephritic syndrome, and nephrotic syndrome, or some combination of these. A small number of patients, mostly adults, develop a rapidly progressive form of glomerulonephritis with many crescents. Not all components of the syndrome need to be present, and individual patients may have purpura, abdominal pain, or urinary abnormalities as the dominant feature. The disease is most common in children 3 to 8 years old, but it also occurs in adults, in whom the renal manifestations are usually more severe. There is a strong background of atopy in about one third of patients, and onset often follows an upper respiratory infection. IgA is deposited in the glomerular mesangium in a distribution similar to that of IgA nephropathy. This has led to the concept that *IgA nephropathy and Henoch-Schönlein purpura are manifestations of the same disease*.[49]

Morphology. On histologic examination, the renal lesions vary from mild focal mesangial proliferation to diffuse mesangial proliferation and/or endocapillary to crescentic glomerulonephritis. Whatever the histologic lesions, the prominent feature by fluorescence microscopy is the **deposition of IgA, sometimes with IgG and C3, in the mesangial region**. The skin lesions consist of subepidermal hemorrhages and a necrotizing vasculitis involving the small vessels of the dermis. IgA deposits are also present in such vessels. Vasculitis also occurs in other organs, such as the gastrointestinal tract, but is rare in the kidney.

The course of the disease is variable, but recurrences of hematuria may persist for many years after onset. Most children have an excellent prognosis. Patients with the more diffuse lesions, crescents, or the nephrotic syndrome have a somewhat poorer prognosis.

Bacterial Endocarditis–Associated Glomerulonephritis

Glomerular lesions occurring in the course of bacterial endocarditis represent a type of immune complex nephritis initiated by complexes of bacterial antigen and antibody. Hematuria and proteinuria of various degrees characterize this entity clinically, but an acute nephritic presentation is not uncommon, and even RPGN may occur in rare instances. The histologic lesions, when present, generally reflect these clinical manifestations. Milder forms have a more focal and segmental necrotizing glomerulonephritis, whereas more severe ones show a diffuse proliferative glomerulonephritis, and the rapidly progressive forms show large numbers of crescents. Immunofluorescence and electron microscopy show the presence of glomerular immune deposits.

Diabetic Nephropathy

Diabetes mellitus is a major cause of renal morbidity and mortality, and diabetic nephropathy is one of the leading causes of chronic kidney failure in the United States (see Chapter 24). Advanced or end-stage kidney disease occurs in as many as 40% of both insulin-dependent type 1 diabetics and type 2 diabetics. By far the most common lesions involve the glomeruli and are associated clinically with three glomerular syndromes: non-nephrotic proteinuria, nephrotic syndrome, and chronic renal failure.[50] However, diabetes also affects the arterioles (causing *hyalinizing arteriolar sclerosis*), increases susceptibility to the development of pyelonephritis and particularly *papillary necrosis*, and causes a variety of tubular lesions. The term *diabetic nephropathy* is applied to the conglomerate of lesions that often occur concurrently in the diabetic kidney.

The morphologic changes in the glomeruli include (1) capillary basement membrane thickening, (2) diffuse mesangial sclerosis, and (3) nodular glomerulosclerosis. The morphologic manifestations of diabetic nephropathy are identical in type 1 and type 2 diabetes and are described below as a single entity.[51,][52]

Pathogenesis.

The pathogenesis of diabetic glomerulosclerosis is intimately linked with that of generalized diabetic microangiopathy, discussed in Chapter 24 . The principal points are as follows[53]:

- The bulk of the evidence suggests that diabetic glomerulosclerosis *is caused by the metabolic defect*, that is, the insulin deficiency, the resultant hyperglycemia, or some other aspects of glucose intolerance. These metabolic defects are responsible for biochemical alterations in the GBM, including increased amounts of collagen type IV and fibronectin and decreased heparan sulfate proteoglycan, and for increased production of reactive oxygen species, which may further damage the glomerular filter.
- *Nonenzymatic glycosylation* of proteins, which is known to occur in diabetics and gives rise to advanced glycosylation end products, may contribute to the glomerulopathy.[54] The mechanisms by which advanced glycosylation end products cause their effects are discussed in Chapter 24 .
- One hypothesis implicates *hemodynamic changes* in the initiation and progression of diabetic glomerulosclerosis. It is well known that the early stages of diabetic nephropathy are characterized by an increased GFR, increased glomerular capillary pressure, *glomerular hypertrophy*, and an increased glomerular filtration area.[51,][55] Hemodynamic alterations and glomerular hypertrophy also occur in experimental streptozotocin-induced diabetes in rats, in which they are associated with proteinuria and can be reversed or inhibited by diabetic control and angiotensin inhibition. It has been speculated that the subsequent morphologic alterations discussed above are somehow influenced by the glomerular hypertrophy and hemodynamic changes, akin to the adaptive responses to ablation of renal mass,

discussed earlier.

To sum up, two processes seem to play a role in the fully developed diabetic glomerular lesions: a metabolic defect, probably linked to advanced glycosylation end products, that accounts for the thickened GBM and increased mesangial matrix that occur in patients; and hemodynamic effects, associated with glomerular hypertrophy, which also contribute to the development of glomerulosclerosis. Both of these processes contribute also to the loss of podocytes, which may undergo apoptosis in response to the metabolic abnormalities and exposure to reactive oxygen species, or become detached from the basement membranes as a consequence of these metabolic changes and/or stretching induced by hemodynamic perturbations.[56] The morphologic alterations and clinical features of diabetic nephropathy are described in Chapter 24 .

Amyloidosis

The various forms of amyloidosis and their pathogenesis are discussed in Chapter 6 . Most types of disseminated amyloidosis may be associated with deposits of amyloid within the glomeruli; most commonly renal amyloid is of light-chain (AL) or AA type. The typical Congo red–positive fibrillary amyloid deposits are present within the mesangium and capillary walls and rarely are localized to the subepithelial space. Eventually, they obliterate the glomerulus completely. Deposits of amyloid also appear in blood vessel walls and in the kidney interstitium. Patients with glomerular amyloid may present with the nephrotic syndrome and later, as a result of destruction of the glomeruli, die of uremia. Characteristically, kidney size tends to be either normal or increased.

Fibrillary Glomerulonephritis and Immunotactoid Glomerulopathy

Fibrillary glomerulonephritis is a morphologic variant of glomerulonephritis associated with characteristic fibrillar deposits in the mesangium and glomerular capillary walls that resemble amyloid fibrils superficially but differ ultrastructurally and do not stain with Congo red.[60] The fibrils most often are 18 to 24 nm in diameter and hence are larger than the 10 to 12 nm fibrils characteristic of amyloid. The glomerular lesions usually show membranoproliferative or mesangioproliferative patterns by light microscopy, and by immunofluorescence microscopy, there is selective deposition of polyclonal IgG, often of the IgG4 subclass, complement C3, and Igκ and Igλ light chains. Clinically, patients develop nephrotic syndrome, hematuria, and progressive renal insufficiency. The disease recurs in kidney transplants.

In *immunotactoid glomerulopathy*, a much rarer condition, the deposits are microtubular in structure and 30 to 50 nm in width. Patients often have circulating paraproteins and/or monoclonal Ig deposition in glomeruli.[57]

The pathogenesis of both of these entities is unknown.

Other Systemic Disorders

Goodpasture syndrome (Chapter 15), *microscopic polyangiitis*, and *Wegener granulomatosis* (Chapter 11) are commonly associated with glomerular lesions, as described in the discussion of these diseases. Suffice it to say here that the glomerular lesions in these three conditions can be histologically similar and are principally characterized by foci of glomerular necrosis and crescent formation. In the early or mild forms of involvement, there is focal and segmental, sometimes necrotizing, glomerulonephritis, and most of these patients will have hematuria with mild decline in GFR. In the more severe cases associated with RPGN, there is more extensive necrosis, fibrin deposition, and extensive formation of epithelial (cellular) crescents, which can become organized to form fibrocellular and fibrous crescents if the glomerular injury evolves into segmental or global scarring (sclerosis).

Essential mixed cryoglobulinemia is another systemic condition in which deposits of cryoglobulins composed principally of IgG-IgM complexes induce cutaneous vasculitis, synovitis, and a proliferative glomerulonephritis, typically MPGN. Most cases of essential mixed cryoglobulinemia have been associated with infection with hepatitis C virus, and this condition in particular is associated with glomerulonephritis, usually MPGN type I.

Plasma cell dyscrasias may also induce glomerular lesions. *Multiple myeloma* and other dyscrasias producing circulating monoclonal immunoglobulins are associated with (1) amyloidosis, in which the fibrils are usually composed of monoclonal λ light chains, (2) deposition of monoclonal immunoglobulins or light chains in the GBM, and (3) distinctive nodular glomerular lesions resulting from the deposition of *nonfibrillar* light chains. This so-called *light-chain* or *monoclonal Ig deposition disease* sometimes occurs in the absence of overt myeloma and is usually characterized by deposition of monoclonal Igκ or Igλ light chains in glomeruli. The glomeruli show PAS-positive mesangial nodules, lobular accentuation, and mild mesangial hypercellularity. These lesions must be differentiated from diabetic nodular glomerulosclerosis and other glomerulopathies that can cause nodular mesangial expansion, such as MPGN. These patients usually present with proteinuria or the nephrotic syndrome, hypertension, and progressive azotemia. Other renal manifestations of multiple myeloma are discussed later.

3.10.3 Tubular & Interstitial Diseases

Most forms of tubular injury involve the interstitium as well; therefore, diseases affecting these two components are discussed together. Under this heading we consider two major groups of processes: (1) ischemic or toxic tubular injury, leading to *acute kidney injury (AKI)* and acute renal failure, and (2) inflammatory reactions of the tubules and interstitium *(tubulointerstitial nephritis)*.

ACUTE KIDNEY INJURY (AKI) (ACUTE TUBULAR NECROSIS, ATN)

AKI, a term increasingly favored over the often synonymously used terms acute tubular necrosis (ATN) and acute tubular injury, is a clinicopathologic entity characterized clinically by acute diminution of renal function and often, but not invariably, morphologic evidence of tubular injury. It is the most common cause of acute renal failure,[58,][59] which signifies rapid reduction of renal function and urine flow, falling within 24 hours to less than 400 mL per day. It can be caused by a variety of conditions, including

- *Ischemia, due to decreased or interrupted blood flow*, examples of which include diffuse involvement of the intrarenal blood vessels such as in microscopic polyangiitis, malignant hypertension, microangiopathies and systemic conditions associated with thrombosis (e.g., hemolytic uremic syndrome [HUS], thrombotic thrombocytopenic pupura [TTP], and disseminated intravascular coagulation [DIC]), or decreased effective circulating blood volume
- *Direct toxic injury to the tubules* (e.g., by drugs, radiocontrast dyes, myoglobin, hemoglobin, radiation)
- *Acute tubulointerstitial nephritis*, most commonly occurring as a hypersensitivity reaction to drugs
- *Urinary obstruction* by tumors, prostatic hypertrophy, or blood clots (so-called postrenal acute renal failure)

AKI accounts for some 50% of cases of acute renal failure in hospitalized patients. Other causes of acute renal failure are discussed elsewhere in this chapter.

AKI is a reversible renal lesion that arises in a variety of clinical settings. Most of these, ranging from severe trauma to acute pancreatitis, have in common a period of inadequate blood flow to the peripheral organs, usually accompanied by marked hypotension and shock. This pattern of AKI is called *ischemic AKI*. The second pattern, called *nephrotoxic AKI*, is caused by a multitude of drugs, such as gentamicin

and other antibiotics; radiographic contrast agents; poisons, including heavy metals (e.g., mercury); and organic solvents (e.g., carbon tetrachloride). Combinations of ischemic and nephrotoxic AKI also can occur, exemplified by mismatched blood transfusions and other hemolytic crises causing *hemoglobinuria* and skeletal muscle injuries causing *myoglobinuria*. Such injuries result in characteristic intratubular hemoglobin or myoglobin casts, respectively; the toxic iron content of these globin molecules contributes to the AKI. In addition to its frequency, the potential reversibility of AKI adds to its clinical importance. Proper management means the difference between full recovery and death.

Pathogenesis.

The critical events in both ischemic and nephrotoxic AKI are believed to be (1) tubular injury and (2) persistent and severe disturbances in blood flow[60] (Fig. 20-23).

- *Tubule cell injury:* Tubular epithelial cells are particularly sensitive to ischemia and are also vulnerable to toxins. Several factors predispose the tubules to toxic injury, including a vast charged surface for tubular reabsorption, active transport systems for ions and organic acids, a high metabolic rate and oxygen consumption requirement so as to perform these transport and reabsorption functions, and the capability for effective concentration.
  Ischemia causes numerous structural and functional alterations in epithelial cells, as discussed in Chapter 1 . The structural changes include those of reversible injury (such as cellular swelling, loss of brush border and polarity, blebbing, and cell detachment) and those associated with lethal injury (necrosis and apoptosis). Biochemically there is depletion of ATP; accumulation of intracellular calcium; activation of proteases (e.g., calpain), which cause cytoskeletal disruption; activation of phospholipases, which damage membranes; generation of reactive oxygen species; and activation of caspases, which induce apoptotic cell death. One early reversible result of ischemia is *loss of cell polarity* due to redistribution of membrane proteins (e.g., the enzyme Na^+, K^+-ATPase) from the basolateral to the luminal surface of the tubular cells, resulting in abnormal ion transport across the cells, and *increased sodium delivery to distal tubules*. The latter incites vasoconstriction via *tubuloglomerular feedback*, which will be discussed below. In addition, ischemic tubular cells express cytokines (such as monocyte chemoattractant protein 1) and adhesion molecules (such as intercellular adhesion molecule 1), thus recruiting leukocytes that appear to participate in the subsequent injury. In time, injured cells detach from the basement membranes and cause *luminal obstruction*, increased intratubular pressure, and decreased GFR. In addition, fluid from the damaged tubules leaks into the interstitium, resulting in interstitial edema, increased interstitial pressure, and further damage to the tubule. All these effects, as shown in Figure 20-23 , contribute to the decreased GFR.
- *Disturbances in blood flow:* Ischemic renal injury is also characterized by *hemodynamic alterations* that cause reduced GFR. The major one is *intrarenal vasoconstriction*, which results in both reduced glomerular blood flow and reduced oxygen delivery to the functionally important tubules in the outer medulla (thick ascending limb and straight segment of the proximal tubule). Several vasoconstrictor pathways have been implicated, including the renin-angiotensin system, stimulated by increased distal sodium delivery (via *tubuloglomerular feedback*), and *sublethal endothelial injury*, leading to increased release of the vasoconstrictor *endothelin* and decreased production of the vasodilators *nitric oxide* and *prostacyclin (prostaglandin I_2)*. There is also some evidence of a direct effect of ischemia or toxins on the glomerulus, causing a reduced glomerular ultrafiltration coefficient, possibly due to mesangial contraction.

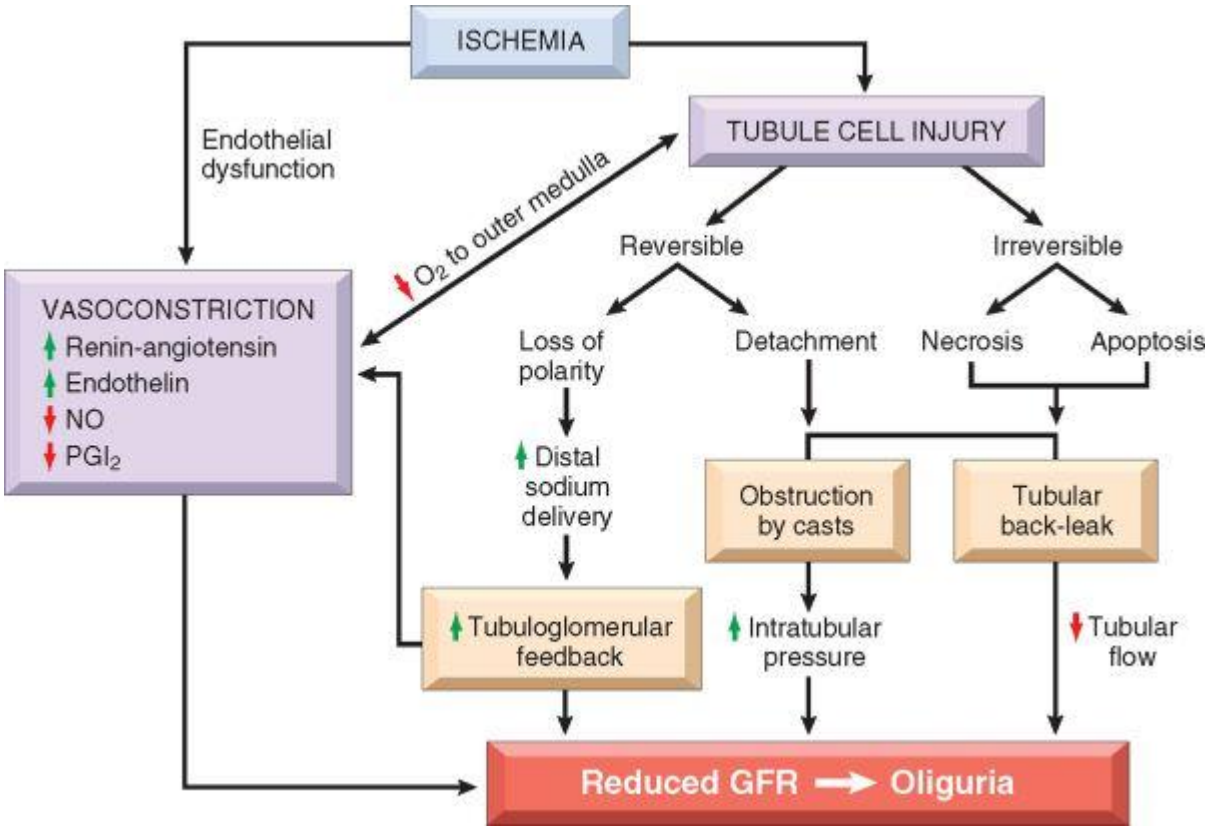

FIGURE 20-23 Postulated sequence in acute kidney injury. GFR, glomerular filtration rate; NO, nitric oxide; PGI_2, prostaglandin I2 (prostacyclin). *(Modified from Brady HR et al.: Acute renal failure. In Brenner BM [ed]: Brenner and Rector's The Kidney, 5th ed, Vol II. Philadelphia, WB Saunders, 1996, p 1210).*

The patchiness of tubular necrosis and maintenance of the integrity of the basement membrane along many segments allow ready repair of the necrotic foci and recovery of function if the precipitating cause is removed. This repair is dependent on the capacity of reversibly injured epithelial cells to proliferate and differentiate. Re-epithelialization is mediated by a variety of growth factors and cytokines produced locally by the tubular cells themselves (autocrine stimulation) or by inflammatory cells in the vicinity of necrotic foci (paracrine stimulation).[61] Of these, epidermal growth factor, TGF-α, insulin-like growth factor type 1, and hepatocyte growth factor have been shown to be particularly important in renal tubular repair. Growth factors, indeed, are being explored as possible therapeutic agents to enhance re-epithelialization in AKI, although clinical trials to date have been disappointing.[61]

Morphology. Ischemic AKI is characterized by focal tubular epithelial necrosis at multiple points along the nephron, with large skip areas in between, often accompanied by rupture of basement membranes (tubulorrhexis) and occlusion of tubular lumens by casts[62] (Figs. 20-24 and 20-25). The straight portion of the proximal tubule and the ascending thick limb in the renal medulla are especially vulnerable, but focal lesions may also occur in the distal tubule, often in conjunction with casts. Paradoxically, the clinical syndrome of AKI is often associated with lesser degrees of tubular injury. This includes attenuation or loss of proximal tubule brush borders, simplification of cell structure, cell swelling and vacuolization, and sloughing of non-necrotic tubular cells into the tubular

lumina (see Fig. 20-25). The severity of the morphologic findings often does not correlate well with the severity of the clinical manifestations.

Eosinophilic hyaline casts, as well as pigmented granular casts, are common, particularly in distal tubules and collecting ducts. These casts consist principally of Tamm-Horsfall protein (a urinary glycoprotein normally secreted by the cells of ascending thick limb and distal tubules) in conjunction with other plasma proteins. Other findings in ischemic AKI are interstitial edema and accumulations of leukocytes within dilated vasa recta. There is also evidence of epithelial regeneration: flattened epithelial cells with hyperchromatic nuclei and mitotic figures are often present. In the course of time this regeneration repopulates the tubules so that, no residual evidence of damage is seen.

Toxic AKI is manifested by acute tubular injury, most obvious in the proximal convoluted tubules. On histologic examination the tubular necrosis may be entirely nonspecific, but it is somewhat distinctive in poisoning with certain agents. With mercuric chloride, for example, severely injured cells may contain large acidophilic inclusions. Later, these cells become totally necrotic, are desquamated into the lumen, and may undergo calcification. Carbon tetrachloride poisoning, in contrast, is characterized by the accumulation of neutral lipids in injured cells; again, such fatty change is followed by necrosis. Ethylene glycol produces marked ballooning and hydropic or vacuolar degeneration of proximal convoluted tubules. Calcium oxalate crystals are often found in the tubular lumens in such poisoning.

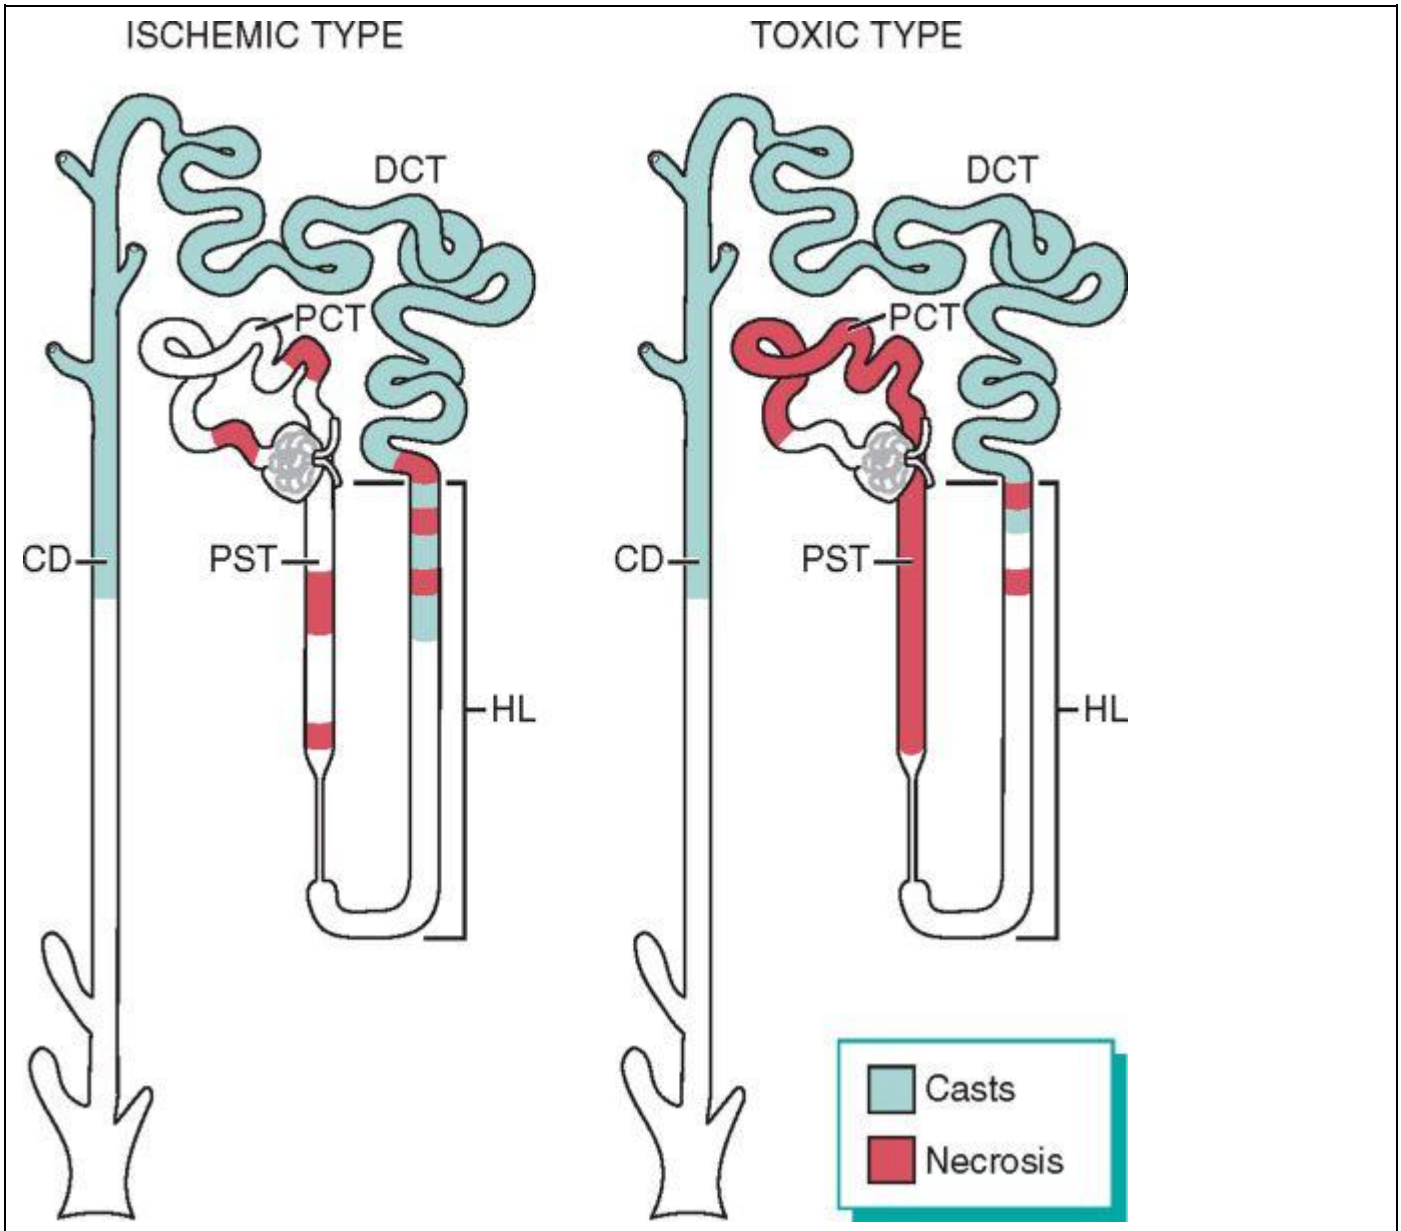

FIGURE 20-24 Patterns of tubular damage in ischemic and toxic acute kidney injury. In the ischemic type, tubular necrosis is patchy, relatively short lengths of tubules are affected, and straight segments of proximal tubules (PST) and ascending limbs of Henle's loop (HL) are most vulnerable. In toxic acute kidney injury, extensive necrosis is present along the proximal convoluted tubule segments (PCT) with many toxins (e.g., mercury), but necrosis of the distal tubule, particularly ascending HL, also occurs. In both types, lumens of the distal convoluted tubules (DCT) and collecting ducts (CD) contain casts.

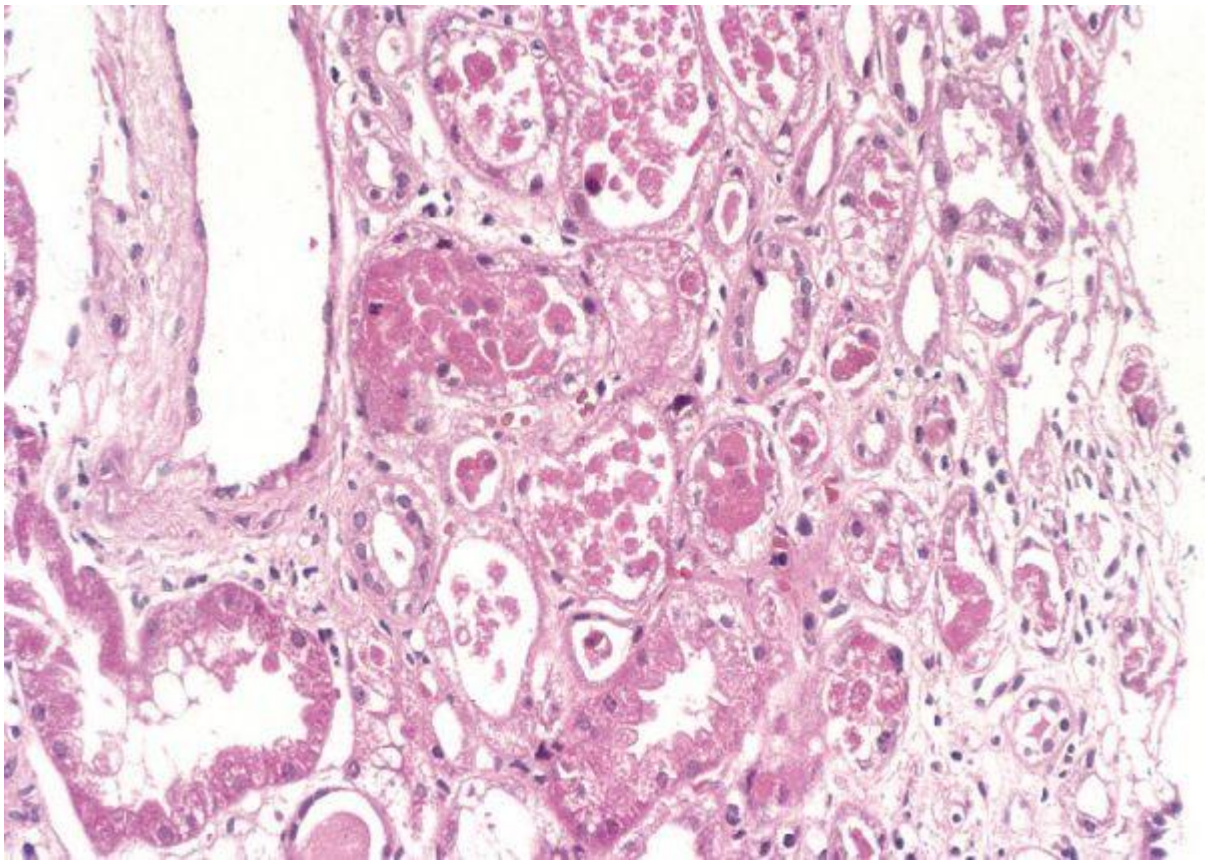

FIGURE 20-25 Acute kidney injury. Some of the tubular epithelial cells in the tubules are necrotic, and many have become detached (from their basement membranes) and been sloughed into the tubular lumens, whereas others are swollen, vacuolated, and regenerating. *(Courtesy of Dr. Agnes Fogo, Vanderbilt University, Nashville, TN.)*

Clinical Course.

The clinical course of AKI is highly variable, but the classic case may be divided into *initiation*, *maintenance*, and *recovery* stages. The *initiation phase*, lasting for about 36 hours, is dominated by the inciting medical, surgical, or obstetric event in the ischemic form of AKI. The only indication of renal involvement is a slight decline in urine output with a rise in BUN. At this point, oliguria could be explained on the basis of a transient decrease in blood flow and declining GFR.

The *maintenance phase* is characterized by sustained decreases in urine output to between 40 and 400 mL/day (oliguria), salt and water overload, rising BUN concentrations, hyperkalemia, metabolic acidosis, and other manifestations of uremia. With appropriate attention to the balance of water and blood electrolytes, including dialysis, the patient can be supported through this oliguric crisis.

The *recovery phase* is ushered in by a steady increase in urine volume that may reach up to 3 L/day. The tubules are still damaged, so large amounts of water, sodium, and potassium are lost in the flood of urine. *Hypokalemia, rather than hyperkalemia, becomes a clinical problem*. There is a peculiar increased vulnerability to infection at this stage. Eventually, renal tubular function is restored and concentrating abilityimproves. At the same time, BUN and creatinine levels begin to return to normal.

Subtle tubular functional impairment may persist for months, but most patients who reach this phase eventually recover completely.

The prognosis of AKI depends on the clinical setting. Recovery is expected with nephrotoxic AKI when the toxin has not caused serious damage to other organs, such as the liver or heart. With current supportive care, 95% of those who do not succumb to the precipitating cause recover. Conversely, in shock related to sepsis, extensive burns, or other causes of multi-organ failure, the mortality rate can rise to more than 50%.

Up to 50% of patients with AKI do not have oliguria and instead often have increased urine volumes. This so-called *nonoliguric AKI* occurs particularly often with nephrotoxins, and it generally tends to follow a more benign clinical course.

TUBULOINTERSTITIAL NEPHRITIS

This group of renal diseases is characterized by histologic and functional alterations that involve predominantly the tubules and interstitium. We have previously seen that chronic tubulointerstitial injury may occur in diseases that primarily affect the glomerulus (see Fig. 20-22) and that such injury may be an important cause of progression in these diseases.[18] *Secondary tubulointerstitial nephritis* is also present in a variety of vascular, cystic (polycystic kidney disease), and metabolic (diabetes) renal disorders, in which it may also contribute to progressive damage. Here we discuss disorders in which tubulointerstitial injury seems to be a primary event. *These disorders have diverse causes and different pathogenetic mechanisms* (Table 20-8). Glomerular and vascular abnormalities may also be present but either are mild or occur only in advanced stages of these diseases.

Balkan nephropathy Nephronophthisis–medullary cystic disease complex “Idiopathic” interstitial nephritis

Tubulointerstitial nephritis can be acute or chronic. Acute tubulointerstitial nephritis has a rapid clinical onset and is characterized histologically by interstitial edema, often accompanied by leukocytic infiltration of the interstitium and tubules, and focal tubular necrosis. In *chronic interstitial nephritis* there is infiltration with predominantly mononuclear leukocytes, prominent interstitial fibrosis, and widespread tubular atrophy. Morphologic features that are helpful in separating acute from chronic tubulointerstitial nephritis include edema and, when present, eosinophils and neutrophils in the acute form, while fibrosis and tubular atrophy characterize the chronic form.

These conditions are distinguished clinically from the glomerular diseases by the absence, in early stages, of such hallmarks of glomerular injury as nephritic or nephrotic syndrome and by the presence of defects in tubular function. The latter may be subtle and include impaired ability to concentrate urine, evidenced clinically by polyuria or nocturia; salt wasting; diminished ability to excrete acids (metabolic acidosis); and isolated defects in tubular reabsorption or secretion. The advanced forms, however, may be difficult to distinguish clinically from other causes of renal insufficiency.

Some of the specific conditions listed in Table 20-8 are discussed elsewhere in this book. In this section we deal principally with pyelonephritis and interstitial diseases induced by drugs.

Pyelonephritis and Urinary Tract Infection

Pyelonephritis is a renal disorder affecting the tubules, interstitium, and renal pelvis and is one of the most common diseases of the kidney. It occurs in two forms. *Acute pyelonephritis* is caused by bacterial infection and is the renal lesion associated with urinary tract infection. *Chronic pyelonephritis* is a more complex disorder; bacterial infection plays a dominant role, but other factors (vesicoureteral reflux, obstruction) are involved in its pathogenesis. Pyelonephritis is a serious complication of *urinary tract infections* that affect the bladder (cystitis), the kidneys and their collecting systems (pyelonephritis), or both. Bacterial infection of the lower urinary tract may be completely asymptomatic (asymptomatic bacteriuria) and most often remains localized to the bladder without the development of renal infection. However, lower urinary tract infection always carries the potential of spread to the kidney.

Etiology and Pathogenesis.

The dominant etiologic agents, accounting for more than 85% of cases of urinary tract infection, are the gram-negative bacilli that are normal inhabitants of the intestinal tract.[63] By far the most common is

Escherichia coli, followed by *Proteus*, *Klebsiella*, and *Enterobacter*. *Streptococcus faecalis*, also of enteric origin, staphylococci, and virtually every other bacterial and fungal agent can also cause lower urinary tract and renal infection. In immunocompromised persons, particularly those with transplanted organs, viruses such as *Polyomavirus*, cytomegalovirus, and adenovirus can also be a cause of renal infection.

In most patients with urinary tract infection, the infecting organisms are derived from the patient's own fecal flora. This is thus a form of endogenous infection. There are two routes by which bacteria can reach the kidneys: (1) through the bloodstream (hematogenous infection) and (2) from the lower urinary tract (ascending infection) (Fig. 20-26). The hematogenous route is the less common of the two and results from seeding of the kidneys by bacteria from distant foci in the course of septicemia or infective endocarditis. Hematogenous infection is more likely to occur in the presence of ureteral obstruction, in debilitated patients, in patients receiving immunosuppressive therapy, and with nonenteric organisms, such as staphylococci and certain fungi and viruses.

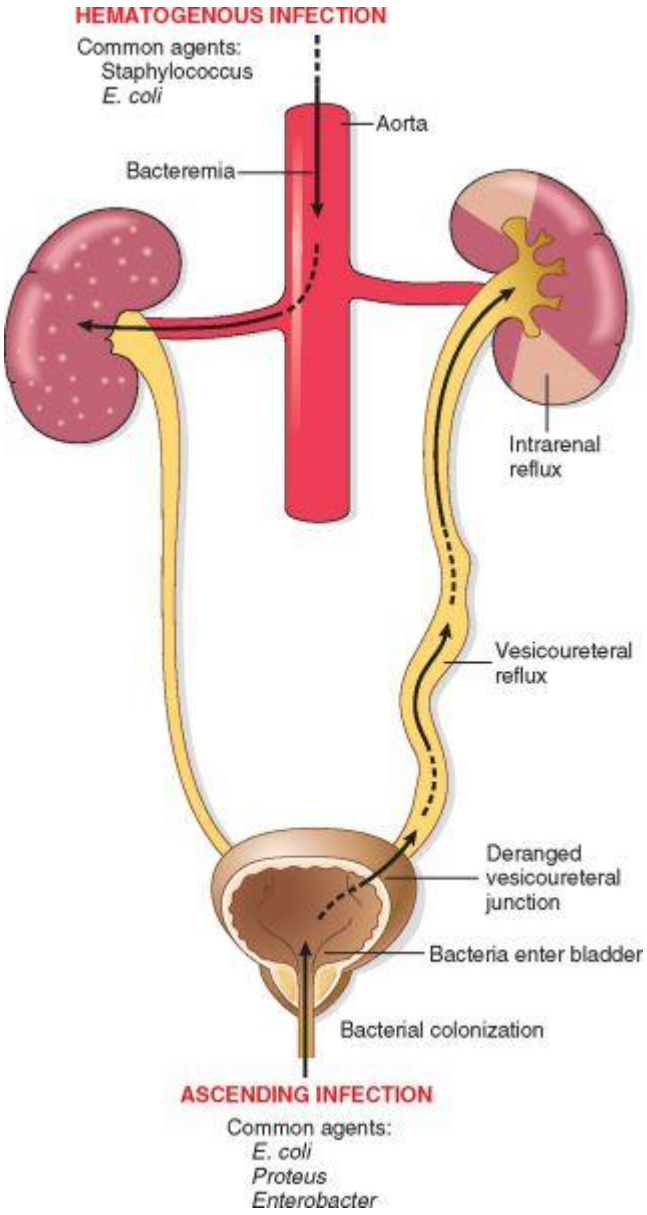

FIGURE 20-26 Schematic representation of pathways of renal infection. Hematogenous infection results from bacteremic spread. More

common is ascending infection, which results from a combination of urinary bladder infection, vesicoureteral reflux, and intrarenal reflux.

Ascending infection is the most common cause of clinical pyelonephritis. Normal human bladder and bladder urine are sterile; therefore, a number of steps must occur for renal infection to occur:

- The first step in ascending infection seems to be the *colonization of the distal urethra and introitus* (in the female) by coliform bacteria. This colonization is influenced by the ability of bacteria to adhere to urethral mucosal epithelial cells. Such bacterial adherence, as discussed in Chapter 8 , involves adhesive molecules (adhesins) on the P-fimbriae (pili) of bacteria that interact with receptors on the surface of uroepithelial cells. Specific adhesins (e.g., that encoded by the pyelonephritis-associated pili [*pap*] gene[64]) are associated with infection. In addition, certain types of fimbriae promote renal tropism, persistence of infection, or an enhanced inflammatory response.[64]
- *From the urethra to the bladder*, organisms gain entrance during urethral catheterization or other instrumentation. Long-term catheterization, in particular, carries a risk of infection. In the absence of instrumentation, *urinary infections are much more common in females*, and this has been ascribed to the shorter urethra in females, as well as the absence of antibacterial properties such as are found in prostatic fluid, hormonal changes affecting adherence of bacteria to the mucosa, and urethral trauma during sexual intercourse, or a combination of these factors.
- *Urinary tract obstruction and stasis of urine*. Ordinarily, organisms introduced into the bladder are cleared by the continual flushing of voiding and by antibacterial mechanisms. However, outflow obstruction or bladder dysfunction results in incomplete emptying and increased residual volume of urine. In the presence of stasis, bacteria introduced into the bladder can multiply unhindered without being flushed out or destroyed. Accordingly, urinary tract infection is particularly frequent among patients with lower urinary tract obstruction, such as may occur with benign prostatic hypertrophy, tumors, or calculi, or with neurogenic bladder dysfunction caused by diabetes or spinal cord injury.
- *Vesicoureteral reflux*. Although obstruction is an important predisposing factor in ascending infection, it is *incompetence of the vesicoureteral valve* that allows bacteria to ascend the ureter into the renal pelvis. The normal ureteral insertion into the bladder is a competent one-way valve that prevents retrograde flow of urine, especially during micturition, when the intravesical pressure rises. An incompetent vesicoureteral orifice allows the reflux of bladder urine into the ureters *(vesicoureteral reflux)* (Fig. 20-27). Reflux is most often due to a congenital absence or shortening of the intravesical portion of the ureter, such that the ureter is not compressed during micturition. In addition, bladder infection itself, probably as a result of the action of bacterial or inflammatory products on ureteral contractility, can cause or accentuate vesicoureteral reflux, particularly in children. Vesicoureteral reflux is not uncommon; it is estimated to affect 1% to 2% of otherwise normal children.[65] *Acquired vesicoureteral reflux* in adults can result from persistent bladder atony caused by spinal cord injury. The effect of vesicoureteral reflux is similar to that of an obstruction in that there is residual urine in the urinary tract after voiding, which favors bacterial growth.
- *Intrarenal reflux*. Vesicoureteral reflux also affords a ready mechanism by which the infected bladder urine can be propelled up to the renal pelvis and deep into the renal parenchyma through open ducts at the tips of the papillae (intrarenal reflux). Intrarenal reflux is most common in the upper and lower poles of the kidney, where papillae tend to have flattened or concave tips rather than the convex pointed type present in the midzones of the kidney (and depicted in most textbooks). Reflux can be demonstrated radiographically by a voiding cystourethrogram: The bladder is filled with a radiopaque dye, and films are taken during micturition. Vesicoureteral reflux can be demonstrated in about 30% of infants and children with urinary tract infection (see Fig. 20-27).

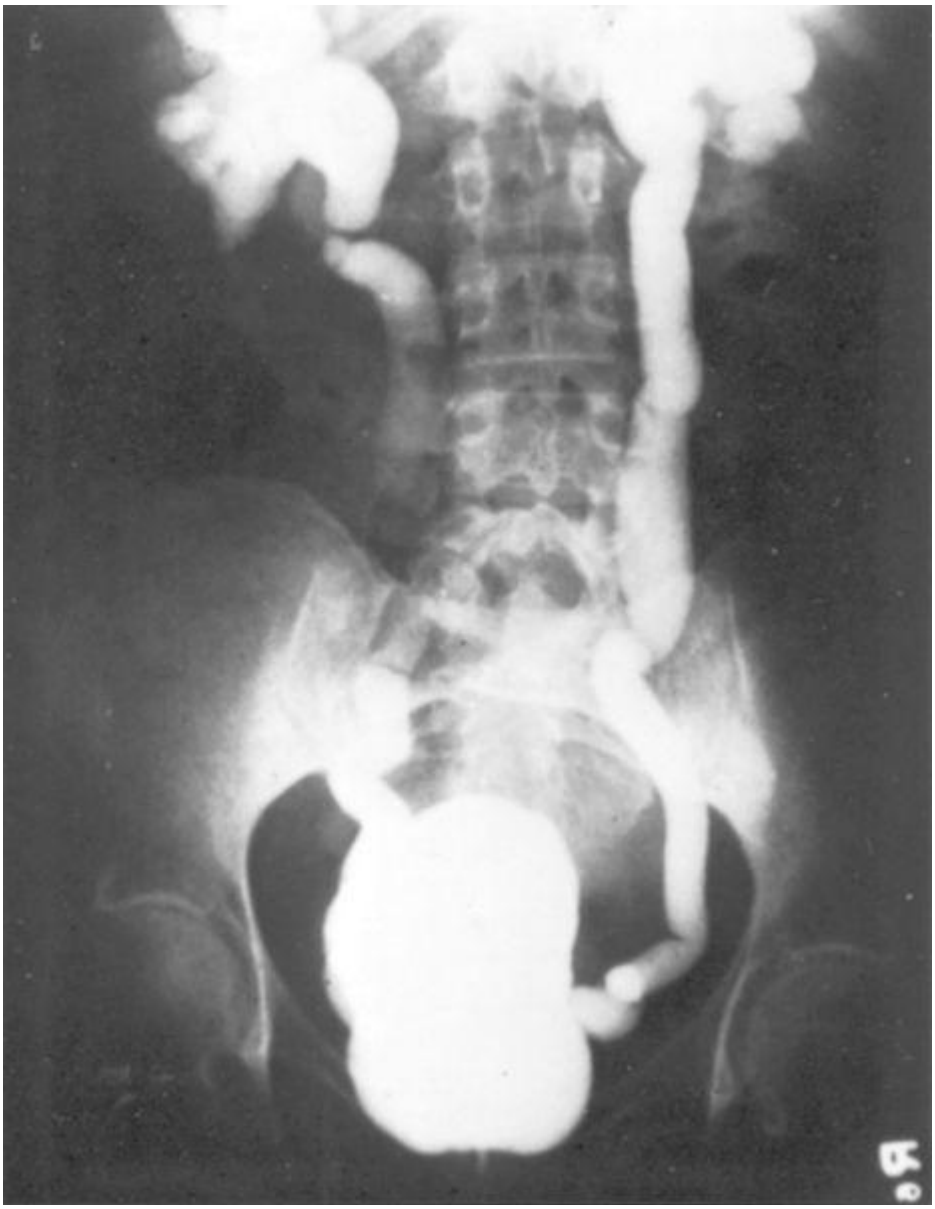

FIGURE 20-27 Vesicoureteral reflux demonstrated by a voiding cystourethrogram. Dye injected into the bladder refluxes into both dilated ureters, filling the pelvis and calyces.

In the absence of vesicoureteral reflux, infection usually remains localized in the bladder. Thus, the majority of individuals with repeated or persistent bacterial colonization of the urinary tract suffer from cystitis and urethritis *(lower urinary tract infection)* rather than pyelonephritis.

Acute Pyelonephritis

Acute pyelonephritis is an acute suppurative inflammation of the kidney caused by bacterial and sometimes viral (e.g., polyomavirus) infection, whether hematogenous and induced by septicemic spread or ascending and associated with vesicoureteral reflux.[66]

Morphology. The hallmarks of acute pyelonephritis are **patchy interstitial suppurative inflammation, intratubular aggregates of neutrophils, and tubular necrosis**. The suppuration may occur as discrete focal abscesses involving one or both kidneys, which can extend to large wedge-shaped areas of suppuration (Fig. 20-28). The distribution of these lesions is unpredictable and haphazard, but in pyelonephritis associated with reflux, damage occurs most commonly in the lower and upper poles.

In the early stages, the neutrophilic infiltration is limited to the interstitial tissue. Soon, however, the reaction involves tubules and produces a characteristic abscess with the destruction of the engulfed tubules (Fig. 20-29). Since the tubular lumens present a ready pathway for the extension of the infection, large masses of intraluminal neutrophils frequently extend along the involved nephron into the collecting tubules. Characteristically, glomeruli seem to be relatively resistant to the infection. Large areas of severe necrosis, however, eventually destroy the glomeruli, and fungal pyelonephritis (e.g., *Candida*) often affects glomeruli.

Three complications of acute pyelonephritis are encountered in special circumstances.

- **Papillary necrosis** is seen mainly in diabetics and in those with urinary tract obstruction. Papillary necrosis is usually bilateral but may be unilateral. One or all of the pyramids of the affected kidney may be involved. On cut section, the tips or distal two thirds of the pyramids have areas of gray-white to yellow necrosis (Fig. 20-30). On microscopic examination the necrotic tissue shows characteristic coagulative necrosis, with preservation of outlines of tubules. The leukocytic response is limited to the junctions between preserved and destroyed tissue.
- **Pyonephrosis** is seen when there is total or almost complete obstruction, particularly when it is high in the urinary tract. The suppurative exudate is unable to drain and thus fills the renal pelvis, calyces, and ureter with pus.
- **Perinephric abscess** is an extension of suppurative inflammation through the renal capsule into the perinephric tissue.

After the acute phase of pyelonephritis, healing occurs. The neutrophilic infiltrate is replaced by one that is predominantly composed of macrophages, plasma cells, and (later) lymphocytes. The inflammatory foci are eventually replaced by irregular scars that can be seen on the cortical surface as fibrous depressions. Such scars are characterized microscopically by tubular atrophy, interstitial fibrosis, and a lymphocytic infiltrate in a characteristic patchy, jigsaw pattern with intervening preserved parenchyma. **The pyelonephritic scar is almost always associated with inflammation, fibrosis, and deformation of the underlying calyx and pelvis**, reflecting the role of ascending infection and vesicoureteral reflux in the pathogenesis of the disease.

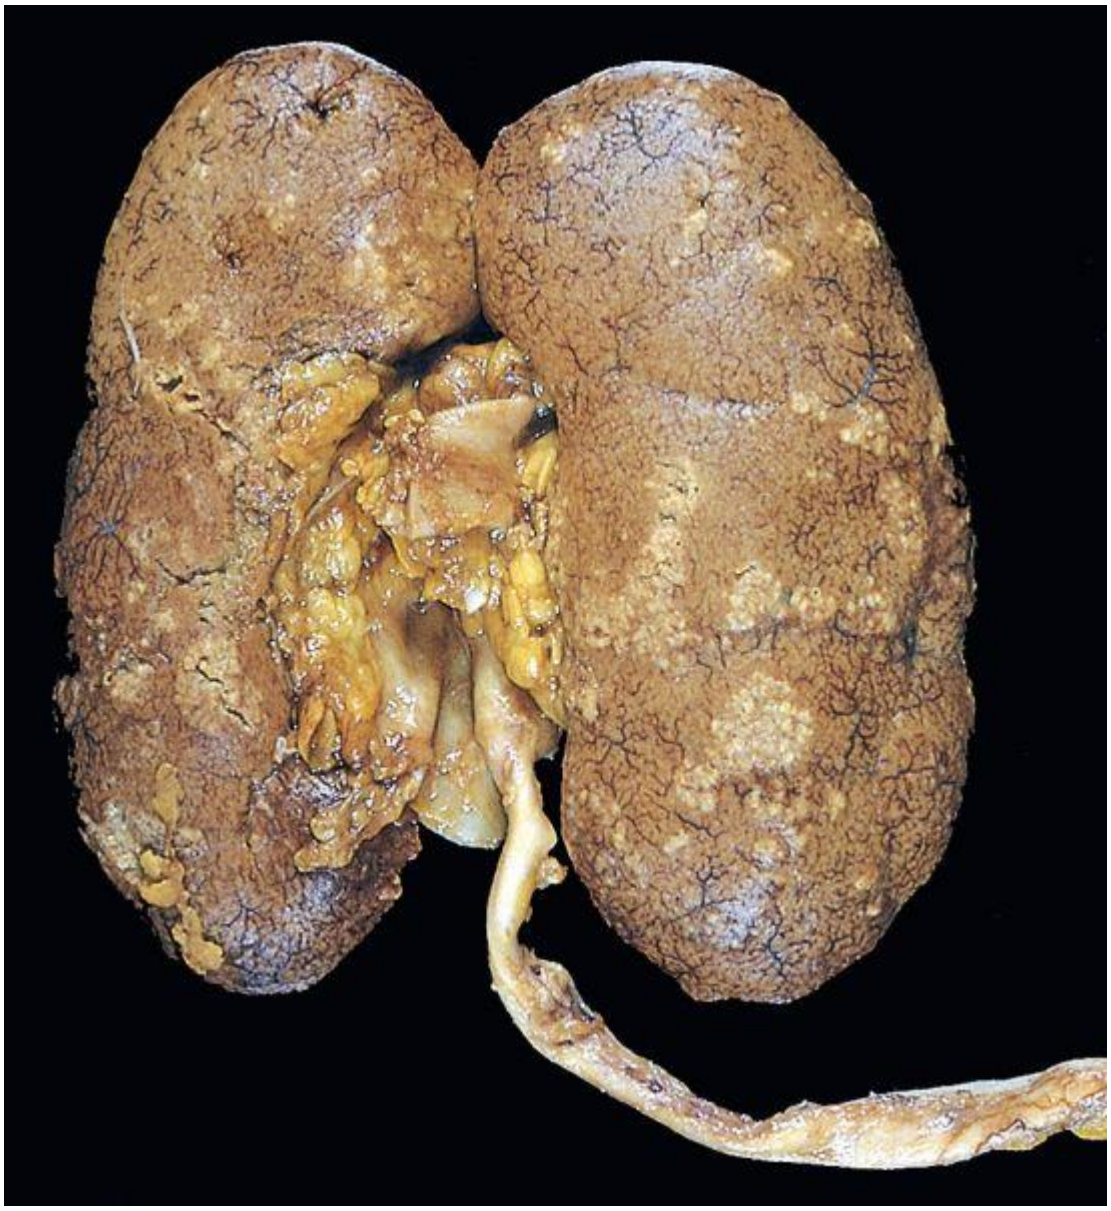

FIGURE 20-28 Acute pyelonephritis. Cortical surface shows grayish white areas of inflammation and abscess formation.

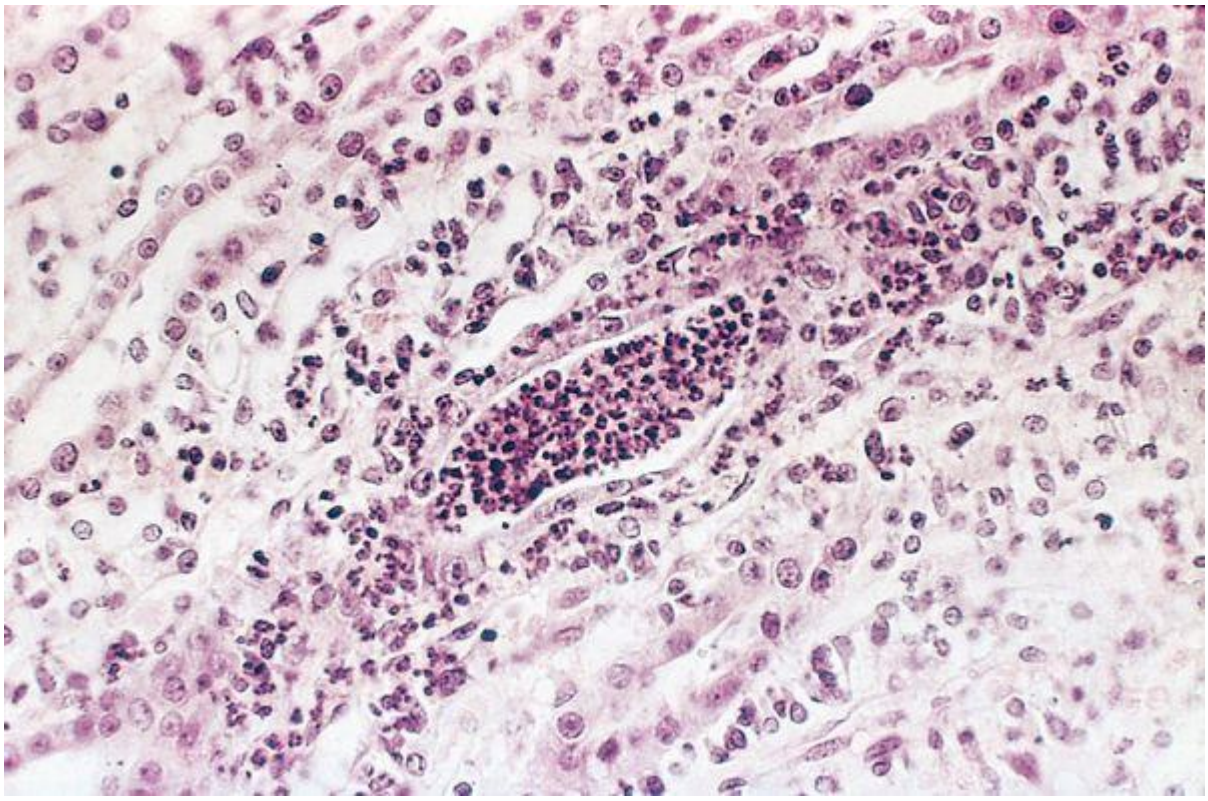

FIGURE 20-29 Acute pyelonephritis marked by an acute neutrophilic exudate within tubules and interstitial inflammation.

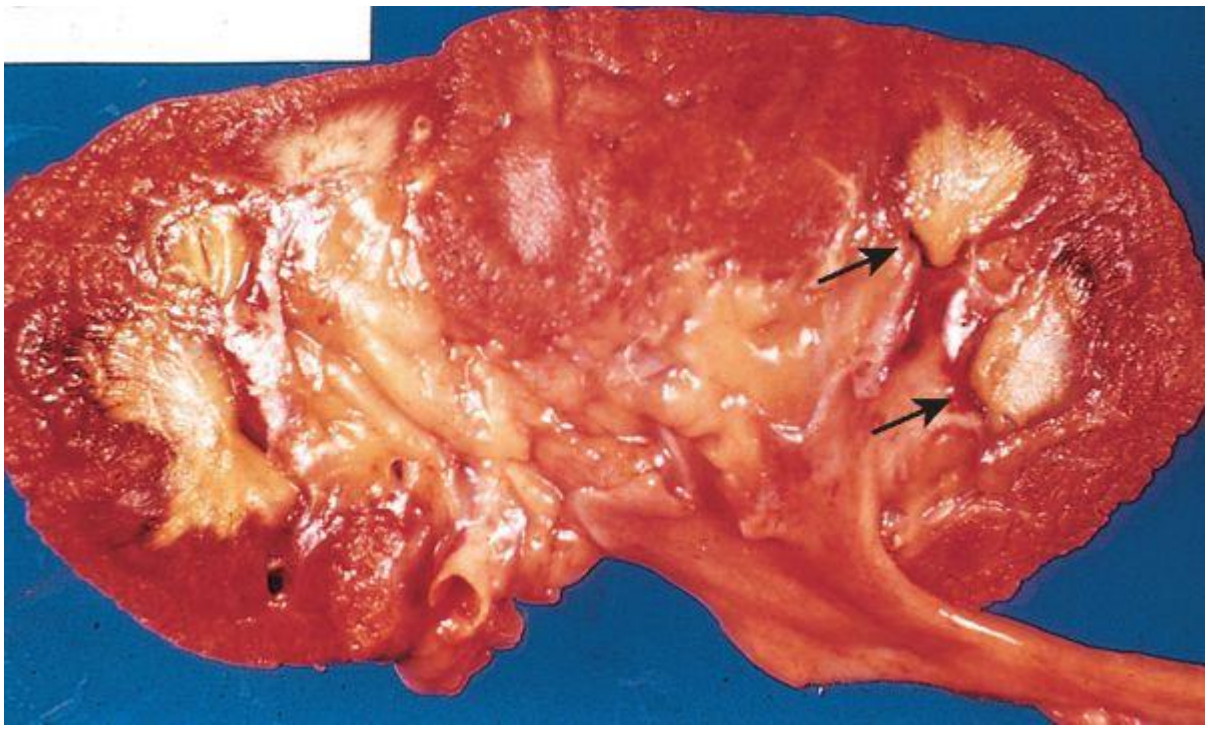

FIGURE 20-30 Papillary necrosis. Areas of pale-gray necrosis involve the papillae (*arrows*).

Clinical Features.

Acute pyelonephritis is often associated with predisposing conditions, some of which were mentioned before. These include the following:

- *Urinary tract obstruction*, either congenital or acquired
- *Instrumentation* of the urinary tract, most commonly catheterization
- *Vesicoureteral reflux*
- *Pregnancy*. Between 4% and 6% of pregnant women develop bacteriuria sometime during pregnancy, and 20% to 40% of these eventually develop symptomatic urinary infection if not treated.
- *Gender and age*. After the first year of life (when congenital anomalies in males commonly become evident) and up to around age 40 years, infections are much more frequent in females. With increasing age the incidence in males rises as a result of prostatic hypertrophy and instrumentation.
- *Preexisting renal lesions*, causing intrarenal scarring and obstruction
- *Diabetes mellitus*, in which increased susceptibility to infection, neurogenic bladder dysfunction, and more frequent instrumentation are predisposing factors
- *Immunosuppression and immunodeficiency*

When acute pyelonephritis is clinically apparent, the onset is usually sudden, with pain at the costovertebral angle and systemic evidence of infection, such as fever and malaise. There are usually indications of bladder and urethral irritation, such as dysuria, frequency, and urgency. The urine contains many leukocytes (pyuria) derived from the inflammatory infiltrate, but pyuria does not differentiate upper from lower urinary tract infection. The finding of leukocyte *casts*, typically rich in neutrophils (pus casts), indicates renal involvement, because casts are formed only in tubules. The diagnosis of infection is established by quantitative urine culture.

Uncomplicated acute pyelonephritis usually follows a benign course, and the symptoms disappear within a few days after the institution of appropriate antibiotic therapy. Bacteria, however, may persist in the urine, or there may be recurrence of infection with new serologic types of *E. coli* or other organisms. Such bacteriuria then either disappears or may persist, sometimes for years. In the presence of unrelieved urinary obstruction, diabetes mellitus, or immunodeficiency, acute pyelonephritis may be more serious, leading to repeated septicemic episodes. The superimposition of *papillary necrosis* may lead to acute renal failure.

An emerging viral pathogen causing pyelonephritis in kidney allografts is *polyomavirus*. Latent infection with polyomavirus is widespread in the general population, but immunosuppression of the allograft recipient can lead to reactivation of latent infection and the development of a nephropathy resulting in allograft failure in as many as 1% to 5% of kidney transplant recipients.[67] This form of pyelonephritis, now referred to as *polyomavirus nephropathy*, is characterized by viral infection of tubular epithelial cell nuclei, leading to nuclear enlargement and intranuclear inclusions visible by light microscopy (viral cytopathic effect). The inclusions are composed of virions arrayed in distinctive crystalline-like lattices when visualized by electron microscopy (Fig. 20-31). An interstitial inflammatory response is invariably present. Treatment consists of a reduction in immunosuppression.

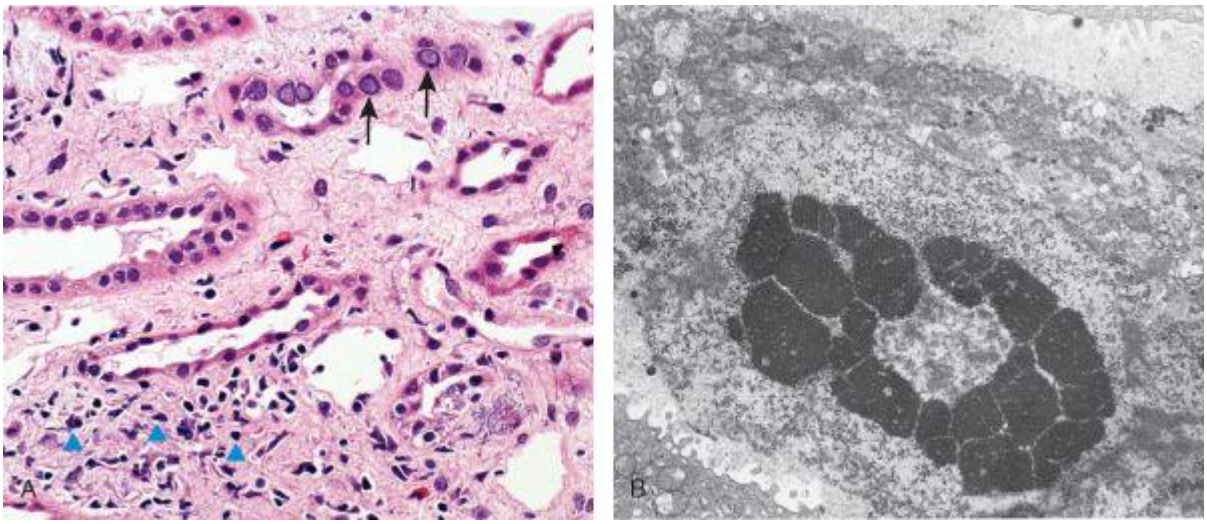

FIGURE 20-31 Polyomavirus nephropathy. **A**, The kidney shows enlarged tubular epithelial cells with nuclear inclusions *(arrows)* and interstitial inflammation *(arrowheads)*. **B**, Intranuclear viral inclusions visualized by electron microscopy. *(Courtesy of Dr. Jean Olson, Department of Pathology, University of California San Francisco, San Francisco, CA.)*

Chronic Pyelonephritis and Reflux Nephropathy

Chronic pyelonephritis is a disorder in which *chronic tubulointerstitial inflammation and renal scarring are associated with pathologic involvement of the calyces and pelvis* (Fig. 20-32). Pelvocalyceal damage is important in that virtually all the disease etiologies listed in Table 20-8 produce chronic tubulointerstitial alterations, but with the exception of chronic pyelonephritis and analgesic nephropathy, none affect the calyces. Chronic pyelonephritis is an important cause of end-stage kidney disease; at one time it accounted for as many as 10% to 20% of patients in renal transplant or dialysis units, until predisposing conditions such as reflux became better recognized. This condition remains an important cause of kidney destruction in children with severe lower urinary tract abnormalities.

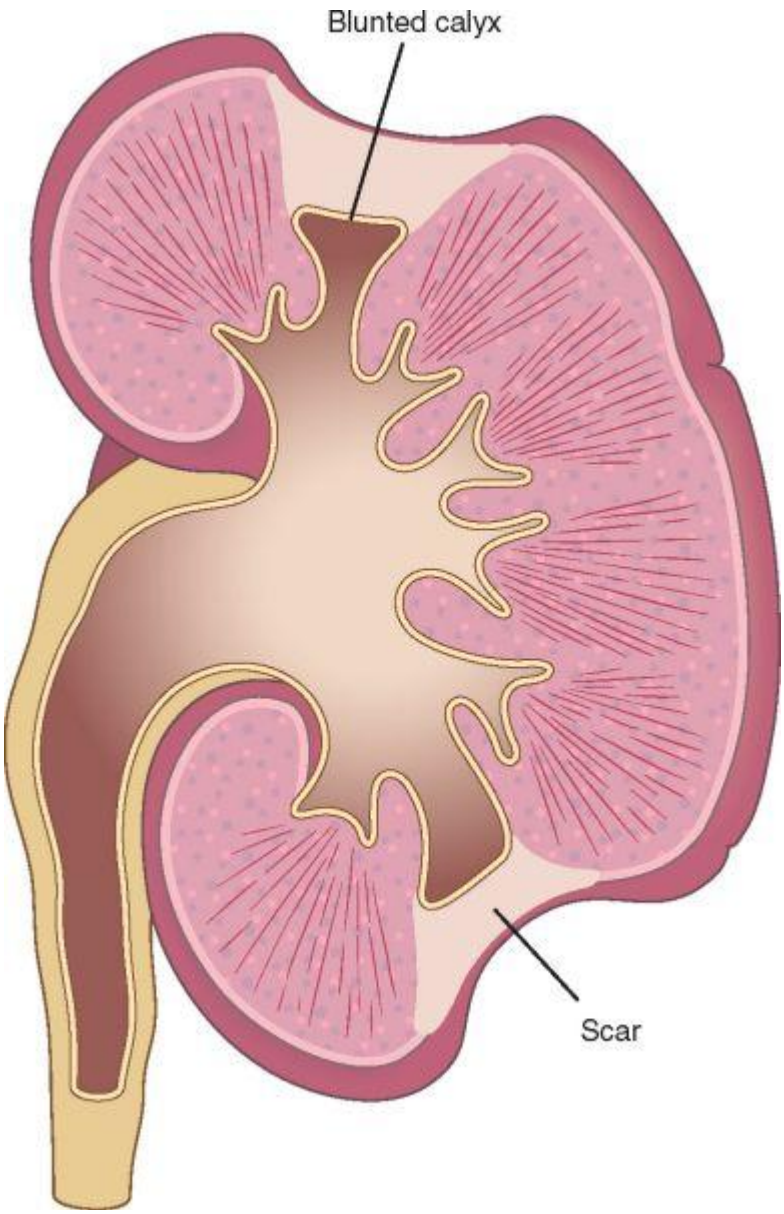

FIGURE 20-32 Typical coarse scars of chronic pyelonephritis associated with vesicoureteral reflux. The scars are usually polar and are associated with underlying blunted calyces.

Chronic pyelonephritis can be divided into two forms: chronic reflux-associated and chronic obstructive.

Reflux Nephropathy.

This is by far the more common form of chronic pyelonephritic scarring. Renal involvement in reflux nephropathy occurs early in childhood as a result of superimposition of a urinary infection on congenital vesicoureteral reflux and intrarenal reflux. Reflux may be unilateral or bilateral; thus, the resultant renal damage may cause scarring and atrophy of one kidney or involve both, leading to chronic renal insufficiency. Vesicoureteral reflux occasionally causes renal damage in the absence of infection (sterile reflux), but only when obstruction is severe.

Chronic Obstructive Pyelonephritis.

We have seen that obstruction predisposes the kidney to infection. Recurrent infections superimposed on diffuse or localized obstructive lesions lead to recurrent bouts of renal inflammation and scarring, resulting in a picture of chronic pyelonephritis. In this condition, the effects of obstruction contribute to the parenchymal atrophy; indeed, it is sometimes difficult to differentiate the effects of bacterial infection from those of obstruction alone. The disease can be bilateral, as with posterior urethral valves, resulting in renal insufficiency unless the anomaly is corrected, or unilateral, such as occurs with calculi and unilateral obstructive anomalies of the ureter.

Morphology. The characteristic changes of chronic pyelonephritis are seen on gross examination (Figs. 20-32 and 20-33). The kidneys usually are irregularly scarred; if bilateral, the involvement is asymmetric. This contrasts with chronic glomerulonephritis, in which both kidneys are diffusely and symmetrically scarred. The hallmarks of chronic pyelonephritis are coarse, discrete, corticomedullary scars overlying dilated, blunted, or deformed calyces, and flattening of the papillae (see Fig. 20-33). The scars can vary from one to several in number and may affect one or both kidneys. Most are in the upper and lower poles, consistent with the frequency of reflux in these sites.

The microscopic changes involve predominantly tubules and interstitium. The tubules show atrophy in some areas and hypertrophy or dilation in others. Dilated tubules with flattened epithelium may be filled with colloid casts (thyroidization). There are varying degrees of chronic interstitial inflammation and fibrosis in the cortex and medulla. In the presence of active infection there may be neutrophils in the interstitium and pus casts in the tubules. Arcuate and interlobular vessels demonstrate obliterative intimal sclerosis in the scarred areas; and in the presence of hypertension, hyaline arteriosclerosis is seen in the entire kidney. There is often fibrosis around the calyceal epithelium as well as a marked chronic inflammatory infiltrate. Glomeruli may appear normal except for periglomerular fibrosis, or exhibit a variety of changes, including ischemic fibrous obliteration and secondary changes related to hypertension. Individuals with chronic pyelonephritis and reflux nephropathy who develop proteinuria in advanced stages show secondary focal segmental glomerulosclerosis, as described later.

Xanthogranulomatous pyelonephritis is an unusual and relatively rare form of chronic pyelonephritis characterized by accumulation of foamy macrophages intermingled with plasma cells, lymphocytes, polymorphonuclear leukocytes, and occasional giant cells. Often associated with *Proteus* infections and obstruction, the lesions sometimes produce large, yellowish orange nodules that may be grossly confused with renal cell carcinoma.

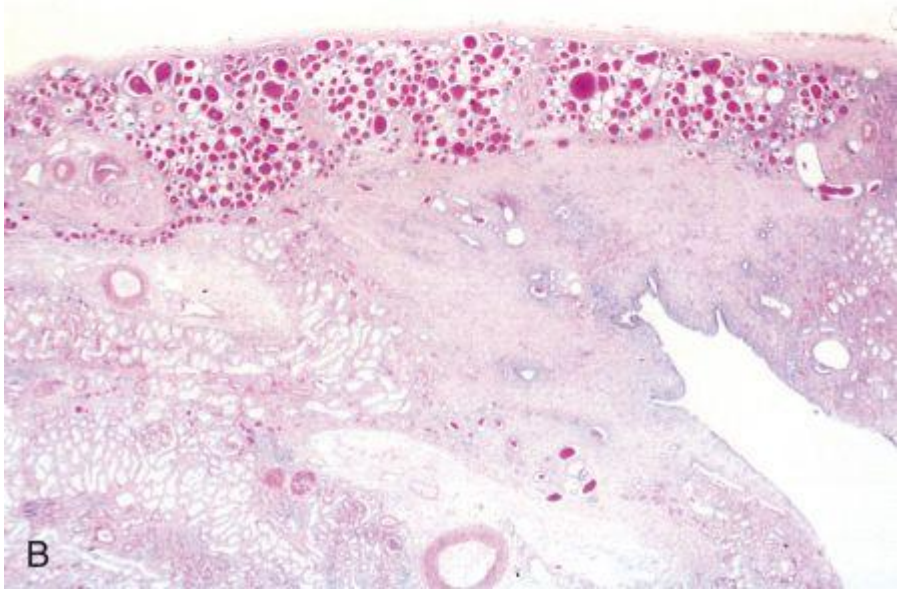

FIGURE 20-33 A, Chronic pyelonephritis. The surface *(left)* is irregularly scarred. The cut section *(right)* reveals characteristic dilation and blunting of calyces. The ureter is dilated and thickened, a finding that is consistent with chronic vesicoureteral reflux. **B**, Low-power view showing a corticomedullary renal scar with an underlying dilated deformed calyx. Note the thyroidization of tubules in the cortex.

Clinical Features.

Chronic obstructive pyelonephritis may be insidious in onset or present with clinical manifestations of acute recurrent pyelonephritis, such as back pain, fever, frequent pyuria, and bacteriuria. Chronic pyelonephritis associated with reflux may have a silent onset. These patients come to medical attention relatively late in the course of their disease because of the gradual onset of renal insufficiency and hypertension or because of the discovery of pyuria or bacteriuria on routine examination. Reflux nephropathy is often discovered when hypertension in children is investigated. Loss of tubular function—in particular of concentrating ability—gives rise to polyuria and nocturia. Radiographic studies show asymmetrically contracted kidneys with characteristic coarse scars and blunting and

deformity of the calyceal system. Significant bacteriuria may be present, but it is often absent in the late stages.

Although proteinuria is usually mild, some individuals with pyelonephritic scars develop secondary *focal segmental glomerulosclerosis* with significant proteinuria, even in the nephrotic range, usually several years after the scarring has occurred and often in the absence of continued infection or persistent vesicoureteral reflux. The appearance of proteinuria and focal segmental glomerulosclerosis is a poor prognostic sign, and patients with these findings may proceed to chronic or end-stage renal failure. The glomerulosclerosis, as we have discussed, may be attributable to the adaptive glomerular alterations secondary to loss of renal mass caused by pyelonephritic scarring (renal ablation nephropathy).

Tubulointerstitial Nephritis Induced by Drugs and Toxins

Toxins and drugs can produce renal injury in at least three ways: (1) They may trigger an interstitial immunological reaction, exemplified by the acute hypersensitivity nephritis induced by such drugs as methicillin; (2) they may cause acute renal failure, as described earlier; and (3) they may cause subtle but cumulative injury to tubules that takes years to become manifest, resulting in chronic renal insufficiency.[68] The last type of damage is especially treacherous, because it may be clinically unrecognized until significant renal damage has occurred. Such is the case with analgesic abuse nephropathy, which is usually detected only after the onset of chronic renal insufficiency.

Acute Drug-Induced Interstitial Nephritis

This is a well-recognized adverse reaction to a constantly increasing number of drugs. First reported after the use of sulfonamides, acute tubulointerstitial nephritis most frequently occurs with synthetic penicillins (methicillin, ampicillin), other synthetic antibiotics (rifampin), diuretics (thiazides), NSAIDs, and miscellaneous drugs (allopurinol, cimetidine). The disease begins about 15 days (range: 2–40) after exposure to the drug and is characterized by *fever*, *eosinophilia* (which may be transient), *a rash* in about 25% of patients, and *renal abnormalities*. The latter take the form of hematuria, mild proteinuria, and leukocyturia (often including eosinophils). A *rising serum creatinine level or acute renal failure with oliguria develops in about 50% of cases*, particularly in older patients.

Pathogenesis.

Many features of the disease suggest an immune mechanism. The immune response is idiosyncratic and not dose-related. Clinical evidence of hypersensitivity includes the latent period, the eosinophilia and rash, the fact that the onset of nephropathy is not dose-related, and the recurrence of hypersensitivity after re-exposure to the same or a cross-reactive drug. In some patients, serum IgE levels are increased, and IgE-containing plasma cells and basophils are present in the lesions, suggesting that the *late-phase reaction of an IgE-mediated (type I) hypersensitivity* may be involved in the pathogenesis (Chapter 6). In other cases, mononuclear or granulomatous infiltrate, together with positive results of skin tests to drug haptens, suggest a T cell–mediated delayedhypersensitivity reaction (type IV).

The most likely sequence of events is that the drugs act as haptens, which covalently bind to some cytoplasmic or extracellular component of tubular cells and become immunogenic. The resultant injury is then due to IgE and/or cell-mediated immune reactions to tubular cells or their basement membranes.

Morphology. On histologic examination the abnormalities are in the interstitium, which shows variable but frequently pronounced edema and infiltration by mononuclear cells, principally lymphocytes and macrophages. Eosinophils and neutrophils may be present (Fig. 20-34), often in clusters and large numbers, and plasma cells and basophils are sometimes found in small numbers.

With some drugs (e.g., methicillin, thiazides), interstitial non-necrotizing granulomas containing giant cells may be seen. "Tubulitis," the infiltration of tubules by lymphocytes, is common. Variable degrees of tubular necrosis and regeneration are present. The glomeruli are normal except in some cases caused by NSAIDs, when minimal-change disease and the nephrotic syndrome develop concurrently (see the discussion of NSAIDs later in the chapter).

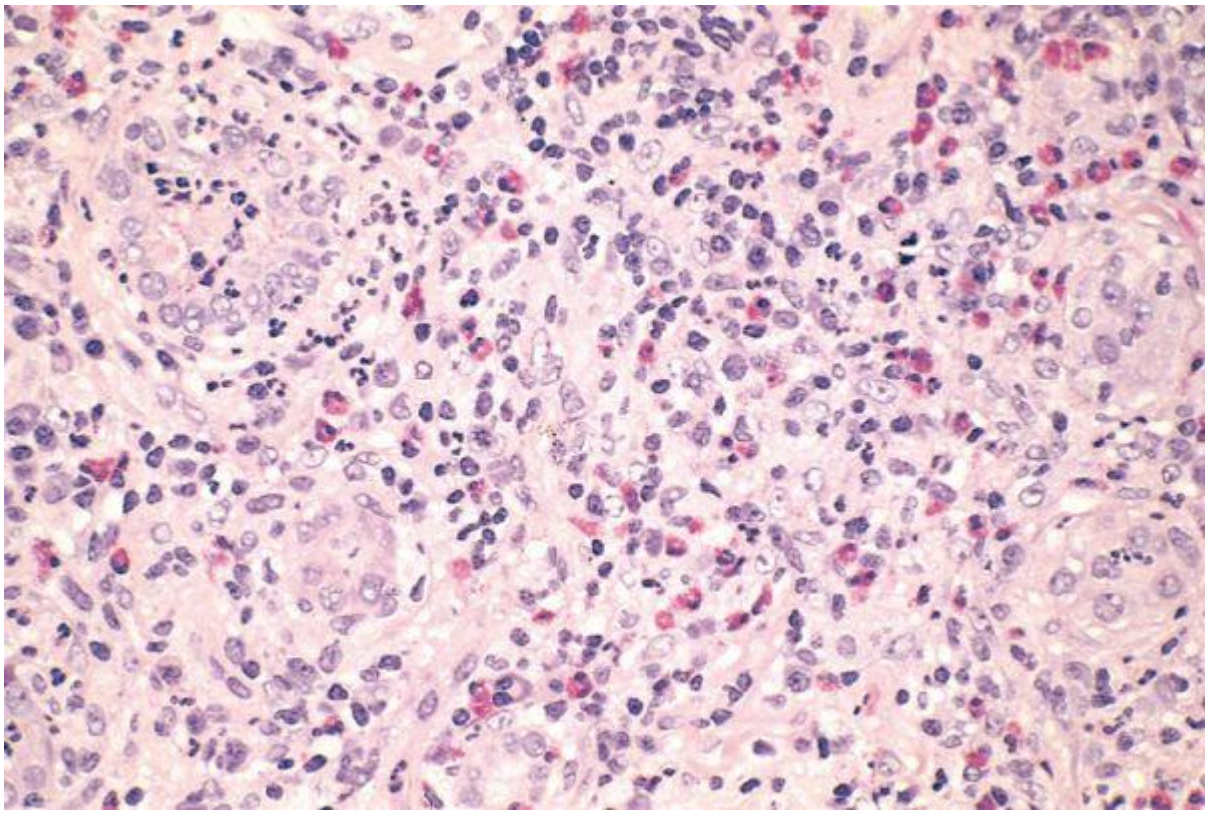

FIGURE 20-34 Drug-induced interstitial nephritis, with prominent eosinophilic and mononuclear cell infiltrate. *(Courtesy of Dr. H. Rennke, Brigham and Women's Hospital, Boston, MA.)*

Clinical Features.

It is important to recognize drug-induced renal failure because withdrawal of the offending drug is followed by recovery, although it may take several months, and irreversible damage occurs occasionally in older subjects. It is also important to remember that while drugs are the leading identifiable cause of acute interstitial nephritis, in many affected patients (approximately 30% to 40%) an offending drug or mechanism cannot be identified.

Analgesic Nephropathy

This is a form of chronic renal disease caused by excessive intake of analgesic mixtures and characterized morphologically by chronic tubulointerstitial nephritis and renal papillary necrosis.[69]

The incidence of analgesic nephropathy reflects the consumption of analgesics in various populations throughout the world. In some parts of Australia, it ranked as one of the most common causes of chronic renal insufficiency until public health measures reduced its incidence. Its incidence in the United States

is relatively low but varies among states, being highest in the southeast. Overall, it accounted for 9%, 3%, and 1% of patients undergoing dialysis in Australia, Europe, and the United States, respectively, before the recent surge in end-stage renal disease attributable to diabetes reduced these relative percentages. The renal damage was first ascribed to phenacetin, but the analgesic mixtures that are consumed often contain, in addition, aspirin, caffeine, acetaminophen (a metabolite of phenacetin), and codeine. Patients who develop this disease usually ingest large quantities of mixtures of at least two antipyretic analgesics. Most patients consume phenacetin-containing mixtures, and cases ascribed to ingestion of aspirin, phenacetin, or acetaminophen alone are uncommon. In most countries, restriction of over-the-counter sale of phenacetin or analgesic mixtures has reduced the incidence of the disorder but has not eradicated it, presumably because non-phenacetin-containing mixtures are available.

Pathogenesis.

Papillary necrosis is readily induced experimentally by a mixture of aspirin and phenacetin, usually combined with water depletion. It is now clear that in the sequence of events leading to renal damage, *papillary necrosis occurs first, and cortical tubulointerstitial nephritis follows as a consequence of impeded urine outflow*. The phenacetin metabolite acetaminophen, which can deplete cells of glutathione, then injures these cells by subsequent generation of *oxidative metabolites*. Aspirin induces its potentiating effect by inhibiting the vasodilatory effects of prostaglandins, predisposing the papillae to ischemia. Thus, the papillary damage may be due to a combination of direct toxic effects of phenacetin metabolites and ischemic injury to both tubular cells and vessels.

Morphology. In gross appearance the kidneys are either normal or slightly reduced in size, and the cortex shows depressed areas representing cortical atrophy overlying necrotic papillae. The papillae show various stages of necrosis, calcification, fragmentation, and sloughing. This gross appearance contrasts with the papillary necrosis seen in diabetic patients, in which all papillae are at the same stage of injury. On microscopic examination the papillary changes may take one of several forms. In early cases there is patchy necrosis, but in the advanced form the entire papilla is necrotic, often remaining in place as a structureless mass containing "ghosts" of tubules and foci of dystrophic calcification (Fig. 20-35). Segments of entire portions of the papilla may then be sloughed and excreted in the urine.

The cortical changes consist of loss and atrophy of tubules and interstitial fibrosis and inflammation. These changes are mainly due to obstructive atrophy caused by the tubular damage in the papillae. The cortical columns of Bertin are characteristically spared from this atrophy.

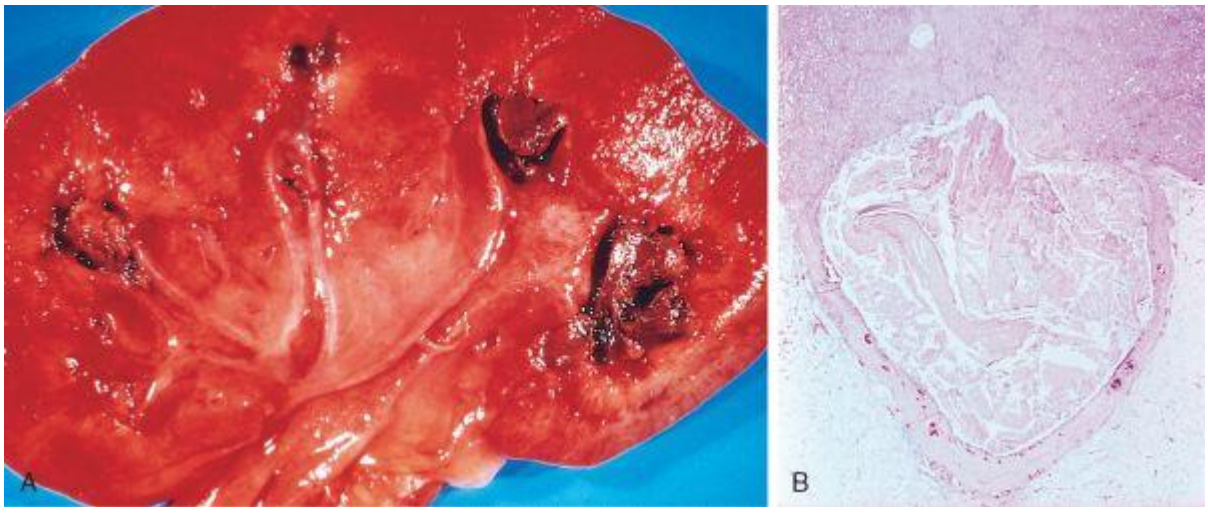

FIGURE 20-35 Analgesic nephropathy. A, The brownish necrotic papilla, transformed to a necrotic, structureless mass, fills the pelvis. B, Microscopic view. Note the fibrosis in the medulla. *(Courtesy of Dr. F.J. Gloor, Institut für Pathologie, Kantonsspital, St. Gallen, Switzerland.)*

Clinical Features.

Analgesic nephropathy is more common in women than in men and is particularly prevalent in individuals with recurrent headaches and muscle pain, in psychoneurotic patients, and in factory workers. Early renal findings include inability to concentrate the urine (hyposthenuria), as would be expected for papillary lesions. Acquired distal renal tubular acidosis contributes to the development of renal stones. Headache, anemia, gastrointestinal symptoms, and hypertension are common accompaniments of analgesic nephropathy. Urinary tract infection complicates about 50% of cases. On occasion, entire tips of necrotic papillae are excreted, and these may cause gross hematuria or renal colic due to obstruction of the ureter by necrotic fragments. Magnetic resonance and computed tomographic imaging are helpful in detecting papillary necrosis and calcifications. Progressive impairment of renal function may lead to chronic renal failure, but *with drug withdrawal, renal function may either stabilize or actually improve*.

Unfortunately, a small percentage of patients with analgesic nephropathy develop *transitional papillary carcinoma of the renal pelvis*. Whether the carcinogenic effect is due to a metabolite of phenacetin or to some other component of the analgesic compounds is unsettled.

Papillary necrosis is not specific for analgesic nephropathy. It is also seen in diabetes mellitus, as was mentioned earlier, as well as in urinary tract obstruction, sickle cell disease or trait (described later), and focally in renal tuberculosis. Table 20-9 lists certain features of papillary necrosis in these conditions.

TABLE 20-9 -- Causes of Papillary Necrosis

	Diabetes Mellitus	Analgesic Nephropathy	Sickle-Cell Disease	Obstruction
Male-to-female ratio	1:3	1:5	1:1	9:1
Time course	10 years	7 years of abuse	Variable	Variable
Infection	80%	25%	±	90%
Calcification	Rare	Frequent	Rare	Frequent
Number of papillae affected	Several; all of same stage	Almost all; different stages of necrosis	Few	Variable

Data from Seshan S et al. (eds): Classification and Atlas of Tubulointerstitial and Vascular Diseases. Baltimore, Williams & Wilkins, 1999.

Nephropathy Associated with NSAIDs

NSAIDs, one of the most common classes of drugs currently in use, produce several forms of renal injury. Although these complications are uncommon, they should be kept in mind since NSAIDs are frequently administered to patients with other potential causes of renal disease. Many NSAIDs are nonselective cyclooxygenase inhibitors, and their adverse renal effects are related to their ability to inhibit cyclooxygenase-dependent prostaglandin synthesis. The selective COX-2 inhibitors, while

sparing the gastrointestinal tract, do affect the kidneys because COX-2 is expressed in human kidneys.[70] NSAID-associated renal syndromes include

- Hemodynamically induced *acute renal failure*, due to the decreased synthesis of vasodilatory prostaglandins. This is particularly likely to occur in the setting of other renal diseases or conditions causing volume depletion.
- *Acute hypersensitivity interstitial nephritis*, resulting in acute renal failure, as described earlier.
- *Acute interstitial nephritis and minimal-change disease*. This curious association of two diverse renal conditions, one leading to renal failure and the other to nephrotic syndrome, suggests a hypersensitivity reaction affecting the interstitium and possibly the glomeruli, but also is consistent with injury to podocytes mediated by cytokines released as part of the inflammatory process.
- *Membranous nephropathy*, with the nephrotic syndrome, is a recently appreciated association, also of unclear pathogenesis.

Aristolochic Nephropathy

A syndrome of chronic tubulointerstitial nephritis caused by aristolochic acid, a supplement found in some herbal remedies, has been recognized recently. The drug forms covalent adducts with DNA and causes a distinctive picture of renal failure and interstitial fibrosis associated with a relative paucity of infiltrating leukocytes. As with analgesic nephropathy, there is an increased incidence of carcinoma in the kidney and urinary tract. Ingestion of aristolochic acid has also been identified as the cause of Balkan nephropathy, a chronic tubulointerstitial nephritis common in that part of the world.[71]

Other Tubulointerstitial Diseases

Urate Nephropathy

Three types of nephropathy can occur in persons with hyperuricemic disorders:

- *Acute uric acid nephropathy* is caused by the precipitation of uric acid crystals in the renal tubules, principally in collecting ducts, leading to obstruction of nephrons and the development of acute renal failure. This type is particularly likely to occur in individuals with leukemias and lymphomas who are undergoing chemotherapy; the drugs increase the death of tumor cells, and uric acid is produced as released nucleic acids are broken down. Precipitation of uric acid is favored by the acidic pH in collecting tubules.
- *Chronic urate nephropathy*, or gouty nephropathy, occurs in patients with more protracted forms of hyperuricemia. The lesions are ascribed to the deposition of monosodium urate crystals in the acidic milieu of the distal tubules and collecting ducts as well as in the interstitium. *These deposits have a distinct histologic appearance and may form variably birefringent needle-like crystals either in the tubular lumens or in the interstitium* (Fig. 20-36). The urates induce a *tophus* consisting of foreign-body giant cells, other mononuclear cells, and a fibrotic reaction (Chapter 26). Tubular obstruction by the urates causes cortical atrophy and scarring. Renal arterial and arteriolar thickening is common as a result of the relatively high frequency of hypertension in patients with gout. Clinically, urate nephropathy is a subtle disease associated with tubular defects that may progress slowly. Individuals with gout who actually develop a chronic nephropathy commonly have evidence of increased exposure to lead, sometimes by way of drinking “moonshine” whiskey contaminated with lead.
- The third renal syndrome in hyperuricemia is *nephrolithiasis*; uric acid stones are present in 22% of individuals with gout and 42% of those with secondary hyperuricemia (see later discussion of renal stones).

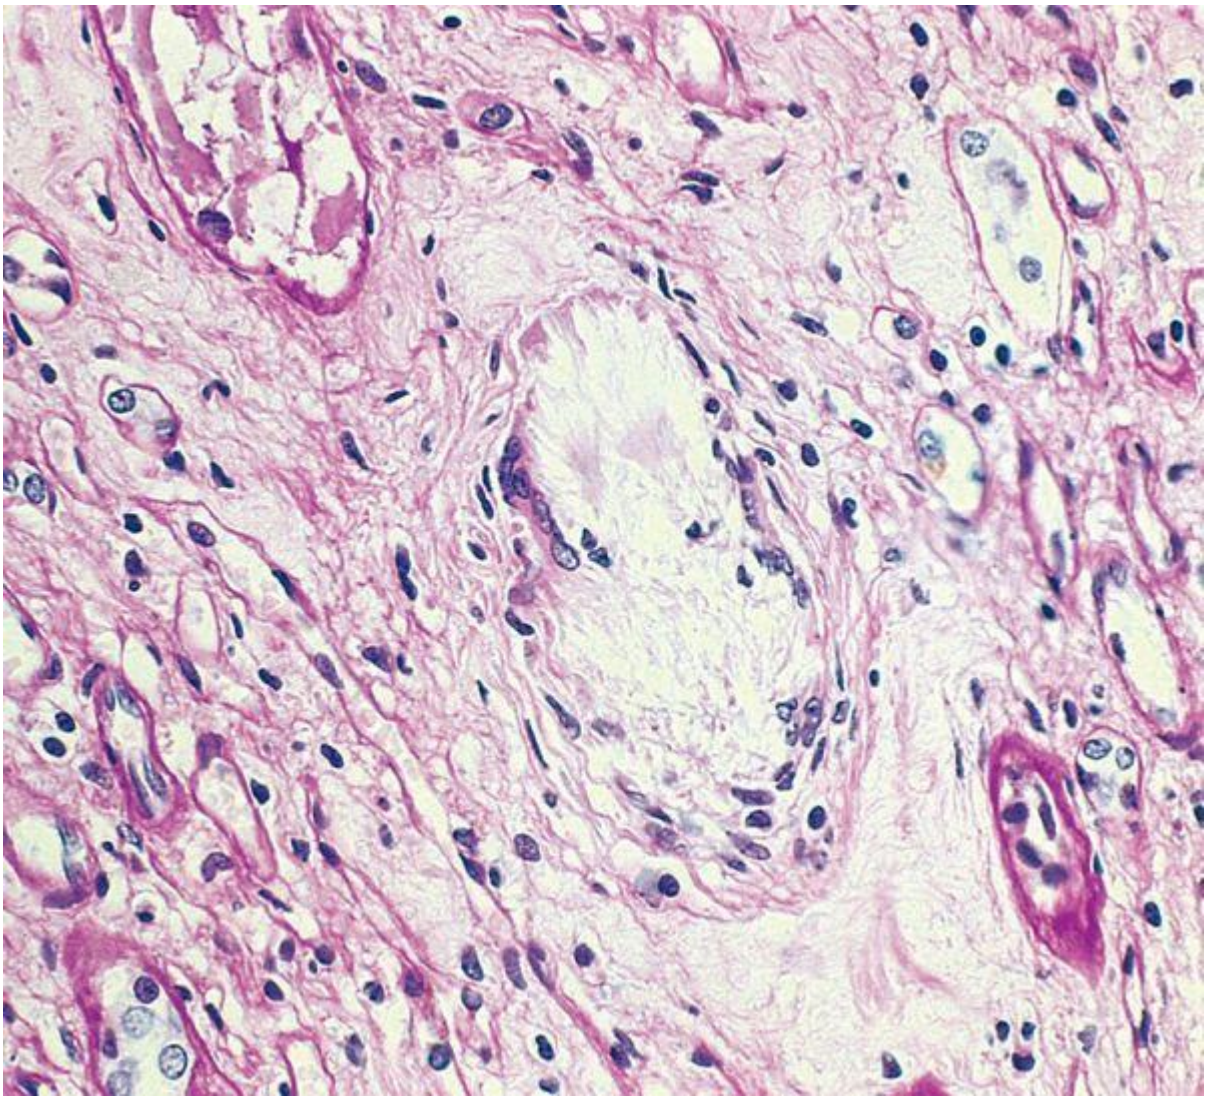

FIGURE 20-36 Urate crystals in the renal medulla. Note the giant cells and fibrosis around the crystals.

Hypercalcemia and Nephrocalcinosis

Disorders associated with hypercalcemia, such as hyperparathyroidism, multiple myeloma, vitamin D intoxication, metastatic cancer, or excess calcium intake (milk-alkali syndrome), may induce the formation of calcium stones and deposition of calcium in the kidney (nephrocalcinosis). Extensive degrees of calcinosis, under certain conditions, may lead to chronic tubulointerstitial disease and renal insufficiency. The earliest damage induced by the hypercalcemia is to the tubular epithelial cells in the form of mitochondrial distortion and other signs of cell injury. Subsequently, calcium deposits appear within the mitochondria, cytoplasm, and basement membrane. Calcified cellular debris may obstruct tubular lumens and cause obstructive atrophy of nephrons and secondary interstitial fibrosis and inflammation. Atrophy of entire cortical areas drained by calcified tubules may occur, accounting for the alternating areas of normal and scarred parenchyma seen in such kidneys.

The earliest functional defect is an inability to concentrate the urine. Other tubular defects, such as tubular acidosis and salt-losing nephritis, may also occur. With further damage, a slowly progressive

renal insufficiency develops. This is usually due to nephrocalcinosis, but many of these patients also have calcium stones and secondary pyelonephritis.

Acute Phosphate Nephropathy

Extensive accumulations of calcium phosphate crystals in tubules can occur in patients consuming high doses of oral phosphate solutions in preparation for colonoscopy.[72] These patients are not hypercalcemic, but excess phosphate load, perhaps complicated by dehydration, causes marked precipitation of calcium phosphate, typically presenting as renal insufficiency several weeks after the exposure. Patients typically only partially recover renal function.

Light-Chain Cast Nephropathy ("Myeloma Kidney")

Nonrenal malignant tumors, particularly those of hematopoietic origin, affect the kidneys in several ways (Table 20-10). The most common involvements are tubulointerstitial, caused by complications of the tumor (hypercalcemia, hyperuricemia, obstruction of ureters) or therapy (irradiation, hyperuricemia, chemotherapy, infections in immunosuppressed patients). As the survival rate of persons with malignant neoplasms increases, so do these renal complications. We limit the discussion here to the tubulointerstitial lesions in *multiple myeloma* that sometimes dominate the clinical picture in people with this disease.

TABLE 20-10 -- Renal Disease Related to Nonrenal Neoplasms

Direct tumor invasion of renal parenchyma Ureters (obstruction) Artery (renovascular hypertension)
Hypercalcemia
Hyperuricemia
Amyloidosis (AL, light-chain type)
Excretion of abnormal proteins (multiple myeloma)
Glomerulopathies Membranous nephropathy, secondary (carcinomas) Minimal-change disease (Hodgkin's disease) Membranoproliferative glomerulonephritis (leukemias and lymphomas) Monoclonal immunoglobin/light-chain deposition disease (multiple myeloma)
Effects of radiation therapy, chemotherapy, secondary infection

Overt renal insufficiency occurs in half of those with multiple myeloma and related lymphoplasmacytic disorders. Several factors contribute to renal damage:

- *Bence Jones proteinuria and cast nephropathy*. The main cause of renal dysfunction is related to Bence Jones (light-chain) proteinuria. Renal failure correlates well with the presence and amount of such proteinuria and is uncommon in its absence. Two mechanisms seem to account for the renal toxicity of Bence Jones proteins. First, some light chains are directly toxic to epithelial cells, apparently because of their intrinsic physicochemical properties. Second, Bence Jones proteins combine with the urinary glycoprotein (Tamm-Horsfall protein) under acidic conditions to form large, histologically distinct tubular casts that obstruct the tubular lumens and induce a characteristic inflammatory reaction around the casts

(light-chain cast nephropathy).

- *Amyloidosis*, of AL type formed from free light chains (usually of λ type), which occurs in 6% to 24% of individuals with myeloma.
- *Light-chain deposition disease*. In some patients, light chains (usually of κ type) deposit in GBMs and mesangium in nonfibrillar forms, causing a glomerulopathy (described earlier), or in tubular basement membranes, which may cause tubulointerstitial nephritis.
- *Hypercalcemia and hyperuricemia* are often present in these patients.

Morphology. The tubulointerstitial changes in light-chain cast nephropathy are fairly characteristic. The Bence Jones tubular casts appear as pink to blue amorphous masses, sometimes concentrically laminated and often fractured, which fill and distend the tubular lumens. Some of the casts are surrounded by multinucleate giant cells that are derived from mononuclear phagocytes (Fig. 20-37). The adjacent interstitial tissue usually shows a nonspecific inflammatory response and fibrosis. On occasion, the casts erode their way from the tubules into the interstitium and here evoke a granulomatous inflammatory reaction. Amyloidosis, light-chain deposition disease, nephrocalcinosis, and infection may also be present.

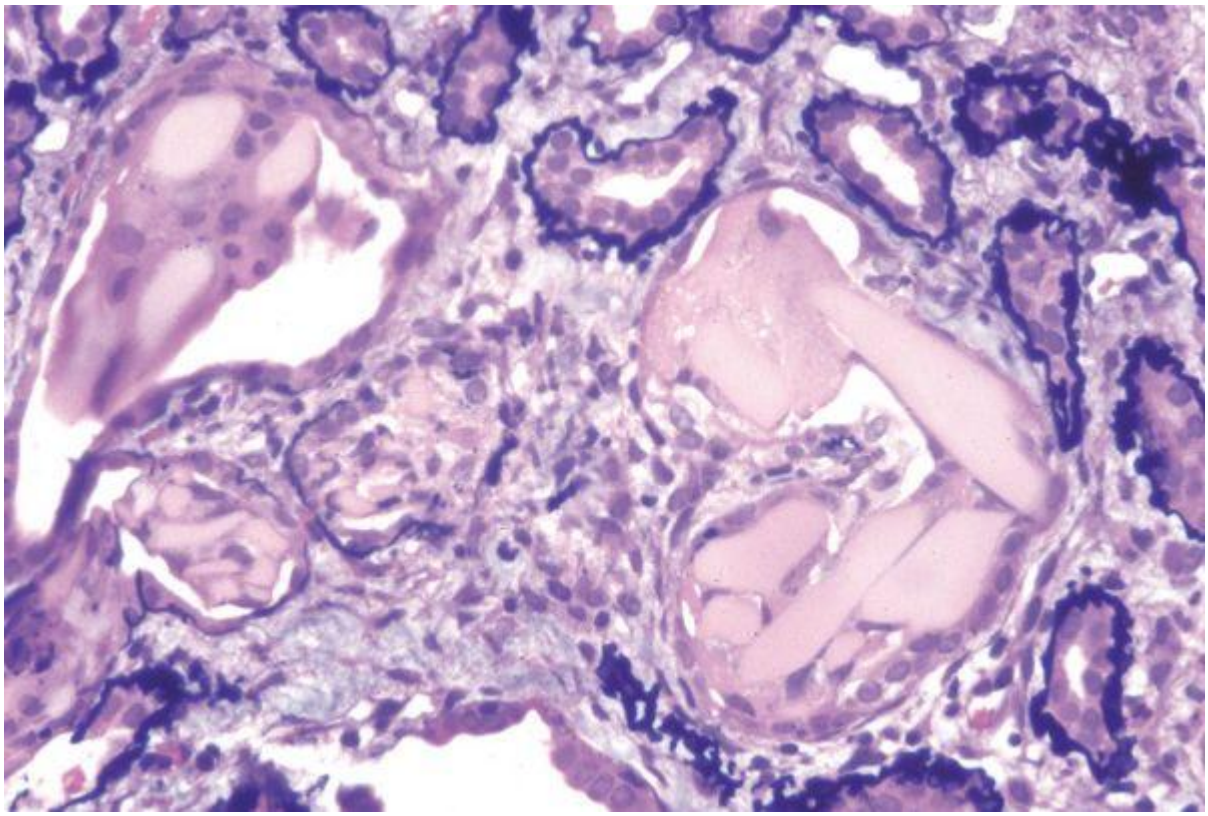

FIGURE 20-37 Light-chain cast nephropathy. Note the angulated and tubular casts, surrounded by macrophages, including multinucleate cells.

Clinical Features.

Clinically, the renal manifestations are of several types. In the most common form, *chronic renal failure* develops insidiously and usually progresses slowly during a period of several months to years. Another

form occurs suddenly and is manifested by *acute renal failure* with oliguria. Precipitating factors in these patients include dehydration, hypercalcemia, acute infection, and treatment with nephrotoxic antibiotics. *Bence Jones proteinuria* occurs in 70% of individuals with multiple myeloma; the presence of significant non–light-chain proteinuria (e.g., albuminuria) suggests AL amyloidosis or light-chain deposition disease.

3.10.4 Vascular Diseases

Nearly all diseases of the kidney involve the renal blood vessels secondarily. Systemic vascular diseases, such as various forms of vasculitis, also affect renal vessels, and their effects on the kidney are often clinically important. Hypertension, as we discussed in Chapter 11 , is intimately linked with the kidney, because kidney disease can be both the cause and consequence of increased blood pressure.[73] In this chapter we discuss benign and malignant nephrosclerosis and renal artery stenosis, lesions associated with hypertension, and sundry lesions involving mostly smaller vessels of the kidney.

BENIGN NEPHROSCLEROSIS

Benign nephrosclerosis is the term used for the renal pathology associated with sclerosis of renal arterioles and small arteries. The resultant effect is focal ischemia of parenchyma supplied by vessels with thickened walls and consequent narrowed lumens. The parenchymal effects include glomerulosclerosis and chronic tubulointersititial injury, producing a reduction in functional renal mass. Nephrosclerosis at autopsy is associated with increasing age, more frequent in blacks than whites, and may be seen in the absence of hypertension.[74,][75] Hypertension and diabetes mellitus, however, increase the incidence and severity of the lesions.

Pathogenesis.

Two processes participate in the arterial lesions:

- Medial and intimal thickening, as a response to hemodynamic changes, aging, genetic defects, or some combination of these
- Hyaline deposition in arterioles, caused partly by extravasation of plasma proteins through injured endothelium and partly by increased deposition of basement membrane matrix

Morphology. The kidneys are either normal or moderately reduced in size, with average weights between 110 and 130 gm. The cortical surfaces have a fine, even granularity that resembles grain leather (Fig. 20-38). The loss of mass is due mainly to cortical scarring and shrinking.

On histologic examination there is narrowing of the lumens of arterioles and small arteries, caused by thickening and hyalinization of the walls **(hyaline arteriolosclerosis)** (Fig. 20-39). Corresponding to the fine surface granulations are microscopic subcapsular scars with sclerotic glomeruli and tubular dropout, alternating with better preserved parenchyma. In addition, the interlobular and arcuate arteries show a characteristic lesion that consists of medial hypertrophy, reduplication of the elastic lamina, and increased myofibroblastic tissue in the intima, which combine to narrow the lumen. This change, called fibroelastic hyperplasia, often accompanies hyaline arteriolosclerosis and increases in severity with age and in the presence of hypertension.

Consequent to the vascular narrowing, there is patchy ischemic atrophy, which consists of (1) foci of tubular atrophy and interstitial fibrosis and (2) a variety of glomerular alterations. The latter include collapse of the GBM, deposition of collagen within the Bowman space, periglomerular fibrosis, and total sclerosis of glomeruli. When the ischemic changes are pronounced and affect large areas of

parenchyma, they can produce regional scars and histologic alterations that may resemble those seen in renal ablation injury, mentioned earlier.

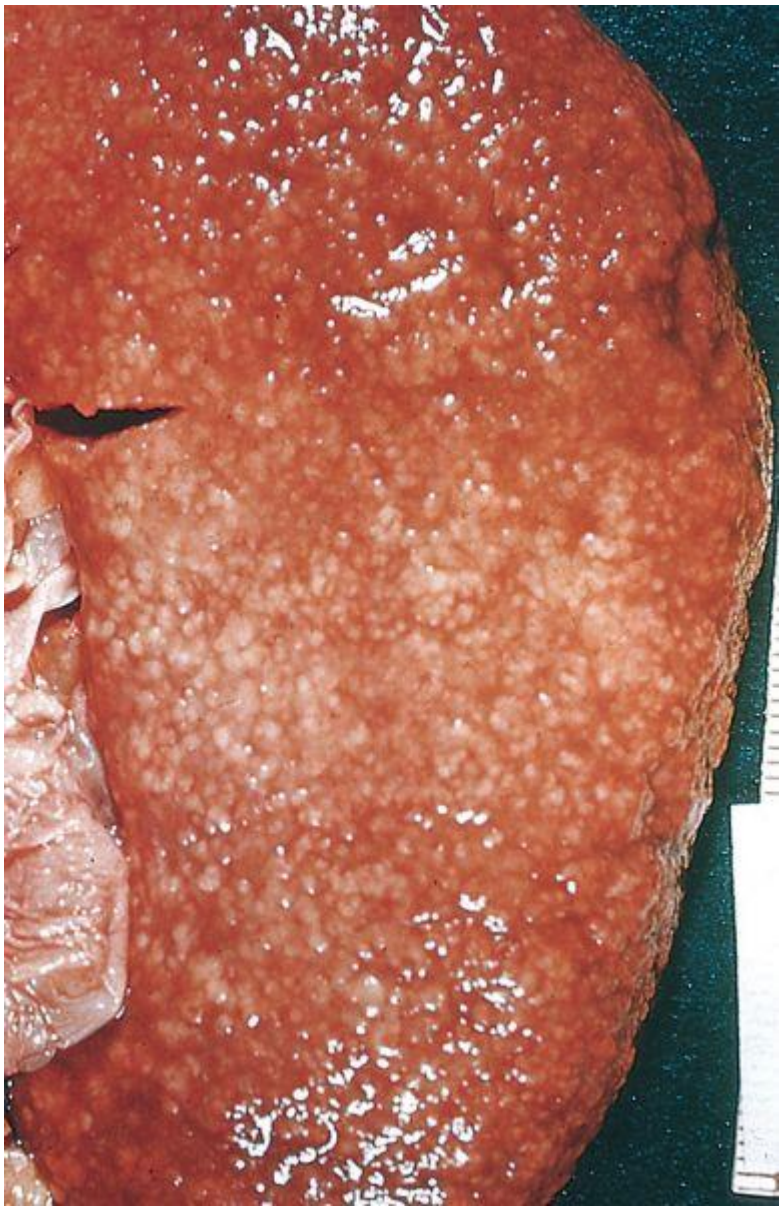

FIGURE 20-38 Close-up of the gross appearance of the cortical surface in benign nephrosclerosis illustrating the fine, leathery granularity of the surface.

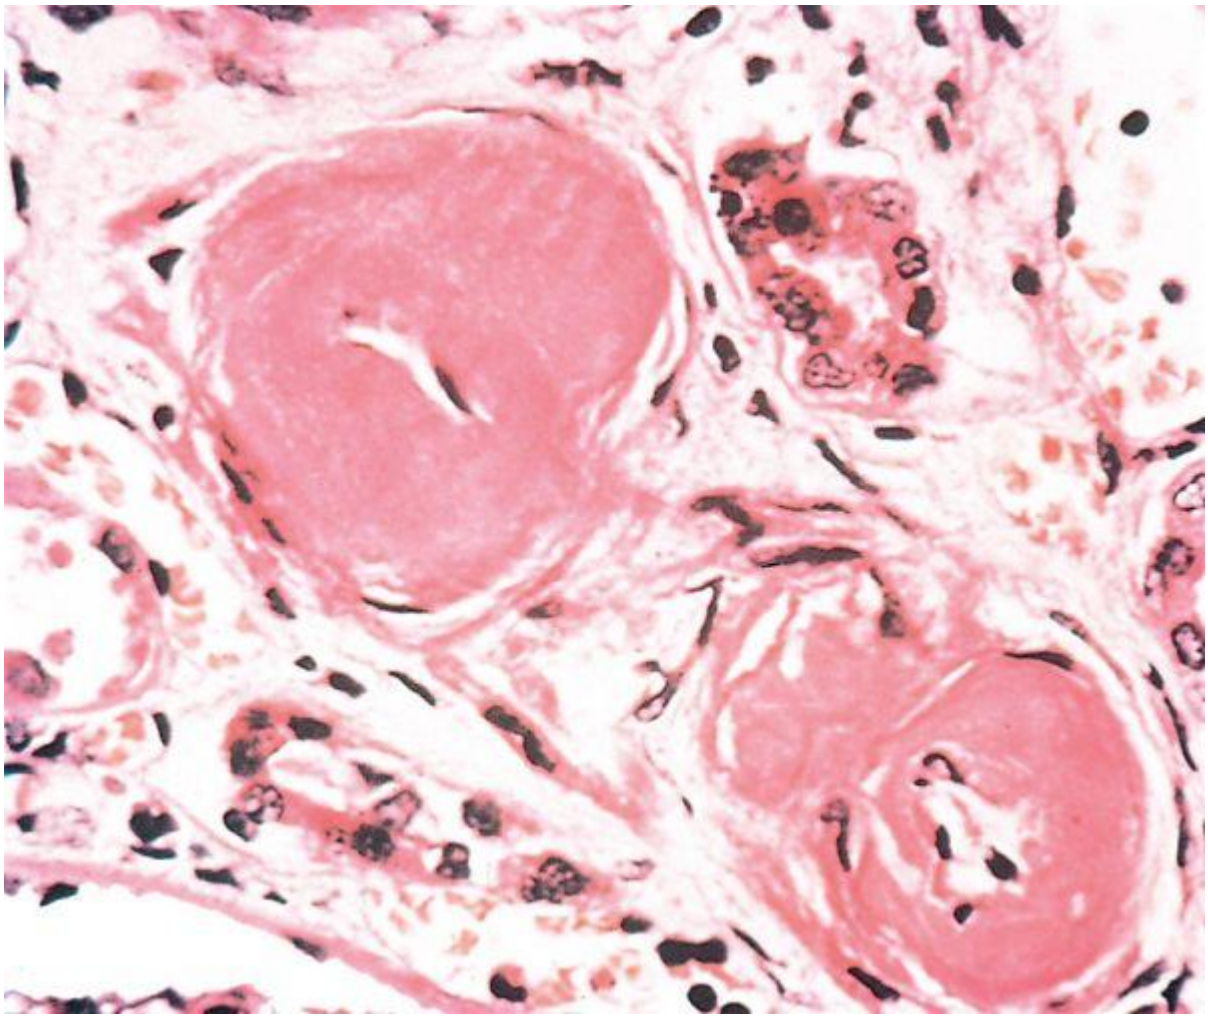

FIGURE 20-39 Hyaline arteriolosclerosis. High-power view of two arterioles with hyaline deposition, marked thickening of the walls, and a narrowed lumen. *(Courtesy of Dr. M.A. Venkatachalam, Department of Pathology, University of Texas Health Sciences Center, San Antonio, TX.)*

Clinical Features.

It is unusual for uncomplicated benign nephrosclerosis to cause renal insufficiency or uremia. There are usually moderate reductions in renal blood flow, but the GFR is normal or only slightly reduced. On occasion, there is mild proteinuria. However, three groups of hypertensive patients with benign nephrosclerosis are at increased risk of developing renal failure: people of African descent, people with more severe blood pressure elevations, and persons with a second underlying disease, especially diabetes. In these groups renal insufficiency may supervene after prolonged benign hypertension, but more rapid renal failure results from the development of the malignant or accelerated phase of hypertension, discussed next.

MALIGNANT HYPERTENSION AND ACCELERATED NEPHROSCLEROSIS

Malignant nephrosclerosis is the form of renal disease associated with the malignant or accelerated phase of hypertension.[76] This dramatic pattern of hypertension may occasionally develop in previously

normotensive individuals but often is superimposed on preexisting essential benign hypertension, secondary forms of hypertension, or an underlying chronic renal disease, particularly glomerulonephritis or reflux nephropathy (Chapter 11). It is also a frequent cause of death from uremia in individuals with scleroderma. Malignant hypertension is relatively uncommon, occurring in 1% to 5% of all people with elevated blood pressure. In its pure form it usually affects younger individuals, and occurs more often in men and in blacks.

Pathogenesis.

The basis for this turn for the worse in hypertensive subjects is unclear, but the following sequence of events is suggested. The initial insult seems to be some form of vascular damage to the kidneys. This might result from long-standing benign hypertension, with eventual injury to the arteriolar walls, or the initiating injury may spring de novo from arteritis, a coagulopathy, or some injury causing acute exacerbation of the hypertension. In any case, the result is increased permeability of the small vessels to fibrinogen and other plasma proteins, endothelial injury, focal death of cells of the vascular wall, and platelet deposition. This leads to the appearance of *fibrinoid necrosis* of arterioles and small arteries, swelling of the vascular intima, and intravascular thrombosis. Mitogenic factors from platelets (e.g., PDGF), plasma, and other cells cause hyperplasia of intimal smooth muscle of vessels, resulting in the hyperplastic arteriolosclerosis that is typical of malignant hypertension and further narrowing of the lumens. The kidneys become markedly ischemic. With severe involvement of the renal afferent arterioles, the renin-angiotensin system receives a powerful stimulus; indeed, *patients with malignant hypertension have markedly elevated levels of plasma renin*. This sets up a self-perpetuating cycle in which angiotensin II causes intrarenal vasoconstriction, and the attendant renal ischemia perpetuates renin secretion. Other vasoconstrictors (e.g., endothelin) and loss of vasodilators (nitric oxide) may also contribute to vasoconstriction. Aldosterone levels are also elevated, and salt retention undoubtedly contributes to the elevation of blood pressure. The consequences of the markedly elevated blood pressure on the blood vessels throughout the body are known as *malignant arteriosclerosis*, and the renal disorder is malignant nephrosclerosis.

Morphology. On gross inspection the kidney size depends on the duration and severity of the hypertensive disease. Small, pinpoint petechial hemorrhages may appear on the cortical surface from rupture of arterioles or glomerular capillaries, giving the kidney a peculiar “flea-bitten” appearance.

Two histologic alterations characterize blood vessels in malignant hypertension (Fig. 20-40):

- **Fibrinoid necrosis of arterioles**. This appears as an eosinophilic granular change in the blood vessel wall, which stains positively for fibrin by histochemical or immunofluorescence techniques. This change represents an acute event; it may be accompanied by limited inflammatory infiltrate within the wall, but prominent inflammation is not seen. Sometimes the glomeruli become necrotic and infiltrated with neutrophils, and the glomerular capillaries may thrombose.
- In the interlobular arteries and arterioles, there is intimal thickening caused by a proliferation of elongated, concentrically arranged smooth muscle cells, together with fine concentric layering of collagen and accumulation of pale-staining material that probably represents accumulations of proteoglycans and plasma proteins. This alteration has been referred to as **onion-skinning** because of its concentric appearance. The lesion, also called hyperplastic arteriolitis, correlates well with renal failure in malignant hypertension. There may be superimposed intraluminal thrombosis. The arteriolar and arterial lesions result in considerable narrowing of all vascular lumens, ischemic atrophy and, at times, infarction distal to the abnormal vessels.

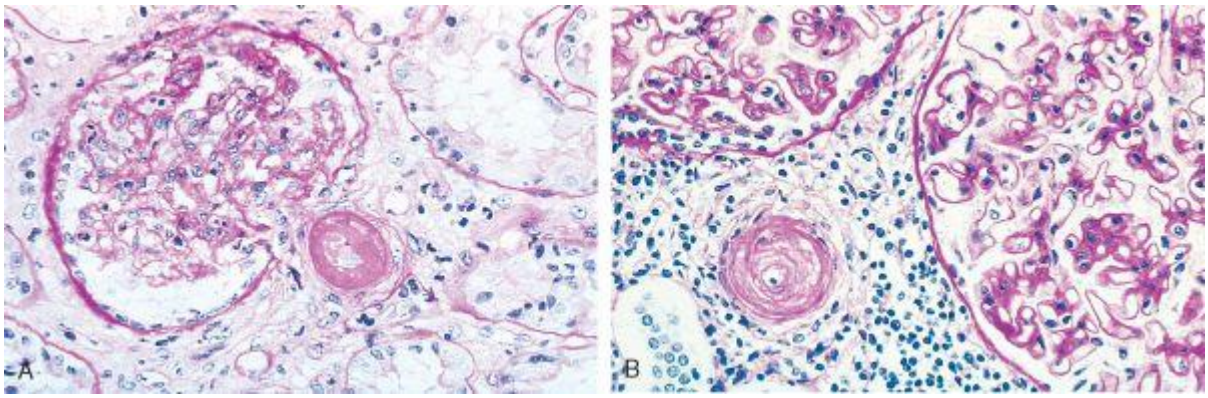

FIGURE 20-40 Malignant hypertension. **A**, Fibrinoid necrosis of afferent arteriole (PAS stain). **B**, Hyperplastic arteriolitis (onion-skin lesion). *(Courtesy of Dr. H. Rennke, Brigham and Women's Hospital, Boston, MA.)*

Clinical Features.

The full-blown syndrome of malignant hypertension is characterized by systolic pressures greater than 200 mm Hg and diastolic pressures greater than 120 mm Hg, papilledema, retinal hemorrhages, encephalopathy, cardiovascular abnormalities, and renal failure. Most often, the early symptoms are related to increased intracranial pressure and include headaches, nausea, vomiting, and visual impairments, particularly scotomas or spots before the eyes. "Hypertensive crises" are sometimes encountered, characterized by episodes of loss of consciousness or even convulsions. At the onset of rapidly mounting blood pressure, there is marked proteinuria and microscopic or sometimes macroscopic hematuria but no significant alteration in renal function. Soon, however, renal failure makes its appearance. The syndrome is a true medical emergency requiring the institution of aggressive and prompt antihypertensive therapy to prevent the development of irreversible renal lesions. Before the introduction of current antihypertensive drugs, malignant hypertension was associated with a 50% mortality rate within 3 months of onset, progressing to 90% within a year. At present, however, about 75% of patients survive 5 years, and 50% survive with restoration of pre-crisis renal function.

RENAL ARTERY STENOSIS

Unilateral renal artery stenosis is a relatively uncommon cause of hypertension, responsible for 2% to 5% of cases, but is important because it represents a potentially curable form of hypertension with surgical treatment. Furthermore, important insights into renal mechanisms of hypertension came from studies of experimental and human renal artery stenosis.

Pathogenesis.

The classic experiments of Goldblatt and colleagues[78] showed that constriction of one renal artery in dogs results in hypertension and that the magnitude of the effect is roughly proportional to the amount of constriction. Later experiments in rats confirmed these results, and in time it was shown that the hypertensive effect, at least initially, is due to stimulation of renin secretion by cells of the juxtaglomerular apparatus and the subsequent production of the vasoconstrictor angiotensin II. *A large proportion of individuals with renovascular hypertension have elevated plasma or renal vein renin levels*, and almost all show a reduction of blood pressure when given drugs that block the activity of angiotensin II. Furthermore, unilateral renal renin hypersecretion can be normalized after renal

revascularization, usually resulting in a decrease in blood pressure. Other factors, however, may contribute to the maintenance of renovascular hypertension after the renin-angiotensin system has initiated it, including *sodium retention* and possibly endothelin and loss of nitric oxide.

Morphology. The most common cause of renal artery stenosis (70% of cases) is occlusion by an atheromatous plaque at the origin of the renal artery. This lesion occurs more frequently in men, and the incidence increases with advancing age and diabetes mellitus. The plaque is usually concentrically placed, and superimposed thrombosis often occurs.

The second type of lesion leading to stenosis is so-called **fibromuscular dysplasia** of the renal artery. This is a heterogeneous group of lesions characterized by fibrous or fibromuscular thickening and may involve the intima, the media, or the adventitia of the artery. These lesions are thus subclassified into intimal, medial, and adventitial hyperplasia, the medial type being by far the most common (Fig. 20-41). The stenoses, as a whole, are more common in women and tend to occur in younger age groups (i.e., in the third and fourth decades). The lesions may consist of a single well-defined constriction or a series of narrowings, usually in the middle or distal portion of the renal artery. They may also involve the segmental branches and may be bilateral.

The ischemic kidney is usually reduced in size and shows signs of diffuse ischemic atrophy, with crowded glomeruli, atrophic tubules, interstitial fibrosis, and focal inflammatory infiltrates. The arterioles in the ischemic kidney are usually protected from the effects of high pressure, thus showing only mild arteriolosclerosis. In contrast, the contralateral nonischemic kidney may show more severe arteriolosclerosis, depending on the severity of the hypertension.

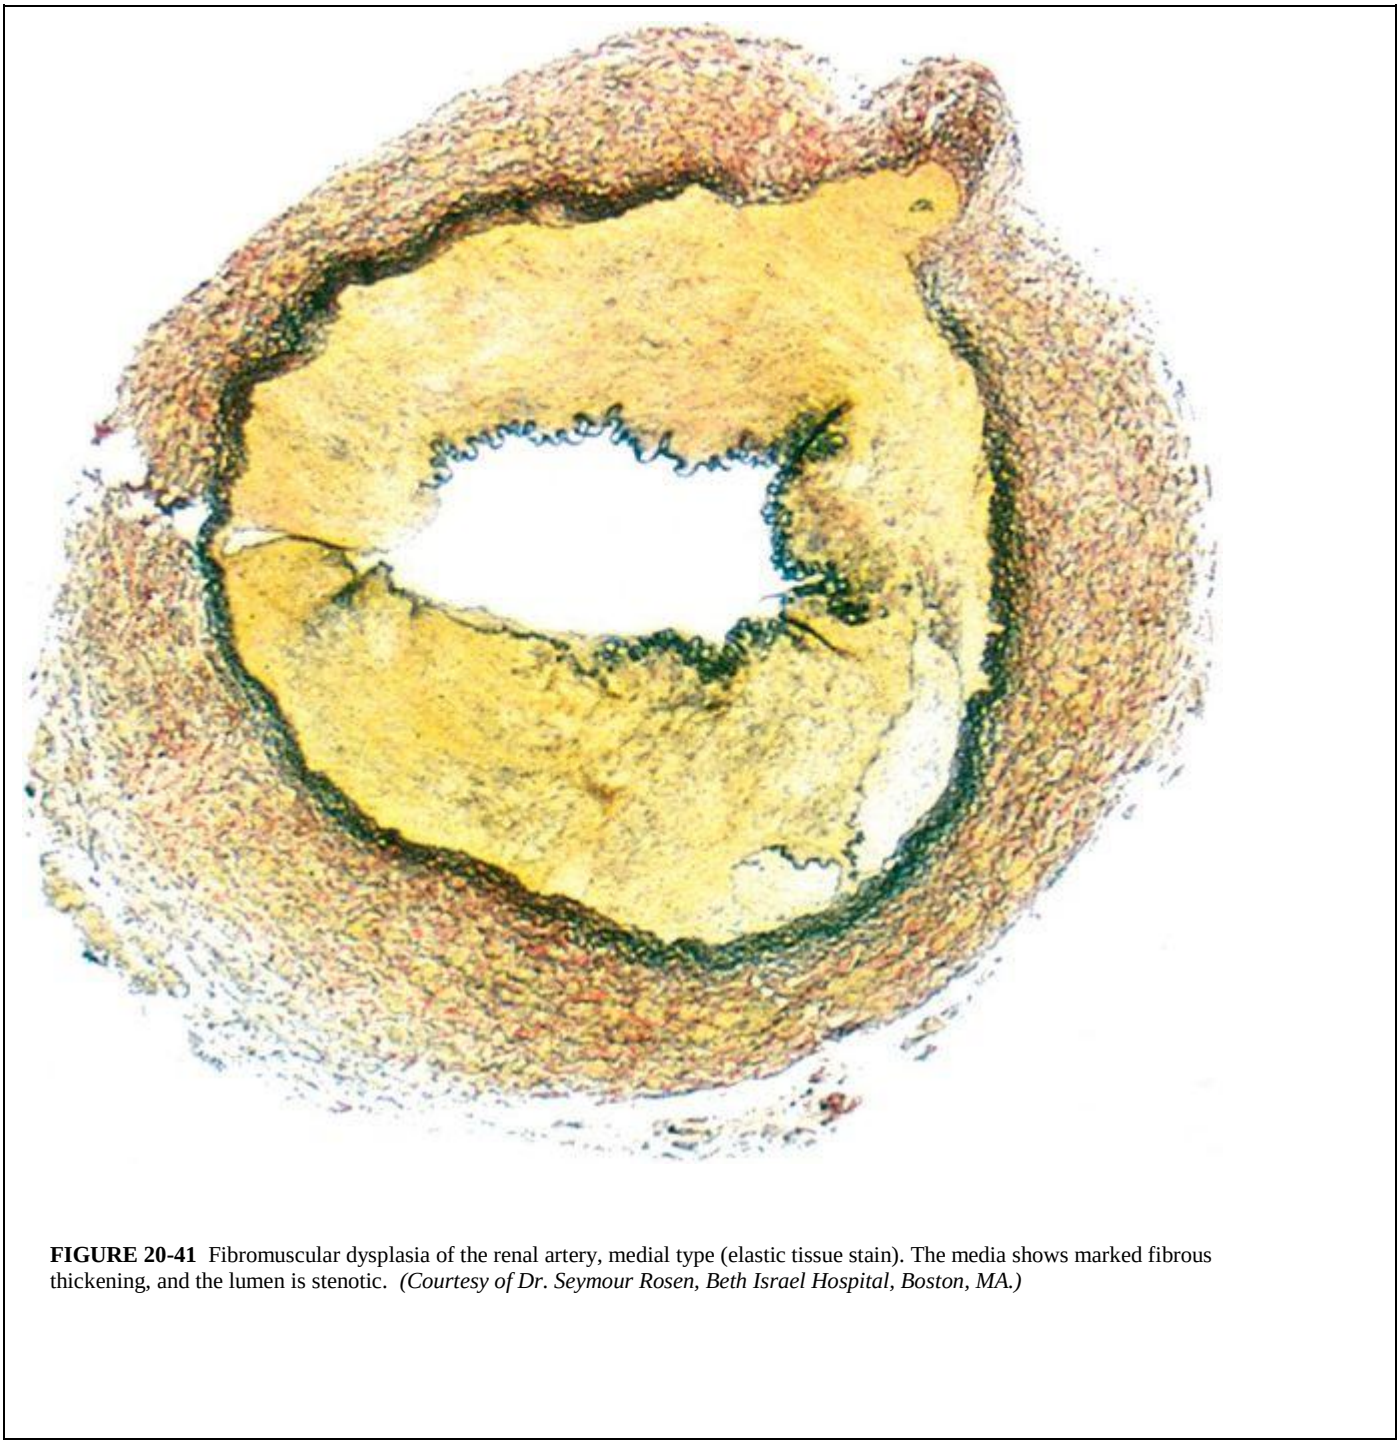

FIGURE 20-41 Fibromuscular dysplasia of the renal artery, medial type (elastic tissue stain). The media shows marked fibrous thickening, and the lumen is stenotic. *(Courtesy of Dr. Seymour Rosen, Beth Israel Hospital, Boston, MA.)*

Clinical Course.

Few distinctive features suggest the presence of renal artery stenosis, and in general, these patients resemble those with essential hypertension. On occasion, a bruit can be heard on auscultation of the affected kidneys. Elevated plasma or renal vein renin, response to angiotensin-converting enzyme inhibitor, renal scans, and intravenous pyelography may aid with diagnosis, but arteriography is required to localize the stenotic lesion. The cure rate after surgery is 70% to 80% in well-selected cases.

THROMBOTIC MICROANGIOPATHIES

As was described in Chapter 14 , *this group of disorders is characterized clinically by microangiopathic hemolytic anemia, thrombocytopenia, and (in many cases) renal failure, and morphologically by*

thrombotic lesions in capillaries and arterioles in various tissue beds, including those of the kidney (Fig. 20-42).[79,][80] Schistocytes (fragmented red cells) in peripheral blood smears provide an important clue to the diagnosis. Unlike DIC, these disorders are generally associated with normal coagulation times and normal or only slightly elevated fibrin split products.

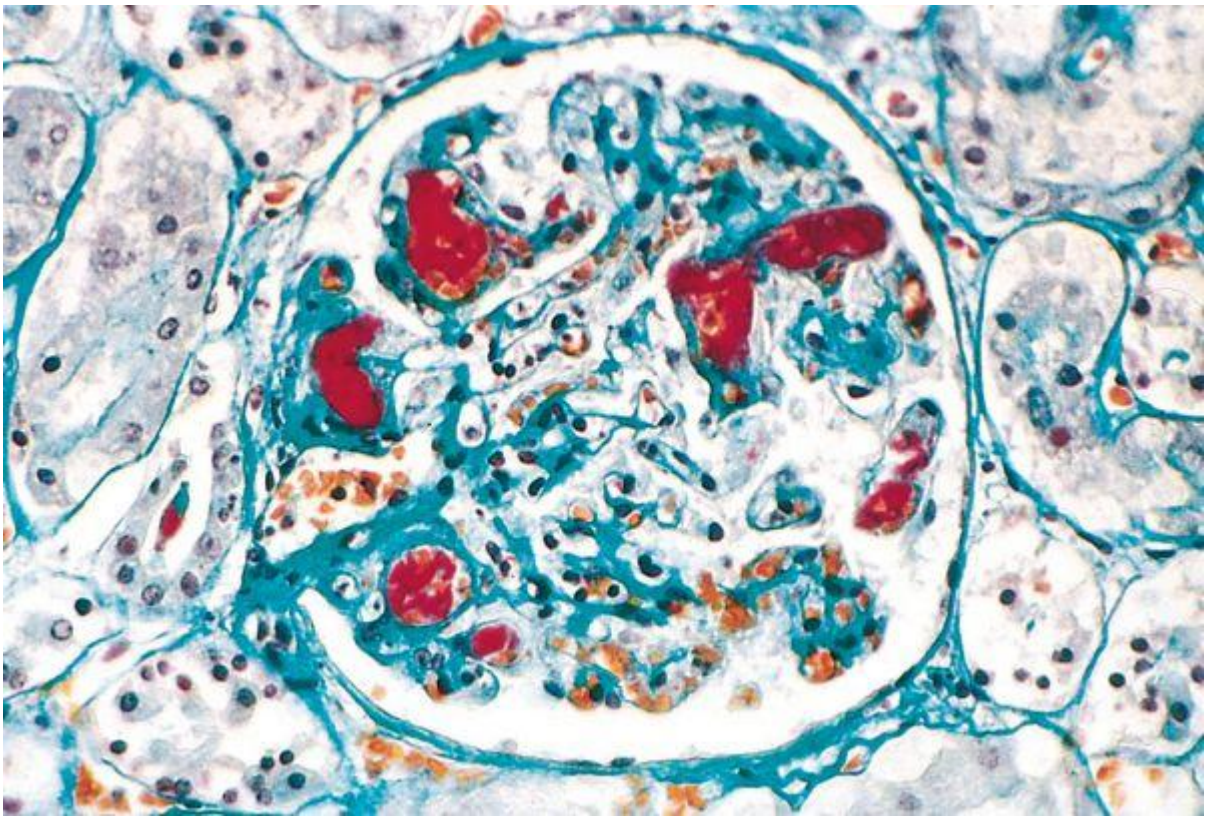

FIGURE 20-42 Fibrin stain showing platelet-fibrin thrombi (*red*) in the glomerular capillaries, characteristic of thrombotic microangiopathic disorders.

The classification of these disorders has been muddied by the fact that the two main forms, hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP), show considerable overlap in their clinical features.[80,][81] However, it is now evident that the category of HUS/TTP includes several entities with distinct causes, natural histories, and therapeutic approaches. We will thus classify these disorders according to our current understanding of their causes or associations, as follows:

1. *Typical HUS (synonyms: epidemic, classic, diarrheapositive)*, most frequently associated with consumption of food contaminated by bacteria producing Shiga-like toxins
2. *Atypical HUS (synonyms: non-epidemic, diarrheanegative)*, associated with:
    a. Inherited mutations of complement-regulatory proteins
    b. Diverse acquired causes of endothelial injury, including: antiphospholipid antibodies; complications of pregnancy and oral contraceptives; vascular renal diseases such as scleroderma and hypertension; chemotherapeutic and immunosuppressive drugs; and radiation
3. *TTP*, which is often associated with inherited or acquired deficiencies of ADAMTS13, a plasma metalloprotease that regulates the function of von Willebrand factor (vWF)

Pathogenesis.

Within the thrombotic microangiopathies, two pathogenetic triggers dominate: (1) *endothelial injury*, and (2) *platelet activation and aggregation*. As will be discussed, endothelial injury appears to be the primary cause of HUS, whereas platelet activation may be the inciting event in TTP.

Endothelial Injury.

In typical (epidemic, classic, diarrhea-positive) HUS, the trigger for endothelial injury and activation is usually a Shiga-like toxin, while in inherited forms of atypical HUS the cause of the endothelial injury appears to be excessive, inappropriate activation of complement. Many other exposures and conditions can occasionally precipitate a HUS-like picture, presumably also by injuring the endothelium. The endothelial injury in HUS appears to cause platelet activation and thrombosis within microvascular beds. There is evidence that reduced endothelial production of prostaglandin I_2 and NO (both inhibitors of platelet aggregation) contributes to thrombosis. The reduction in these two factors and increased production of endothelium-derived endothelin may also promote vasoconstriction, exacerbating the hypoperfusion of tissues. Finally, adhesion molecules expressed on injured endothelium result in the recruitment of leukocytes, which may also contribute to thrombosis, as described in Chapter 4 .

Platelet Aggregation.

In contrast to HUS, in TTP the initiating event appears to be platelet aggregation induced by very large multimers of vWF, which accumulate due to a deficiency of ADAMTS13, a plasma protease that cleaves vWF multimers into smaller sizes. The deficiency of ADAMTS13 is most often caused by autoantibodies that inhibit ADAMTS13 function. Less commonly, a chronic relapsing and remitting form of TTP is associated with inherited deficiencies of ADAMTS13. Very large vWF multimers can bind platelet surface glycoproteins and activate platelets spontaneously, providing a pathophysiologic explanation for the microthrombi that are observed in vascular beds.[80,][82]

Regardless of the trigger, tissue dysfunction in all forms of HUS/TTP appears to result from the formation of microthrombi, *vascular obstruction*, and tissue ischemia.[80] We will first describe the various subtypes of HUS/TTP, and then return to the morphologic features that are common to all.

Typical (epidemic, classic, diarrhea-positive) Hemolytic-Uremic Syndrome.

This is the best-characterized form of HUS. Most cases occur following intestinal infection with strains of *E. coli* (the most common being O157:H7) that produce Shiga-like toxins,[83] so-called because they resemble those made by *Shigella dysenteriae* (Chapter 17). Epidemics have been traced to various sources, most commonly the ingestion of contaminated ground meat (as in hamburgers), but also drinking water, raw milk, and person-to-person transmission. However, most cases of typical HUS caused by *E. coli* are sporadic. Less commonly, infections by other agents, including *Shigella dysenteriae*, can give rise to a similar clinical picture.

Typical HUS can occur in adults, particularly the elderly, but it affects children preferentially, in whom it is one of the main causes of acute renal failure. Following a prodrome of influenza-like or diarrheal symptoms, there is a *sudden onset of bleeding manifestations (especially hematemesis and melena), severe oliguria, and hematuria, associated with microangiopathic hemolytic anemia, thrombocytopenia, and (in some patients) prominent neurologic changes*. Hypertension is present in about half the patients.

Shiga-like toxin injures endothelial cells, inducing increased expression of leukocyte adhesion molecules; increased endothelin and decreased nitric oxide production; and in the presence of cytokines such as TNF, endothelial apoptosis. These alterations lead to platelet activation and induce vasoconstriction, resulting in the characteristic microangiopathy. There is also some evidence that Shiga-like toxins bind and directly activate platelets.

In typical HUS, if the renal failure is managed properly with dialysis, most patients recover normal renal function in a matter of weeks. However, due to underlying renal damage the long-term (15 to 25 year) outlook is more guarded. In one study, only 10 of 25 patients with prior epidemic HUS had normal renal function, and 7 had chronic kidney disease.

Atypical (non-epidemic, diarrhea-negative) Hemolytic-Uremic Syndrome.

Atypical HUS occurs mainly in adults in a number of different settings. More than half of those affected have an inherited deficiency of complement-regulatory proteins, most commonly factor H, which normally breaks down the alternative pathway C3 convertase and protects cells from damage by uncontrolled complement activation (Chapter 2).[82] A small number of patients have mutations in two other proteins that regulate complement, complement factor I and CD46 (membrane cofactor protein). Patients with genetic mutations in complement-regulatory proteins may develop HUS at any age. Roughly half of affected individuals have a course marked by multiple relapses and progression to end-stage renal disease. As the deficiencies in complement-regulatory factors are life-long, it is a mystery why the onset of HUS is delayed; additional unknown co-factors that trigger the development of HUS are suspected.

A variety of miscellaneous conditions or exposures are occasionally associated with atypical forms of HUS. These include:

1. The *antiphospholipid syndrome*, either primary or secondary to SLE (lupus anticoagulant). The syndrome is described in detail in Chapter 4 . In this setting the microangiopathy tends to follow a chronic course.
2. Complications of pregnancy or the postpartum period. So-called *postpartum renal failure* is a form of HUS that usually occurs after an uneventful pregnancy, 1 day to several months after delivery. The condition has a grave prognosis, although recovery can occur in milder cases.
3. *Vascular diseases affecting the kidney*, such as systemic sclerosis and malignant hypertension.
4. Chemotherapeutic and immunosuppressive drugs, such as mitomycin, cyclosporine, cisplatin, and gemcitabine.
5. Irradiation of the kidney.

Patients with atypical HUS do not fare as well as those with typical HUS, in large part because the underlying conditions may be chronic and difficult to treat.[80] As in typical HUS, some patients have neurologic symptoms; the disease in these patients can be distinguished from TTP by the presence of normal ADAMTS13 levels in the plasma (see below).

Thrombotic Thrombocytopenic Purpura.

TTP is classically manifested by the pentad of fever, neurologic symptoms, microangiopathic hemolytic anemia, thrombocytopenia, and renal failure.[80] As discussed above, it is usually caused by antibodies (either autoimmune or drug-induced) or genetic defects that lead to functional deficits in ADAMTS13.[82] The most common cause of deficient ADAMTS13 activity is inhibitory autoantibodies, and the majority of those with such antibodies are women. Regardless of cause, most patients present as adults at ages younger than 40.

In TTP, central nervous system involvement is the dominant feature, whereas renal involvement occurs in only about 50% of patients. The clinical findings are dictated by the distribution of the microthrombi, which are found in arterioles throughout the body. Untreated, the disease was once highly fatal, but in those with autoantibodies exchange transfusions and immunosuppressive therapy have reduced the mortality to less than 50%. As in HUS associated with inherited deficiencies of complement regulatory

proteins, it is not understood why those with life-long genetic deficiency of ADAMTS13 present in adulthood. Such patients tend to follow a relapsing and remitting course.

Morphology. The morphological findings in the various forms of HUS/TTP show considerable overlap, and vary mainly according to chronicity rather than cause. In acute, active disease the kidney may show patchy or diffuse cortical necrosis (described later) and subcapsular petechiae. On microscopic examination, the glomerular capillaries are occluded by thrombi composed of aggregated platelets and to a lesser extent fibrin. The capillary walls are thickened due to endothelial cell swelling and subendothelial deposits of cell debris and fibrin. Disruption of the mesangial matrix and damage to the mesangial cells often results in mesangiolyis. Interlobular arteries and arterioles often show fibrinoid necrosis of the wall and occlusive thrombi. Chronic disease is confined to patients with atypical HUS or TTP, and has features that stem from continued injury and attempts at healing. The renal cortex reveals various degrees of scarring. By light microscopy the glomeruli are mildly hypercellular and have marked thickening of the capillary walls associated with splitting or reduplication of the basement membrane (so called double contours or tram tracks). The walls of arteries and arterioles often exhibit increased layers of cells and connective tissue ("onion-skinning") that narrow the vessel lumens. These changes lead to persistent hypoperfusion and ischemic atrophy of the parenchyma, which manifests clinically as renal failure and hypertension.

OTHER VASCULAR DISORDERS

Atherosclerotic Ischemic Renal Disease

We have seen that atherosclerotic unilateral renal artery stenosis can lead to hypertension. *Bilateral renal artery disease*, usually diagnosed definitively by arteriography, now seems to be a fairly common cause of chronic ischemia with renal insufficiency in older individuals, sometimes in the absence of hypertension.[84,][85] The importance of recognizing this condition is that surgical revascularization is beneficial in reversing further decline in renal function.

Atheroembolic Renal Disease

Embolization of fragments of atheromatous plaques from the aorta or renal artery into intraparenchymal renal vessels occurs in elderly patients with severe atherosclerosis, especially after surgery on the abdominal aorta, aortography, or intra-aortic cannulization. These emboli can be recognized in the lumens and walls of arcuate and interlobular arteries by their content of cholesterol crystals, which appear as rhomboid clefts (Fig. 20-43). The clinical consequences of atheroemboli vary according to the number of emboli and the preexisting state of renal function. Frequently they have no functional significance. However, acute renal failure may develop in elderly patients in whom renal function is already compromised, principally after abdominal surgery on atherosclerotic aneurysms.

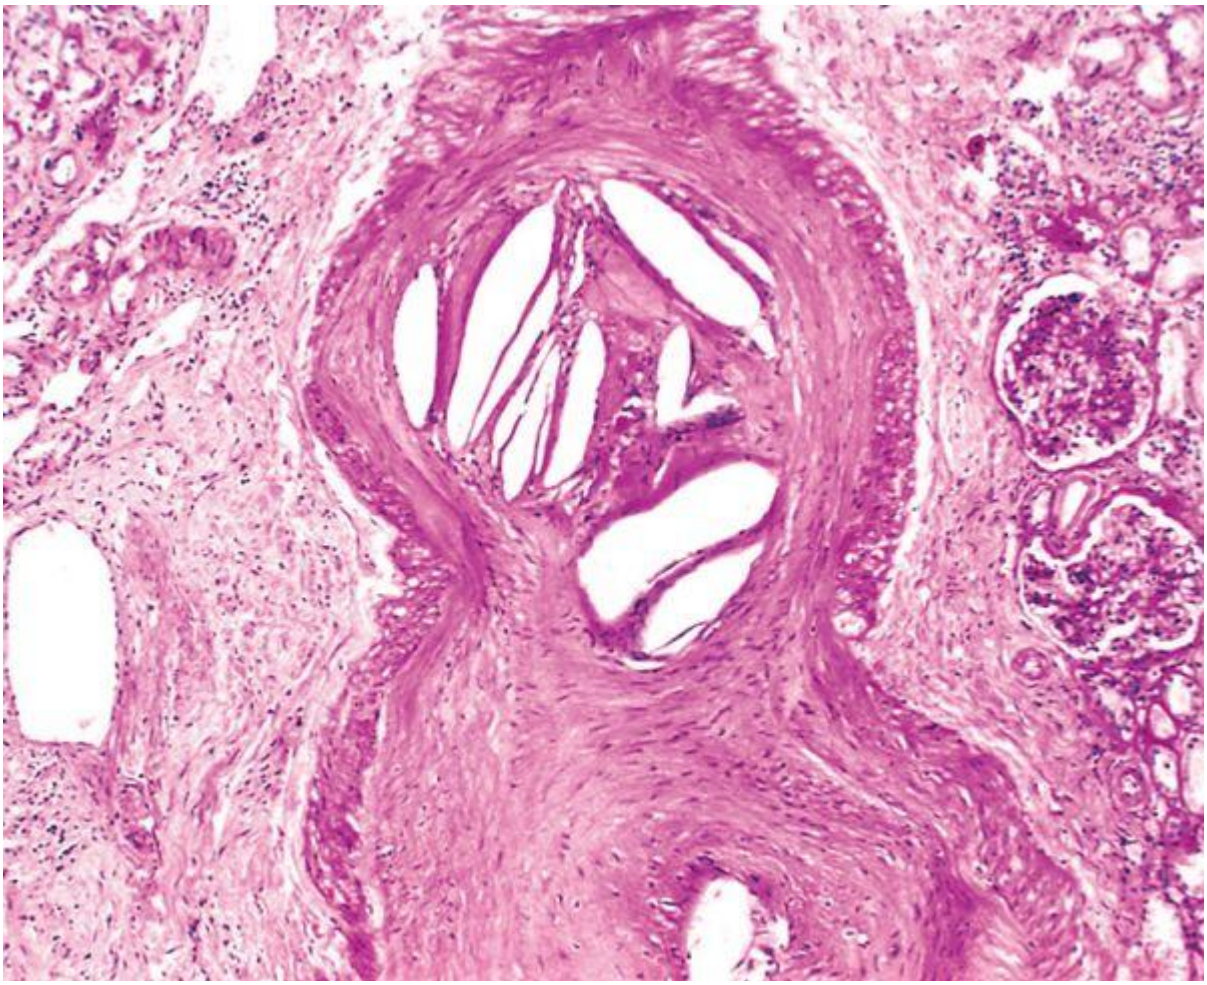

FIGURE 20-43 Atheroemboli with typical cholesterol clefts in an interlobar artery.

Sickle-Cell Disease Nephropathy

Sickle-cell disease (homozygous) or trait (heterozygous) may lead to a variety of alterations in renal morphology and function, some of which produce clinically significant abnormalities. The various manifestations are termed *sickle-cell nephropathy*.

The most common clinical and functional abnormalities are *hematuria* and a *diminished concentrating ability* (hyposthenuria). These are thought to be due largely to accelerated sickling in the hypertonic hypoxic milieu of the renal medulla; the hyperosmolarity dehydrates red cells and increases intracellular HbS concentrations, which likely explains why even those with sickle trait are affected. Patchy *papillary necrosis* may occur in both homozygotes and heterozygotes; this is sometimes associated with cortical scarring. *Proteinuria* is also common in sickle-cell disease, occurring in about 30% of patients. It is usually mild to moderate, but on occasion the overt nephrotic syndrome arises, associated with sclerosing glomerular lesions.

Diffuse Cortical Necrosis

This is an uncommon condition that occurs most frequently after an obstetric emergency, such as abruptio placentae (premature separation of the placenta), septic shock, or extensive surgery. When

bilateral and symmetric, it is fatal in the absence of supportive therapy. The cortical destruction has the features of ischemic necrosis. Glomerular and arteriolar microthrombi are found in most cases, and clearly contribute to the necrosis and renal damage. The morphologic features have considerable overlap with thrombotic microangiopathy and disseminated intravascular coagulation, but the pathogenetic sequence of events in this injury remains obscure.

Morphology. The gross alterations of massive ischemic necrosis are sharply limited to the cortex (Fig. 20-44). The histologic appearance is that of acute ischemic infarction. The lesions may be patchy, with areas of coagulative necrosis and apparently better preserved cortex. Intravascular and intraglomerular thromboses may be prominent but are usually focal, and acute necroses of small arterioles and capillaries may occasionally be present. Hemorrhages occur into the glomeruli, together with the formation of fibrin plugs in the glomerular capillaries.

FIGURE 20-44 Diffuse cortical necrosis. The pale ischemic necrotic areas are confined to the cortex and columns of Bertin.

Massive acute cortical necrosis is of grave significance, since it gives rise to sudden anuria, terminating rapidly in uremic death. Instances of unilateral or patchy involvement are compatible with survival.

Renal Infarcts

The kidneys are favored sites for the development of infarcts. Contributing to this predisposition is the extensive blood flow to the kidneys (one fourth of the cardiac output), but probably more important is the "end-organ" nature of the arterial blood supply and the extremely limited collateral circulation from extrarenal sites (essentially small blood vessels penetrating from the renal capsule). Although thrombosis in advanced atherosclerosis and the acute vasculitis of polyarteritis nodosa may occlude arteries, most infarcts are due to embolism. A major source of such emboli is mural thrombosis in the left atrium and ventricle as a result of myocardial infarction. Vegetative endocarditis, aortic aneurysms, and aortic atherosclerosis are less frequent sources of emboli.

Morphology. Because of the end-organ type of arterial supply, most renal infarcts are of the "white" anemic variety. They may be solitary lesions or may be multiple and bilateral. Within 24 hours infarcts become sharply demarcated, pale, yellow-white areas that may contain small irregular foci of hemorrhagic discoloration. They are usually ringed by a zone of intense hyperemia.

On section the infarcts are wedge-shaped, with the base against the cortical surface and the apex pointing toward the medulla. There may be a narrow rim of preserved subcortical tissue that has been spared by the collateral capsular circulation. In time these acute areas of ischemic necrosis undergo progressive fibrous scarring, giving rise to depressed, pale, gray-white scars that assume a V-shape on section. The histologic changes in renal infarction are those of ischemic coagulative necrosis, described in Chapter 1 .

Many renal infarcts are clinically silent. Sometimes, pain with tenderness localized to the costovertebral angle occurs, associated with showers of red cells in the urine. Large infarcts of one kidney are probably associated with narrowing of the renal artery or one of its major branches, which in turn may be a cause of hypertension.

3.10.5 Congenital Anomalies

About 10% of all people are born with potentially significant malformations of the urinary system. Renal dysplasias and hypoplasias account for 20% of chronic renal failure in children.

Congenital renal disease can be hereditary but is most often the result of an acquired developmental defect that arises during gestation. As was discussed in Chapter 10 , defects in genes involved in development, including the Wilms tumor–associated genes, cause urogenital anomalies. As a rule, developmental abnormalities involve structural components of the kidney and urinary tract, causing syndromes termed CAKUT (congenital abnormalities of the kidney and urinary tract). However, genetic abnormalities also cause enzymatic or metabolic defects in tubular transport, such as cystinuria and renal tubular acidosis. Here, we restrict the discussion to structural anomalies involving primarily the kidney. All except horseshoe kidney are uncommon. Anomalies of the lower urinary tract are discussed in Chapter 21 .

Agenesis of the Kidney.

Bilateral agenesis, which is incompatible with life, is usually encountered in stillborn infants. It is often associated with many other congenital disorders (e.g., limb defects, hypoplastic lungs) and leads to early death. Unilateral agenesis is an uncommon anomaly that is compatible with normal life if no other abnormalities exist. The opposite kidney is usually enlarged as a result of compensatory hypertrophy. Some patients eventually develop progressive glomerular sclerosis in the remaining kidney as a result of

the adaptive changes in hypertrophied nephrons, discussed earlier in the chapter, and in time, chronic kidney disease ensues.

Hypoplasia.

Renal hypoplasia refers to failure of the kidneys to develop to a normal size. This anomaly may occur bilaterally, resulting in renal failure in early childhood, but it is more commonly encountered as a unilateral defect. True renal hypoplasia is extremely rare; most cases reported probably represent acquired scarring due to vascular, infectious, or other parenchymal diseases rather than an underlying developmental failure. Differentiation between congenital and acquired atrophic kidneys may be impossible, but *a truly hypoplastic kidney shows no scars and has a reduced number of renal lobes and pyramids*, usually six or fewer. In one form of hypoplastic kidney, *oligomeganephronia*, the kidney is small with fewer nephrons that are markedly hypertrophied.

Ectopic Kidneys.

The development of the definitive metanephros may occur in ectopic foci, usually at abnormally low levels. These kidneys lie either just above the pelvic brim or sometimes within the pelvis. They are usually normal or slightly small in size but otherwise are not remarkable. Because of their abnormal position, kinking or tortuosity of the ureters may cause some obstruction to urinary flow, which predisposes to bacterial infections.

Horseshoe Kidneys.

Fusion of the upper or lower poles of the kidneys produces a horseshoe-shaped structure that is continuous across the midline anterior to the great vessels. This anatomic anomaly is common and is found in about 1 in 500 to 1000 autopsies. Ninety percent of such kidneys are fused at the lower pole, and 10% are fused at the upper pole.

MULTICYSTIC RENAL DYSPLASIA

This sporadic disorder is due to an abnormality in metanephric differentiation *characterized histologically by the persistence in the kidney of abnormal structures—cartilage, undifferentiated mesenchyme, and immature collecting ductules—and by abnormal lobar organization*. Most cases are associated with ureteropelvic obstruction, ureteral agenesis or atresia, and other anomalies of the lower urinary tract.

Dysplasia can be unilateral or bilateral and is almost always cystic. The kidney is usually enlarged, extremely irregular, and multicystic (Fig. 20-45A). The cysts vary in size from microscopic structures to some that are several centimeters in diameter. On histologic examination, they are lined by flattened epithelium. Although normal nephrons are present, many have immature collecting ducts. The characteristic histologic feature is the *presence of islands of undifferentiated mesenchyme, often with cartilage, and immature collecting ducts* (Fig. 20-45B).

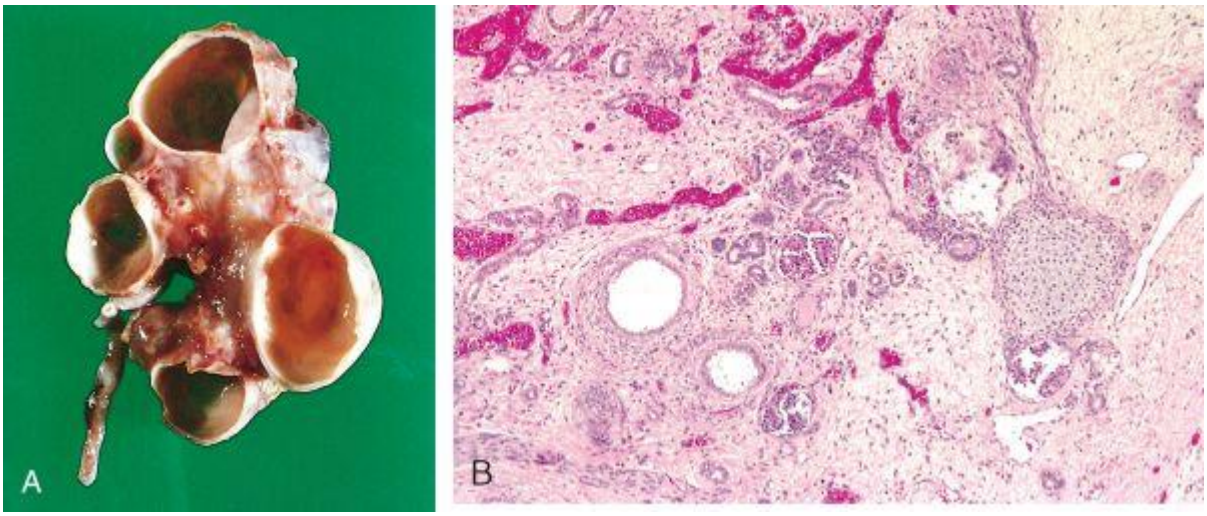

FIGURE 20-45 Multicystic renal dysplasia. **A**, Gross appearance. **B**, Histologic section showing disorganized architecture, dilated tubules with cuffs of primitive stroma, and an island of cartilage (H & E stain). *(**A**, Courtesy of Dr. D. Schofield, Children's Hospital, Los Angeles, CA; **B**, courtesy of Dr. Laura Finn, Children's Hospital, Seattle, WA.)*

When unilateral, the dysplasia is discovered by the appearance of a flank mass that leads to surgical exploration and nephrectomy. The function of the opposite kidney is normal, and such patients have an excellent prognosis after surgical removal of the affected kidney. In bilateral multicystic renal dysplasia, renal failure may ultimately result.

3.10.6 Cystic Diseases of the Kidney

Cystic diseases of the kidney are heterogeneous, comprising hereditary, developmental, and acquired disorders. As a group, they are important for several reasons: (1) They are reasonably common and often represent diagnostic problems for clinicians, radiologists, and pathologists; (2) some forms, such as adult polycystic kidney disease, are major causes of chronic kidney disease; and (3) they can occasionally be confused with malignant tumors. A useful classification of renal cysts is as follows:[86]

1. Multicystic renal dysplasia
2. Polycystic kidney disease
    a. Autosomal-dominant (adult) polycystic disease
    b. Autosomal-recessive (childhood) polycystic disease
3. Medullary cystic disease
    a. Medullary sponge kidney
    b. Nephronophthisis
4. Acquired (dialysis-associated) cystic disease
5. Localized (simple) renal cysts
6. Renal cysts in hereditary malformation syndromes (e.g., tuberous sclerosis)
7. Glomerulocystic disease
8. Extraparenchymal renal cysts (pyelocalyceal cysts, hilar lymphangitic cysts)

Only the more important of the cystic diseases are discussed below. Table 20-11 summarizes the characteristic features of the principal renal cystic diseases.

TABLE 20-11 -- Summary of Renal Cystic Diseases

	Inheritance	Pathologic Features	Clinical Features or Complications	Typical Outcome	Diagrammatic Representation
Adult polycystic kidney disease	Autosomal dominant	Large multicystic kidneys, liver cysts, berry aneurysms	Hematuria, flank pain, urinary tract infection, renal stones, hypertension	Chronic renal failure beginning at age 40–60 years	Childhood polycystic kidney disease	Autosomal recessive	Enlarged, cystic kidneys at birth	Hepatic fibrosis	Variable, death in infancy or childhood	
Medullary sponge kidney	None	Medullary cysts on excretory urography	Hematuria, urinary tract infection, recurrent renal stones	Benign	
Familial juvenile nephronophthisis	Autosomal recessive	Corticomedullary cysts, shrunken kidneys	Salt wasting, polyuria, growth retardation, anemia	Progressive renal failure beginning in childhood	
Adult-onset medullary cystic disease	Autosomal dominant	Corticomedullary cysts, shrunken kidneys	Salt wasting, polyuria	Chronic renal failure beginning in adulthood	

	Inheritance	Pathologic Features	Clinical Features or Complications	Typical Outcome	Diagrammatic Representation
Simple cysts	None	Single or multiple cysts in normal-sized kidneys	Microscopic hematuria	Benign	
Acquired renal cystic disease	None	Cystic degeneration in end-stage kidney disease	Hemorrhage, erythrocytosis, neoplasia	Dependence on dialysis	

AUTOSOMAL-DOMINANT (ADULT) POLYCYSTIC KIDNEY DISEASE

Autosomal-dominant (adult) polycystic kidney disease (ADPKD) is a hereditary disorder characterized by multiple expanding cysts of both kidneys that ultimately destroy the renal parenchyma and cause renal failure.[87] It is a common condition affecting roughly 1 of every 400 to 1000 live births and accounting for about 5% to 10% of cases of chronic renal failure requiring transplantation or dialysis. The pattern of inheritance is autosomal dominant, with high penetrance. Despite the autosomal dominant inheritance, as will be described later, the manifestation of the disease requires mutation of both alleles of either PKD gene. The disease is universally bilateral; reported unilateral cases probably represent multicystic dysplasia. The cysts initially involve only portions of the nephrons, so renal function is retained until about the fourth or fifth decade of life. ADPKD is genetically heterogeneous. Family studies show that the disease is caused by mutations in genes located on chromosome 16p13.3 (*PKD1*) and 4q21 (*PKD2*), and rare unlinked families point toward the presence of at least one additional disease-associated gene. Mutations of *PKD1* account for about 85% of cases (most of the remainder involving *PKD2*) and are associated with a more severe disease, end-stage renal disease or death occurring at an average age of 53 years as compared with 69 years for *PKD2*.[88] For *PKD1* mutations, the likelihood of developing renal failure is less than 5% by 40 years of age, rising to more than 35% by 50 years, more than 70% at 60 years of age, and more than 95% by 70 years of age.[89] Corresponding figures for *PKD2* are less than 5% at 50 years of age, about 15% at 60 years of age, and about 45% at 70 years of age.[87,][90] Although the major pathologic process is in the kidneys, adult polycystic kidney disease is a systemic disorder in which cysts and other anomalies also arise in other organs (discussed later).

Genetics and Pathogenesis.

A wide range of different mutations in *PKD1* and *PKD2* has been described, and this allelic heterogeneity has complicated genetic diagnosis of this disorder.

- The *PKD1* gene encodes a large (460-kD) integral membrane protein named *polycystin-1*, which has a large extracellular region, multiple transmembrane domains, and a short cytoplasmic tail.[90] It has been localized to tubular epithelial cells, particularly those of the distal nephron. At present its precise function is not known, but it contains domains that are usually involved in cell-cell and cell-matrix interactions.
- The *PKD2* gene product *polycystin-2* is an integral membrane protein.[90] It has been localized to all segments of the renal tubules and is also expressed in many extrarenal tissues. Polycystin-2 functions as a Ca2+-permeable cation channel, and a basic defect in ADPKD is a disruption in the regulation of intracellular Ca2+ levels.

The pathogenesis of polycystic disease is not established, but the hypothesis that is currently favored places the cilia-centrosome complex of tubular epithelial cells at the center of the disorder (Fig. 20-46).

[91] [92] [93] The epithelial cells of the kidney each contain a single nonmotile primary cilium, a 2–3 μm long hairlike organelle that projects into the tubular lumen from the apical surface of tubular cells. The cilium is made up of microtubules, and arises from and is attached to a basal body derived from the centriole. The cilia are part of a system of organelles and cellular structures that sense mechanical signals. It is believed that the apical cilia function in the kidney tubule as a mechanosensor to monitor changes in fluid flow and shear stress, while intercellular junctional complexes monitor forces between cells, and focal adhesions sense attachment to extracellular matrices. In response to external signals, these sensors regulate ion flux (cilia can induce Ca2+ flux in cultured kidney epithelial cells) and cellular behavior, including cell polarity and proliferation. The hypothesis that defects in mechanosensing, Ca2+ flux, and signal transduction underlie cyst formation is supported several observations.

- Both polycystin-1 and polycystin-2 are localized to the primary cilium.[91,][93] Other genes that are mutated in cystic diseases (such as the *NPHP* genes described below) encode proteins that are also localized to cilia and/or basal bodies.
- Knockout of the PKD1 gene in one model organism (the worm *C. elegans*) results in ciliary abnormalities and cyst formation.[92]
- Tubular cells obtained from mice with a deletion of the *PKD1* gene (which causes embryonic lethality in this species) have normal cilia architecture but not the flow-induced Ca2+ flux that occurs in normal tubular cells.[92]

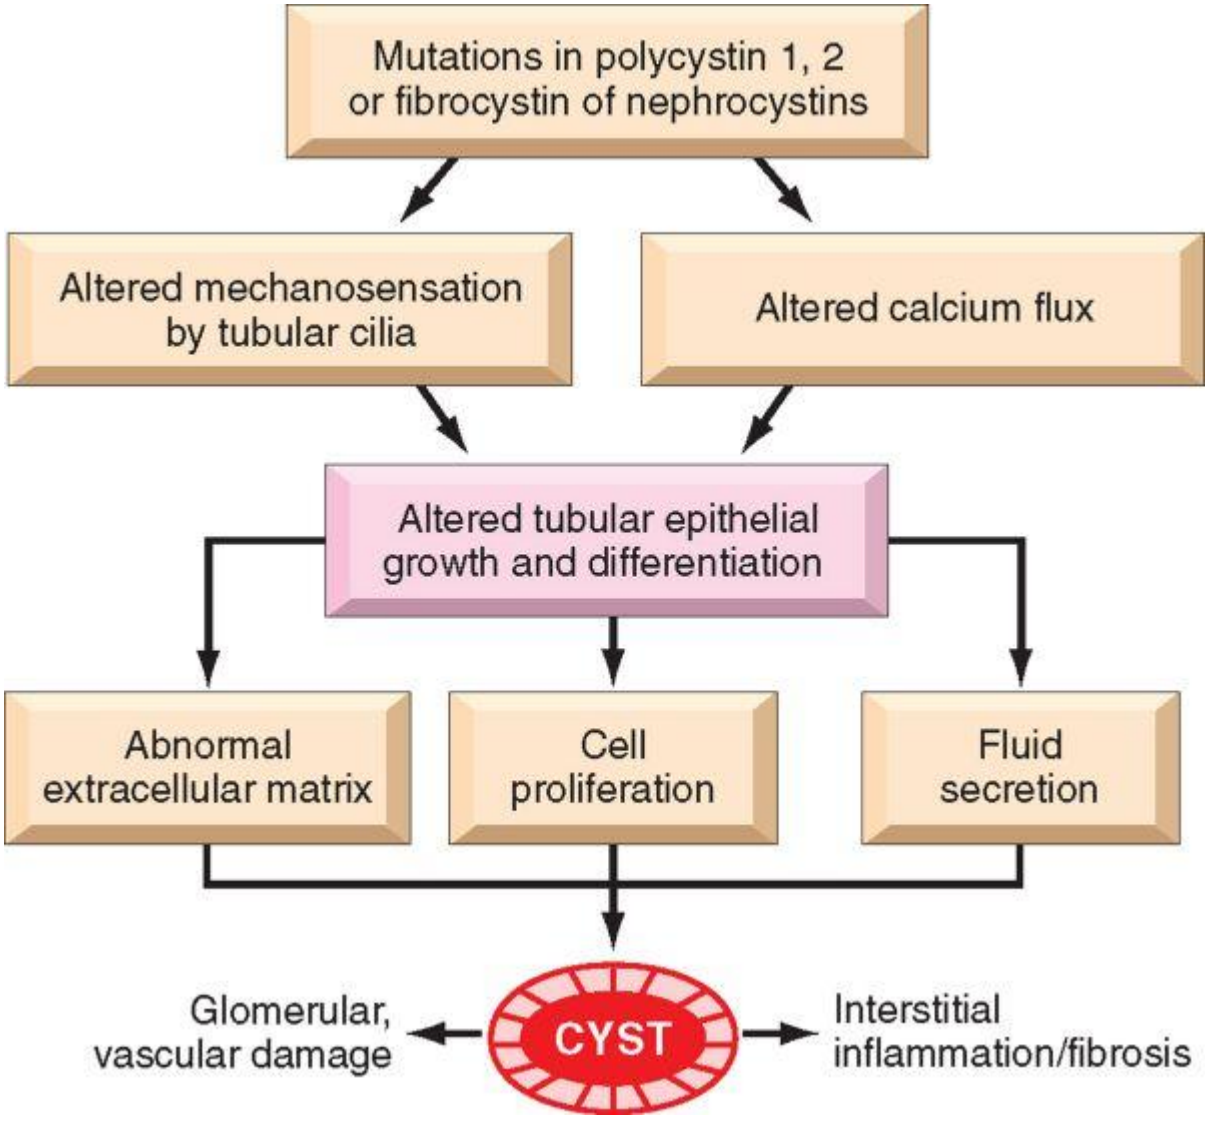

FIGURE 20-46 Possible mechanisms of cyst formation in polycystic kidney disease (see text).

Polycystin-1 and polycystin-2 may form a protein complex that acts to regulate intracellular Ca2+ in response to fluid flow, perhaps because fluid moving through the kidney tubules causes ciliary bending that opens Ca2+ channels.[91,][93] Mutation of either of the *PKD* genes would lead to loss of the polycystin complex or the formation of an aberrant complex. The consequent disruption of normal polycystin activity then leads to changes in intracellular Ca2+ level and, given the second-messenger effects of Ca2+, to changes in *cellular proliferation*, *basal levels of apoptosis*, *interactions with the ECM*, and *secretory function of the epithelia* that together result in the characteristic feature of ADPKD. The interaction of *PKD1* and *PKD2* gene products probably accounts for the similar phenotype in the disease induced by mutations in either of the two genes.[91] The increase in the number of cells caused by abnormal proliferation, and the expanding volume of intraluminal fluid caused by abnormal secretion from epithelial cells lining the cysts, result in progressive cyst enlargement. In addition, cyst fluids have been shown to harbor mediators, derived from epithelial cells, that enhance fluid secretion and induce inflammation. These abnormalities contribute to further enlargement of cysts and the interstitial fibrosis characteristic of progressive polycystic kidney disease.

Morphology. In gross appearance, the kidneys are usually bilaterally enlarged and may achieve enormous sizes; weights as high as 4 kg for each kidney have been reported. The external surface appears to be composed solely of a mass of cysts, up to 3 to 4 cm in diameter, with no intervening parenchyma (Fig. 20-47A and B). However, microscopic examination reveals functioning nephrons dispersed between the cysts. The cysts may be filled with a clear, serous fluid or, more usually, with turbid, red to brown, sometimes hemorrhagic fluid. As these cysts enlarge, they may encroach on the calyces and pelvis to produce pressure defects. The cysts arise from the tubules throughout the nephron and therefore have variable lining epithelia. On occasion, papillary epithelial formations and polyps project into the lumen. Bowman capsules are occasionally involved in cyst formation, and glomerular tufts may be seen within the cystic space.

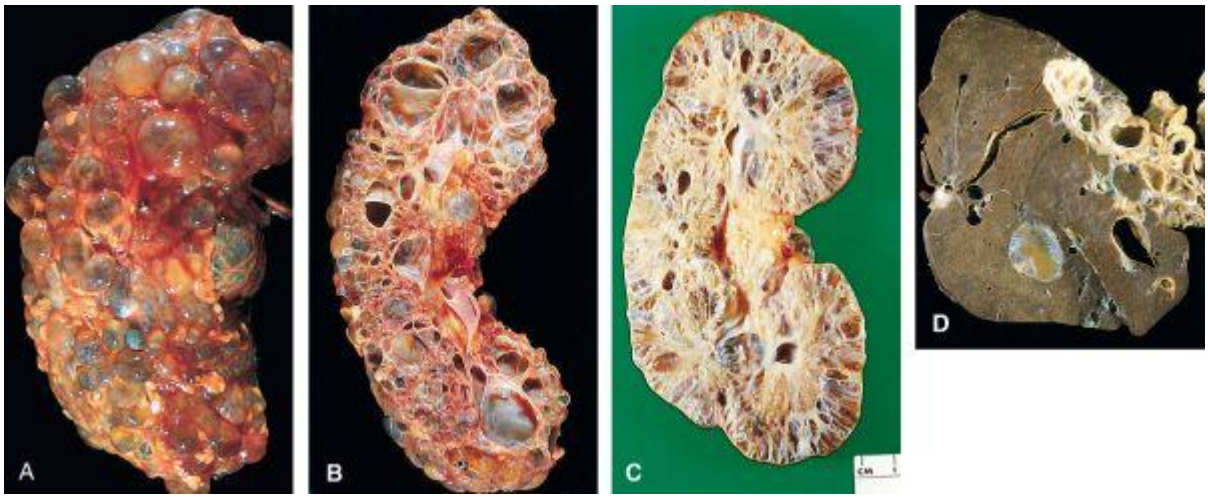

FIGURE 20-47 **A** and **B**, Autosomal-dominant adult polycystic kidney disease (ADPKD) viewed from the external surface and bisected. The kidney is markedly enlarged and contains numerous dilated cysts. **C**, Autosomal-recessive childhood PKD, showing smaller cysts and

dilated channels at right angles to the cortical surface. **D**, Liver cysts in adult PKD.

Clinical Features.

Many of these patients remain asymptomatic until renal insufficiency announces the presence of the disease. In others, hemorrhage or progressive dilation of cysts may produce pain. Excretion of blood clots causes renal colic. The enlarged kidneys, usually apparent on abdominal palpation, may induce a dragging sensation. The disease occasionally begins with the insidious onset of hematuria, followed by other features of progressive chronic kidney disease, such as proteinuria (rarely more than 2 gm/day), polyuria, and hypertension. Patients with *PKD2* mutations tend to have an older age at onset and later development of renal failure. Both genetic and environmental factors influence disease severity. Progression is accelerated in blacks (largely correlated with sickle-cell trait), in males, and in the presence of hypertension.

Individuals with polycystic kidney disease also tend to have extrarenal congenital anomalies.[87] *About 40% have one to several cysts in the liver (polycystic liver disease) that are usually asymptomatic*. The cysts are derived from biliary epithelium. Cysts occur much less frequently in the spleen, pancreas, and lungs. Intracranial berry aneurysms, presumably from altered expression of polycystin in vascular smooth muscle, arise in the circle of Willis, and subarachnoid hemorrhages from these account for death in about 4% to 10% of individuals. *Mitral valve prolapse* and other cardiac valvular anomalies occur in 20% to 25% of patients, but most are asymptomatic. The clinical diagnosis is made by radiologic imaging techniques.

This form of chronic renal failure is remarkable in that patients may survive for many years with azotemia slowly progressing to uremia. Ultimately, about 40% of adult patients die of coronary or hypertensive heart disease, 25% of infection, 15% of a ruptured berry aneurysm or hypertensive intracerebral hemorrhage, and the rest of other causes.

AUTOSOMAL-RECESSIVE (CHILDHOOD) POLYCYSTIC KIDNEY DISEASE

Autosomal-recessive (childhood) polycystic kidney disease (ARPKD) is genetically distinct from adult polycystic kidney disease. *Perinatal*, *neonatal*, *infantile*, and *juvenile* subcategories have been defined, depending on the time of presentation and presence of associated hepatic lesions. The first two are the most common; serious manifestations are usually present at birth, and the young infant might succumb rapidly to renal failure.

In most cases, the disease is caused by mutations of the *PKHD1* gene, which maps to chromosome region 6p21–p23. The *PKHD1* gene encodes a large novel protein, *fibrocystin*.[94] The gene is highly expressed in adult and fetal kidney and also in liver and pancreas. Fibrocystin is a 447-kD integral membrane protein with a large extracellular region, a single transmembrane component, and a short cytoplasmic tail. The extracellular region contains multiple copies of a domain forming an Ig-like fold. Like polycystins 1 and 2, fibrocystin also has been localized to the primary cilium of tubular cells.[93] The function of fibrocystin is unknown, but its putative conformational structure indicates it may be a cell surface receptor with a role in collecting-duct and biliary differentiation.

Analysis of ARPKD patients has revealed a wide range of different mutations. The vast majority of cases are compound heterozygotes (i.e. inherit a different mutant allele from each of the two parents). This complicates molecular diagnosis of ARPKD.

Morphology. The kidneys are enlarged and have a smooth external appearance. On cut section, numerous small cysts in the cortex and medulla give the kidney a spongelike appearance. Dilated elongated channels are present at right angles to the cortical surface, completely replacing the medulla and cortex (Fig. 20-47C). On microscopic examination, there is cylindrical or, less commonly, saccular dilation of all collecting tubules. The cysts have a uniform lining of cuboidal cells, reflecting their origin from the collecting ducts. In almost all cases the liver has cysts associated with portal fibrosis (Fig. 20-47D) and proliferation of portal bile ducts.

Patients who survive infancy (infantile and juvenile forms) may develop a peculiar type of hepatic fibrosis characterized by bland periportal fibrosis and the proliferation of welldifferentiated biliary ductules, a condition now termed *congenital hepatic fibrosis*. In older children the hepatic disease is the predominant clinical concern. Such patients may develop portal hypertension with splenomegaly. Curiously, congenital hepatic fibrosis sometimes occurs in the absence of polycystic kidneys and has been reported occasionally in the presence of adult polycystic kidney disease.

CYSTIC DISEASES OF RENAL MEDULLA

The three major types of medullary cystic disease are *medullary sponge kidney*, a relatively common and usually innocuous structural change, and *nephronophthisis and adult-onset medullary cystic disease*, which are almost always associated with renal dysfunction.

Medullary Sponge Kidney

The term medullary sponge kidney should be restricted to lesions consisting of multiple cystic dilations of the collecting ducts in the medulla. The condition occurs in adults and is usually discovered radiographically, either as an incidental finding or sometimes in relation to secondary complications. The latter include calcifications within the dilated ducts, hematuria, infection, and urinary calculi. Renal function is usually normal. On gross inspection the papillary ducts in the medulla are dilated, and small cysts may be present. The cysts are lined by cuboidal epithelium or occasionally by transitional epithelium. Unless there is superimposed pyelonephritis, cortical scarring is absent. The pathogenesis is unknown.

Nephronophthisis and Adult-Onset Medullary Cystic Disease

This is a group of progressive renal disorders. The common characteristic is the presence of a variable number of *cysts in the medulla, usually concentrated at the corticomedullary junction*. Initial injury probably involves the distal tubules with tubular basement membrane disruption, followed by chronic and progressive tubular atrophy involving both medulla and cortex and interstitial fibrosis. Although the presence of medullary cysts is important, the *cortical tubulointerstitial damage is the cause of the eventual renal insufficiency*.

Three variants of the nephronophthisis disease complex are recognized: (1) sporadic, nonfamilial; (2) familial juvenile nephronophthisis (most common); and (3) renal-retinal dysplasia (15%) in which the kidney disease is accompanied by ocular lesions. The familial forms are inherited as autosomal recessive traits and usually become manifest in childhood or adolescence. As a group, the nephronophthisis complex is now thought to be the most common genetic cause of end-stage renal disease in children and young adults. Adult-onset medullary cystic disease, at one time considered to be part of the nephronophthisis spectrum, has an autosomal dominant pattern of transmission and is now considered a distinct entity.

Affected children present first with polyuria and polydipsia, which reflect a marked defect in the concentrating ability of renal tubules. Sodium wasting and tubular acidosis are also prominent. Some variants of juvenile nephronophthisis can have extrarenal associations, including ocular motor abnormalities, retinal dystrophy, liver fibrosis, and cerebellar abnormalities. The expected course is progression to terminal renal failure during a period of 5 to 10 years.

Pathogenesis.

At least seven responsible gene loci have been identified. Three genes, *NPH1*, *NPH2*, and *NPH3*, are mutated in the juvenile forms of nephronophthisis.[95] The protein products of NPH1 and NPH3–NPH6 have been identified (collectively called *nephrocystins*), but their functions are not yet known. As discussed earlier, these proteins are present in the primary cilia, basal bodies attached to these cilia, or the centrosome organelle from which the basal bodies originate. The NPHP2 gene product has been identified as *inversin*, which mediates left-right patterning during embryogenesis.[91] Two genes (*MCKD1* and *MCKD2*), with autosomal dominant transmission, have been identified as causing medullary cystic disease that is characterized by progression to end-stage kidney disease in adult life.[87]

Morphology. The kidneys are small, have contracted granular surfaces, and show cysts in the medulla, most prominently at the corticomedullary junction (Fig. 20-48). Small cysts are also seen in the cortex. The cysts are lined by flattened or cuboidal epithelium and are usually surrounded by either inflammatory cells or fibrous tissue. In the cortex there is widespread atrophy and thickening of the basement membranes of the proximal and distal tubules, together with interstitial fibrosis. Some glomeruli may be hyalinized, but in general, glomerular structure is preserved.

FIGURE 20-48 Medullary cystic disease. Cut section of kidney showing cysts at the corticomedullary junction and in the medulla.

There are few specific clues to diagnosis, because the medullary cysts might be too small to be visualized radiographically. The disease should be strongly considered in children or adolescents with otherwise unexplained chronic renal failure, a positive family history, and chronic tubulointerstitial nephritis on biopsy.

ACQUIRED (DIALYSIS-ASSOCIATED) CYSTIC DISEASE

The kidneys from patients with end-stage renal disease who have undergone prolonged dialysis sometimes show numerous cortical and medullary cysts. The cysts measure 0.5 to 2 cm in diameter, contain clear fluid, are lined by either hyperplastic or flattened tubular epithelium, and often contain calcium oxalate crystals. They probably form as a result of obstruction of tubules by interstitial fibrosis or by oxalate crystals.

Most are asymptomatic, but sometimes the cysts bleed, causing hematuria. The most ominous complication is the development of renal cell carcinoma in the walls of these cysts, occurring in 7% of dialyzed patients observed for 10 years.

SIMPLE CYSTS

These occur as multiple or single, usually cortical, cystic spaces that vary widely in diameter. They are commonly 1 to 5 cm but may reach 10 cm or more in size. They are translucent, lined by a gray, glistening, smooth membrane, and filled with clear fluid. On microscopic examination these membranes are composed of a single layer of cuboidal or flattened cuboidal epithelium, which in many instances may be completely atrophic.

Simple cysts are common postmortem findings without clinical significance. On occasion, hemorrhage into them may cause sudden distention and pain, and calcification of the hemorrhage may give rise to bizarre radiographic shadows. The main importance of cysts lies in their differentiation from kidney tumors when they are discovered either incidentally or because of hemorrhage and pain. Radiologic studies show that in contrast to renal tumors, renal cysts have smooth contours, are almost always avascular, and give fluid rather than solid signals on ultrasonography.

3.10.7 Urinary Tract Obstruction (Obstructive Uropathy)

Recognition of urinary obstruction is important because *obstruction increases susceptibility to infection and to stone formation, and unrelieved obstruction almost always leads to permanent renal atrophy*, termed *hydronephrosis* or *obstructive uropathy*. Fortunately, many causes of obstruction are surgically correctable or medically treatable.

Obstruction may be sudden or insidious, partial or complete, unilateral or bilateral; it may occur at any level of the urinary tract from the urethra to the renal pelvis. It can be caused by lesions that are *intrinsic* to the urinary tract or *extrinsic* lesions that compress the ureter.[96] The common causes are as follows (Fig. 20-49):

1. *Congenital anomalies:* posterior urethral valves and urethral strictures, meatal stenosis, bladder neck obstruction; ureteropelvic junction narrowing or obstruction; severe vesicoureteral reflux
2. *Urinary calculi*
3. *Benign prostatic hypertrophy*
4. *Tumors:* carcinoma of the prostate, bladder tumors, contiguous malignant disease (retroperitoneal lymphoma), carcinoma of the cervix or uterus
5. *Inflammation:* prostatitis, ureteritis, urethritis, retroperitoneal fibrosis

6. *Sloughed papillae or blood clots*
7. *Pregnancy*
8. *Uterine prolapse and cystocele*
9. *Functional disorders:* neurogenic (spinal cord damage or diabetic nephropathy) and other functional abnormalities of the ureter or bladder (often termed *dysfunctional obstruction*)

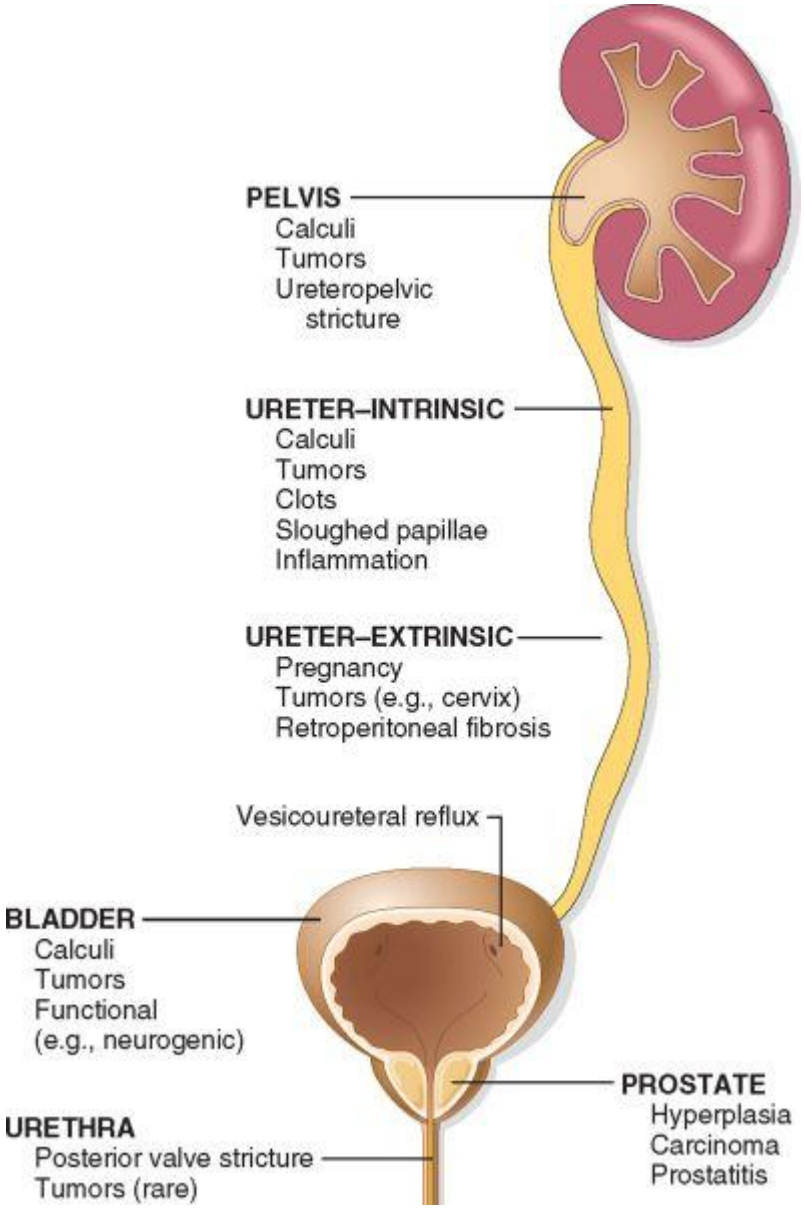

FIGURE 20-49 Obstructive lesions of the urinary tract.

Hydronephrosis is the term used to describe dilation of the renal pelvis and calyces associated with progressive atrophy of the kidney due to obstruction to the outflow of urine. Even with complete obstruction, glomerular filtration persists for some time because the filtrate subsequently diffuses back into the renal interstitium and perirenal spaces, where it ultimately returns to the lymphatic and venous systems. Because of this continued filtration, the affected calyces and pelvis become dilated, often

markedly so. The high pressure in the pelvis is transmitted back through the collecting ducts into the cortex, causing renal atrophy, but it also compresses the renal vasculature of the medulla, causing a diminution in inner medullary blood flow. The medullary vascular defects are initially reversible, but lead to medullary functional disturbances. Accordingly, the initial functional alterations caused by obstruction are largely tubular, manifested primarily by impaired concentrating ability. Only later does the GFR begin to fall. *Obstruction also triggers an interstitial inflammatory reaction, leading eventually to interstitial fibrosis*, by mechanisms similar to those discussed earlier (see Fig. 20-9).

Morphology. When the obstruction is sudden and complete, glomerular filtration is reduced. It leads to mild dilation of the pelvis and calyces and sometimes to atrophy of the renal parenchyma. When the obstruction is subtotal or intermittent, glomerular filtration is not suppressed, and progressive dilation ensues. Depending on the level of urinary block, the dilation may affect the bladder first, or the ureter and then the kidney.

The kidney may be slightly to massively enlarged, depending on the degree and the duration of the obstruction. The earlier features are those of simple dilation of the pelvis and calyces, but in addition there is often significant interstitial inflammation, even in the absence of infection. In chronic cases the picture is one of cortical tubular atrophy with marked diffuse interstitial fibrosis. Progressive blunting of the apices of the pyramids occurs, and these eventually become cupped. In far-advanced cases the kidney may become transformed into a thin-walled cystic structure having a diameter of up to 15 to 20 cm (Fig. 20-50) with striking parenchymal atrophy, total obliteration of the pyramids, and thinning of the cortex.

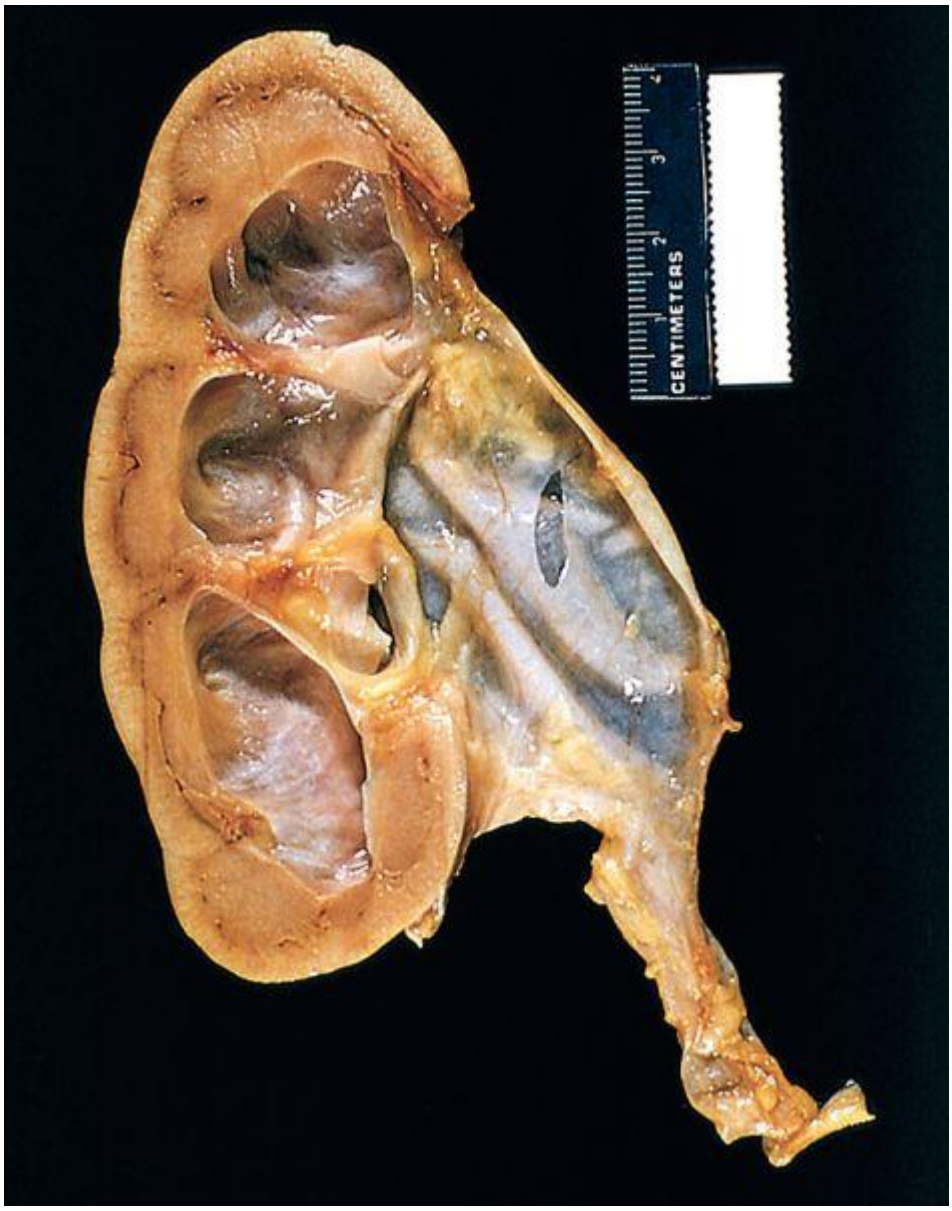

FIGURE 20-50 Hydronephrosis of the kidney, with marked dilation of the pelvis and calyces and thinning of the renal parenchyma.

Clinical Features.

Acute obstruction may provoke pain attributed to distention of the collecting system or renal capsule. Most of the early symptoms are produced by the underlying cause of the hydronephrosis. Thus, calculi lodged in the ureters may give rise to renal colic, and prostatic enlargements may give rise to bladder symptoms.

Unilateral complete or partial hydronephrosis may remain silent for long periods, since the unaffected kidney can maintain adequate renal function. Sometimes its existence first becomes apparent in the course of intravenous pyelography. It is regrettable that this disease tends to remain asymptomatic, because in its early stages, perhaps the first few weeks, relief of obstruction leads to reversion to normal function. *Ultrasonography* is a useful noninvasive technique in the diagnosis of obstructive uropathy.

In *bilateral partial obstruction* the earliest manifestation is inability to concentrate the urine, reflected by polyuria and nocturia. Some patients have acquired distal tubular acidosis, renal salt wasting, secondary renal calculi, *and a typical picture of chronic tubulointerstitial nephritis* with scarring and atrophy of the papilla and medulla. Hypertension is common in such patients.

Complete bilateral obstruction results in oliguria or anuria and is incompatible with survival unless the obstruction is relieved. Curiously, after relief of complete urinary tract obstruction, postobstructive *diuresis* occurs. This can often be massive, with the kidney excreting large amounts of urine that is rich in sodium chloride.

3.10.8 Urolithiasis (Renal Calculi, Stones)

Stones may form at any level in the urinary tract, but most arise in the kidney. Urolithiasis is a frequent clinical problem, affecting 5% to 10% of Americans in their lifetime.[97] Men are affected more often than women, and the peak age at onset is between 20 and 30 years. Familial and hereditary predisposition to stone formation has long been known. Many inborn errors of metabolism, such as gout, cystinuria, and primary hyperoxaluria, provide examples of hereditary disease characterized by excessive production and excretion of stone-forming substances.

Cause and Pathogenesis.

There are four main types of calculi[98] (Table 20-12): (1) *calcium stones (about 70%)*, composed largely of calcium oxalate or calcium oxalate mixed with calcium phosphate; (2) another 15% are so-called *triple stones* or *struvite stones*, composed of magnesium ammonium phosphate; (3) 5% to 10% are *uric acid stones*; and (4) 1% to 2% are *made up of cystine*. An organic mucoprotein matrix, making up 1% to 5% of the stone by weight, is present in all calculi. Although there are many causes for the initiation and propagation of stones, *the most important determinant is an increased urinary concentration of the stones' constituents, such that it exceeds their solubility (supersaturation). A low urine volume* in some metabolically normal patients may also favor supersaturation.

TABLE 20-12 -- Prevalence of Various Types of Renal Stones

Stone Type	Percentage of All Stones
CALCIUM OXALATE AND PHOSPHATE	70
Idiopathic hypercalciuria (50%)	
Hypercalciuria and hypercalcemia (10%)	
Heperoxaluria (5%)	
Enteric (4.5%)	
Primary (0.5%)	
Hyperuricosuria (20%)	
Hypocitraturia	
No known metabolic abnormality (15% to 20%)	
MAGNESIUM AMMONIUM PHOSPHATE (STRUVITE)	15–20
URIC ACID	5–10
Associated with hyperuricemia	
Associated with hyperuricosuria	
Idiopathic (50% of uric stones)	

Stone Type	Percentage of All Stones
CYSTINE	1–2
OTHERS OR UNKNOWN	±5

Calcium oxalate stones (Table 20-12) are associated in about 5% of patients with *hypercalcemia* and *hypercalciuria*, such as occurs with hyperparathyroidism, diffuse bone disease, sarcoidosis, and other hypercalcemic states. About 55% have *hypercalciuria without hypercalcemia*. This is caused by several factors, including hyperabsorption of calcium from the intestine (absorptive hypercalciuria), an intrinsic impairment in renal tubular reabsorption of calcium (renal hypercalciuria), or idiopathic fasting hypercalciuria with normal parathyroid function. As many as 20% of calcium oxalate stones are associated with increased uric acid secretion *(hyperuricosuric calcium nephrolithiasis)*, with or without hypercalciuria. The mechanism of stone formation in this setting involves "nucleation" of calcium oxalate by uric acid crystals in the collecting ducts. Five percent are associated with *hyperoxaluria*, either hereditary (primary oxaluria) or, more commonly, acquired by intestinal overabsorption in patients with enteric diseases. The latter, so-called enteric hyperoxaluria, also occurs in vegetarians, because much of their diet is rich in oxalates. *Hypocitraturia*, associated with acidosis and chronic diarrhea of unknown cause, may produce calcium stones. *In a variable proportion of individuals with calcium stones*, no cause can be found (idiopathic calcium stone disease).

Magnesium ammonium phosphate stones are formed largely after infections by bacteria (e.g., *Proteus* and some staphylococci) that convert urea to ammonia. The resultant alkaline urine causes the precipitation of magnesium ammonium phosphate salts. These form some of the largest stones, as the amounts of urea excreted normally are huge. Indeed, so-called *staghorn calculi* occupying large portions of the renal pelvis are almost always a consequence of infection.

Uric acid stones are common in individuals with hyperuricemia, such as gout, and diseases involving rapid cell turnover, such as the leukemias. However, *more than half of all patients with uric acid calculi have neither hyperuricemia nor increased urinary excretion of uric acid*. In this group, it is thought that an unexplained tendency to excrete urine of pH below 5.5 may predispose to uric acid stones, because uric acid is insoluble in acidic urine. In contrast to the radiopaque calcium stones, uric acid stones are radiolucent.

Cystine stones are caused by genetic defects in the renal reabsorption of amino acids, including cystine, leading to cystinuria. Stones form at low urinary pH.

It can therefore be appreciated that increased concentration of stone constituents, changes in urinary pH, decreased urine volume, and the presence of bacteria influence the formation of calculi. *However, many calculi occur in the absence of these factors; conversely, individuals with hypercalciuria, hyperoxaluria, and hyperuricosuria often do not form stones*. It has therefore been postulated that stone formation is enhanced by a *deficiency in inhibitors of crystal formation in urine*. The list of such inhibitors is long, including pyrophosphate, diphosphonate, citrate, glycosaminoglycans, osteopontin, and a glycoprotein called *nephrocalcin*.

Morphology. Stones are unilateral in about 80% of patients. The favored sites for their formation are within the renal calyces and pelves (Fig. 20-51) and in the bladder. If formed in the renal pelvis they tend to remain small, having an average diameter of 2 to 3 mm. These may have smooth contours or may take the form of an irregular, jagged mass of spicules. Often many stones are found within one kidney. On occasion, progressive accretion of salts leads to the development of branching structures

known as staghorn calculi, which create a cast of the pelvic and calyceal system.

FIGURE 20-51 Nephrolithiasis. A large stone impacted in the renal pelvis. *(Courtesy of Dr. E. Mosher, Brigham and Women's Hospital, Boston, MA.)*

Clinical Features.

Stones are of importance when they obstruct urinary flow or produce ulceration and bleeding. They may be present without producing any symptoms or they may cause significant renal damage. In general, smaller stones are most hazardous, because they may pass into the ureters, producing colic, one of the most intense forms of pain, and ureteral obstruction. Larger stones cannot enter the ureters and are more likely to remain silent within the renal pelvis. Commonly, these larger stones first manifest themselves by hematuria. Stones also predispose to superimposed infection, both by their obstructive nature and by the trauma they produce.

3.10.9 Tumors of the Kidney

Both benign and malignant tumors occur in the kidney. With the exception of oncocytoma, the benign tumors rarely cause clinical problems. Malignant tumors on the other hand, are of great importance clinically and deserve considerable emphasis. By far the most common of these malignant tumors is

renal cell carcinoma, followed by Wilms tumor, which is found in children and is described in Chapter 10 , and finally urothelial tumors of the calyces and pelves.

BENIGN TUMORS

Renal Papillary Adenoma

Small, discrete adenomas arising from the renal tubular epithelium are found commonly (7% to 22%) at autopsy. They are most frequently papillary and are therefore called *papillary adenomas* in the most recent classifications.[99]

Morphology. These are small tumors, usually less than 0.5 cm in diameter. They are present invariably within the cortex and appear grossly as pale yellow-gray, discrete, well-circumscribed nodules. On microscopic examination, they are composed of complex, branching, papillomatous structures with numerous complex fronds. Cells may also grow as tubules, glands, cords, and sheets of cells. The cells are cuboidal to polygonal in shape and have regular, small central nuclei, scanty cytoplasm, and no atypia.

By histologic criteria, these tumors do not differ from low-grade papillary renal cell adenocarcinoma and indeed share some immunohistochemical and cytogenetic features (trisomies 7 and 17) with papillary cancers, to be discussed later. The size of the tumor is used as a prognostic feature, with a cutoff of 3 cm separating those that metastasize from those that rarely do.[99] However, because of occasional reports of small tumors that have metastasized, the current view is to regard all adenomas, regardless of size, as potentially malignant until an unequivocal marker of benignity is discovered.

Angiomyolipoma

This is a benign tumor consisting of vessels, smooth muscle, and fat. *Angiomyolipomas are present in 25% to 50% of patients with tuberous sclerosis*, a disease caused by loss-of-function mutations in the TSC1 or TSC2 tumor suppressor genes. It is characterized by lesions of the cerebral cortex that produce epilepsy and mental retardation, a variety of skin abnormalities, and unusual benign tumors at other sites, such as the heart (Chapters 12 and 28 . The clinical importance of angiomyolipoma is due largely to their susceptibility to spontaneous hemorrhage.

Oncocytoma

This is an epithelial tumor composed of large eosinophilic cells having small, round, benign-appearing nuclei that have large nucleoli. It is thought to arise from the intercalated cells of collecting ducts. It is not an uncommon tumor, accounting for approximately 5% to 15% of surgically resected renal neoplasms. *Ultrastructurally the eosinophilic cells have numerous mitochondria*. In gross appearance the tumors are tan or mahogany brown, relatively homogeneous, and usually well encapsulated. However, they may achieve a large size (up to 12 cm in diameter). There are some familial cases in which these tumors are multicentric rather than solitary.

MALIGNANT TUMORS

Renal Cell Carcinoma (Adenocarcinoma of the Kidney)

Renal cell carcinomas represent about 3% of all newly diagnosed visceral cancers in the United States and account for 85% of renal cancers in adults. There are approximately 30,000 new cases per year and 12,000 deaths from the disease.[100] The tumors occur most often in older individuals, usually in the sixth and seventh decades of life, and show a 2 : 1 male preponderance. Because of their gross yellow color and the resemblance of the tumor cells to clear cells of the adrenal cortex, they were at one time

called *hypernephroma*. It is now clear that all these tumors arise from tubular epithelium and are therefore renal adenocarcinomas.

Epidemiology.

Tobacco is the most significant risk factor. Cigarette smokers have double the incidence of renal cell carcinoma, and pipe and cigar smokers are also more susceptible. An international study has identified additional risk factors, including obesity (particularly in women); hypertension; unopposed estrogen therapy; and exposure to asbestos, petroleum products, and heavy metals.[101,][102] There is also an increased incidence in patients with chronic renal failure and acquired cystic disease (see earlier) and in tuberous sclerosis.

Most renal cancer is sporadic, but unusual forms of autosomal dominant familial cancers occur, usually in younger individuals. Although they account for only 4% of renal cancers, familial variants have been enormously instructive in studying renal carcinogenesis.

- *Von Hippel-Lindau (VHL) syndrome:* Half to two thirds of individuals with VHL (nearly all, if they live long enough) (Chapter 28) develop renal cysts and bilateral, often multiple, renal cell carcinomas. As we shall see, *current studies implicate the VHL gene in the development of both familial and sporadic clear cell tumors*.
- *Hereditary (familial) clear cell carcinoma*, without the other manifestations of VHL but with abnormalities involving the same or a related gene, is another familial variant.
- *Hereditary papillary carcinoma*. This autosomal dominant form is manifested by multiple bilateral tumors with papillary histology. These tumors show a series of cytogenetic abnormalities and, as will be described, mutations in the *MET* proto-oncogene.

Classification of renal cell carcinoma: histology, cytogenetics, and genetics.

The classification of renal cell carcinoma is based on correlative cytogenetic, genetic, and histologic studies of both familial and sporadic tumors.[103,][104] The major types of tumor are as follows (Fig. 20-52):

1. *Clear cell carcinoma*. This is the most common type, accounting for 70% to 80% of renal cell cancers. The tumors are made up of cells with clear or granular cytoplasm and are *nonpapillary*. They can be familial, but in most cases (95%) are sporadic. In 98% of these tumors, whether familial, sporadic, or associated with VHL, there is loss of sequences on the short arm of chromosome 3. This occurs by deletion (3p–) or by unbalanced chromosomal translocation (3;6, 3;8, 3;11) resulting in loss of chromosome 3 spanning 3p12 to 3p26. This region harbors the *VHL* gene (3p25.3).[105] A second nondeleted allele of the *VHL* gene shows somatic mutations or hypermethylation-induced inactivation in up to 80% of clear cell cancers, indicating that the *VHL* gene acts as a tumor suppressor gene in both sporadic and familial cancers (Chapter 7).[106] The *VHL* gene encodes a protein that is part of a ubiquitin ligase complex involved in targeting other proteins for degradation.[106] Important among the targets of the VHL protein is hypoxia-inducible factor-1 (HIF-1). When *VHL* is mutated, HIF-1 levels remain high, and this constitutively active protein increases the transcription and production of hypoxia-inducible, pro-angiogenic proteins such as VEGF, PDGF, TGF-α, and TGF-β. In addition, insulin-like growth factor 1, another VHL target, is up-regulated. Thus, both cell growth and angiogenesis are stimulated. At least two other tumor suppressor genes have also been mapped to 3p.[107]
2. *Papillary carcinoma* accounts for 10% to 15% of renal cancers. It is characterized by a papillary growth pattern and also occurs in both familial and sporadic forms. These tumors are not associated with 3p deletions. The most common cytogenetic abnormalities are trisomies 7, 16, and 17 and loss of Y in male patients in the sporadic form, and trisomy 7 in the familial form. The gene for the familial form has been mapped to a locus on chromosome 7, encompassing the locus for *MET*, a proto-oncogene that serves as the tyrosine kinase receptor for *hepatocyte growth factor*.[108] This gene has also been shown to be mutated in a proportion of the sporadic cases of papillary carcinoma. Described in Chapter 3 , hepatocyte growth factor (also called scatter factor) mediates growth, cell mobility, invasion, and morphogenetic differentiation. Unlike clear cell carcinomas, papillary carcinomas are frequently multifocal in origin.

3. *Chromophobe renal carcinoma* represents 5% of renal cell cancers and is composed of cells with prominent cell membranes and pale eosinophilic cytoplasm, usually with a halo around the nucleus. On cytogenetic examination these tumors show multiple chromosome losses and extreme hypodiploidy. They are, like the benign oncocytoma, thought to grow from intercalated cells of collecting ducts and have an excellent prognosis compared with that of the clear cell and papillary cancers. Histologic distinction from oncocytoma can be difficult.

4. *Collecting duct (Bellini duct) carcinoma* represents approximately 1% or less of renal epithelial neoplasms. They arise from collecting duct cells in the medulla. Several chromosomal losses and deletions have been described for this tumor, but a distinct pattern has not been identified. Histologically these tumors are characterized by nests of malignant cells enmeshed within a prominent fibrotic stroma, typically in a medullary location.

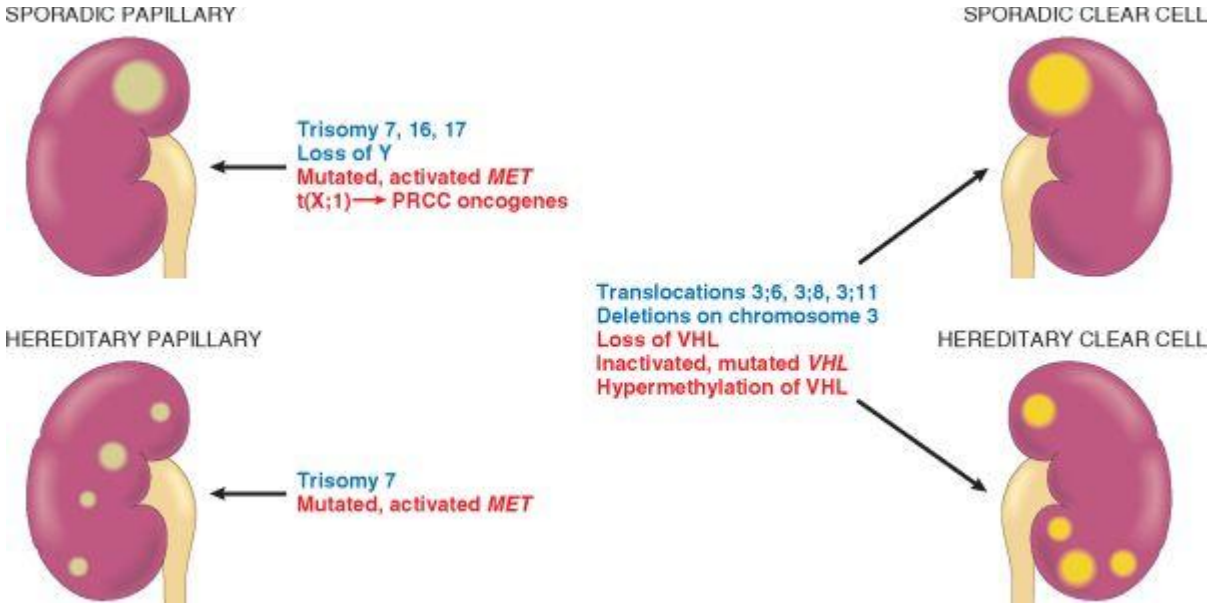

FIGURE 20-52 Cytogenetics (blue) and genetics (red) of clear cell versus papillary renal cell carcinoma. *(Courtesy of Dr. Keith Ligon, Brigham and Women's Hospital, Boston, MA.)*

New variants of renal cell carcinoma that are distinctive (histologically, genetically, and clinically) are being recognized as a result of molecular profiling, illustrating how application of these techniques may improve our clinical understanding and management of these neoplasms.[109]

Morphology. Renal cell carcinomas may arise in any portion of the kidney, but more commonly affects the poles. Clear cell carcinomas arise most likely from proximal tubular epithelium, and usually occur as solitary unilateral lesions. They are spherical masses, which can vary in size, composed of bright yellow-gray-white tissue that distorts the renal outline. The yellow color is a consequence of the prominent lipid accumulations in tumor cells. There are commonly large areas of ischemic, opaque, gray-white necrosis, and foci of hemorrhagic discoloration. The margins are usually sharply defined and confined within the renal capsule (Fig. 20-53). **Papillary tumors**, thought to arise from distal convoluted tubules, can be multifocal and bilateral. They are typically hemorrhagic and cystic, especially when large. Papillary carcinomas are the most common type of renal cancer in patients who develop dialysis-associated cystic disease.

As tumors enlarge they may bulge into the calyces and pelvis and eventually may fungate through the walls of the collecting system to extend into the ureter. One of the striking characteristics of renal cell carcinoma is its tendency to invade the renal vein (see Fig. 20-53) and grow as a solid column of cells within this vessel. Further growth may produce a continuous cord of tumor in the inferior vena cava that may extend into the right side of the heart.

In **clear cell carcinoma** the growth pattern varies from solid to trabecular (cordlike) or tubular (resembling tubules). The tumor cells have a rounded or polygonal shape and abundant clear or granular cytoplasm, which contains glycogen and lipids (Fig. 20-54A). The tumors have delicate branching vasculature and may show cystic as well as solid areas. Most tumors are well differentiated, but some show marked nuclear atypia with formation of bizarre nuclei and giant cells. **Papillary carcinoma** is composed of cuboidal or low columnar cells arranged in papillary formations. Interstitial foam cells are common in the papillary cores (Fig. 20-54B). Psammoma bodies may be present. The stroma is usually scanty but highly vascularized. **Chromophobe renal carcinoma** is made up of pale eosinophilic cells, often with a perinuclear halo, arranged in solid sheets with a concentration of the largest cells around blood vessels (Fig. 20-54C). **Collecting duct carcinoma** is a rare variant showing irregular channels lined by highly atypical epithelium with a hobnail pattern. Sarcomatoid changes arise infrequently in all types of renal cell carcinoma and are a decidedly ominous feature.

Clinical Features.

The three classic diagnostic features of renal cell carcinoma are *costovertebral pain*, *palpable mass*, and *hematuria*, but these are seen in only 10% of cases. The most reliable of the three is hematuria, but it is usually intermittent and may be microscopic; thus, the tumor may remain silent until it attains a large size. At this time it is often associated with generalized constitutional symptoms, such as fever, malaise, weakness, and weight loss. This pattern of asymptomatic growth occurs in many patients, so the tumor may have reached a diameter of more than 10 cm when it is discovered. Currently, an increasing number of tumors are being discovered in the asymptomatic state by incidental radiologic studies (e.g., computed tomographic scan or magnetic resonance imaging) usually performed for nonrenal indications.

Renal cell carcinoma is classified as one of the great mimics in medicine, because it tends to produce a diversity of systemic symptoms not related to the kidney. In addition to fever and constitutional symptoms mentioned earlier, renal cell carcinomas produce a number of paraneoplastic syndromes (Chapter 7), ascribed to abnormal hormone production, including *polycythemia, hypercalcemia, hypertension, hepatic dysfunction, feminization or masculinization, Cushing syndrome, eosinophilia, leukemoid reactions, and amyloidosis*.

One of the common characteristics of this tumor is its *tendency to metastasize widely before giving rise to any local symptoms or signs*. In 25% of new patients with renal cell carcinoma, there is radiologic evidence of metastases at the time of presentation. The most common locations of metastasis are the lungs (more than 50%) and bones (33%), followed in frequency by the regional lymph nodes, liver, adrenal, and brain.

The average 5-year survival rate of persons with renal cell carcinoma is about 45% and as high as 70% in the absence of distant metastases. With renal vein invasion or extension into the perinephric fat, the figure is reduced to approximately 15% to 20%. Nephrectomy has been the treatment of choice, but partial nephrectomy to preserve renal function is being done with increasing frequency and similar outcome.

Urothelial Carcinomas of the Renal Pelvis

Approximately 5% to 10% of primary renal tumors originate from the urothelium of the renal pelvis (Fig. 20-55). These tumors span the range from apparently benign papillomas to invasive urothelial (transitional cell) carcinomas.

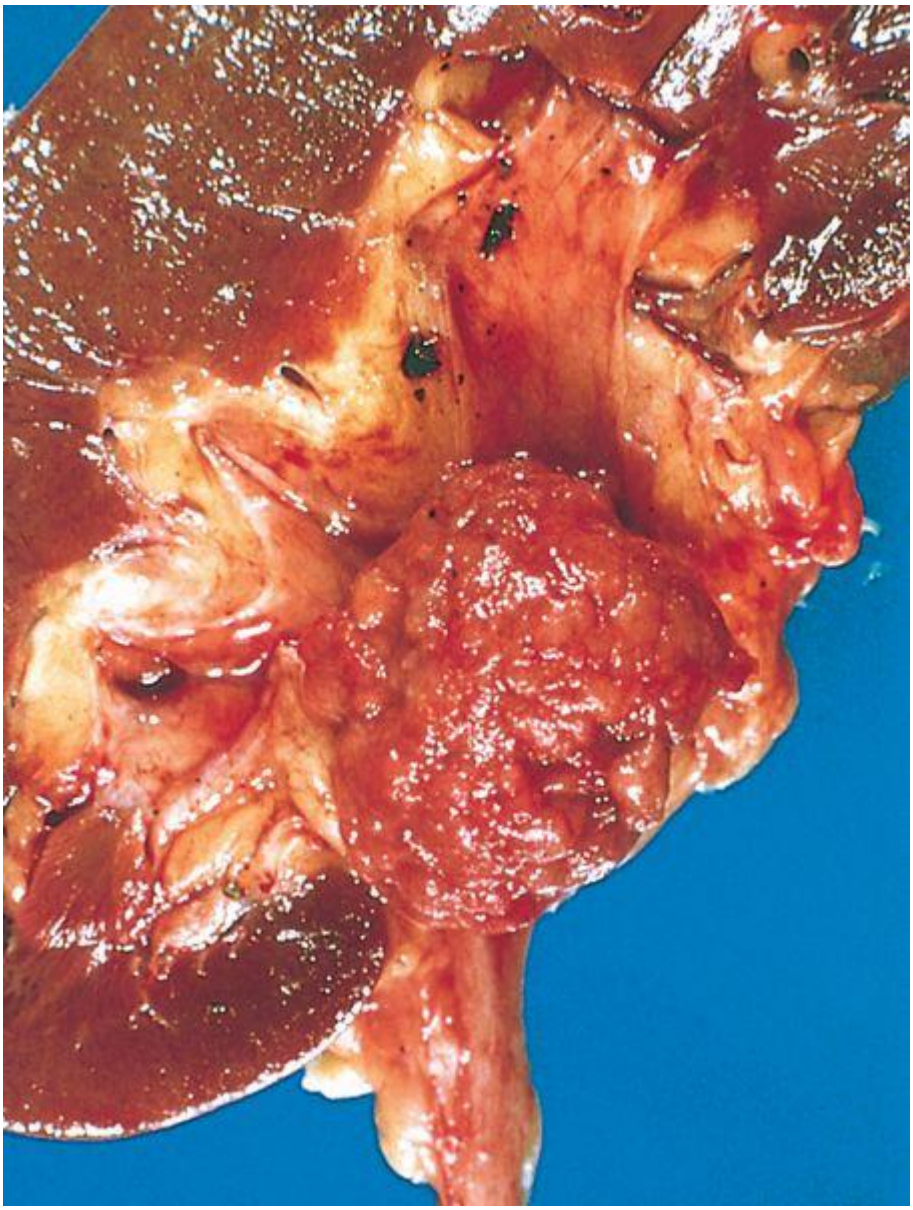

FIGURE 20-55 Urothelial carcinoma of the renal pelvis. The pelvis has been opened to expose the nodular irregular neoplasm, just proximal to the ureter.

Renal pelvic tumors usually become clinically apparent within a relatively short time, because they lie within the pelvis and, by fragmentation, produce noticeable hematuria. They are almost invariably small when discovered. These tumors may block the urinary outflow and lead to palpable hydronephrosis and flank pain. On histologic examination, pelvic tumors are the exact counterpart of those found in the urinary bladder; further details are in Chapter 21 .

Urothelial tumors may occasionally be multiple, involving the pelvis, ureters, and bladder. In 50% of renal pelvic tumors there is a preexisting or concomitant bladder urothelial tumor. On histologic examination, there are also foci of atypia or carcinoma in situ in grossly normal urothelium remote from the pelvic tumor. As already mentioned, there is an increased incidence of urothelial carcinomas of the renal pelvis and bladder in individuals with analgesic nephropathy and Balkan nephropathy.

Infiltration of the wall of the pelvis and calyces is common. For this reason, despite their apparently small, deceptively benign appearance, the prognosis for these tumors is not good. Reported 5-year survival rates vary from 50% to 100% for low-grade noninvasive lesions to 10% with high-grade infiltrating tumors.

3.11 21. The Lower Urinary Tract & Male Genital System

3.11.1 The Lower Urinary Tract

THE LOWER URINARY TRACT

Despite differing embryonic origins, the various components of the lower urinary tract have many morphologic similarities. The renal pelves, ureters, bladder, and urethra (save for its terminal portion) are lined by a special form of transitional epithelium (urothelium). The surface layer consists of large, flattened "umbrella cells" with abundant cytoplasm that horizontally cover several underlying cells. The umbrella cells have a trilaminar asymmetric unit membrane and possess apical plaques composed of specific proteins called *uroplakins*. The underlying urothelium is composed of several layers of cells with oval smaller nuclei often with linear nuclear grooves and less cytoplasm. This epithelium rests on a well-developed basement membrane, beneath which is a lamina propria. The lamina propria in the urinary bladder contains wisps of smooth muscle that form a discontinuous muscularis mucosae. It is important to differentiate the muscularis mucosae from the deeper well-defined larger muscle bundles of the detrusor muscle (muscularis propria), since bladder cancers are staged on the basis of invasion of the latter. The bladder musculature is capable, with obstruction to the flow of urine, of great thickening.

The ureters lie throughout their course in a retroperitoneal position. Retroperitoneal tumors or fibrosis may trap the ureters in neoplastic or dense, fibrous tissue, sometimes obstructing them. As ureters enter the pelvis, they pass anterior to either the common iliac or the external iliac artery. In the female pelvis they lie close to the uterine arteries and are therefore vulnerable to injury in operations on the female genital tract. There are three points of slight narrowing—at the ureteropelvic junction, where they enter the bladder, and where they cross the iliac vessels—all providing loci where renal calculi may become impacted when they pass from the kidney to the bladder. As the ureters enter the bladder they pursue an oblique course, terminating in a slitlike orifice. The obliquity of this intramural segment of the ureteral orifice permits the enclosing bladder musculature to act like a sphincteric valve, blocking the upward reflux of urine even in the presence of marked distention of the urinary bladder. As discussed in Chapter 20 , a defect in the intravesical portion of the ureter leads to vesicoureteral reflux.

The close relationship of the female genital tract to the bladder makes possible the spread of disease from one tract to the other. In middle-aged and elderly women, relaxation of pelvic support leads to prolapse (descent) of the uterus, pulling with it the floor of the bladder. In this fashion the bladder is protruded into the vagina, creating a pouch *(cystocele)* that fails to empty readily with micturition. In males the seminal vesicles and prostate have similar close relationships, being situated just posterior and inferior to the neck of the bladder. Thus, enlargement of the prostate, so common in middle to later life, constitutes an important cause of urinary tract obstruction. In the subsequent sections we discuss the major pathologic lesions in the ureters, urinary bladder, and urethra separately.

3.11.1.1 Ureters

CONGENITAL ANOMALIES

Congenital anomalies of the ureters are found in about 2% or 3% of all autopsies. Although most have little clinical significance, certain anomalies may contribute to obstruction to the flow of urine and thus cause clinical disease. Anomalies of the ureterovesical junction that potentiate reflux are discussed with pyelonephritis in Chapter 20 .

Double and bifid ureters. Double ureters are almost invariably associated either with totally distinct double renal pelves or with the anomalous development of a large kidney having a partially bifid pelvis terminating in separate ureters. Double ureters may pursue separate courses to the bladder but

commonly are joined within the bladder wall and drain through a single ureteral orifice. The majority of double ureters are unilateral and of no clinical significance.

Ureteropelvic junction (UPJ) obstruction, a congenital disorder, results in hydronephrosis. It usually presents in infants or children, much more commonly in boys. However, it is bilateral in 20% of cases and may be associated with other congenital anomalies. It is the most common cause of hydronephrosis in infants and children. In adults, UPJ obstruction is more common in women and is most often unilateral. The condition has been ascribed to abnormal organization of smooth muscle bundles at the UPJ, to excess stromal deposition of collagen between smooth muscle bundles, or rarely to congenitally extrinsic compression by polar renal vessels. There is agenesis of the kidney on the opposite side in a significant number of cases, probably resulting from obstructive lesions in utero.

Diverticula, saccular outpouchings of the ureteral wall, are uncommon lesions that are usually asymptomatic and are found on imaging studies. They appear as congenital or acquired defects and are of importance as pockets of stasis and secondary infections. Dilation *(hydroureter)*, elongation, and tortuosity of the ureters may occur as congenital anomalies or as acquired defects.

INFLAMMATION

Ureteritis, though associated with inflammation, is typically not associated with infection and is of little clinical consequence.

Morphology. The accumulation or aggregation of lymphocytes forming germinal centers in the subepithelial region may cause slight elevations of the mucosa and produce a fine granular mucosal surface **(ureteritis follicularis)**. At other times the mucosa may become sprinkled with fine cysts varying in diameter from 1 to 5 mm lined by flattened urothelium **(ureteritis cystica)** (Fig. 21-1).

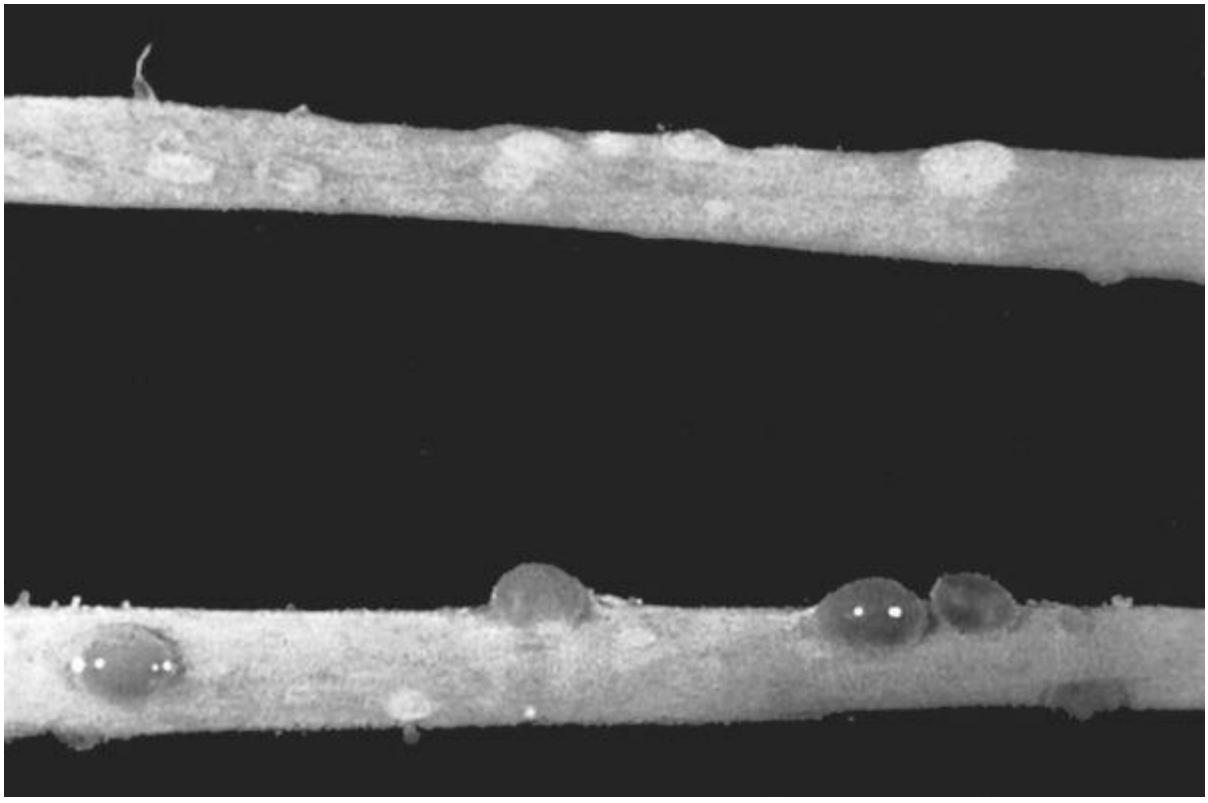

FIGURE 21-1 Opened ureters showing ureteritis cystica. Note smooth cysts projecting from the mucosa.

TUMORS AND TUMOR-LIKE LESIONS

Primary tumors of the ureter are rare. Small *benign tumors* of the ureter are generally of mesenchymal origin. *Fibroepithelial polyp* is a tumor-like lesion that grossly presents as a small mass projecting into the lumen, often in children. The lesion occurs more commonly in the ureters but may also appear in the bladder, renal pelves, and urethra. The polyp is composed of a loose, vascularized connective tissue mass lying beneath the mucosa.

Primary *malignant tumors* of the ureter resemble those arising in the renal pelvis, calyces, and bladder. The majority are urothelial carcinomas (Fig. 21-2). They are found most frequently during the sixth and seventh decades of life and cause obstruction of the ureteral lumen. They are sometimes multiple and commonly occur concurrently with similar neoplasms in the bladder or renal pelvis.

FIGURE 21-2 Papillary transitional cell carcinoma extensively involving the ureter. *(Courtesy of Dr. Cristina Magi-Galluzzi, The Johns Hopkins Hospital, Baltimore, MD.)*

OBSTRUCTIVE LESIONS

A great variety of pathologic lesions may obstruct the ureters and give rise to *hydroureter*, *hydronephrosis*, and sometimes *pyelonephritis* (Chapter 20). It is not the ureteral dilation that is of

significance in these cases, but the consequent involvement of the kidneys. The more important causes, divided into those of intrinsic or extrinsic origin, are listed in Table 21-1 . Unilateral obstruction typically results from proximal causes, whereas bilateral obstruction arises from distal causes, such as nodular hyperplasia of the prostate. Only sclerosing retroperitoneal fibrosis is discussed further.

TABLE 21-1 -- Major Causes of Ureteral Obstruction

Type of Obstruction	Cause
INTRINSIC	
Calculi	Of renal origin, rarely more than 5 mm in diameter
	Larger renal stones cannot enter ureters
	Impact at loci of ureteral narrowing—ureteropelvic junction, where ureters cross iliac vessels, and where they enter bladder—and cause excruciating “renal colic”
Strictures	Congenital or acquired (inflammations)
Tumors	Transitional cell carcinomas arising in ureters
	Rarely, benign tumors or fibroepithelial polyps
Blood clots	Massive hematuria from renal calculi, tumors, or papillary necrosis
Neurogenic	Interruption of the neural pathways to the bladder
EXTRINSIC	
Pregnancy	Physiologic relaxation of smooth muscle or pressure on ureters at pelvic brim from enlarging fundus
Periureteral inflammation	Salpingitis, diverticulitis, peritonitis, sclerosing retroperitoneal fibrosis
Endometriosis	With pelvic lesions, followed by scarring
Tumors	Cancers of the rectum, bladder, prostate, ovaries, uterus, cervix; lymphomas, sarcomas

Sclerosing Retroperitoneal Fibrosis.

This refers to an uncommon cause of ureteral narrowing or obstruction characterized by a *fibrous proliferative inflammatory process encasing the retroperitoneal structures and causing hydronephrosis*.[1] The disorder occurs in middle to late age. In some cases specific causes can be identified, such as drugs (ergot derivatives, β-adrenergic blockers), adjacent inflammatory conditions (vasculitis, diverticulitis, Crohn disease), or malignant disease (lymphomas, urinary tract carcinomas). However, 70% of cases have no obvious cause and are considered primary or idiopathic (Ormond disease). Several cases have been reported with similar fibrotic changes in other sites (such as mediastinal fibrosis, sclerosing cholangitis, and Riedel fibrosing thyroiditis), suggesting that the disorder is systemic in distribution but preferentially involves the retroperitoneum. Thus, an autoimmune reaction, sometimes triggered by drugs, has been proposed as the immediate cause of the systemic disease.

On microscopic examination the inflammatory fibrosis is marked by a prominent infiltrate of lymphocytes, often with germinal centers, plasma cells, and eosinophils. Treatment involves surgical extrication of the ureters from the surrounding fibrous tissue (ureterolysis).

3.11.1.2 Urinary Bladder

Diseases of the bladder, particularly inflammation (cystitis), constitute an important source of clinical signs and symptoms. Usually, however, these disorders are more disabling than lethal. Cystitis is particularly common in young women of reproductive age. Tumors of the bladder are an important source of both morbidity and mortality.

CONGENITAL ANOMALIES

Diverticula.

A bladder or vesical diverticulum consists of a pouchlike evagination of the bladder wall. Diverticula may arise as congenital defects but more commonly are acquired lesions caused by persistent urethral obstruction.

The *congenital form* may be due to a focal failure of development of the normal musculature or to some urinary tract obstruction during fetal development. *Acquired diverticula* are most often seen with prostatic enlargement (hyperplasia or neoplasia), producing obstruction to urine outflow and marked muscle thickening of the bladder wall. The increased intravesical pressure causes outpouching of the bladder wall and the formation of diverticula. They are frequently multiple and have narrow necks located between the interweaving hypertrophied muscle bundles. In both the congenital and the acquired forms, the diverticulum usually consists of a round to ovoid, saclike pouch that varies from less than 1 cm to 5 to 10 cm in diameter.

Although most diverticula are small and asymptomatic, they may be clinically significant, since they constitute sites of urinary stasis and predispose to infection and the formation of bladder calculi. They may also predispose to vesicoureteral reflux as a result of impingement on the ureter. Rarely, carcinomas may arise in bladder diverticuli. When invasive cancers arise in diverticula, they tend to be more advanced in stage as a result of the thin or absent muscle wall of a diverticulum.

Exstrophy.

Exstrophy of the bladder is a developmental failure in the anterior wall of the abdomen and the bladder, so that the bladder either communicates directly through a large defect with the surface of the body or lies as an opened sac (Fig. 21-3). The exposed bladder mucosa may undergo colonic glandular metaplasia and is subject to infections that often spread to upper levels of the urinary system. Patients have an increased risk of adenocarcinoma arising in the bladder remnant.[2] These lesions are amenable to surgical correction, and long-term survival is possible.

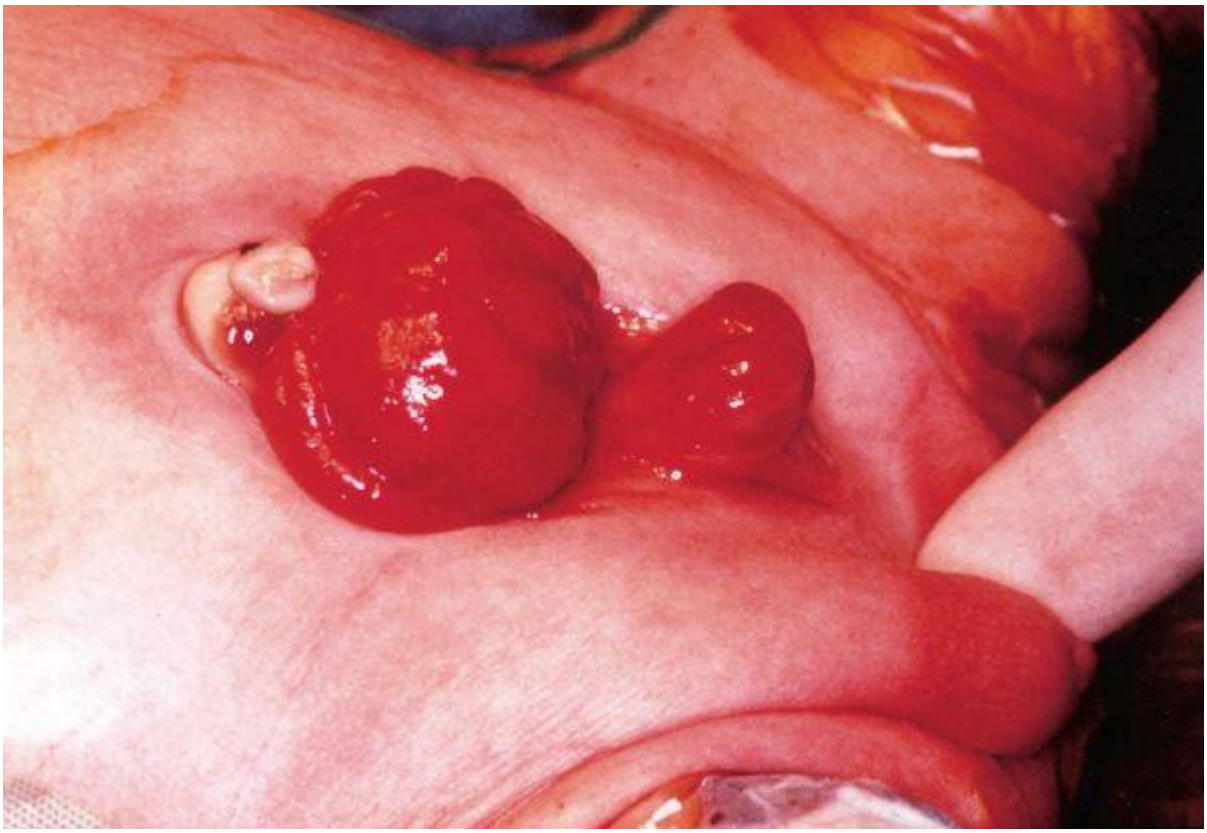

FIGURE 21-3 Exstrophy of the bladder in a newborn boy. The tied umbilical cord is seen above the hyperemic mucosa of the everted bladder. Below is an incompletely formed penis with marked epispadias. *(Courtesy of Dr. John Gearhart, The Johns Hopkins Hospital, Baltimore, MD.)*

Miscellaneous Anomalies.

Vesicoureteral reflux is the most common and serious anomaly. As a major contributor to renal infection and scarring, it was discussed earlier, in Chapter 20 , in the consideration of pyelonephritis. Abnormal connections between the bladder and the vagina, rectum, or uterus may create *congenital vesicouterine fistulas*.

Rarely, the *urachus* (the canal that connects the fetal bladder with the allantois) may remain patent in part or in whole. When totally patent, a fistulous urinary tract is created that connects the bladder with the umbilicus. At times, only the central region of the urachus persists, giving rise to *urachal cysts*, lined by either urothelium or metaplastic glandular epithelium. *Carcinomas*, mostly glandular tumors, may arise from such cysts (see "Neoplasms"). These account for only a minority of all bladder cancers (0.1% to 0.3%) but 20% to 40% of bladder adenocarcinomas.

INFLAMMATION

Acute and Chronic Cystitis

The pathogenesis of cystitis and the common bacterial etiologic agents are discussed in Chapter 20 in the consideration of urinary tract infections. As emphasized earlier, bacterial pyelonephritis is frequently preceded by infection of the urinary bladder, with retrograde spread of microorganisms into the kidneys and their collecting systems. The common etiologic agents of cystitis are the coliforms:

Escherichia coli, followed by *Proteus, Klebsiella*, and *Enterobacter*. Women are more likely to develop cystitis as a result of their shorter urethras. *Tuberculous cystitis* is almost always a sequel to renal tuberculosis. *Candida albicans* and, much less often, cryptococcal agents cause cystitis, particularly in immunosuppressed patients or those receiving long-term antibiotics. Schistosomiasis *(Schistosoma haematobium)* is rare in the United States but is common in certain Middle Eastern countries, notably Egypt. Viruses (e.g., adenovirus), *Chlamydia*, and *Mycoplasma* may also cause cystitis. Predisposing factors include bladder calculi, urinary obstruction, diabetes mellitus, instrumentation, and immune deficiency. Finally, irradiation of the bladder region gives rise to *radiation cystitis*.

Morphology. Most cases of cystitis take the form of nonspecific acute or chronic inflammation of the bladder. In gross appearance there is hyperemia of the mucosa, sometimes associated with exudate. Patients receiving **cytotoxic antitumor drugs**, such as cyclophosphamide, may develop **hemorrhagic cystitis**.[3] Adenovirus infection also causes a hemorrhagic cystitis.

Persistence of the infection leads to **chronic cystitis**, which differs from the acute form only in the character of the inflammatory infiltrate. **Follicular cystitis**, characterized by the aggregation of lymphocytes into lymphoid follicles within the bladder mucosa and underlying wall, is not necessarily associated with infection. **Eosinophilic cystitis**, manifested by infiltration with submucosal eosinophils, typically also represents nonspecific subacute inflammation, although rarely it is a manifestation of a systemic allergic disorder. The ubiquitous presence of mild chronic inflammation in the bladder unaccompanied by clinical symptoms should not be given the diagnosis of chronic cystitis.

All forms of cystitis are characterized by a triad of symptoms: (1) frequency, which in acute cases may necessitate urination every 15 to 20 minutes; (2) lower abdominal pain localized over the bladder region or in the suprapubic region; and (3) dysuria—pain or burning on urination.

The local symptoms of cystitis may be disturbing, but these infections are also important as antecedents to pyelonephritis. Cystitis is sometimes a secondary complication of some underlying disorder such as prostatic enlargement, cystocele of the bladder, calculi, or tumors. These primary diseases must be corrected before the cystitis can be relieved.

Special Forms of Cystitis

Several variants of cystitis are distinctive by their morphologic appearance or causation.

Interstitial Cystitis (Chronic Pelvic Pain Syndrome).

This is a *persistent, painful form of chronic cystitis occurring most frequently in women*.[4] It is characterized clinically by intermittent, often severe suprapubic pain, urinary frequency, urgency, hematuria and dysuria without evidence of bacterial infection, and cystoscopic findings of fissures and punctate hemorrhages (glomerulations) in the bladder mucosa after luminal distention. Some but not all patients show morphologic features of chronic mucosal ulcers *(Hunner ulcers)*; this is termed the *late (classic, ulcerative) phase*. Although mast cells are characteristic of this disease, there is no uniformity in the literature about their specificity and diagnostic utility. Late in the disease, transmural fibrosis may ensue, leading to a contracted bladder. The major role of biopsy is not to specifically diagnose the disease as much as it is to rule out carcinoma in situ, which may mimic interstitial cystitis clinically. Its etiology is unknown, its evaluation and diagnosis remain controversial, and its treatment is largely empiric.[5]

Malacoplakia.

This designation refers to a *peculiar pattern of vesical inflammatory reaction characterized macroscopically by soft, yellow, slightly raised mucosal plaques 3 to 4 cm in diameter* (Fig. 21-4), and *histologically by infiltration with large, foamy macrophages mixed with occasional multinucleate giant cells and interspersed lymphocytes*.[6] The macrophages have an abundant granular cytoplasm due to phagosomes stuffed with particulate and membranous debris of bacterial origin. In addition, laminated mineralized concretions resulting from deposition of calcium in enlarged lysosomes, known as Michaelis-Gutmann bodies, are typically present within the macrophages (Fig. 21-5). Similar lesions have been described in the colon, lungs, bones, kidneys, prostate, and epididymis.

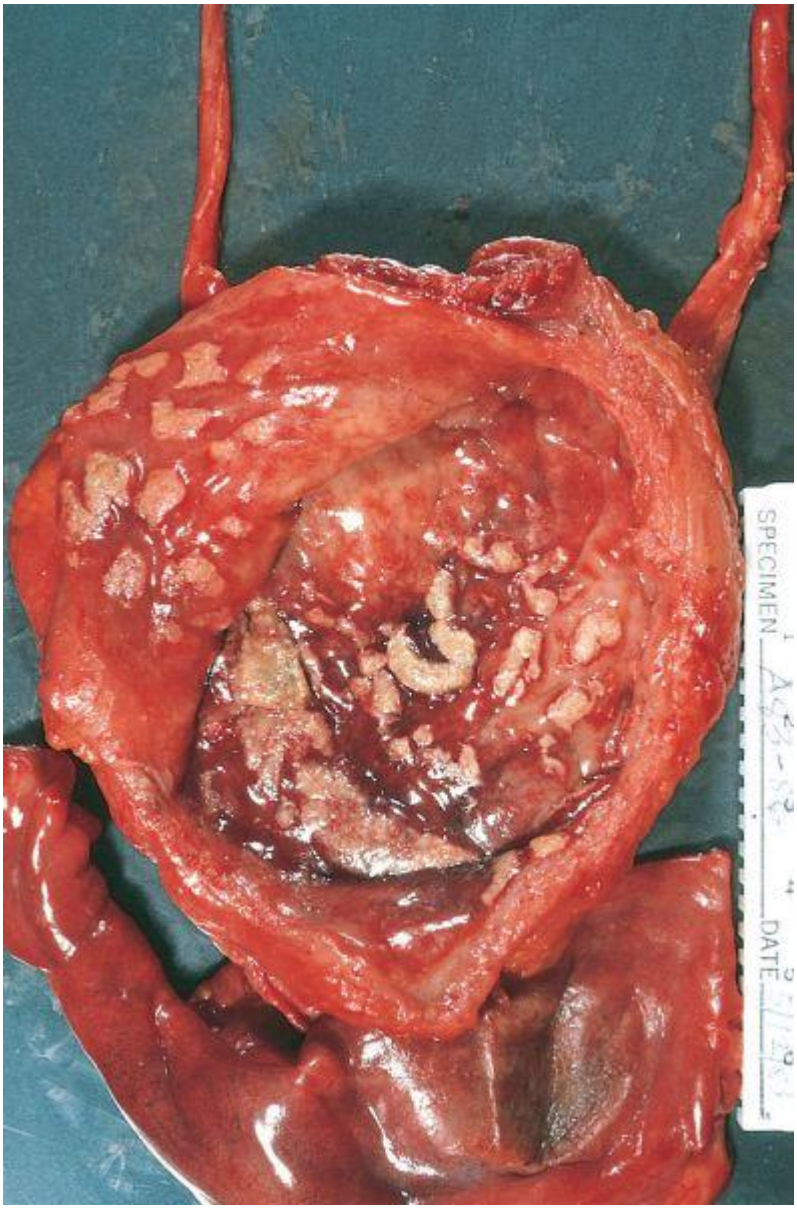

FIGURE 21-4 Cystitis with malacoplakia of bladder showing inflammatory exudate and broad, flat plaques.

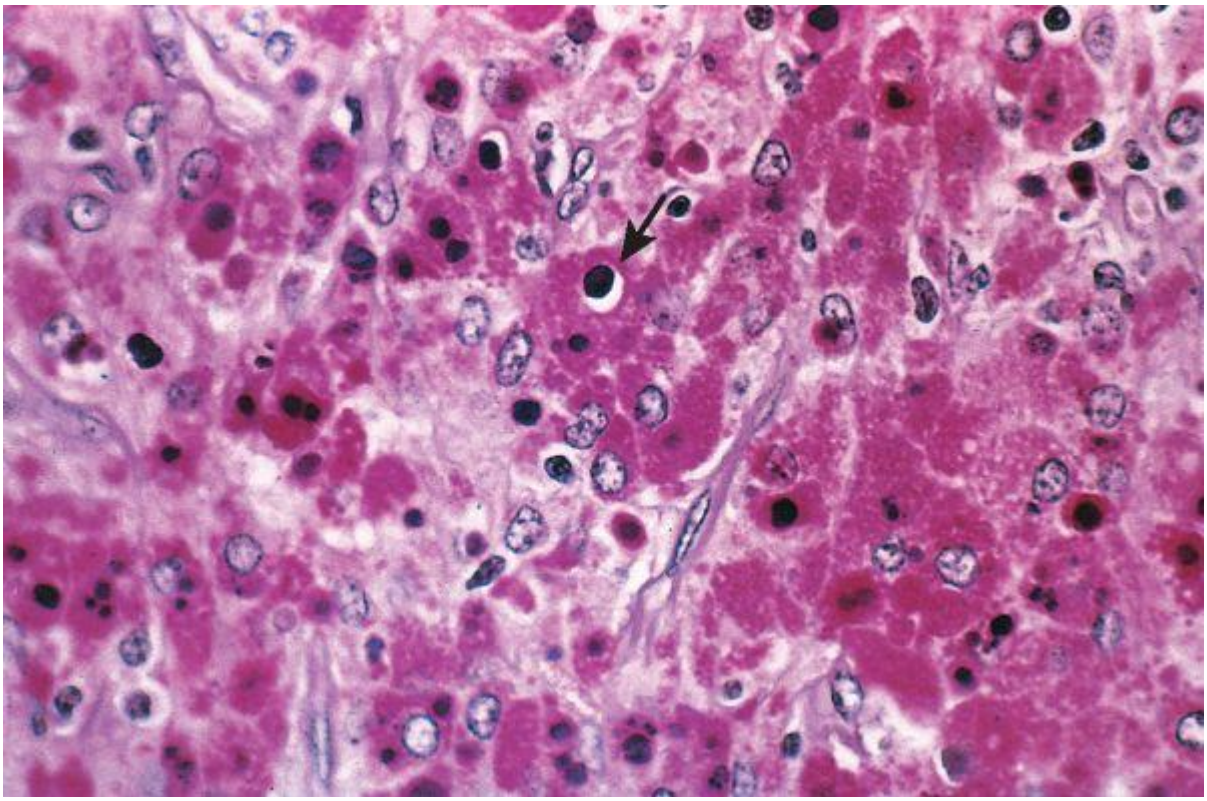

FIGURE 21-5 Malacoplakia, periodic acid–Schiff (PAS) stain. Note the large macrophages with granular PAS-positive cytoplasm and several dense, round Michaelis-Gutmann bodies surrounded by artifactual cleared holes in the upper middle field (*arrow*).

Malacoplakia is clearly related to chronic bacterial infection, mostly by *E. coli* or occasionally *Proteus* species. It occurs with increased frequency in immunosuppressed transplant recipients. The unusual-appearing macrophages and giant phagosomes point to defects in phagocytic or degradative function of macrophages, such that phagosomes become overloaded with undigested bacterial products.

Polypoid Cystitis.

Polypoid cystitis is an inflammatory condition resulting from irritation to the bladder mucosa.[7,][8] Although indwelling catheters are the most commonly cited culprits, any injurious agent may give rise to this lesion. The urothelium is thrown into broad bulbous polypoid projections as a result of marked submucosal edema. Polypoid cystitis may be confused with papillary urothelial carcinoma both clinically and histologically.

METAPLASIC LESIONS

Cystitis Glandularis and Cystitis Cystica.

These terms refer to common lesions of the urinary bladder in which nests of urothelium (Brunn nests) grow downward into the lamina propria and undergo transformation of their central epithelial cells into cuboidal or columnar epithelium lining *(cystitis glandularis)* or cystic spaces filled with clear fluid lined by flattened urothelium *(cystitis cystica)*. Because the two processes often coexist, the condition is typically referred to as *cystitis cystica et glandularis*. In a variant of cystitis glandularis goblet cells are present, and the epithelium resembles intestinal mucosa *(intestinal or colonic metaplasia)*. Both variants are common microscopic incidental findings in relatively normal bladders, although they can also arise

from inflammation and metaplasia. In contrast to earlier reports, lesions showing extensive intestinal metaplasia are not associated with an increased risk for the development of adenocarcinoma (except when associated with exstrophy).[9]

Squamous Metaplasia.

As a response to injury, the urothelium is often replaced by squamous epithelium, which is a more durable lining. This should be distinguished from glycogenated squamous epithelium that is normally found in women at the trigone.

Nephrogenic Adenoma.

Nephrogenic adenoma is an unusual lesion that in the past was believed to represent metaplasia of the urothelium in response to injury.[10,][11] It has now been demonstrated to result from shed renal tubular cells that implant in sites of injured urothelium.[12] The term *nephrogenic adenoma* was originally given because the lesion resembles renal tubules histologically, but the term also reflects the pathogenesis of the lesion. The overlying urothelium may be focally replaced by cuboidal epithelium, which can assume a papillary growth pattern. In addition, a tubular proliferation in the underlying lamina propria and superficial detrusor muscle can mimic a malignant process.[13] Although typically less than a centimeter, lesions may be sizable, and may resemble cancer clinically.

NEOPLASMS

Bladder cancer accounts for approximately 7% of cancers and 3% of cancer mortality in the United States.[14] About 95% of bladder tumors are of epithelial origin, the remainder being mesenchymal tumors (Table 21-2). Most epithelial tumors are composed of urothelial (transitional cell) type and are thus interchangeably called *urothelial or transitional tumors*, but squamous and glandular carcinomas also occur. Here we focus on urothelial tumors and touch briefly on the others.

TABLE 21-2 -- Tumors of the Urinary Bladder

Mixed carcinoma
Adenocarcinoma
Small-cell carcinoma
Sarcomas

Urothelial Tumors

Urothelial tumors represent about 90% of all bladder tumors and run the gamut from small benign lesions that may never recur to aggressive cancers associated with a high risk of death. Many of these tumors are multifocal at presentation. Though most commonly seen in the bladder, any of the urothelial lesions described below may be seen at any site where there is urothelium, from the renal pelvis to the distal urethra.

There are two distinct precursor lesions to invasive urothelial carcinoma: non-invasive papillary tumors, and flat non-invasive urothelial carcinoma. The most common precursor lesions are the non-invasive papillary tumors, which originate from papillary urothelial hyperplasia.[15] These tumors have a range of atypical changes, and are graded according to their biological behavior. The other precursor lesion to invasive carcinoma, flat non-invasive urothelial carcinoma is referred to as carcinoma in situ or CIS. As discussed in Chapter 7 , CIS is a histologic term used to describe epithelial lesions that have cytologic changes of malignancy, but are confined to the epithelium, without basement membrane invasion.[16] Such lesions are considered to be high grade. In about one half of individuals with invasive bladder cancer, the tumor has already invaded the bladder wall, at the time of presentation, and no precursor lesions may be detected. It is presumed that the precursor lesion has been destroyed by the high-grade invasive component, which typically appears as a large frequently ulcerated mass. Although invasion into the lamina propria worsens the prognosis, the major decrease in survival is associated with invasion of the muscularis propria (detrusor muscle). Once muscularis propria invasion occurs, there is a 30% 5-year mortality rate.

In Table 21-3 , we have listed two of the most common grading systems of these tumors. The World Health Organization (WHO) 1973 classification grades tumors into a rare totally benign papilloma and three grades of transitional cell carcinoma (grades I, II, and III). A more recent classification, based on a consensus reached at a conference by the International Society of Urological Pathology (ISUP) in 1998 and adopted by the WHO in 2004, recognizes a rare benign papilloma, a group of papillary urothelial neoplasms of low malignant potential, and two grades of carcinoma (low and high grade).[16,][17]

TABLE 21-3 -- Grading of Urothelial (Transitional Cell) Tumors

WHO/ISUP Grades
Urothelial papiloma

Papillary urothelial carcinoma, grade 1
Papillary urothelial carcinoma, grade 2
Papillary urothelial carcinoma, grade 3

WHO, World Health Organization; ISUP, International Society of Urological Pathology.

Morphology. The gross patterns of urothelial tumors vary from purely papillary to nodular or flat (Fig. 21-6). Papillary lesions appear as red, elevated excrescences varying in size from less than 1 cm in diameter to large masses up to 5 cm in diameter (Fig. 21-7). Multicentric origins may produce separate tumors. As noted, the histologic changes encompass a spectrum from benign papilloma to highly aggressive anaplastic cancers. Overall, the majority of papillary tumors are low grade. Most

arise from the lateral or posterior walls at the bladder base.

- **Papillomas** represent 1% or less of bladder tumors, and are usually seen in younger patients.[18] The tumors typically arise singly as small (0.5 to 2.0 cm), delicate, structures, superficially attached to the mucosa by a stalk and are referred to as **exophytic papillomas**. The individual finger-like papillae have a central core of loose fibrovascular tissue covered by epithelium that is **histologically identical to normal urothelium** (Fig. 21-8). Recurrences and progression rarely occur, yet patients still need long-term follow-up. In contrast to exophytic papillomas, **inverted papillomas** are benign lesions, cured by excision and consist of inter-anastomosing cords of cytologically bland urothelium that extend down into the lamina propria.[19,][20]
- **Papillary urothelial neoplasms of low malignant potential (PUNLMPs)** share many histologic features with papilloma, the only differences being either thicker urothelium or diffuse nuclear enlargement in PUNLMPs. Mitotic figures are rare. At cystoscopy, PUNLMPs tend to be larger than papillomas and may be indistinguishable from low- and high-grade papillary cancers. PUNLMPs may recur with the same morphology, are not associated with invasion, and only rarely recur as higher grade tumors associated with invasion and progression.
- **Low-grade papillary urothelial carcinomas** are characterized by an orderly appearance both architecturally and cytologically. The cells are evenly spaced (i.e., maintain polarity) and cohesive. There is minimal but definite evidence of nuclear atypia consisting of scattered hyperchromatic nuclei, infrequent mitotic figures predominantly toward the base, and mild variation in nuclear size and shape (Fig. 21-9). Low-grade cancers can recur and, though infrequent, can invade. Only rarely do these tumors pose a threat to the patient's life.
- **High-grade papillary urothelial cancers** contain cells that may be dyscohesive with large hyperchromatic nuclei. Some of the tumor cells show frank anaplasia (Fig. 21-10). Mitotic figures, including atypical ones, are frequent. Architecturally, there is disarray and loss of polarity. These tumors have a much higher incidence of invasion into the muscular layer, a higher risk of progression than low-grade lesions, and, when associated with invasion, a significant metastatic potential.

In most analyses, less than 10% of low-grade cancers invade, but as many as 80% of high-grade urothelial carcinomas are invasive.[21,][22] Aggressive tumors may extend not only into the bladder wall, but, in more advanced stages, invade the adjacent prostate, seminal vesicles, ureters, and retroperitoneum. Some tumors produce fistulous communications to the vagina or rectum. About 40% of these deeply invasive tumors metastasize to regional lymph nodes. Hematogenous dissemination, principally to the liver, lungs, and bone marrow, may result.

Carcinoma in situ (CIS or flat urothelial carcinoma) is defined by the presence of cytologically malignant cells within a flat urothelium.[16,] [23] [24] [25] [26] CIS may range from full-thickness cytologic atypia to scattered malignant cells in an otherwise normal urothelium, the latter termed **pagetoid spread** (Fig. 21-11). A common feature similar to high-grade papillary urothelial carcinoma is the lack of cohesiveness, which leads to the shedding of malignant cells into the urine. When shedding is widespread, it may result in a denuded urothelium with only a few CIS cells clinging to the basement membrane. CIS usually appears grossly as an area of mucosal reddening, granularity, or thickening without producing an evident intraluminal mass. It is commonly multifocal and may involve most of the bladder surface and extend into the ureters and urethra. If untreated, 50% to 75% of CIS cases progress to muscle-invasive cancer.

Invasive urothelial cancer (Fig. 21-12) may be associated with papillary urothelial cancer, usually high grade, or CIS. The extent of the invasion into the muscularis mucosae is of prognostic significance, and understaging on biopsy is a significant problem. The extent of spread **(staging)** at the time of initial diagnosis is the most important factor in determining the outlook for a patient (Table 21-4). Almost all infiltrating urothelial carcinomas are high grade, such that grading of the infiltrating component is not critical, as opposed to the importance of grading noninvasive papillary urothelial carcinoma.

Variants of Urothelial Carcinoma. Unusual variants of urothelial cancer include the nested variant with deceptively bland cytology, lymphoepithelioma-like carcinoma, and micropapillary carcinoma. [27] [28] [29] [30] [31] [32]

Other Epithelial Tumors.

Squamous cell carcinomas represent about 3% to 7% of bladder cancers in the United States, but in countries where urinary schistosomiasis is endemic, they occur much more frequently.[33,][34] Pure squamous cell carcinomas are nearly always associated with chronic bladder irritation and infection. **Mixed urothelial carcinomas with areas of squamous carcinoma** are more frequent than pure squamous cell carcinomas. Most are invasive, fungating tumors or are infiltrative and ulcerative. The level of cytologic differentiation varies widely, from highly differentiated lesions producing abundant keratin to more anaplastic tumors with only focal evidence of squamous differentiation.

Adenocarcinomas of the bladder are rare and histologically identical to adenocarcinomas seen in the gastrointestinal tract.[35,][36] Some arise from urachal remnants or in association with extensive intestinal metaplasia (discussed earlier).

Small-cell carcinomas, indistinguishable from small-cell carcinomas of the lung, arise in the bladder often in association with urothelial, squamous, or adenocarcinoma.[37]

Epidemiology and Pathogenesis.

The incidence of carcinoma of the bladder is higher in men than in women, in developed than in developing nations, and in urban than in rural dwellers. The male-to-female ratio for urothelial tumors is approximately 3 : 1. About 80% of patients are between the ages of 50 and 80 years. Bladder cancer, with rare exceptions, is not familial.

Several factors have been implicated in the causation of urothelial carcinoma. Some of the more important contributors include the following:

- *Cigarette smoking* is clearly the most important influence, increasing the risk threefold to sevenfold, depending on the pack-years and smoking habits. Between 50% and 80% of all bladder cancers among men are associated with the use of cigarettes. Cigars, pipes, and smokeless tobacco are associated with a smaller risk.
- *Industrial exposure to arylamines*, particularly 2naphthylamine as well as related compounds, as pointed out in the discussion of chemical carcinogenesis (Chapter 7). The cancers appear 15 to 40 years after the first exposure.
- *Schistosoma haematobium* infections in endemic areas (Egypt, Sudan) are an established risk. The ova are deposited in the bladder wall and incite a brisk chronic inflammatory response that induces progressive mucosal squamous metaplasia and dysplasia and, in some instances, neoplasia. Seventy percent of the cancers are squamous, the remainder being urothelial or, least commonly, glandular.
- Long-term use of analgesics is implicated, as it is in analgesic nephropathy (Chapter 20).
- Heavy long-term exposure to cyclophosphamide, an immunosuppressive agent, induces, as noted, hemorrhagic cystitis, and increases the risk of bladder cancer.
- Prior exposure of the bladder to irradiation, often administered for other pelvic malignancies, increases the risk of urothelial carcinoma. In this setting, bladder cancer occurs many years after the irradiation.

Several genetic alterations have been observed in urothelial carcinoma.[38] [39] [40] [41] [42] Particularly common (occurring in 30% to 60% of tumors) are chromosome 9 monosomy or deletions of 9p and 9q

as well as deletions of 17p, 13q, 11p, and 14q. The *chromosome 9 deletions are the only genetic changes present frequently in superficial papillary tumors and occasionally in noninvasive flat tumors*. The 9p deletions (9p21) involve the tumor suppressor gene *p16 (INK4a)*, which encodes an inhibitor of a cyclin-dependent kinase (Chapter 7), and also the related tumor suppressor gene *p15*. The identity of the putative second tumor suppressor locus on chromosome 9q is not yet known. On the other hand, many invasive urothelial carcinomas show *deletions of 17p*, including the region of the *p53* gene, as well as mutations in *p53*, suggesting that alterations in p53 contribute to the progression of urothelial carcinoma. Mutations in *p53* are also found in CIS.

On the basis of these findings, a model for bladder carcinogenesis has been proposed. In this two-pathway model the first pathway is *initiated by deletions of tumor suppressor genes* on 9p and 9q, leading to superficial papillary tumors, a few of which may then acquire *p53* mutations and progress to invasion; a second pathway, possibly *initiated by p53 mutations*, leads to CIS and, with loss of chromosome 9, progression to invasion (Chapter 7).

Clinical Course of Bladder Cancer.

Bladder tumors classically produce *painless hematuria*. This is their dominant and sometimes only clinical manifestation. Frequency, urgency, and dysuria occasionally accompany the hematuria. When the ureteral orifice is involved, pyelonephritis or hydronephrosis may follow. About 60% of neoplasms, when first discovered, are single, and 70% are localized to the bladder.

Individuals with urothelial tumors, whatever their grade, have a tendency to develop new tumors after excision, and *recurrences* may show a higher grade. The risk of recurrence and progression is related to several variables, including tumor size, stage, grade, multifocality, prior recurrence rate, and associated dysplasia and/or CIS in the surrounding mucosa. [43] [44] [45] [46] [47] [48] Although the term recurrence is used, most of the subsequent tumors arise at different sites from the original lesion. Recurrent tumors reflect in some cases new tumors, and in other instances they share the same clonal abnormalities as the initial tumor and represent a true recurrence of the initial lesion caused by shedding and implantation of the original tumor cells.

The prognosis depends on the histologic grade of the papillary tumor and the stage at diagnosis. Papillomas, papillary urothelial neoplasms of low malignant potential, and low-grade papillary urothelial cancer yield a 98% 10-year survival rate regardless of the number of recurrences; only a few patients (<10%) have progression of their disease to higher grade lesions. High-grade papillary urothelial carcinomas invade and lead to death in about 25% of cases. Patients with primary (de novo) CIS, as opposed to CIS associated with infiltrating urothelial carcinoma, are less likely to progress to muscle-invasive cancer (28% versus 59%) or die of disease (7% versus 45%).[49] Invasive urothelial carcinoma is associated with a 30% mortality rate once tumor invades into the lamina propria. Overall, squamous cell carcinoma and adenocarcinoma are associated with a worse prognosis than urothelial carcinoma, yet stage for stage they are all similar.

The clinical challenge with these neoplasms is early detection and adequate follow-up. A significant issue is that 50% of invasive bladder cancers present with muscle-invasive disease and a relatively poor prognosis despite therapy. For tumors detected at an earlier stage, cystoscopy and biopsy are the mainstays of diagnosis. Of value in these circumstances are *cytologic examinations* and newer urine tests that detect the presence of various markers such as human complement factor H–related protein, telomerase, fibrin-fibrinogen degradation products, mucins, carcinoembryonic antigen, hyaluronic acid, hyaluronidase, nuclear matrix proteins, and chromosomal abnormalities detected by fluorescent in situ hybridization in cells in the urine.[50,][51] The major limitation of cytologic examination is the under-recognition of low-grade papillary neoplasms, whereas tests measuring urine markers have relatively low specificity, due to positive results caused by other conditions associated with injured urothelium.

The treatment for bladder cancer depends on the grade, stage, and whether the lesion is flat or papillary.[52] For small, localized papillary tumors that are not high grade, the initial diagnostic transurethral resection is the only surgical procedure done. Patients are closely followed with periodic cystoscopies and urine cytologies for the rest of their lives to detect recurrence. Research is ongoing to determine whether less invasive urine marker studies can be used as follow-up tests to increase the interval between cystoscopic procedures. After the biopsy site has healed, patients at high risk of recurrence and/or progression (CIS; papillary tumors that are high grade, multifocal, have a history of rapid recurrence, or are associated with lamina propria invasion) receive topical immunotherapy consisting of intravesicle instillation of an attenuated strain of tuberculous bacillus called bacillus Calmette-Guérin (BCG). The bacteria elicit a local inflammatory reaction that destroys the tumor. Radical cystectomy is typically performed for (1) tumor invading the muscularis propria, (2) CIS or high-grade papillary cancer refractory to BCG, and (3) CIS extending into the prostatic urethra and extending down the prostatic ducts, where BCG will not come into contact with the neoplastic cells. Advanced bladder cancer is treated by chemotherapy.

Mesenchymal Tumors

Benign Tumors.

A great variety of benign mesenchymal tumors may arise in the bladder, having the histologic features of their counterparts elsewhere. Collectively, they are rare. The most common is *leiomyoma*.[53] They all tend to grow as isolated, intramural, encapsulated, oval-to-spherical masses, varying in diameter up to several centimeters.

Sarcomas.

True sarcomas are distinctly uncommon in the bladder. Inflammatory myofibroblastic tumors and various carcinomas may assume sarcomatoid growth patterns and be mistaken histologically for sarcomas.[54,][55] As a group, sarcomas tend to produce large masses (varying up to 10 to 15 cm in diameter) that protrude into the vesicle lumen. Their soft, fleshy, gray-white gross appearance suggests their sarcomatous nature. The most common sarcoma in infancy or childhood is *embryonal rhabdomyosarcoma*.[56] In some of these cases they manifest as a polypoid grapelike mass *(sarcoma botryoides)*. The most common sarcoma in the bladder in adults is leiomyosarcoma[53] (Chapter 26).

Secondary Tumors

Secondary malignant involvement of the bladder is most often by direct extension from primary lesions in nearby organs, cervix, uterus, prostate, and rectum. Lymphomas may involve the bladder as a component of systemic disease, but also, rarely, as primary bladder lymphoma.[57]

OBSTRUCTION

Obstruction to the bladder neck is of major clinical importance, mainly because of its eventual effect on the kidney. In males the most important lesion is enlargement of the prostate gland due to nodular hyperplasia (Fig. 21-13). Bladder obstruction is somewhat less common in females and is most often caused by cystocele of the bladder. Infrequent causes are (1) congenital urethral strictures, (2) inflammatory urethral strictures, (3) inflammatory fibrosis and contraction of the bladder, (4) bladder tumors, either benign or malignant, (5) invasion of the bladder neck by tumors arising in contiguous organs, (6) mechanical obstructions caused by foreign bodies and calculi, and (7) injury to the innervation of the bladder causing neurogenic bladder.

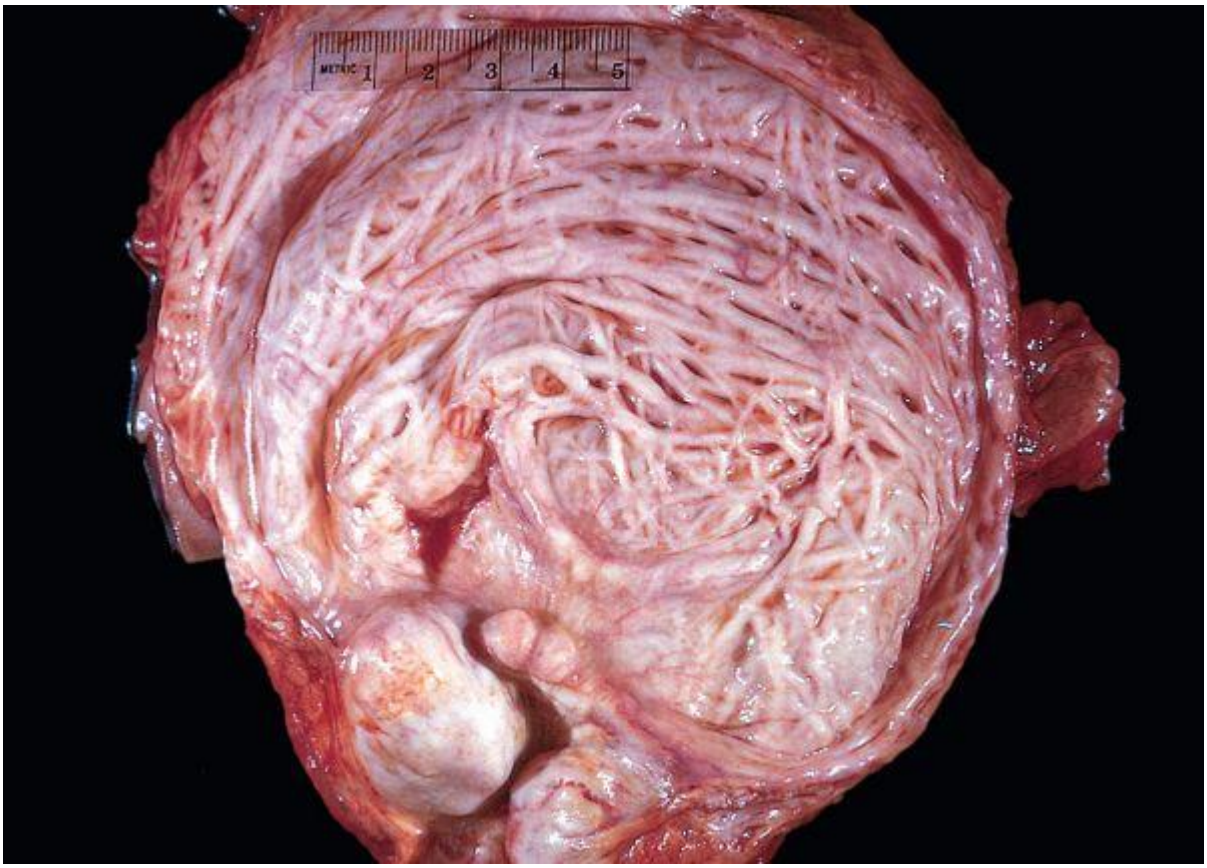

FIGURE 21-13 Hypertrophy and trabeculation of bladder wall secondary to polypoid hyperplasia of the prostate.

Morphology. In the early stages there is only some thickening of the bladder wall due to smooth muscle hypertrophy. With progressive hypertrophy the individual muscle bundles greatly enlarge and produce trabeculation of the bladder wall. In the course of time, crypts form and may then become converted into diverticula.

In some cases of acute obstruction or in terminal disease when the patient's normal reflex mechanisms are depressed, the bladder may become extremely dilated. The enlarged bladder may reach the brim of the pelvis or even the level of the umbilicus. In these cases the bladder wall is markedly thinned and without trabeculations.

3.11.1.3 Urethra
INFLAMMATION

Urethritis is classically divided into gonococcal and nongonococcal. *Gonococcal urethritis* is one of the earliest manifestations of this venereal infection. *Nongonococcal urethritis* is common and can be caused by a variety of bacteria, among which *E. coli* and other enteric organisms predominate. Urethritis is often accompanied by cystitis in women and by prostatitis in men. In many instances bacteria cannot be isolated. Various strains of *Chlamydia* (e.g., *C. trachomatis*) are the cause of 25% to 60% of nongonococcal urethritis in men and about 20% in women. *Mycoplasma (Ureaplasma*

urealyticum) also accounts for the symptoms of urethritis in many cases. Urethritis is also one component of *Reiter syndrome*, which comprises the clinical triad of arthritis, conjunctivitis, and urethritis (Chapter 26).

The morphologic changes are entirely typical of inflammation in other sites within the urinary tract. The urethral involvement is not itself a serious clinical problem but may cause considerable local pain, itching, and frequency, and may represent a forerunner of more serious disease at higher levels of the urogenital tract.

TUMORS AND TUMOR-LIKE LESIONS

Urethral caruncle is an inflammatory lesion presenting as a small, red, painful mass about the external urethral meatus, typically in older females. It may be covered by an intact mucosa but is extremely friable, and the slightest trauma may cause ulceration of the surface and bleeding. On histologic examination, it is composed of an inflamed granulation tissue polyp. Surgical excision affords prompt relief and cure.

Benign epithelial tumors of the urethra include squamous and urothelial papillomas, inverted urothelial papillomas, and condylomas.

Peyronie disease results in fibrous bands involving the corpus cavernosum of the penis. Although some classify it as a variant of fibromatosis, its etiology remains an enigma. Clinically, the lesion results in penile curvature and pain during intercourse.

Primary c*arcinoma of the urethra* is an uncommon lesion (Fig. 21-14). Tumors arising within the proximal urethra tend to show urothelial differentiation and are analogous to those occurring within the bladder. Those lesions found within the distal urethra are more typically squamous carcinomas. Glandular carcinomas occur less frequently in the urethra generally in women. A rare variant is clear cell adenocarcinoma. Some neoplastic lesions of the urethra are similar to those described in the bladder, arising through metaplasia or, less commonly, from periurethral glands. Cancers arising within the prostatic urethra are dealt with in the section on the prostate.

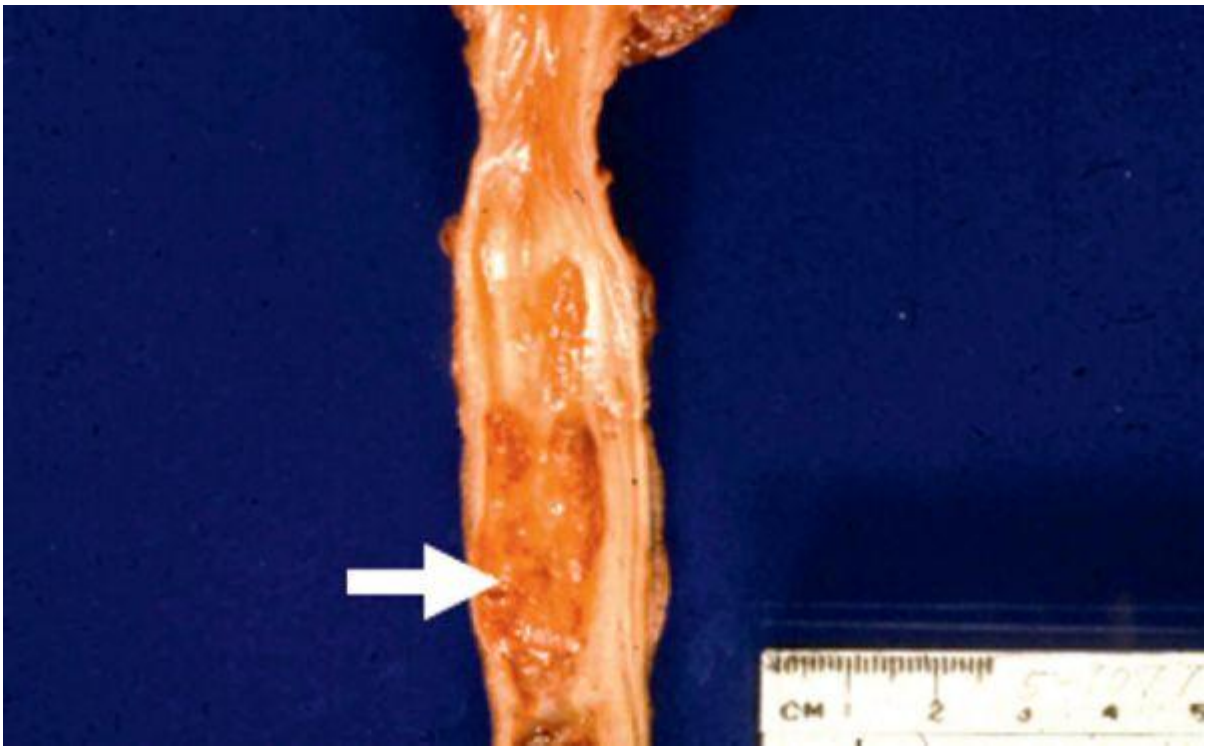

FIGURE 21-14 Carcinoma of urethra with typical fungating growth.

3.11.2 The Male Genital Tract

3.11.2.1 Penis

The penis can be affected by congenital anomalies, inflammations, and tumors, inflammations and tumors being the most important. The venereal infections (e.g., syphilis and gonorrhea) usually begin with penile lesions. Carcinoma of the penis is an uncommon neoplasm in North America.

CONGENITAL ANOMALIES

The penis is the site of many forms of congenital anomalies, only some of which have clinical significance.

Hypospadias and Epispadias

Malformation of the urethral groove and urethral canal may create abnormal openings either on the *ventral surface of the penis (hypospadias)* or on the *dorsal surface (epispadias)*.[58] Though more frequent with epispadias, either of these two anomalies may be associated with failure of normal descent of the testes and with malformations of the urinary tract. Hypospadias, the more common of the two, occurs in approximately 1 in 300 live male births.[59] Even when isolated, these urethral defects may have clinical significance, because the abnormal opening is often constricted, resulting in urinary tract obstruction and an increased risk of ascending urinary tract infections. When the orifices are situated near the base of the penis, normal ejaculation and insemination are hampered or totally blocked. These lesions therefore are possible causes of sterility in men.

Phimosis

When the orifice of the prepuce is too small to permit its normal retraction, the condition is designated *phimosis*. Such an abnormally small orifice may result from anomalous development but is more frequently the result of repeated attacks of infection that cause scarring of the preputial ring.[60] Phimosis is important because it interferes with cleanliness and permits the accumulation of secretions and detritus under the prepuce, favoring the development of secondary infections and possibly carcinoma.

INFLAMMATION

Inflammations of the penis almost invariably involve the glans and prepuce and include a wide variety of specific and nonspecific infections. The specific infections—syphilis, gonorrhea, chancroid, granuloma inguinale, lymphopathia venerea, genital herpes—are sexually transmitted and are discussed in Chapter 8 . Only the nonspecific infections causing so-called balanoposthitis require description here.

Balanoposthitis refers to infection of the glans and prepuce caused by a wide variety of organisms. Among the more common agents are *Candida albicans*, anaerobic bacteria, *Gardnerella*, and pyogenic bacteria.[61] Most cases occur as a consequence of poor local hygiene in uncircumcised males, with accumulation of desquamated epithelial cells, sweat, and debris, termed *smegma*, acting as local irritant. Persistence of such infections leads to inflammatory scarring and, as mentioned earlier, is a common cause of phimosis.

TUMORS

Tumors of the penis are, on the whole, uncommon. The most frequent neoplasms are carcinomas and a benign epithelial tumor, condyloma acuminatum.

Benign Tumors

Condyloma Acuminatum

Condyloma acuminatum is a benign sexually transmitted tumor caused by human papillomavirus (HPV). It is related to the common wart and may occur on any moist mucocutaneous surface of the external genitals in either sex. HPV type 6, and less frequently type 11, are the most frequent agents that cause condylomata acuminata.

Morphology. Condylomata acuminata may occur on the external genitalia or perineal areas. On the penis these lesions occur most often about the coronal sulcus and inner surface of the prepuce. They consist of single or multiple sessile or pedunculated, red papillary excrescences that vary from 1 mm to several millimeters in diameter (Fig. 21-15). Histologically a branching, villous, papillary connective tissue stroma is covered by epithelium that may have considerable superficial hyperkeratosis and thickening of the underlying epidermis (acanthosis) (Fig. 21-16). The normal orderly maturation of the epithelial cells is preserved. Cytoplasmic vacuolization of the squamous cells (koilocytosis), characteristic of HPV infection, is noted in these lesions (Fig. 21-17). Cells may have degenerative (viral) atypia but true dysplasia is rare. Condylomata acuminata tend to recur but only rarely progress into in situ or invasive cancers.

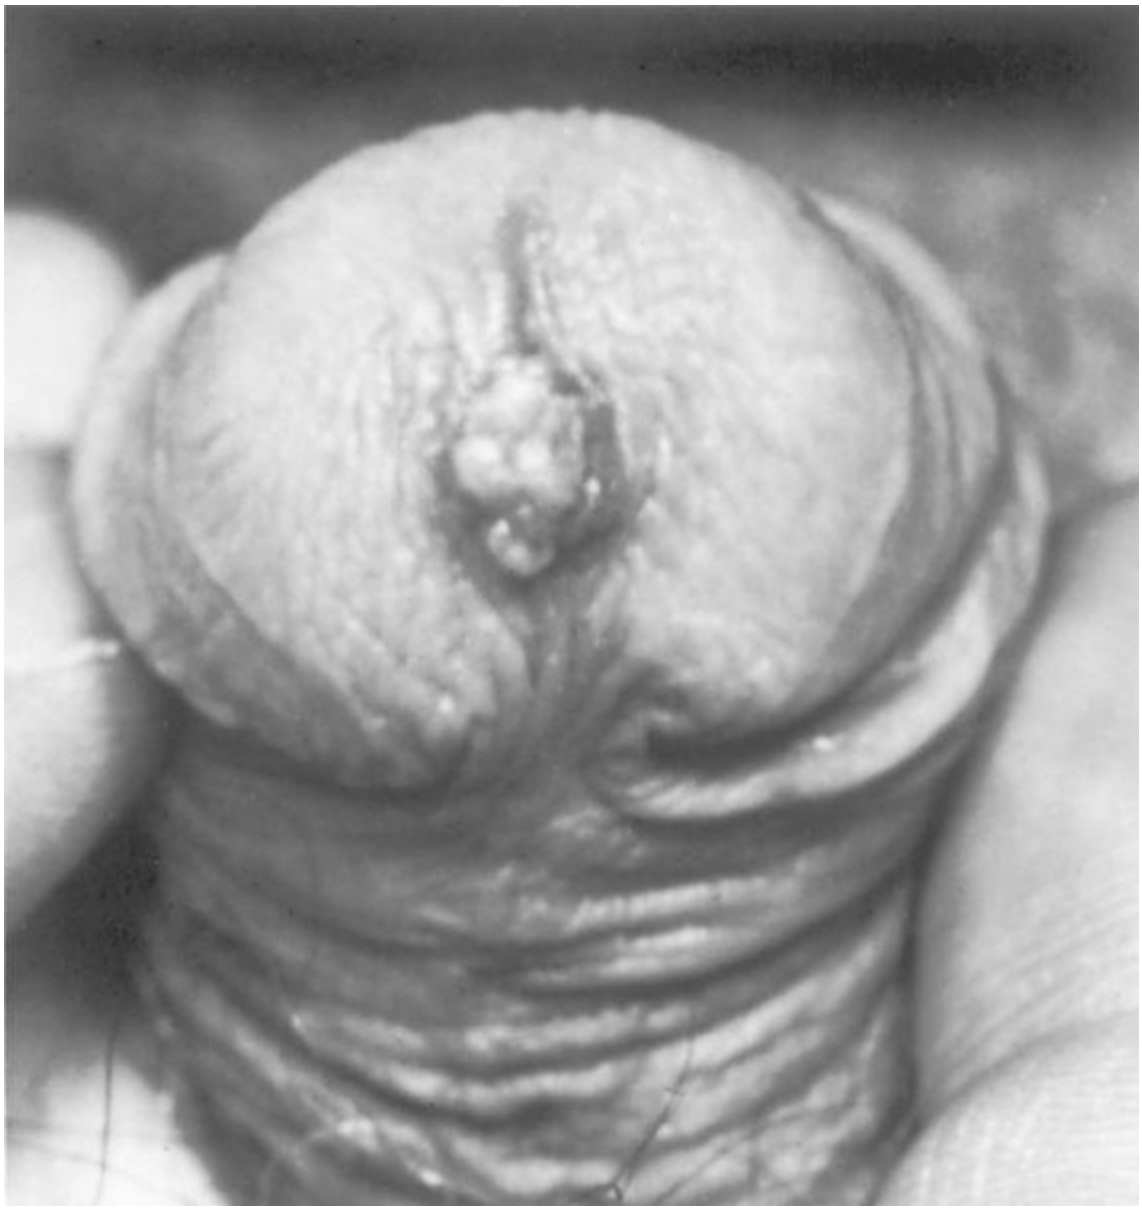

FIGURE 21-15 Condyloma acuminatum of the penis.

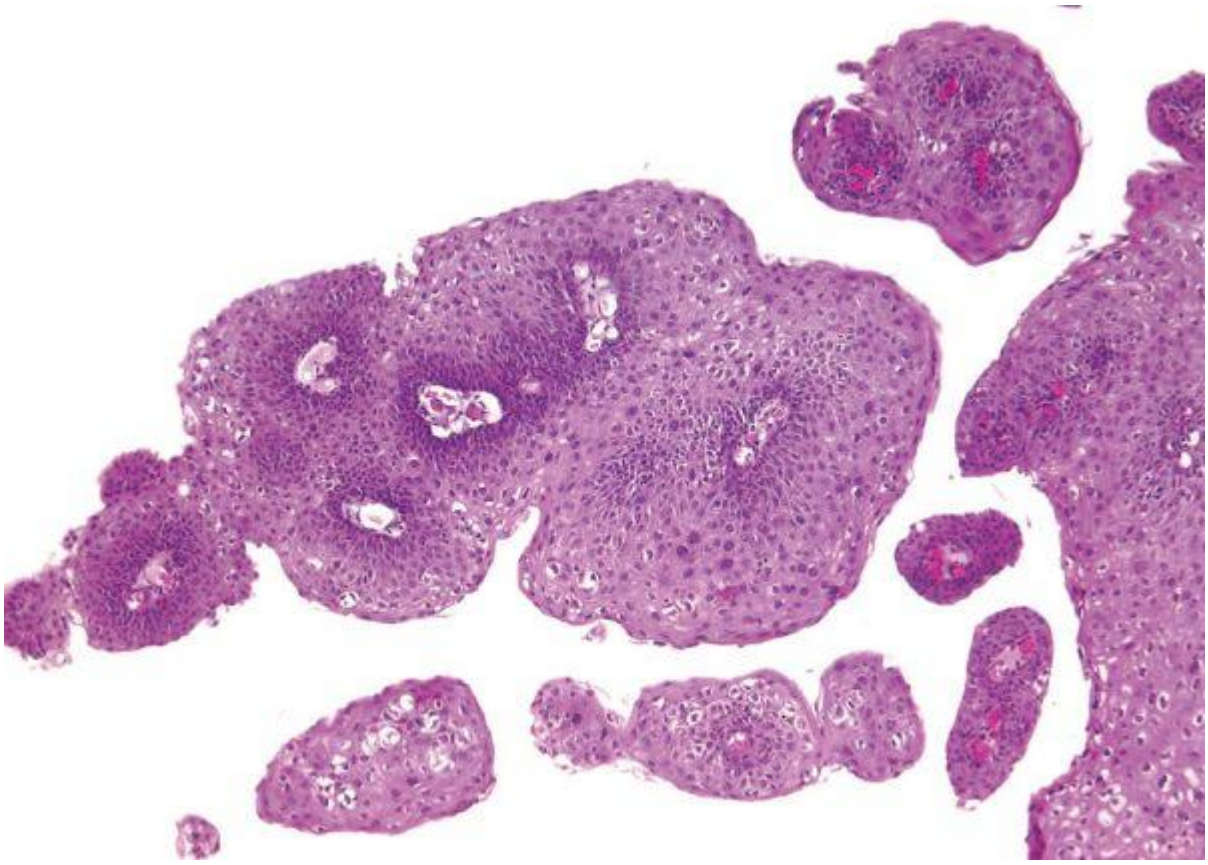

FIGURE 21-16 Condyloma acuminatum of the penis. Low magnification reveals the papillary (villous) architecture, and thickening of the epidermis.

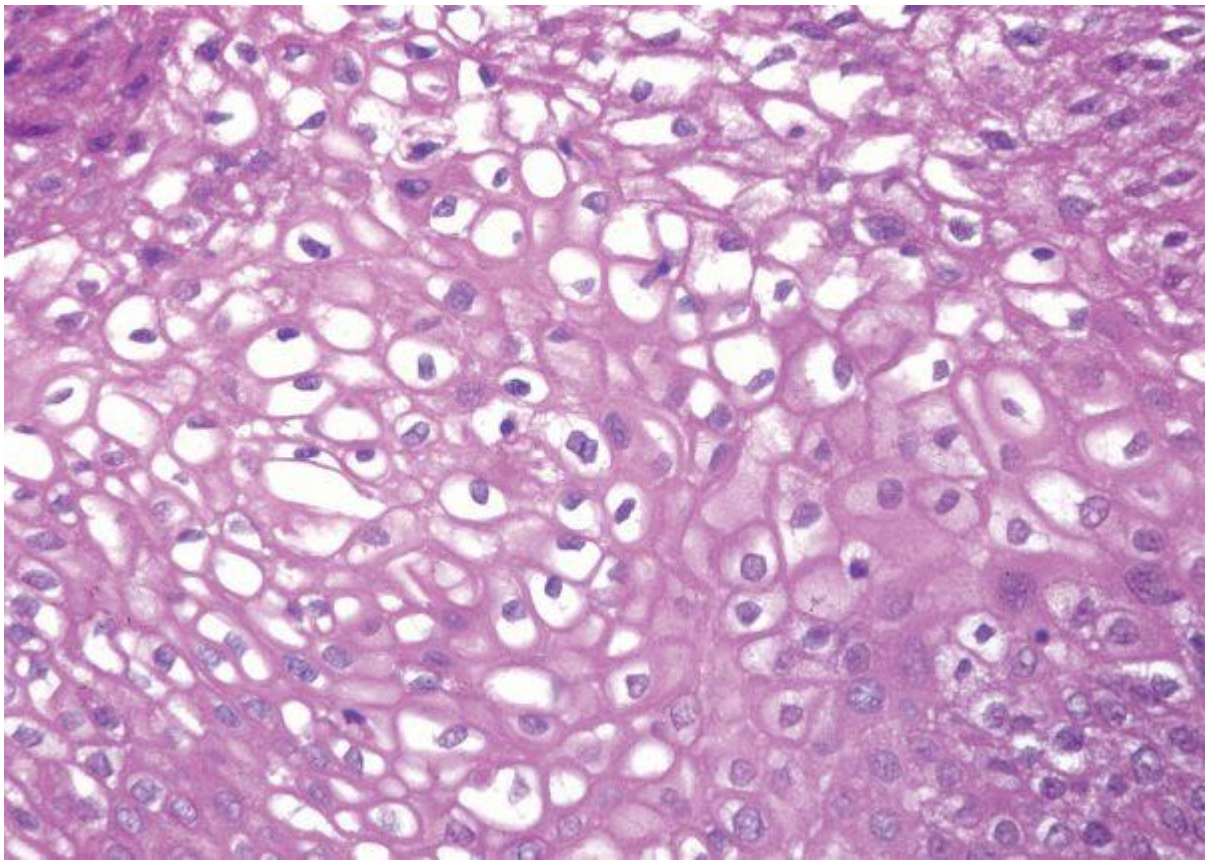

FIGURE 21-17 Condyloma acuminatum of the penis. The epithelium shows vacuolization (koilocytosis) characteristic of human papillomavirus infection.

Malignant Tumors

Carcinoma in Situ (CIS)

In the external male genitalia, two distinct lesions display histologic features of CIS: *Bowen disease* and *bowenoid papulosis*. These lesions have a strong association with infection by HPV, most commonly type 16.[62]

Bowen disease occurs in the genital region of both men and women, usually in those over the age of 35 years. In men it tends to involve the skin of the shaft of the penis and the scrotum. Grossly it appears as a solitary, thickened, gray-white, opaque plaque. It can also manifest on the glans and prepuce as single or multiple shiny red, sometimes velvety plaques. Histologically the epidermis shows proliferation with numerous mitoses, some atypical. The cells are markedly dysplastic with large hyperchromatic nuclei and lack of orderly maturation (Fig. 21-18). Nevertheless, *the dermal-epidermal border is sharply delineated by an intact basement membrane*. Over the span of years, Bowen disease may transform into infiltrating squamous cell carcinoma in approximately 10% of patients. Bowen disease may also be associated with visceral cancer, such as that of the colon or breast, but not as frequently as initially reported.

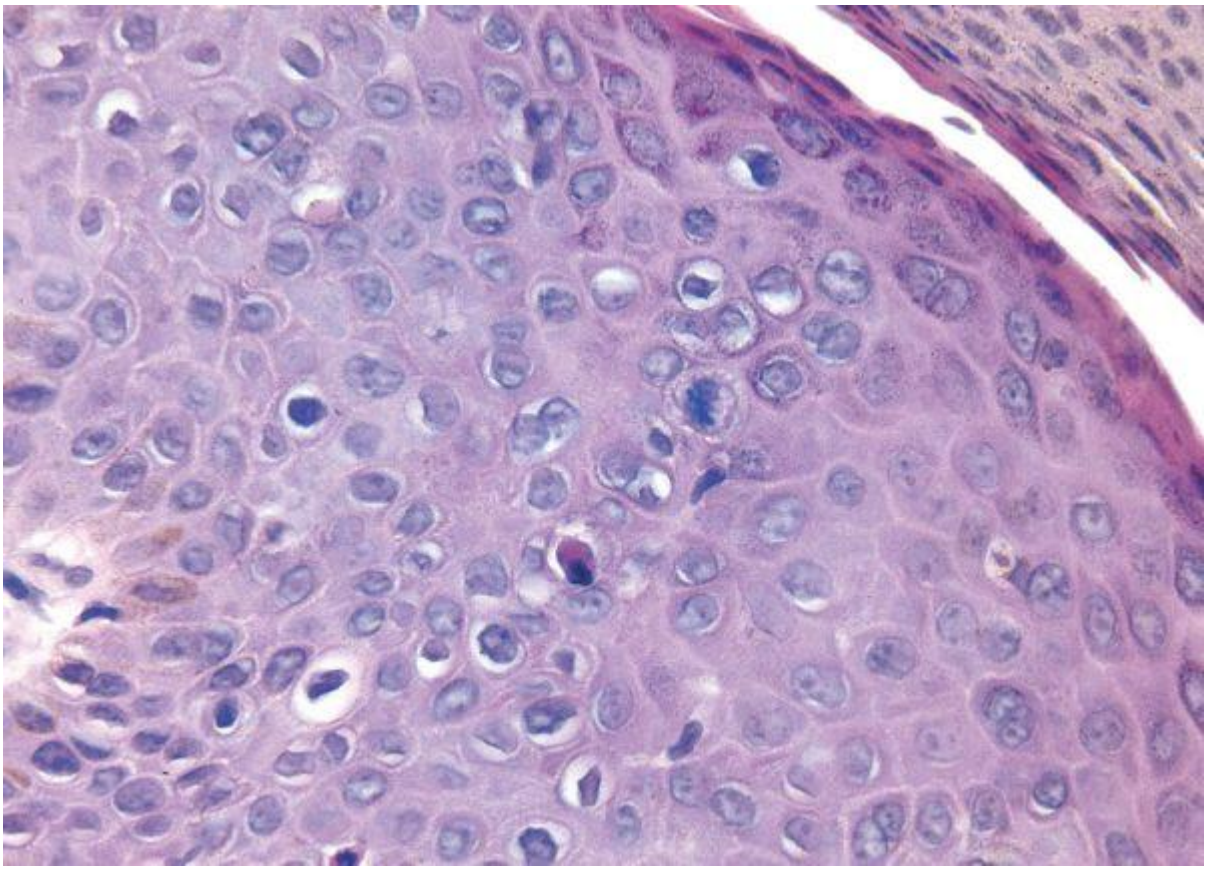

FIGURE 21-18 Bowen disease (carcinoma in situ) of the penis. Note the hyperchromatic, dysplastic dyskeratotic epithelial cells with scattered mitoses above the basal layer. The intact basement membrane is not readily seen in this picture.

Bowenoid papulosis occurs in sexually active adults. Clinically, it differs from Bowen disease by the younger age of patients and the presence of multiple (rather than solitary) reddish brown papular lesions. Histologically, bowenoid papulosis is indistinguishable from Bowen disease and is also related to HPV type 16. However, in contrast to Bowen disease, bowenoid papulosis virtually never develops into an invasive carcinoma and in many cases spontaneously regresses.

Invasive Carcinoma

Squamous cell carcinoma of the penis is an uncommon malignancy in the United States, accounting for fewer than 1% of cancers in males. By contrast, in some parts of Asia, Africa, and South America the incidence of squamous cell carcinoma of the penis ranges from 10% to 20% of male malignancies. Circumcision confers protection, and hence this cancer is extremely rare among Jews and Moslems and is correspondingly more common in populations in which circumcision is not routinely practiced. It is postulated that circumcision is associated with better genital hygiene, which, in turn, reduces exposure to carcinogens that may be concentrated in smegma and decreases the likelihood of infection with potentially oncogenic types of HPV. HPV DNA can be detected in penile squamous cancer in approximately 50% of patients.[62] HPV type 16 is the most frequent culprit, but HPV 18 is also implicated. Cigarette smoking elevates the risk of developing cancer of the penis.[63] Carcinomas are usually found in patients between the ages of 40 and 70.

Morphology. Squamous cell carcinoma of the penis usually begins on the glans or inner surface of the prepuce near the coronal sulcus. Two macroscopic patterns are seen—papillary and flat. The papillary lesions simulate condylomata acuminata and may produce a cauliflower-like fungating mass. Flat lesions appear as areas of epithelial thickening accompanied by graying and fissuring of the mucosal surface. With progression, an ulcerated papule develops (Fig. 21-19). Histologically, both the papillary and the flat lesions are squamous cell carcinomas with varying degrees of differentiation. **Verrucous carcinoma** is an exophytic well-differentiated variant of squamous cell carcinoma that has low malignant potential. These tumors are locally invasive, but they rarely metastasize. Other, less common, subtypes of penile squamous carcinoma include basaloid, warty, and papillary variants.[64,][65]

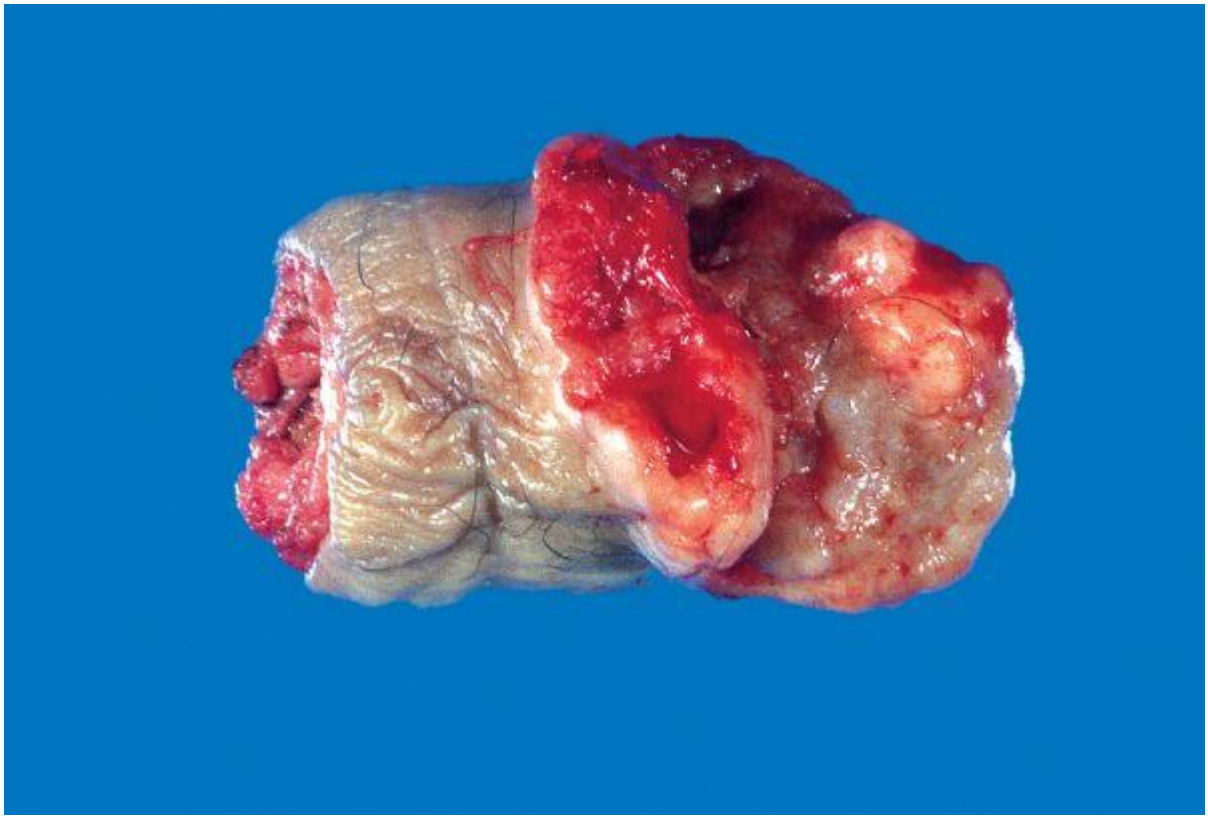

FIGURE 21-19 Carcinoma of the penis. The glans penis is deformed by a firm, ulcerated, infiltrative mass.

Clinical Features.

Invasive squamous cell carcinoma of the penis is a slowly growing, locally invasive lesion that often has been present for a year or more before it is brought to medical attention.[66] The lesions are nonpainful until they undergo secondary ulceration and infection. Metastases to inguinal lymph nodes characterize the early stage, but widespread dissemination is extremely uncommon until the lesion is far advanced. Clinical assessment of regional lymph node involvement is notoriously inaccurate; 50% of men with penile squamous cell carcinoma and clinically enlarged inguinal nodes have only reactive lymphoid hyperplasia when examined histologically. The prognosis is related to the stage of the tumor. In persons with limited lesions without invasion of the inguinal lymph nodes, there is a 66% 5-year survival rate, whereas metastasis to the lymph nodes carries a grim 27% 5-year survival.

3.11.2.2 Testis & Epididymis

Distinct pathological conditions affect the testis and epididymis. In the epididymis, the most important and frequent conditions are inflammatory diseases, whereas in the testis the major lesions are tumors.

CONGENITAL ANOMALIES

With the exception of undescended testes (cryptorchidism), congenital anomalies are extremely rare and include absence of one or both testes and fusion of the testes (so-called *synorchism*).

Cryptorchidism

Cryptorchidism is found in approximately 1% of 1-year-old boys.[67] This anomaly represents a complete or incomplete failure of the intra-abdominal testes to descend into the scrotal sac. It usually occurs as an isolated anomaly but may be accompanied by other malformations of the genitourinary tract, such as hypospadias.

Testicular descent occurs in two morphologically and hormonally distinct phases.[68] During the first, the transabdominal, phase, the testis comes to lie within the lower abdomen or brim of the pelvis. This phase is believed to be controlled by a hormone called *müllerian-inhibiting substance*. In the second, or the inguinoscrotal, phase, the testes descend through the inguinal canal into the scrotal sac. This phase is androgen dependent and is possibly mediated by androgen-induced release of calcitonin gene–related peptide, from the genitofemoral nerve. Although testes may be arrested anywhere along their pathway of descent, defects in transabdominal descent are uncommon, accounting for approximately 5% to 10% of cases. In most patients the undescended testis is palpable in the inguinal canal. *Even though testicular descent is controlled by hormonal factors, cryptorchidism is only rarely associated with a well-defined hormonal disorder*. The condition is completely asymptomatic, and it is found by the patient or the examining physician only when the scrotal sac is discovered not to contain the testis.

Morphology. Cryptorchidism is unilateral in most cases, but it may be bilateral in 25% of patients. Histologic changes in the malpositioned testis begin as early as 2 years of age. They are characterized by an arrest in the development of germ cells associated with marked hyalinization and thickening of the basement membrane of the spermatic tubules (Fig. 21-20). Eventually the tubules appear as dense cords of hyaline connective tissue outlined by prominent basement membranes. There is concomitant increase in interstitial stroma. Because Leydig cells are spared, they appear to be prominent. As might be expected with progressive tubular atrophy, the cryptorchid testis is small in size and is firm in consistency as a result of fibrotic changes. Histologic deterioration, associated with a paucity of germ cells, has also been noted in the contralateral (descended) testis in males with unilateral cryptorchidism, supporting an intrinsic defect in testicular development.

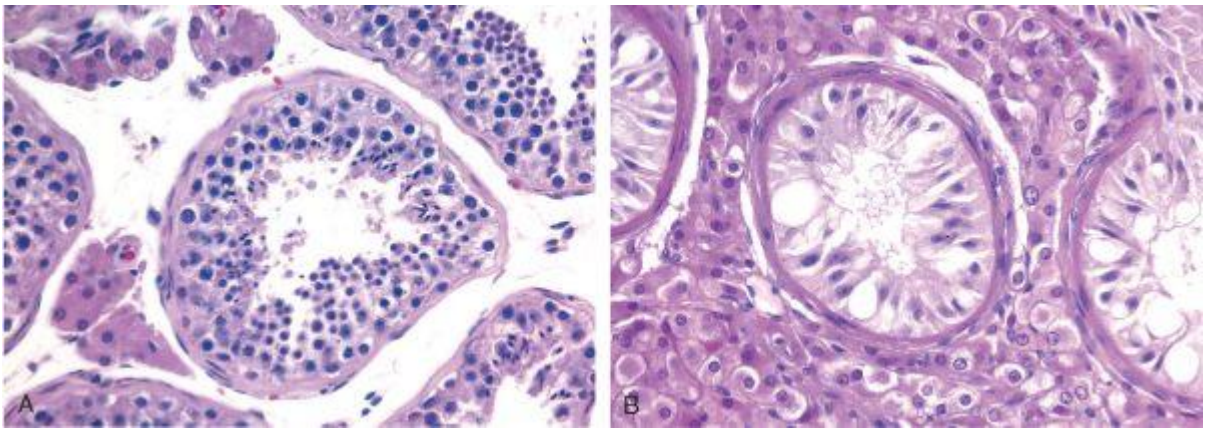

FIGURE 21-20 **A**, Normal testis shows tubules with active spermatogenesis. **B**, Testicular atrophy in cryptorchidism. The tubules show Sertoli cells but no spermatogenesis. There is thickening of basement membranes and an apparent increase in interstitial Leydig cells.

In addition to sterility, cryptorchidism can be associated with other morbidity. When the testis lies in the inguinal canal, it is particularly exposed to trauma and crushing against the ligaments and bones. A concomitant inguinal hernia accompanies the undescended testis in about 10% to 20% of cases. In addition, the undescended testis is at a greater risk of developing testicular cancer than is the descended testis.[69] During the first year of life the majority of inguinal cryptorchid testes descend spontaneously into the scrotum. Those that remain undescended require surgical correction, preferably before histologic deterioration sets in at around 2 years of age.[70] Orchiopexy (placement in the scrotal sac) does not guarantee fertility; deficient spermatogenesis has been reported in 10% to 60% of patients in whom surgical repositioning was performed.[67,][70] To what extent the risk of cancer is reduced after orchiopexy is also unclear. According to some studies, orchiopexy of unilateral cryptorchidism before 10 years of age protects against cancer development.[71] This is not universally accepted, however.[72] Malignant change may occur in the contralateral, normally descended testis. These observations suggest that cryptorchidism is associated with a defect in testicular development and cellular differentiation that is unrelated to anatomic position.

REGRESSIVE CHANGES

Atrophy and Decreased Fertility

Atrophy is a regressive change that affects the scrotal testis and can have any of several causes, including (1) progressive atherosclerotic narrowing of the blood supply in old age, (2) the end stage of an inflammatory orchitis, (3) cryptorchidism, (4) hypopituitarism, (5) generalized malnutrition or cachexia, (6) irradiation, (7) prolonged administration of antiandrogens (treatment for advanced carcinoma of the prostate), and (8) exhaustion atrophy, which may follow the persistent stimulation produced by high levels of follicle-stimulating pituitary hormone. The gross and microscopic alterations follow the pattern already described for cryptorchidism. *Atrophy occasionally occurs as a primary failure of genetic origin, such as in Klinefelter syndrome* (discussed in Chapter 5).

Atrophy is an end-stage pattern of testicular injury. Before this terminal histologic appearance is reached, several other patterns are associated with decreased fertility.[73] These include hypospermatogenesis, maturation arrest, and findings associated with vas deferens obstruction. In some instances a specific cause for the testicular injury can be found, and if it can be removed before the development of atrophy, testicular function can be restored.

INFLAMMATION

Inflammations are distinctly more common in the epididymis than in the testis. Of the three major specific inflammatory states that affect the testis and epididymis, *gonorrhea and tuberculosis almost invariably arise in the epididymis, whereas syphilis affects first the testis*.

Nonspecific Epididymitis and Orchitis

Epididymitis and possible subsequent orchitis are commonly related to infections in the urinary tract (cystitis, urethritis, prostatitis), which reach the epididymis and the testis through either the vas deferens or the lymphatics of the spermatic cord.

The cause of epididymitis varies with the age of the patient. Though uncommon in children, epididymitis in childhood is usually associated with a congenital genitourinary abnormality and infection with gram-negative rods. In sexually active men younger than age 35 years, the sexually transmitted pathogens *C. trachomatis* and *Neisseria gonorrhoeae* are the most frequent culprits. In men older than age 35 the common urinary tract pathogens, such as *E. coli* and *Pseudomonas*, are responsible for most infections.

Morphology. The bacterial invasion induces nonspecific acute inflammation characterized by congestion, edema, and infiltration by neutrophils, macrophages, and lymphocytes. Although the infection, in the early stage, is more or less limited to the interstitial connective tissue, it rapidly extends to involve the tubules and may progress to frank abscess formation or complete suppurative necrosis of the entire epididymis (Fig. 21-21). Usually, having involved the epididymis, the infection extends into the testis to evoke a similar inflammatory reaction. Such inflammatory involvement of the epididymis and testis is often followed by fibrous scarring, which in many cases leads to sterility. Usually the interstitial cells of Leydig are not totally destroyed, so sexual activity is not disturbed.

FIGURE 21-21 Acute epididymitis caused by gonococcal infection. The epididymis is replaced by an abscess. Normal testis is seen on the *right*.

Granulomatous (Autoimmune) Orchitis

Idiopathic granulomatous orchitis presents in middle age as a moderately tender testicular mass of sudden onset sometimes associated with fever. It may appear insidiously, however, as a painless testicular mass mimicking a testicular tumor, hence its importance. Histologically the orchitis is distinguished by granulomas restricted to spermatic tubules. The lesions closely resemble tubercles but differ in that the granulomatous reaction is present diffusely throughout the testis and is confined to the seminiferous tubules. Although an autoimmune basis is suspected, the cause of these lesions remains unknown.

Specific Inflammations

Gonorrhea

Extension of infection from the posterior urethra to the prostate, seminal vesicles, and then to the epididymis is the usual course of a neglected gonococcal infection. Inflammatory changes similar to those described for nonspecific infections occur, with the development of frank abscesses in the epididymis, which may lead to extensive destruction of this organ. In neglected cases, the infection may spread to the testis and produce suppurative orchitis.

Mumps

Mumps is a systemic viral disease that most commonly affects school-aged children. Testicular involvement is extremely uncommon in this age group. In postpubertal males, however, orchitis may develop and has been reported in 20% to 30% of male patients. Most often, acute interstitial orchitis develops about 1 week after the onset of swelling of the parotid glands.

Tuberculosis

Tuberculosis almost invariably begins in the epididymis and may spread to the testis. The infection invokes the classic morphologic reactions of caseating granulomatous inflammation characteristic of tuberculosis elsewhere.

Syphilis

The testis and epididymis are affected in both acquired and congenital syphilis, but *almost invariably the testis is involved first by the infection*. In many cases, the orchitis is not accompanied by epididymitis. The morphologic pattern of the reaction takes two forms: the production of gummas or a diffuse interstitial inflammation characterized by edema and lymphocytic and plasma cell infiltration with the characteristic hallmark of all syphilitic infections (i.e., obliterative endarteritis with perivascular cuffing of lymphocytes and plasma cells).

VASCULAR DISORDERS

Torsion

Twisting of the spermatic cord typically cuts off the venous drainage of the testis. The thick-walled arteries remain patent, so that the intense vascular engorgement may be followed by hemorrhagic infarction. There are two types of testicular torsion. Neonatal torsion occurs either in utero or shortly after birth. It lacks any associated anatomic defect to account for its occurrence. Adult torsion is typically seen in adolescence presenting as sudden onset of testicular pain. It often occurs without any inciting injury; sudden pain heralding the torsion may even occur during sleep. *Torsion is one of the few urologic emergencies*. If the testis is explored surgically and manually untwisted within approximately 6 hours after the onset of torsion, there is a good chance that the testis will remain viable. In contrast to neonatal torsion, adult torsion results from a bilateral anatomic defect where the testis has increased mobility, giving rise to what is termed the *bell-clapper abnormality*. To prevent the catastrophic occurrence of subsequent torsion in the contralateral testis, the testis unaffected by torsion is surgically fixed to the scrotum (orchiopexy).

Morphology. Depending on the duration of the process, the morphologic changes range from intense congestion to widespread extravasation of blood into the interstitial tissue to hemorrhagic testicular infarction (Fig. 21-22). In these late stages the testis is markedly enlarged and is converted virtually into a sac of soft, necrotic, hemorrhagic tissue.

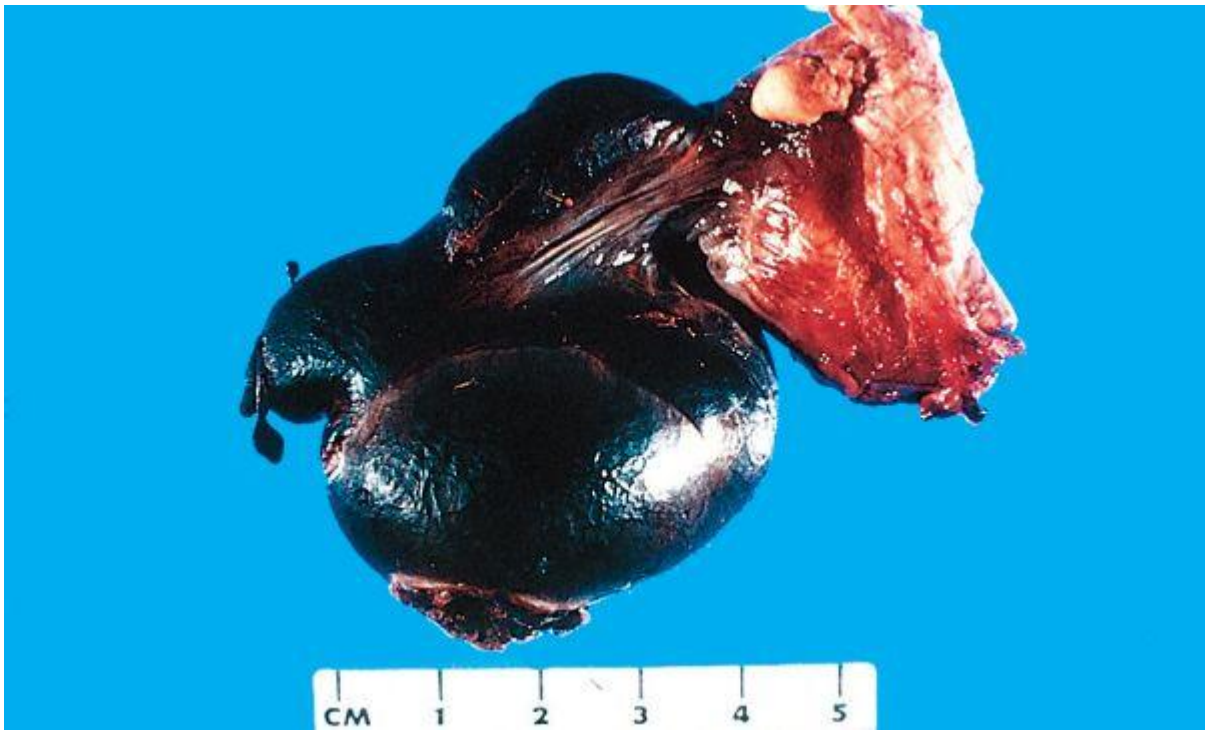

FIGURE 21-22 Torsion of testis.

SPERMATIC CORD AND PARATESTICULAR TUMORS

Lipomas are common lesions involving the proximal spermatic cord, identified at the time of inguinal hernia repair. Although diagnosed as "lipomas," many of these lesions probably represent retroperitoneal adipose tissue that has been pulled into the inguinal canal along with the hernia sac, rather than a true neoplasm.

The most common benign paratesticular tumor is *adenomatoid tumor*. Although these lesions are mesothelial in nature, they are not referred to as mesotheliomas to distinguish them from other mesothelial lesions that may occur at this site. Adenomatoid tumors are usually small nodules, typically occurring near the upper pole of the epididymis. Although grossly well circumscribed, microscopically they may be minimally invasive into the adjacent testis. The importance of this lesion is that it is one of the few benign tumors that occur near the testis. If the pathologist can identify the nature of this lesion in intraoperative frozen sections, local excision of the adenomatoid tumor can spare the patient orchiectomy.

The most common malignant paratesticular tumors located at the distal end of the spermatic cord are rhabdomyosarcomas in children and liposarcomas in adults.

TESTICULAR TUMORS

Testicular neoplasms span an amazing gamut of anatomic types.[17,][74] They are divided into two major categories: germ cell tumors and sex cord–stromal tumors (Table 21-5). Approximately 95% of testicular tumors arise from germ cells. Germ cell tumors are subdivided into seminomas and non-seminomas. Most germ cell tumors are aggressive cancers capable of rapid, wide dissemination,

although with current therapy most can be cured.[75] Sex cord–stromal tumors, in contrast, are generally benign.

Germ Cell Tumors

The incidence of testicular tumors in the United States is approximately 6 per 100,000, resulting in approximately 300 deaths per year. For unexplained reasons there is a worldwide increase in the incidence of these tumors. In the 15- to 34-year age group, they constitute the most common tumor of men and cause approximately 10% of all cancer deaths. In the United States these tumors are much more common in whites than in blacks (ratio 5 : 1).

Environmental Factors and Genetic Predisposition.

Environmental factors play a role in the incidence of testicular germ cell tumors, as demonstrated by population migration studies. The incidence of testicular germ cell tumors in Finland is about two times lower than in Sweden; second generation Finnish immigrants to Sweden, have a tumor incidence that approaches that of the Swedish population. Testicular germ cell tumors are associated with a spectrum of disorders known as *testicular dysgenesis syndrome (TDS)*. This syndrome includes cryptorchidism, hypospadias, and poor sperm quality, and it has been proposed that some of these conditions might be influenced by in utero exposures to pesticides and nonsteroidal estrogens. Cryptorchidism, which is associated with approximately 10% of testicular germ cell tumors, is the most important risk factor. Klinefelter syndrome (a TDS condition) is associated with an increased risk (50 times greater than normal) for the development of mediastinal germ cell tumors, but these patients do not develop testicular tumors.

There is a strong family predisposition associated with the development of testicular germ cell tumors. The relative risk of development of these tumors in fathers and sons of patients with testicular germ cell tumors is four times higher than normal, and is 8 to 10 times higher between brothers. It is possible that genetic polymorphisms at the Xq27 locus may be responsible for this susceptibility, but further studies are needed to validate this hypothesis.

Classification and Pathogenesis.

A simple classification of the most common types of testicular tumors is presented in Table 21-5 . Two broad groups are recognized. *Seminomatous tumors* are composed of cells that ressemble primordial germ cells or early gonocytes. The *non-seminomatous tumors* may be composed of undifferentiated cells that resemble embryonic stem cells, as in the case of embryonal carcinoma, but the malignant cells can differentiate into various lineages generating yolk sac tumors, choriocarcinomas and teratomas. Germ cell tumors may have a single tissue component, but in approximately 60% of cases, the tumors contain *mixtures of seminomatous and non-seminomatous components* and multiple tissues. In teratomas, tissues of the three germ layers are represented as a result of the differentiation of embryonal carcinoma cells. Seminomas constitute approximately 50% of all testicular germ cell neoplasms and are the most common testicular tumor.

Most testicular germ cell tumors originate from lesions called *intratubular germ cell neoplasia (ITGCN)*, which is also referred to as *intratubular germ cell neoplasia unclassified (ITGCNU)*.[76,][77] However, ITGCN has not been implicated as a precursor lesion of pediatric yolk sac tumors and teratomas, or of adult spermatocytic seminoma. ITGCN is believed to occur in utero and stay dormant until puberty, when it may progress into seminomas or non-seminomatous tumors. The lesion consists of atypical primordial germ cells with large nuclei and clear cytoplasm, which are about twice the size of normal germ cells. These cells retain the expression of the transcription factors *OCT3/4* and *NANOG*, which are associated with pluripontentiality (Chapter 3), and are expressed in normal embryonic stem cells. ITGCN share some of the genetic alterations found in germ cell tumors such as the gain of additional copies of the short arm of chromosome 12 (12p) in the form of an isochromosome of its short arm, i(12p). This change is invariably found in invasive tumors regardless of histological type. Activating mutations of c-KIT, which may be present in seminomas, are also present in ITGCN. About 50% of individuals with ITGCN develop invasive germ cell tumors within five years after diagnosis, and it has been proposed that practically all patients with ITGCN eventually develop invasive tumors. ITGCN is essentially a type of carcinoma in situ (CIS), although the term *CIS* is not frequently used to refer to this lesion.

Seminoma

Seminomas are the most common type of germ cell tumor, making up about 50% of these tumors. The peak incidence is the third decade and they almost never occur in infants. An identical tumor arises in the ovary, where it is called *dysgerminoma* (Chapter 22). Seminomas contain an isochromosome 12p, and express *OCT3/4* and *NANOG*. Approximately 25% of these tumors have c-KIT activating mutations. c-KIT amplification has also been repeated, but increased *c-KIT* expression may occur without genetic defects.

Morphology. If not otherwise specified, “seminoma” refers to “classical” or “typical” seminoma that consists of a uniform population of cells. Spermatocytic seminoma, despite its nosologic similarity, is a distinct tumor discussed later. Seminomas produce bulky masses, sometimes ten times the size of the normal testis. The typical seminoma has a homogeneous, gray-white, lobulated cut surface, usually devoid of hemorrhage or necrosis (Fig. 21-23). Generally the tunica albuginea is not penetrated, but occasionally extension to the epididymis, spermatic cord, or scrotal sac occurs.

Microscopically the typical seminoma is composed of sheets of uniform cells divided into poorly demarcated lobules by delicate septa of fibrous tissue containing a moderate amount of lymphocytes (Fig. 21-24A). **The classic seminoma cell is large and round to polyhedral and has a distinct cell membrane; a clear or watery-appearing cytoplasm; and a large, central nucleus with one or two prominent nucleoli** (Fig. 21-24B). Mitoses vary in frequency. The cytoplasm contains varying amounts of glycogen. Seminoma cells are diffusely positive for *c-KIT*, (regardless of c-KIT

mutational status) *OCT4*, and placental alkaline phosphatase (PLAP), with sometimes scattered keratin-positive cells.

Approximately 15% of seminomas contain syncytiotrophoblasts. In this subset of patients, serum human chorionic gonadotropin (HCG) levels are elevated, though not to the extent seen in patients with choriocarcinoma. Seminomas may also be accompanied by an ill-defined granulomatous reaction, in contrast to the well-formed discrete granulomas seen with tuberculosis.

The term **anaplastic seminoma** is used by some to indicate greater cellular and nuclear irregularity with more frequent tumor giant cells and many mitoses. However, since "anaplastic seminoma" is not associated with a worse prognosis when matched stage for stage with classic seminoma and is not treated differently, most authorities do not recognize anaplastic seminoma as a distinct entity.

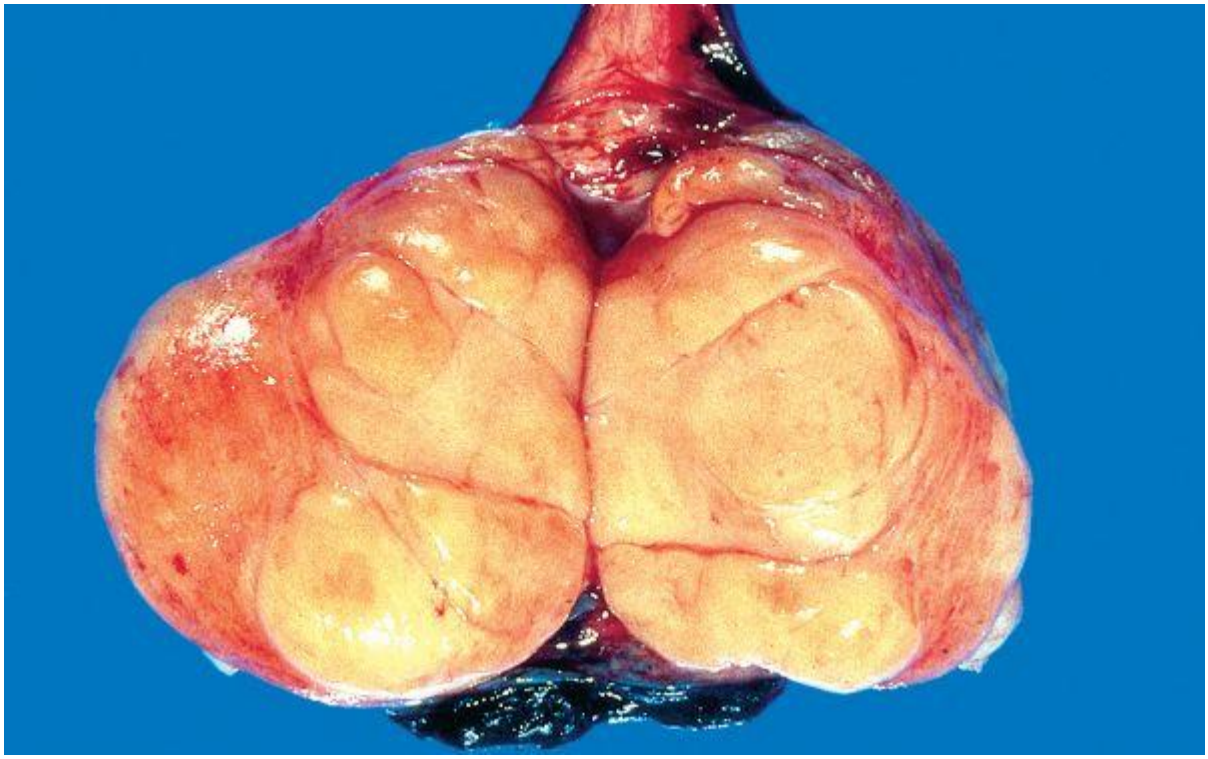

FIGURE 21-23 Seminoma of the testis appears as a fairly well-circumscribed, pale, fleshy, homogeneous mass.

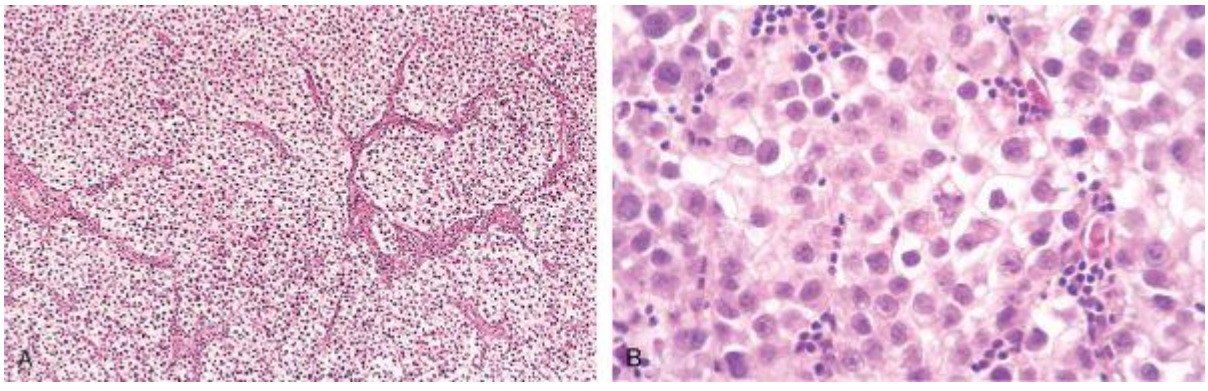

FIGURE 21-24 Seminoma. **A**, Low magnification shows clear seminoma cells divided into poorly demarcated lobules by delicate septa. **B**, Microscopic examination reveals large cells with distinct cell borders, pale nuclei, prominent nucleoli, and a sparse lymphocytic infiltrate.

Spermatocytic Seminoma

Though related by name to seminoma, spermatocytic seminoma is a distinctive tumor both clinically and histologically.[78] Spermatocytic seminoma is an uncommon tumor, representing 1% to 2% of all testicular germ cell neoplasms. The age of involvement is much later than for most testicular tumors: Affected individuals are generally over the age of 65 years. In contrast to classic seminoma, it is a slow-growing tumor that does not produce metastases, and hence the prognosis is excellent. In contrast to typical seminomas, spermatocytic seminomas lack lymphocytes, granulomas, syncytiotrophoblasts, extra-testicular sites of origin, admixture with other germ cell tumors, and association with ITGCN (see "Clinical Features of Testicular Tumors" discussed later).

Morphology. Grossly, spermatocytic seminoma tends to have a soft, pale gray, cut surface that sometimes reveal mucoid cysts. Spermatocytic seminomas contain three cell populations, all intermixed: (1) medium-sized cells, the most numerous, containing a round nucleus and eosinophilic cytoplasm; (2) smaller cells with a narrow rim of eosinophilic cytoplasm resembling secondary spermatocytes; and (3) scattered giant cells, either uninucleate or multinucleate. The chromatin in some intermediate-sized cells is similar to that seen in the meiotic phase of non-neoplastic spermatocytes (spireme chromatin).

Embryonal Carcinoma

Embryonal carcinomas occur mostly in the 20- to 30-year age group. These tumors are more aggressive than seminomas.

Morphology. Grossly, the tumor is smaller than seminoma and usually does not replace the entire testis. On cut surfaces the mass is often variegated, poorly demarcated at the margins, and punctuated by foci of hemorrhage or necrosis (Fig. 21-25). Extension through the tunica albuginea into the epididymis or cord frequently occurs. **Histologically the cells grow in alveolar or tubular patterns, sometimes with papillary convolutions** (Fig. 21-26). Embryonal carcinomas lack the well-formed glands with basally situated nuclei and apical cytoplasm seen in teratomas. **More undifferentiated lesions may display sheets of cells**. The neoplastic cells have an epithelial appearance, are large and anaplastic, and have hyperchromatic nuclei with prominent nucleoli. In contrast to seminoma, the cell borders are usually indistinct, and there is considerable variation in cell and nuclear size and shape. Mitotic figures and tumor giant cells are frequently seen. Embryonal carcinomas share some markers with seminomas such as OCT 3/4 and PLAP, but differ by being positive for cytokeratin and CD30, and negative for c-KIT.[79]

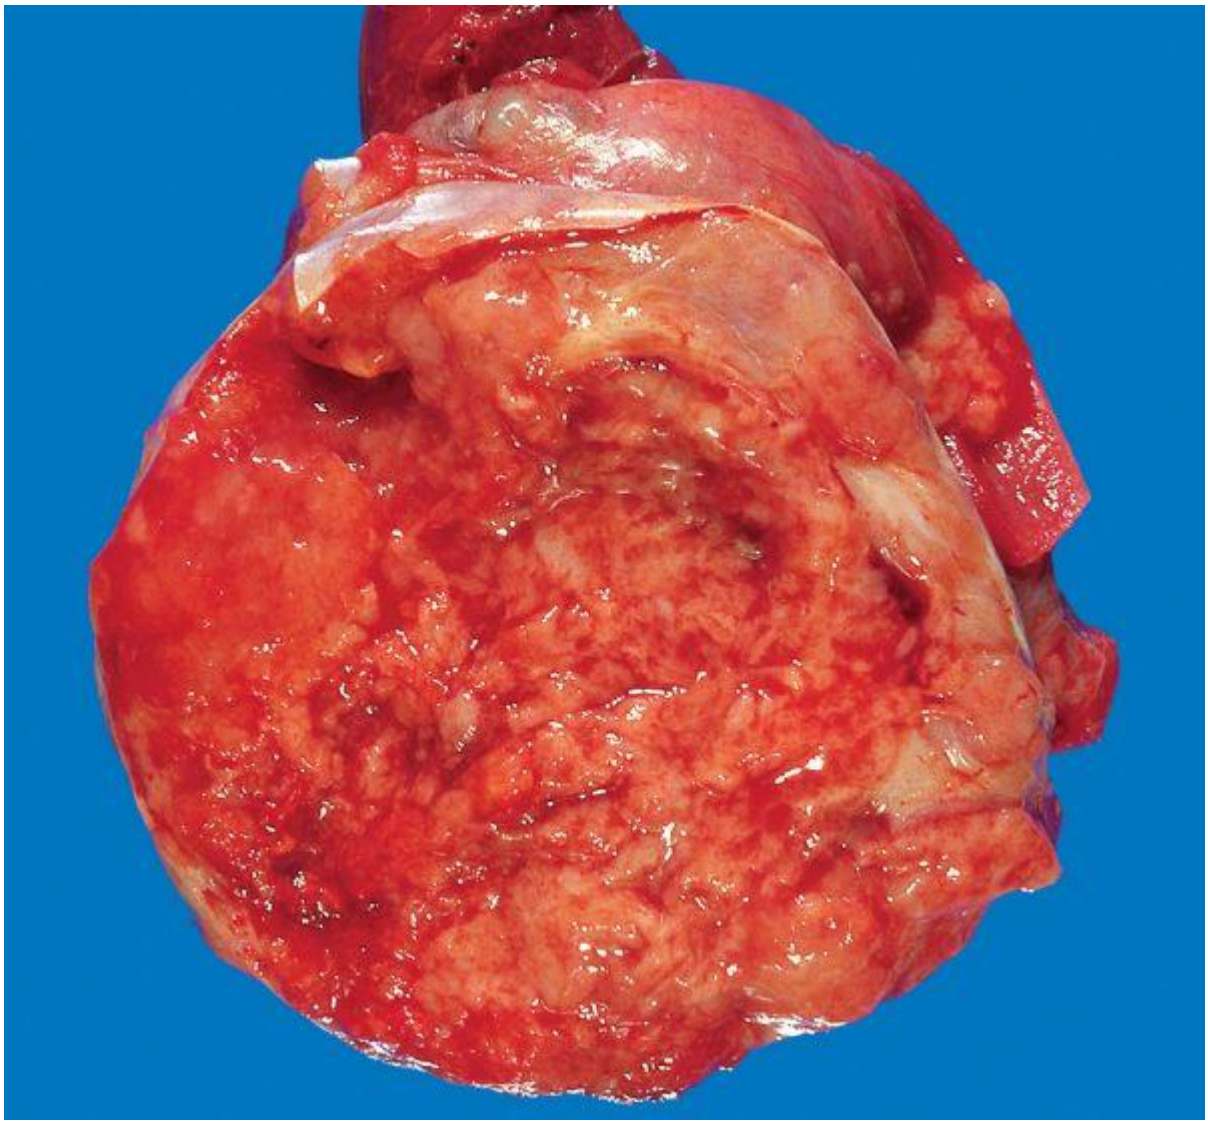

FIGURE 21-25 Embryonal carcinoma. In contrast to the seminoma illustrated in Figure 21-23 , the embryonal carcinoma is a hemorrhagic mass.

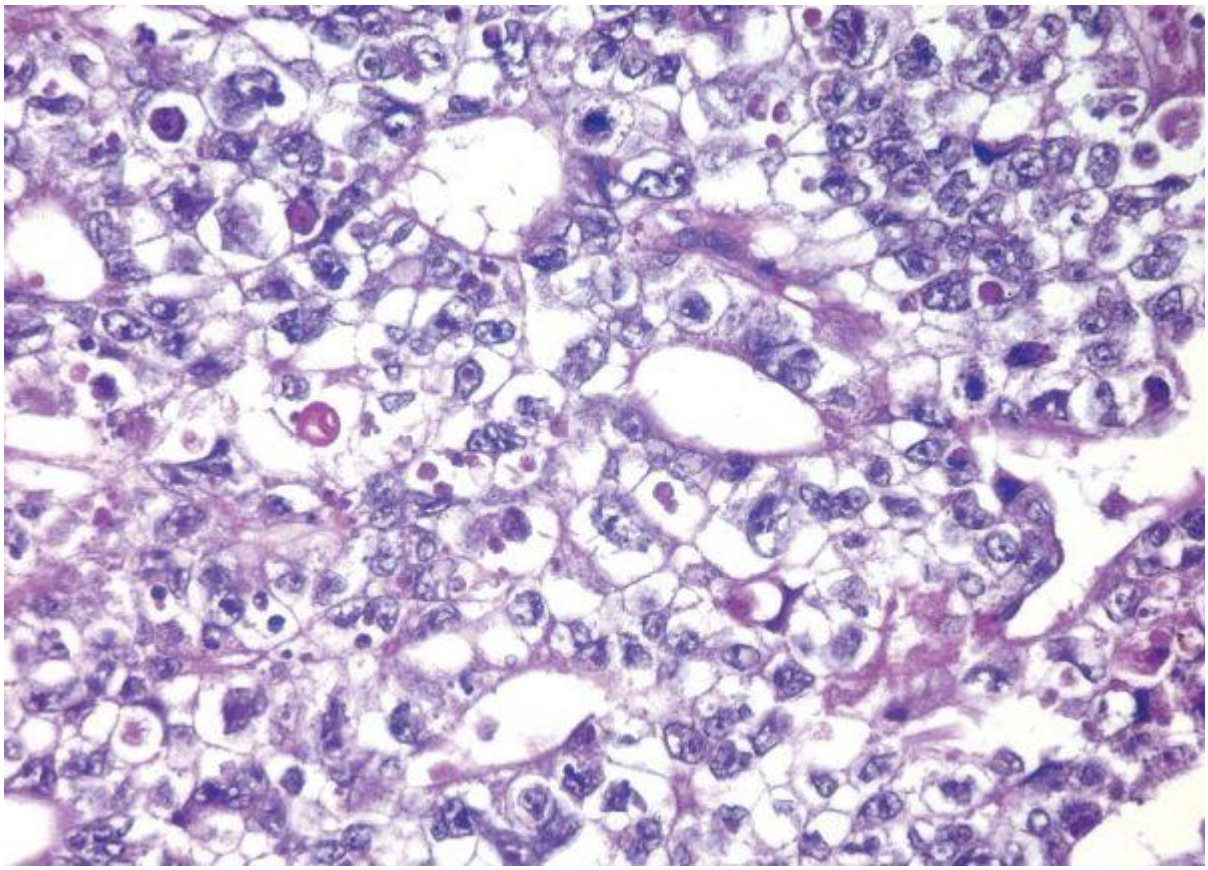

FIGURE 21-26 Embryonal carcinoma shows sheets of undifferentiated cells as well as primitive glandular differentiation. The nuclei are large and hyperchromatic.

Yolk Sac Tumor

Also known as *endodermal sinus tumor*, yolk sac tumor is of interest because it is the most common testicular tumor in infants and children up to 3 years of age. In this age group it has a very good prognosis. In adults the pure form of this tumor is rare; instead, yolk sac elements frequently occur in combination with embryonal carcinoma.

Morphology. Grossly, the tumor is nonencapsulated, and on cross-section it presents a homogeneous, yellow-white, mucinous appearance. Characteristic on microscopic examination is a lacelike (reticular) network of medium-sized cuboidal or flattened cells. In addition, papillary structures, solid cords of cells, and a multitude of other less common patterns may be found. In approximately 50% of tumors, structures resembling endodermal sinuses (Schiller-Duval bodies) may be seen; these consist of a mesodermal core with a central capillary and a visceral and parietal layer of cells resembling primitive glomeruli. Present within and outside the cytoplasm are eosinophilic, hyaline-like globules in which α-fetoprotein (AFP) and α_1-antitrypsin can be demonstrated by immunocytochemical staining. The presence of AFP in the tumor cells is highly characteristic, and it underscores their differentiation into yolk sac cells.

Choriocarcinoma

Choriocarcinoma is a highly malignant form of testicular tumor. In its “pure” form choriocarcinoma is rare, constituting less than 1% of all germ cell tumors.

Morphology. Often they cause no testicular enlargement and are detected only as a small palpable nodule. Typically, these tumors are small, rarely larger than 5 cm in diameter. Hemorrhage and necrosis are extremely common. Histologically the tumors contain two cell types (Fig. 21-27). The syncytiotrophoblastic cells are large and have many irregular or lobular hyperchromatic nuclei and an abundant eosinophilic vacuolated cytoplasm. HCG can be readily demonstrated in the cytoplasm. The cytotrophoblastic cells are more regular and tend to be polygonal, with distinct borders and clear cytoplasm; they grow in cords or masses and have a single, fairly uniform nucleus. More anatomic details are available in the discussion of these neoplasms in the female genital tract (Chapter 22).

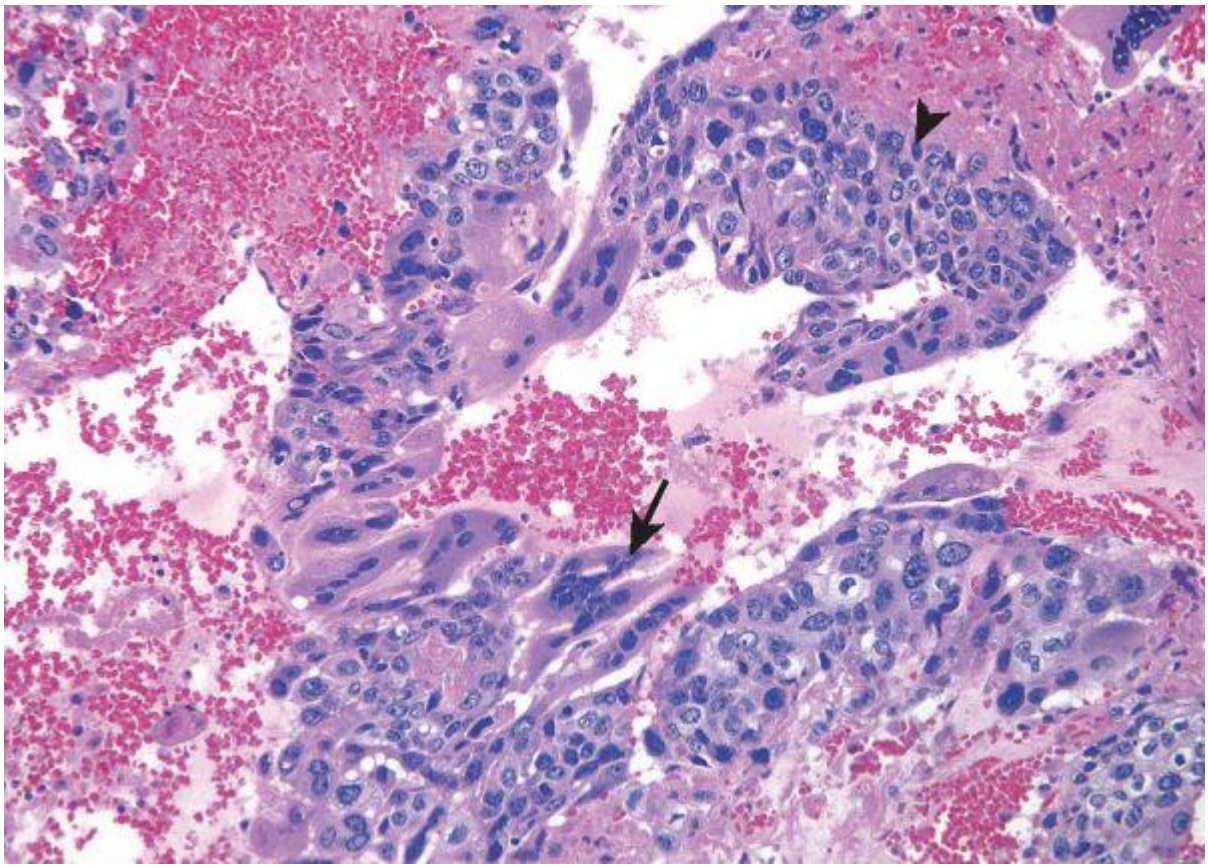

FIGURE 21-27 Choriocarcinoma shows clear cytotrophoblastic cells *(arrowhead)* with central nuclei and syncytiotrophoblastic cells *(arrow)* with multiple dark nuclei embedded in eosinophilic cytoplasm. Hemorrhage and necrosis are seen in the *upper right field*.

Teratoma

The designation *teratoma* refers to a group of complex testicular tumors having various cellular or organoid components reminiscent of normal derivatives from more than one germ layer. They may occur at any age from infancy to adult life. Pure forms of teratoma are fairly common in infants and children, second in frequency only to yolk sac tumors. In adults, pure teratomas are rare, constituting 2%

to 3% of germ cell tumors. However, the frequency of teratomas mixed with other germ cell tumors is approximately 45%.

Morphology. Grossly, teratomas are usually large, ranging from 5 to 10 cm in diameter. Because they are composed of various tissues, the gross appearance is heterogeneous with solid, sometimes cartilaginous, and cystic areas (Fig. 21-28). Hemorrhage and necrosis usually indicate admixture with embryonal carcinoma, choriocarcinoma, or both.

Teratomas are composed of a heterogeneous, helter-skelter collection of differentiated cells or organoid structures, such as neural tissue, muscle bundles, islands of cartilage, clusters of squamous epithelium, structures reminiscent of thyroid gland, bronchial or bronchiolar epithelium, and bits of intestinal wall or brain substance, all embedded in a fibrous or myxoid stroma (Fig. 21-29). Elements may be mature (resembling various adult tissues) or immature (sharing histologic features with fetal or embryonal tissue). Dermoid cysts and epidermoid cysts, are a form of teratoma that are common in the ovary (Chapter 22), but rare in the testis. Unlike testicular teratomas, they have a uniformly benign behavior.

Rarely, a malignant non–germ cell tumors may arise in teratoma.[80] This phenomenon is referred to as “teratoma with malignant transformation,” where there is malignancy in derivatives of one or more germ cell layers. Thus, there may be a focus of squamous cell carcinoma, mucin-secreting adenocarcinoma, or sarcoma. The importance of recognizing a non–germ cell malignancy arising in a teratoma is that the non–germ cell component does not respond to chemotherapy when it spreads outside of the testis. In this case, the only hope for cure resides in the resectability of the tumor. These non–germ cell malignancies have an isochromosome 12p, similar to the germ cell tumors from which they arose.

FIGURE 21-28 Teratoma of testis. The variegated cut surface with cysts reflects the multiplicity of tissue found histologically.

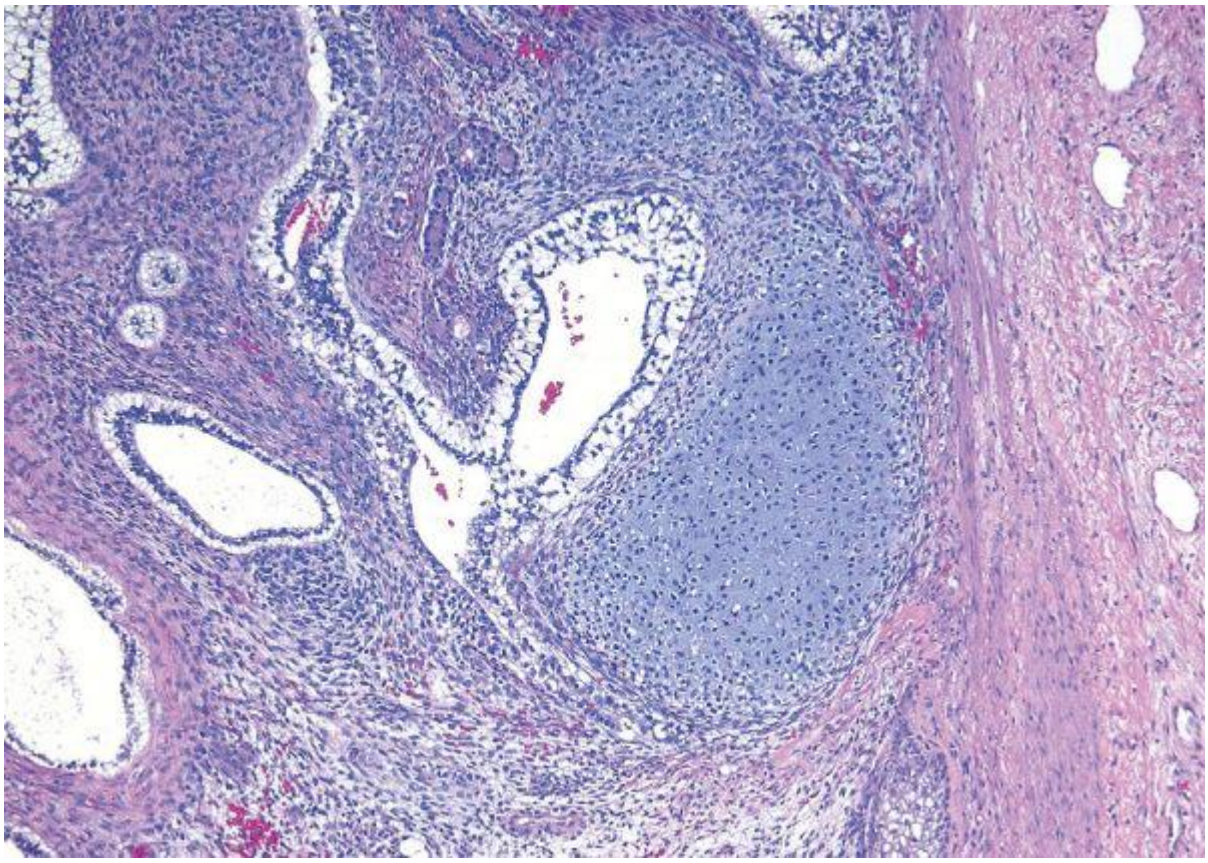

FIGURE 21-29 Teratoma of the testis consisting of a disorganized collection of glands, cartilage, smooth muscle, and immature stroma.

In the child, differentiated mature teratomas usually follow a benign course. *In the postpubertal male all teratomas are regarded as malignant*, capable of metastatic behavior whether the elements are mature or immature. Consequently, it is not critical to detect immaturity in a testicular teratoma of a postpubertal male.

Mixed Tumors

About 60% of testicular tumors are composed of more than one of the "pure" patterns. Common mixtures include: teratoma, embryonal carcinoma, and yolk sac tumor; seminoma with embryonal carcinoma; and embryonal carcinoma with teratoma *(teratocarcinoma)*. In most instances the prognosis is worsened by the inclusion of the more aggressive element.

Clinical Features of Germ Cell Testicular Tumors.

Although *painless enlargement of the testis* is a characteristic feature of germ cell neoplasms, *any solid testicular mass should be considered neoplastic unless proved otherwise*. Biopsy of a testicular neoplasm is associated with a risk of tumor spillage, which would necessitate excision of the scrotal skin in addition to orchiectomy. Consequently, the standard management of a solid testicular mass is radical orchiectomy based on the presumption of malignancy.

Testicular tumors have a characteristic mode of spread. *Lymphatic spread* is common to all forms of testicular tumors. In general retroperitoneal para-aortic nodes are the first to be involved. Subsequent spread may occur to mediastinal and supraclavicular nodes. *Hematogenous spread* is primarily to the lungs, but liver, brain, and bones may also be involved. The histology of metastases may sometimes be different from that of the testicular lesion. For example, an embryonal carcinoma may present a teratomatous picture in the secondary deposits. As discussed earlier, because all these tumors are derived from pluripotent germ cells, the apparent "forward" and "backward" differentiation seen in different locations is not entirely surprising. Another explanation for the differing morphologic patterns in the primary and metastatic site is that minor components in the primary tumor that were unresponsive to chemotherapy survive, resulting in the dominant metastatic pattern.

From a clinical standpoint, tumors of the testis are segregated into two broad categories: *seminoma* and *nonseminomatous germ cell tumors* (NSGCTs). Seminomas tend to remain localized to the testis for a long time, and hence approximately 70% present in clinical stage I (see later). In contrast, approximately 60% of males with NSGCTs present with advanced clinical disease (stages II and III). Metastases from seminomas typically involve lymph nodes. Hematogenous spread occurs later in the course of dissemination. NSGCTs not only metastasize earlier but also use the hematogenous route more frequently. The rare pure choriocarcinoma is the most aggressive NSGCT. It may not cause any testicular enlargement but instead spreads predominantly and rapidly by the bloodstream. Therefore, lungs and liver are involved early in virtually every case. From a therapeutic viewpoint, seminomas are extremely radiosensitive, whereas NSGCTs are relatively radioresistant. *To summarize, as compared with seminomas, NSGCTs are biologically more aggressive and in general have a poorer prognosis*.

In the United States, three clinical stages of testicular tumors are defined:

- Stage I: tumor confined to the testis, epididymis, or spermatic cord
- Stage II: distant spread confined to retroperitoneal nodes below the diaphragm
- Stage III: metastases outside the retroperitoneal nodes or above the diaphragm

Germ cell tumors of the testis often secrete polypeptide hormones and certain enzymes that can be detected in blood by sensitive assays.[81] Such biologic markers include HCG, AFP, and lactate dehydrogenase, which are valuable in the diagnosis and management of testicular cancer. The elevation of lactate dehydrogenase correlates with the mass of tumor cells, and provides a tool to assess tumor burden. Marked elevation of serum AFP or HCG levels are produced by yolk sac tumor and choriocarcinoma elements, respectively. Both of these markers are elevated in more than 80% of individuals with NSGCT at the time of diagnosis. As stated earlier, approximately 15% of seminomas have syncytiotrophoblastic giant cells and minimal elevation of HCG levels, which does not affect prognosis. In the context of testicular tumors, the value of serum markers is fourfold:

- In the evaluation of testicular masses
- In the staging of testicular germ cell tumors. For example, after orchiectomy, persistent elevation of HCG or AFP concentrations indicates stage II disease even if the lymph nodes appear of normal size by imaging studies.
- In assessing tumor burden
- In monitoring the response to therapy. After eradication of tumors there is a rapid fall in serum AFP and HCG. With serial measurements it is often possible to predict recurrence before the patients become symptomatic or develop any other clinical signs of relapse.

The therapy and prognosis of testicular tumors depend largely on clinical stage and on the histologic type. Seminoma, which is extremely radiosensitive and tends to remain localized for long periods, has

the best prognosis. More than 95% of patients with stage I and II disease can be cured. Among NSGCTs, the histologic subtype does not influence the prognosis significantly, and hence these are treated as a group. Approximately 90% of patients with NSGCTs can achieve complete remission with aggressive chemotherapy, and most can be cured. Pure choriocarcinoma has a poor prognosis. However, when it is a minor component of a mixed germ cell tumor, the prognosis is less adversely affected. With all testicular tumors, distant metastases, if present, usually occur within the first 2 years after treatment.

Tumors of Sex Cord–Gonadal Stroma

As indicated in Table 21-5 , sex cord–gonadal stroma tumors are subclassified based on their presumed histogenesis and differentiation. The two most important members of this group—Leydig cell tumors and Sertoli cell tumors—are described here. Details of other tumors in this group can be found in a review.[82]

Leydig Cell Tumors

Tumors of Leydig cells are particularly interesting, because they may elaborate androgens and in some cases both androgens and estrogens, and even corticosteroids.[83,][84] They may arise at any age, although most cases occur between 20 and 60 years of age. As with other testicular tumors, the most common presenting feature is testicular swelling, but in some patients gynecomastia may be the first symptom. In children, hormonal effects, manifested primarily as sexual precocity, are the dominating features.

Morphology. These neoplasms form circumscribed nodules, usually less than 5 cm in diameter. They have a distinctive golden brown, homogeneous cut surface. Histologically, neoplastic Leydig cells usually are remarkably similar to their normal counterparts in that they are large and round or polygonal, and they have an abundant granular eosinophilic cytoplasm with a round central nucleus. The cytoplasm frequently contains lipid granules, vacuoles, or lipofuscin pigment, and, most characteristically, rod-shaped crystalloids of Reinke occur in about 25% of the tumors. Approximately 10% of the tumors in adults are invasive and produce metastases; most are benign.

Sertoli Cell Tumors

Most Sertoli cell tumors are hormonally silent and present as a testicular mass.[85]

Morphology. These neoplasms appear as firm, small nodules with a homogeneous gray-white to yellow cut surface. Histologically the tumor cells are arranged in distinctive trabeculae that tend to form cordlike structures and tubules. Most Sertoli cell tumors are benign, but occasional tumors (~10%) pursue a malignant course.

Gonadoblastoma

Gonadoblastomas are rare neoplasms containing a mixture of germ cells and gonadal stromal elements, that almost always arise in gonads with some form of testrcular dysgenesis (discussed earlier). In some cases the germ cell component becomes malignant, giving rise to seminoma.

Testicular Lymphoma

Although an uncommon tumor of the testis, testicular lymphoma is included here because affected patients present with only a testicular mass, mimicking other, more common, testicular tumors. Aggressive non-Hodgkin lymphomas account for 5% of testicular neoplasms, *and are the most common*

form of testicular neoplasms in men over the age of 60. In most cases, the disease is already disseminated at the time of detection. The most common testicular lyphomas, in decreasing order of frequency, are diffuse large B cell lymphoma, Burkitt Lymphoma, and EBV-positive extranodal NK/T cell lymphoma (Chapter 13). Patients with testicular lymphomas have a higher incidence of central nervous system involvement than those similar tumors located elsewhere.

MISCELLANEOUS LESIONS OF TUNICA VAGINALIS

Brief mention should be made of the tunica vaginalis, which is a mesothelial-lined surface exterior to the testis that may accumulate serous fluid *(hydrocele)* causing considerable enlargement of the scrotal sac. By transillumination it is usually possible to define the clear, translucent character of the contained fluid. Hydrocele sacs are frequently lined by mesothelial cells. Rarely, malignant mesotheliomas also can be seen arising from the tunica vaginalis.

Hematocele indicates the presence of blood in the tunica vaginalis. It is an uncommon condition usually encountered only when there has been either direct trauma to the testis or torsion of the testis with hemorrhagic suffusion into the surrounding tunica vaginalis or in hemorrhagic diseases associated with widespread bleeding diatheses. *Chylocele* refers to the accumulation of lymph in the tunica and is almost always found in patients with elephantiasis who have widespread, severe lymphatic obstruction caused, for example, by filariasis (Chapter 8). *Spermatocele* refers to a small cystic accumulation of semen in dilated efferent ducts or ducts of the rete testis. *Varicocele* is a dilated vein in the spermatic cord. Varicoceles may be asymptomatic but have also been implicated in some men as a contributing factor to infertility. They can be corrected by surgical repair.

3.11.2.3 Prostate

In the normal adult the prostate weighs approximately 20 gm. The prostate is a retroperitoneal organ encircling the neck of the bladder and urethra, and is devoid of a distinct capsule. In the adult, prostatic parenchyma can be divided into four biologically and anatomically distinct zones or regions: the peripheral, central, and transitional zones, and the region of the anterior fibromuscular stroma (Fig. 21-30).[87] The types of proliferative lesions are different in each region. For example, most hyperplasias arise in the transitional zone, whereas most carcinomas originate in the peripheral zone.

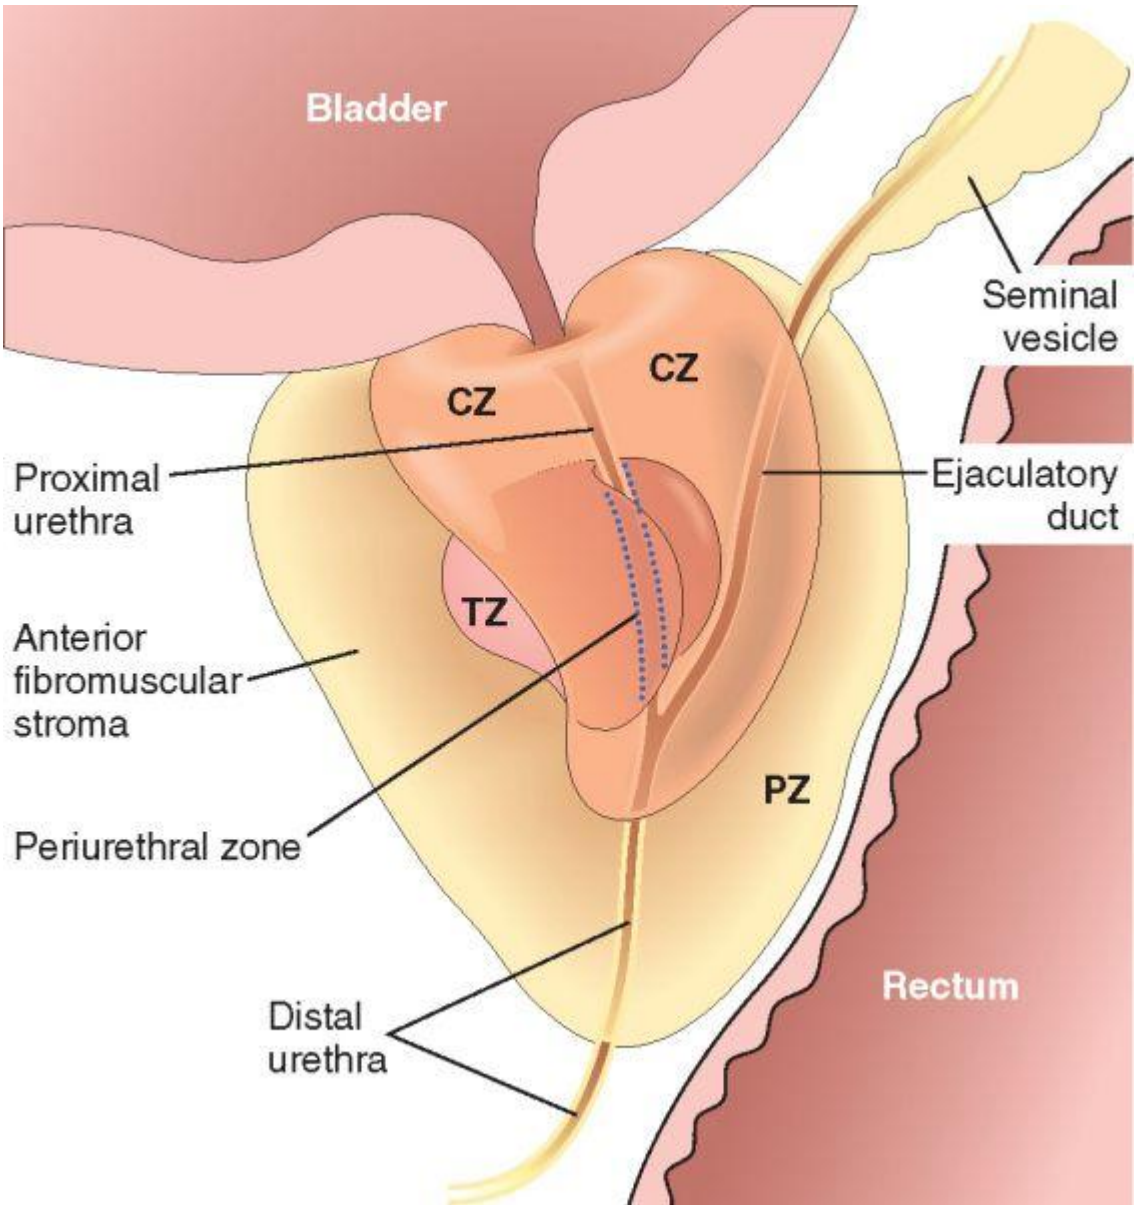

FIGURE 21-30 Adult prostate. The normal prostate contains several distinct regions, including a central zone (CZ), a peripheral zone (PZ), a transitional zone (TZ), and a periurethral zone. Most carcinomas arise from the peripheral glands of the organ and may be palpable during digital examination of the rectum. Nodular hyperplasia, in contrast, arises from more centrally situated glands and is more likely to produce urinary obstruction early than is carcinoma.

Histologically the prostate is composed of glands lined by two layers of cells: a basal layer of low cuboidal epithelium covered by a layer of columnar secretory cells (Fig. 21-31). In many areas there are small papillary infoldings of the epithelium. These glands are separated by abundant fibromuscular stroma. Testicular androgens control the growth and survival of prostatic cells. Castration leads to atrophy of the prostate caused by widespread apoptosis.

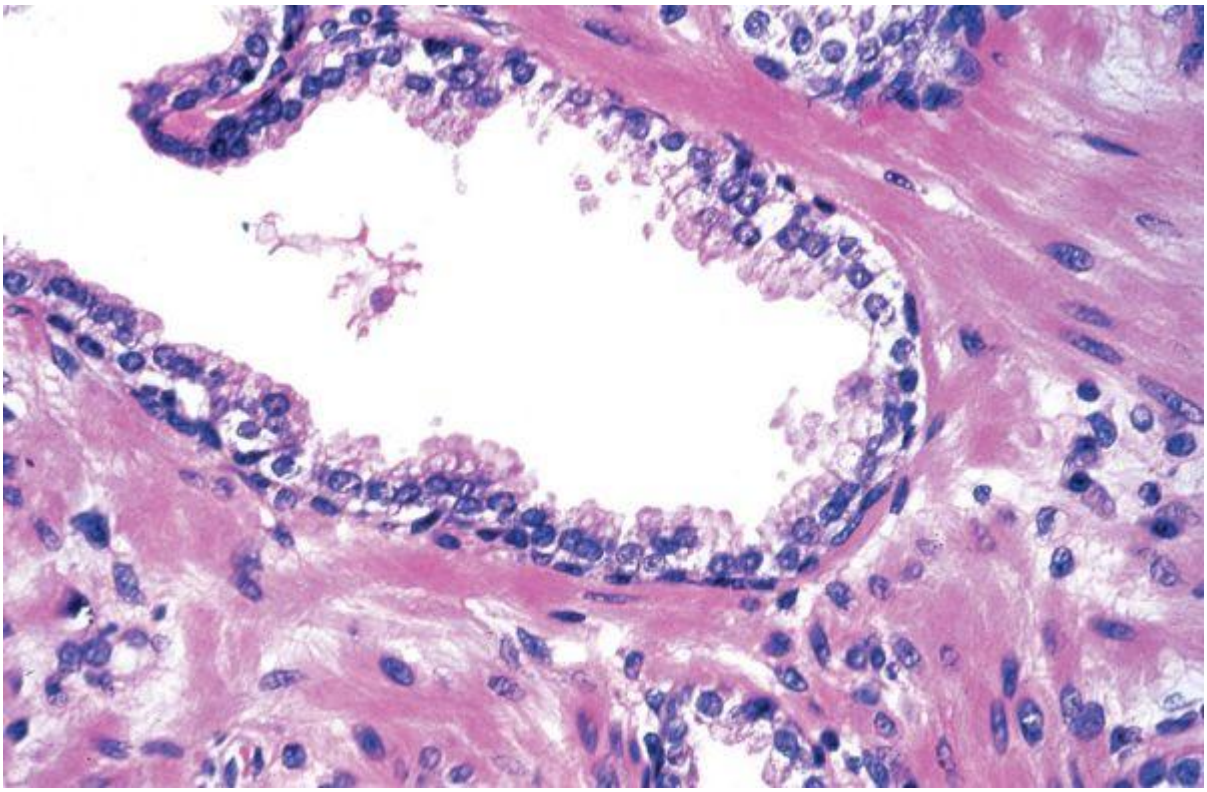

FIGURE 21-31 Benign prostate gland with basal cell and secretory cell layer.

Only three pathologic processes affect the prostate gland with sufficient frequency to merit discussion: inflammation, benign nodular enlargement, and tumors. Of these three, the benign nodular enlargements are by far the most common and occur so often in advanced age that they can almost be construed as a "normal" aging process. Prostatic carcinoma is also an extremely common lesion in men and therefore merits careful consideration. We begin our discussion with consideration of the inflammatory processes.

INFLAMMATION

Prostatitis may be divided into several categories: acute and chronic bacterial prostatitis, chronic abacterial prostatitis, and granulomatous prostatitis.

Acute bacterial prostatitis typically results from bacteria similar to those that cause urinary tract infections. Thus, most cases are caused by various strains of *E. coli*, other gramnegative rods, enterococci, and staphylococci. The organisms become implanted in the prostate usually by intraprostatic reflux of urine from the posterior urethra or from the urinary bladder, but occasionally they seed the prostate by lymphohematogenous routes from distant foci of infection. Prostatitis sometimes follows surgical manipulation of the urethra or prostate gland itself, such as catheterization, cystoscopy, urethral dilation, or resection procedures on the prostate. Clinically, acute bacterial prostatitis is associated with fever, chills, and dysuria. On rectal examination the prostate is exquisitely tender and boggy. The diagnosis can be established by urine culture and clinical features.

Chronic bacterial prostatitis is difficult to diagnose and treat. It may present with low back pain, dysuria, and perineal and suprapubic discomfort. Alternatively, it may be virtually asymptomatic.

Patients often have a history of recurrent urinary tract infections (cystitis, urethritis) caused by the same organism. Because most antibiotics penetrate the prostate poorly, bacteria find safe haven in the parenchyma and constantly seed the urinary tract. Diagnosis of chronic bacterial prostatitis depends on the demonstration of leukocytosis in the expressed prostatic secretions, along with positive bacterial cultures. In most cases, there is no antecedent acute attack, and the disease appears insidiously and without obvious provocation. The implicated organisms are the same as those cited as causes of acute prostatitis.

Chronic abacterial prostatitis is the most common form of prostatitis seen today. *Clinically, it is indistinguishable from chronic bacterial prostatitis. There is no history, however, of recurrent urinary tract infection*. Expressed prostatic secretions contain more than 10 leukocytes per high-power field, but bacterial cultures are uniformly negative.

Granulomatous prostatitis may be specific, where an etiologic infectious agent may be identified or non-specific.[88] In the United States the most common cause is related to instillation of BCG within the bladder for treatment of superficial bladder cancer, discussed earlier in this chapter.[89,][90] BCG is an attenuated mycobacterial strain that gives rise to a histologic picture indistinguishable from that seen with systemic tuberculosis. However, in this setting the finding of granulomas in the prostate is of no clinical significance, and requires no treatment. Fungal granulomatous prostatitis is typically seen only in immunocompromised hosts. Nonspecific granulomatous prostatitis is relatively common and represents a reaction to secretions from ruptured prostatic ducts and acini.[91] Although some of these men have a recent history of urinary tract infection, bacteria are not seen within the tissue in nonspecific granulomatous prostatitis.

Morphology. Acute prostatitis may appear as minute, disseminated abscesses; as large, coalescent focal areas of necrosis; or as diffuse edema, congestion, and boggy suppuration of the entire gland.

In men with symptoms of acute or chronic prostatitis, biopsy or surgical specimens are uncommonly examined microscopically, because the disease is diagnosed on clinical and laboratory findings. In fact biopsy of a man with acute prostatitis is contraindicated, as it may lead to sepsis. It is common in prostate specimens removed surgically to find histologic evidence of acute or chronic inflammation in men with no clinical symptoms of acute or chronic prostatitis. In these instances etiologic infectious agents have yet to be identified.[92] So as not to be confused with the clinical syndromes of acute and chronic prostatitis, these prostate specimens are instead diagnosed in descriptive terms as showing "acute inflammation" or "chronic inflammation" and not as "prostatitis."

BENIGN ENLARGEMENT

Benign Prostatic Hyperplasia (BPH) or Nodular Hyperplasia

BPH is an extremely common disorder in men over age 50.[94] It is characterized by hyperplasia of prostatic stromal and epithelial cells, resulting in the formation of large, fairly discrete nodules in the periurethral region of the prostate. When sufficiently large, the nodules compress and narrow the urethral canal to cause partial, or sometimes virtually complete, obstruction of the urethra.

Incidence.

Histologic evidence of BPH can be seen in approximately 20% of men 40 years of age, a figure that increases to 70% by age 60 and to 90% by age 80. There is no direct correlation, however, between histologic changes and clinical symptoms. Only 50% of those who have microscopic evidence of BPH have clinically detectable enlargement of the prostate, and of these individuals, only 50% develop

clinical symptoms. BPH is a problem of enormous magnitude, with approximately 30% of white American males over 50 years of age having moderate to severe symptoms.

Etiology and Pathogenesis.

Despite the fact that there is an increased number of epithelial cells and stromal components in the periurethral area of the prostate, there is no clear evidence of increased epithelial cell proliferation in human BPH. Instead, it is believed that the main component of the "hyperplastic" process is impaired cell death. It has been proposed that there is an overall reduction of the rate of cell death, resulting in the accumulation of senescent cells in the prostate.[94] In keeping with this androgens (discussed below), which are required for the development of BPH, can not only increase cellular proliferation, but also inhibit cell death.

The main androgen in the prostate, constituting 90% of total prostatic androgens, is dihydrotestosterone (DHT). It is formed in the prostate from the conversion of testosterone by the enzyme type 2 5α-reductase. [93] [94] [95] [96] This enzyme is located almost entirely in stromal cells; epithelial cells of the prostate do not contain type 2 5α reductase, with the exception of a few basal cells. *Thus stromal cells are responsible for androgen-dependent prostatic growth*. Type 1 5α-reductase is not detected in the prostate, or is present at very low levels. However this enzyme may produce DHT from testosterone in liver and skin, and circulating DHT may act in the prostate by an endocrine mechanism.

DHT binds to the nuclear androgen receptor (AR) present in both stromal and epithelial prostate cells. DHT is more potent than testosterone because it has a higher affinity for AR and forms a more stable complex with the receptor. Binding of DHT to AR activates the transcription of androgen-dependent genes. DHT is not a direct mitogen for prostate cells, instead DHT-mediated transcription of genes results in the increased production of several growth factors and their receptors. Most important among these are members of the fibroblast growth factor (FGF) family, and particularly FGF-7 (keratinocyte growth factor; Chapter 3). FGF-7, produced by stromal cells, is probably the most important factor mediating the paracrine regulation of androgen-stimulated prostatic growth. Other growth factors produced in BPH are FGFs 1 and 2, and TGFβ, which promote fibroblast proliferation. Although the ultimate cause of BPH is unknown, it is believed that DHT-induced growth factors act by increasing the proliferation of stromal cells and decreasing the death of epithelial cells.

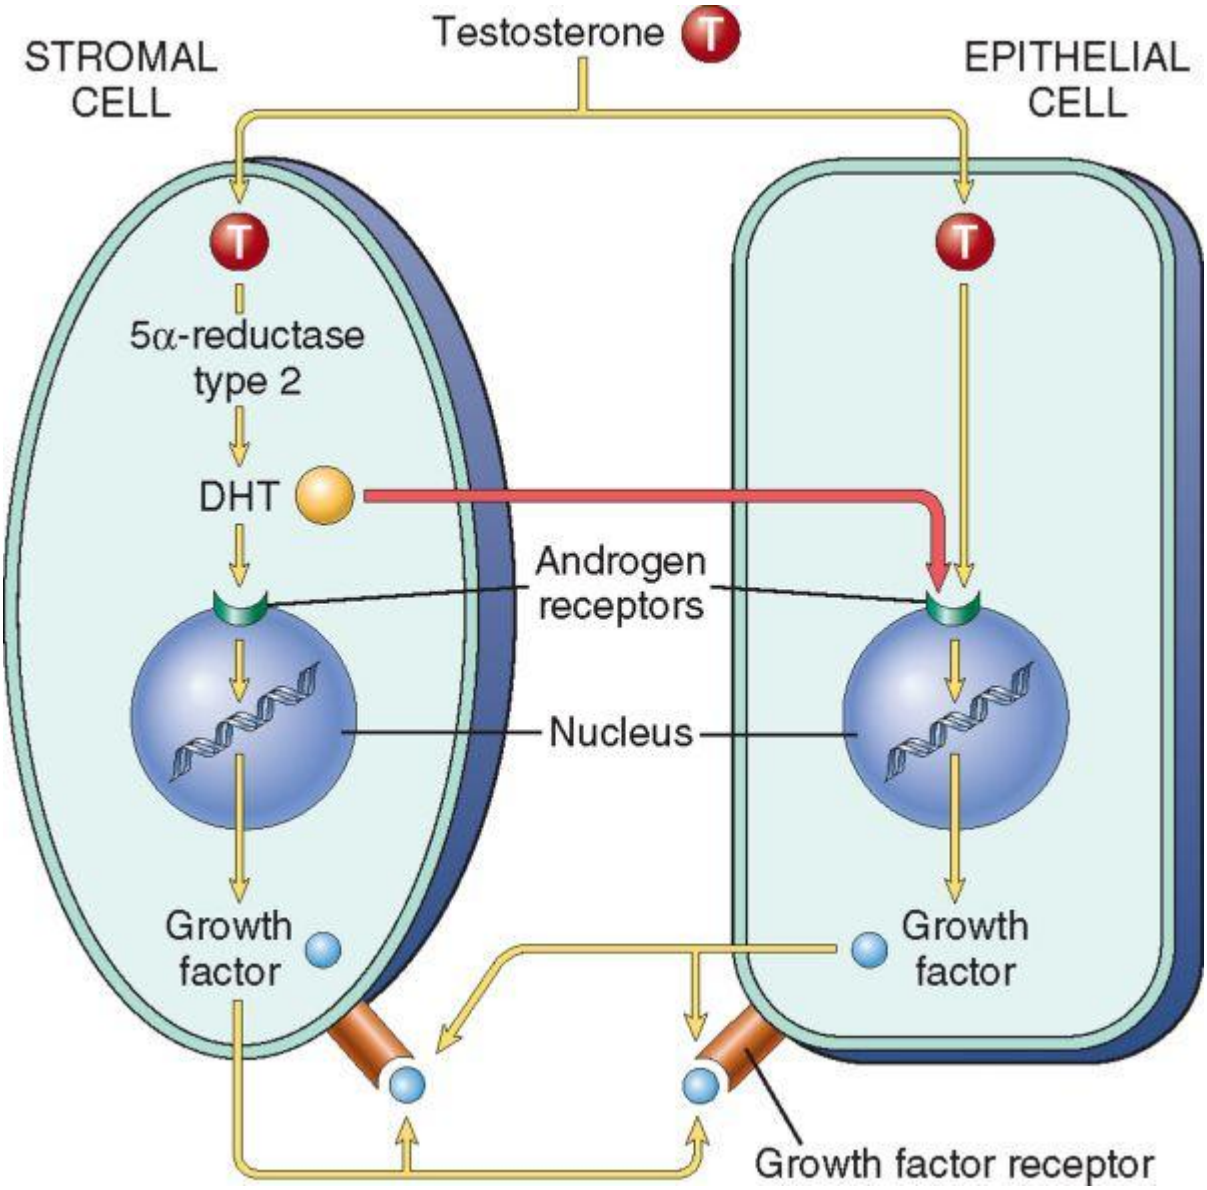

FIGURE 21-32 Simplified scheme of the pathogenesis of prostatic hyperplasia. The central role of the stromal cells in generating dihydrotestosterone (DHT) should be noted. DHT may also be produced in skin and liver by both type 1 and 2 5α-reductase.

Morphology. In the usual case of prostatic enlargement, the prostate weighs between 60 and 100 gm. Nodular hyperplasia of the prostate originates almost exclusively in the inner aspect of the prostate gland (transition zone). The early nodules are composed almost entirely of stromal cells, and later predominantly epithelial nodules arise. From their origin in this strategic location the nodular enlargements may encroach on the lateral walls of the urethra to compress it to a slitlike orifice (Fig. 21-33). In some cases, nodular enlargement may project up into the floor of the urethra as a hemispheric mass directly beneath the mucosa of the urethra, which is termed **median lobe hypertrophy** by clinicians.

On cross-section, the nodules vary in color and consistency. In nodules that contain mostly glands, the tissue is yellow-pink with a soft consistency, and a milky-white prostatic fluid oozes out of these

areas. In nodules composed primarily of fibromuscular stroma, each nodule is pale gray, is tough, does not exude fluid, and is less clearly demarcated from the surrounding uninvolved prostatic tissue. Although the nodules do not have true capsules, the compressed surrounding prostatic tissue creates a plane of cleavage about them.

Microscopically, the hallmark of BPH is nodularity (Fig. 21-33B). The composition of the nodules ranges from purely stromal fibromuscular nodules to fibroepithelial nodules with a glandular predominance. Glandular proliferation takes the form of aggregations of small to large to cystically dilated glands, lined by two layers, an inner columnar and an outer cuboidal or flattened epithelium (Fig. 21-33C). The diagnosis of BPH cannot usually be made on needle biopsy, since the histology of glandular or mixed glandular-stromal nodules of BPH cannot be appreciated in limited samples. Also, needle biopsies do not typically sample the transition zone where BPH occurs. Occasionally foci of reactive squamous metaplasia histologically mimicking urothelial carcinoma can be seen adjacent to prostatic infarcts in prostates with prominent BPH.

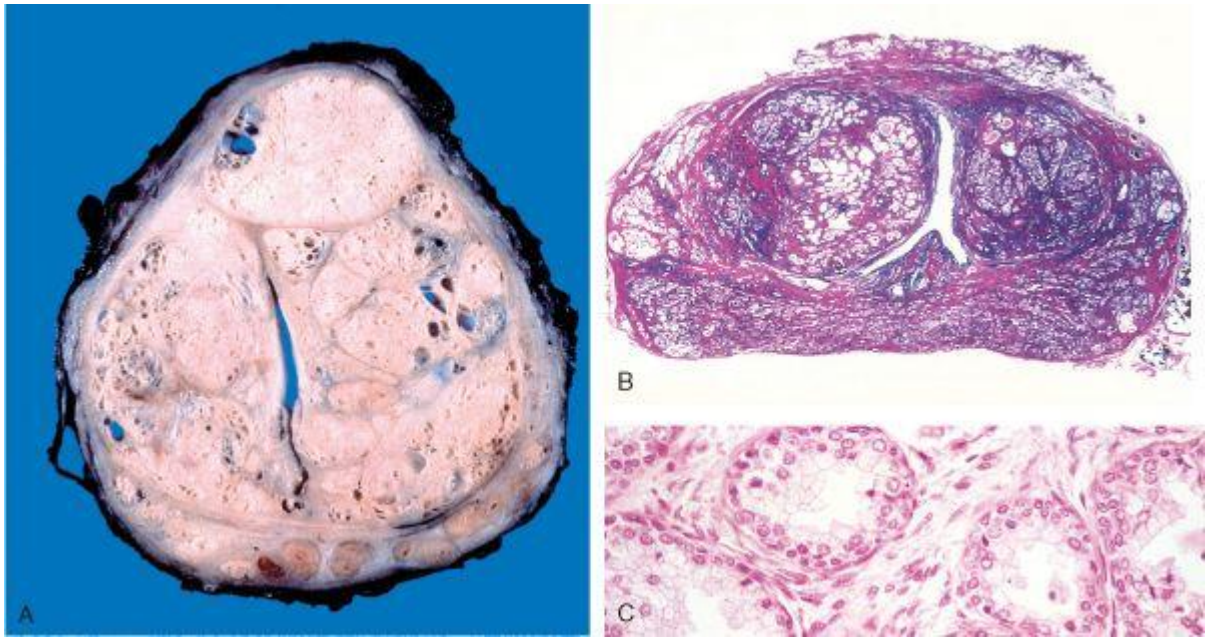

FIGURE 21-33 Nodular prostatic hyperplasia. **A**, Well-defined nodules of BPH compress the urethra into a slitlike lumen. **B**, A microscopic view of a whole mount of the prostate shows nodules of hyperplastic glands on both sides of the urethra. **C**, Under high power the characteristic dual cell population: the inner columnar and outer flattened basal cell can be seen.

Clinical Features.

The pathophysiology of BPH is complex, as it involves several factors. The increased size of the gland, and the smooth muscle-mediated contraction of the prostate cause uretheral obstruction. The increased resistance to urinary outflow leads to bladder hypertrophy and distension, accompanied by urine retention. The inability to empty the bladder completely creates a reservoir of residual urine that is a common source of infection. Patients experience increased urinary frequency, nocturia, difficulty in starting and stopping the stream of urine, overflow dribbling, dysuria (painful micturition), and have an increased risk of developing bacterial infections of the bladder and kidney. In many cases, sudden, acute urinary retention appears for unknown reasons that requires emergency catheterization.

Mild cases of BPH may be treated without medical or surgical therapy, such as by decreasing fluid intake, especially before bedtime; moderating the intake of alcohol and caffeinecontaining products; and following timed voiding schedules. The most commonly used and effective medical therapy for symptoms relating to BPH are α-blockers, which decrease prostate smooth muscle tone via inhibition of α_1-adrenergic receptors.[97,][98] Another common pharmacologic therapy aims to decrease symptoms by physically shrinking the prostate with an agent that inhibits the synthesis of DHT. Inhibitors of 5-α-reductase fall into this category. For moderate to severe cases recalcitrant to medical therapy, a wide range of more invasive procedures exist. Transurethral resection of the prostate (TURP) has been the gold standard in terms of reducing symptoms, improving flow rates, and decreasing post-voiding residual urine. It is indicated as a first line of therapy in certain circumstances, such as recurrent urinary retention. As a result of its morbidity and cost, alternative procedures have been developed. These include high-intensity focused ultrasound, laser therapy, hyperthermia, transurethral electrovaporization, and transurethral needle ablation using radiofrequency. Nodular hyperplasia is not considered to be a premalignant lesion.

TUMORS

Adenocarcinoma

Adenocarcinoma of the prostate is the most common form of cancer in men, accounting for 29% of cancer in the United States in 2007.[99] However, prostate cancer is tied with colorectal cancer in terms of cancer mortality, causing 9% of cancer deaths in the United States in 2007. There is a one in six lifetime probability of being diagnosed with prostate cancer. Over the last 20 years there has been a significant drop in prostate cancer mortality. It is one of the most remarkable tumors, exhibiting a wide range of clinical behaviors from very aggressive lethal cancers to incidentally discovered clinically insignificant cancers.

Incidence.

Cancer of the prostate is typically a disease of men over age 50. However, in men who are at increased risk (see “Etiology”), screening for prostate cancer is recommended to begin at age 40. Consideration has also been given to screen all men at age 40 and again at age 45 to detect uncommon cases of young men with prostate cancer before the disease becomes incurable. The incidence of prostatic cancer at autopsy is quite high. It increases from 20% in men in their 50s to approximately 70% in men between the ages of 70 and 80 years. There are some remarkable and puzzling national and racial differences in the incidence of the disease.[100] Prostatic cancer is uncommon in Asians and occurs most frequently among blacks. In addition to hereditary factors, environment plays a role, as evidenced by the rise in the incidence of the disease in Japanese immigrants to the United States, though not nearly to the level of that of native-born Americans. Also, as the diet in Asia becomes more westernized, the incidence of clinically significant prostate cancer in this region of the world seems to be increasing. Whether this is due to dietary factors or other lifestyle changes is not clear.

Etiology and Pathogenesis.

Our knowledge of the causes of prostate cancer is far from complete. Several factors, including age, race, family history, hormone levels, and environmental influences are suspected to play a role. The increased incidence of this disease upon migration from a low-incidence region to one with a high incidence is consistent with a role for environmental influences. There are many candidate environmental factors, but none has been proven to be causative. For example, increased consumption of fats has been implicated. Other dietary products suspected of preventing or delaying prostate cancer development include lycopenes (found in tomatoes), selenium, soy products, and vitamin D.[101]

Androgens play an important role in prostate cancer. Like their normal counterparts, the growth and survival of prostate cancer cells depends on androgens, which bind to the androgen receptor (AR) and induce the expression of pro-growth and pro-survival genes. Of interest with respect to differences in prostate cancer risk among races, the X-linked AR gene contains a polymorphic sequence composed of repeats of the codon CAG (which codes for glutamine). Very large expansions of this stretch of CAGs cause a rare neurodegenerative disorder, Kennedy disease, characterized by muscle cramping and weakness. However, even in normal individuals, there is sufficient variation in the length of the CAG repeats to affect AR function. ARs with the shortest stretches of polyglutamine have the highest sensitivity to androgens. The shortest polyglutamine repeats on average are found in African Americans, while Caucasians have an intermediate length and Asians have the longest, paralleling the incidence and mortality of prostate cancer in these groups. More directly, the length of the repeats is inversely related to rate at which prostate cancer develops in mouse models.[102]

The importance of androgens in maintaining the growth and survival of prostate cancer cells can be seen in the therapeutic effect of castration or treatment with anti-androgens, which usually induce disease regression. Unfortunately, *most tumors eventually become resistant to androgen blockade*. Tumors escape through a variety of mechanisms, including acquisition of hypersensitivity to low levels of androgen (e.g., through AR gene amplification); mutations in AR that allow it to be activated by non-androgen ligands; and other mutations or epigenetic changes that activate alternative signaling pathways, which may bypass the need for AR altogether.[103] Among the latter are changes that lead to increased activation of the P1-3 kinase/AKT signaling pathway, which is observed most often in tumors that have become resistant to anti-androgen therapy.

There is much interest in the role of other *inherited polymorphisms* in the development of prostate cancer.[104] [105] [106] [107] [108] Compared with men with no family history, men with one first-degree relative with prostate cancer have twice the risk and those with two first-degree relatives have five times the risk of developing prostate cancer. Men with a strong family history of prostate cancer also tend to develop the disease at an earlier age. Men with germline mutations of the tumor suppressor *BRCA*2 have a 20-fold increased risk of prostate cancer, but the vast majority of familial prostate cancers are due to variation in other loci that confer a small increase in cancer risk. Family and genome-wide association studies have identified a number of risk-associated loci, including one at 8q24 that appears to selectively increase the risk among African American men.[108] Of possible interest, a number of the candidate genes in these regions are involved in innate immunity, leading to speculation that inflammation may set the stage for the development of prostate carcinoma, as has been shown with respect to other human cancers (Chapter 7).

Other work is focused on the role of tumor-specific acquired somatic mutations and epigenetic changes. One very common type of somatic mutation in prostate cancer gives rise to *chromosomal rearrangements that juxtapose the coding sequence of an ETS family transcription factor gene (most commonly ERG or ETV1) next to the androgen-regulated TMPRSS2 promoter*.[110] These rearrangements place the involved ETS gene under the control of the *TMPRSS2* promoter and lead to their over-expression in an androgen-dependent fashion. Over-expression of ETS transcription factors makes normal prostate epithelial cells more invasive, possibly through the upregulation of matrix metalloproteases. In addition, tumors with rearranged ETS genes have certain distinctive morphologic features[111] and a different gene expression signature than those lacking ETS gene rearrangements,[112] suggesting that ETS gene rearrangements define a specific molecular sub-class of prostate cancer. ETS rearrangements may also have implications for prostate cancer screening and early diagnosis, as it is possible to detect ETS fusion genes in the urine using sensitive PCR assays.

The most common epigenetic alteration in prostate cancer is hypermethylation of glutathione *S*-transferase (*GSTP1*) gene which down-regualtes GSTP1 expression. The *GSTP1* gene is located on

chromosome 11q13 and is an important part of the pathway that prevents damage from a wide range of carcinogens.[113] Other genes silenced by epigenetic modifications in a subset of prostate cancers include a number of tumor suppressor genes, including *PTEN*, *RB, p16/INK4a*, *MLH1*, *MSH2*, and *APC*.

In addition to prostate specific antigen (PSA, discussed below), other genes and proteins that may serve as biomarkers in prostate cancer have emerged, and some of these appear to play a direct role in the biology of the disease. Three worthy of brief mention are EZH-2 (enhancer of zeste-2), alpha-methylacyl-CoA racemase (AMACR), and *PCA3*. Prostate cancers show a relatively frequent loss of E-cadherin,[114] an adhesion protein that is also down-regulated in invasive signet ring carcinoma of the stomach and lobular carcinoma of the breast. Loss of E-cadherin from prostate cancer cells is associated with expression of high levels of EZH-2, a transcriptional repressor that may contribute to prostate cancer progression.[115] AMACR, an enzyme involved in the beta-oxidation of branched chain amino acids, is selectively upregulated in prostate cancer and its possible precursor lesions as compared to normal prostate (described below)[116,][117], as is *PCA3*, a gene on chromosome 9q that appears to encode a regulatory RNA.[118,][119]

As can be surmised from the multiplicity of abnormalities, prostate carcinoma (like other cancers) is the product of some critical combination of acquired somatic mutations and epigenetic changes. A putative precursor lesion, prostatic intraepithelial neoplasia (PIN), has been described. Prostates containing cancer have a higher frequency and a greater extent of PIN, which is also often seen in proximity to cancer. Studies have revealed that many of the molecular changes seen in invasive cancers are present in PIN (for example, rearrangements involving *ETS* genes are found in a subset[120,][121]), strongly supporting the argument that PIN is a precursor of invasive cancer. What remains unclear is whether PIN inevitably progresses to cancer, or instead sometimes remains latent or even regresses.[122]

Morphology. When the terms **"prostate cancer"** or **"prostate adenocarcinoma"** are used without qualifications it refers to the common or acinar variant of prostate cancer. In approximately 70% of cases, carcinoma of the prostate arises in the peripheral zone of the gland, classically in a posterior location, where it may be palpable on rectal examination (Fig. 21-34). Characteristically, on cross-section of the prostate **the neoplastic tissue is gritty and firm, but when embedded within the prostatic substance it may be extremely difficult to visualize and be more readily apparent on palpation**. Local extension most commonly involves periprostatic tissue, seminal vesicles, and the base of the urinary bladder, which in advanced disease may result in ureteral obstruction. Metastases first spread via lymphatics initially to the obturator nodes and eventually to the para-aortic nodes. Hematogenous spread occurs chiefly to the bones, particularly the axial skeleton, but some lesions spread widely to viscera. Massive visceral dissemination is an exception rather than the rule. The bony metastases are typically osteoblastic and in men point strongly to prostatic cancer (Fig. 21-35). The bones commonly involved, in descending order of frequency, are lumbar spine, proximal femur, pelvis, thoracic spine, and ribs.

Histologically, most lesions are adenocarcinomas that produce well-defined, readily demonstrable gland patterns.[123,][124] The glands are typically smaller than benign glands and are lined by a single uniform layer of cuboidal or low columnar epithelium. In contrast to benign glands, prostate cancer glands are more crowded, and characteristically lack branching and papillary infolding. **The outer basal cell layer typical of benign glands is absent**. The cytoplasm of the tumor cells ranges from pale-clear as seen in benign glands to a distinctive amphophilic appearance. Nuclei are large and often contain one or more large nucleoli. There is some variation in nuclear size and shape, but in general pleomorphism is not marked. Mitotic figures are uncommon.

The histologic diagnosis of prostate cancer on biopsy specimens is one of the more difficult

challenges for pathologists.[125] In part, difficulty stems not only from the scant amount of tissue available for histologic examination removed by the needle biopsy, but also that biopsy often only samples a few malignant glands among many benign glands (Fig. 21-36). Morphologically, prostate cancer is difficult to diagnose in that the clues to malignancy may be subtle, increasing the likelihood of underdiagnosis. There are also many benign mimickers of cancer that can lead the unwary pathologist to a misdiagnosis of cancer. Although there are a few histologic findings on biopsy that are specific for prostate cancer, such as perineural invasion, in general the diagnosis is made based on a constellation of architectural, cytologic, and ancillary findings (Fig. 21-37). As discussed earlier, one distinguishing feature between benign and malignant prostate glands is that benign glands contain basal cells whereas they are absent in cancer (compare benign and malignant glands in Fig. 21-36A , and benign glands in Fig. 21-33C with cancerous glands in Fig. 21-36B).[126] Pathologists have exploited this finding, by using various immunohistologic markers to label basal cells. α-methylacyl-coenzyme A-racemase (AMACR) is up-regulated in prostate cancer and can be detected by immunohistochemistry. The majority of prostate cancers are positive for AMACR, the sensitivity varying among studies from 82% to 100%. The use of all of these markers, while improving the accuracy of the diagnosis of prostate cancer, have their limitations with false positive and false negatives and must be used in conjunction with the routine H&E-stained sections.

In approximately 80% of cases, prostatic tissue removed for carcinoma also harbors presumptive precursor lesions, referred to as **high-grade prostatic intraepithelial neoplasia (PIN)**. [127] [128] PIN consists of architecturally benign prostatic acini lined by cytologically atypical cells with prominent nucleoli. Cytologically PIN and carcinoma may be identical, yet architecturally PIN involves larger branching glands with papillary infolding, in contrast to invasive cancer that is typically characterized by small crowded glands with straight luminal borders. PIN glands are surrounded by a patchy layer of basal cells and an intact basement membrane. There are several lines of evidence relating PIN to invasive cancer. First, both PIN and cancer typically predominate in the peripheral zone and are relatively uncommon in other zones. If one compares prostates without cancer to those with cancer, prostates containing cancer have a higher frequency and a greater extent of PIN. PIN is also often seen in proximity to cancer, in some cases the cancer appearing to bud off of the PIN. Many of the molecular changes seen in invasive cancers are also present in PIN, supporting the view that PIN is an intermediate lesion between normal and invasive cancer. Despite all this evidence, we do not know the natural history of PIN, and in particular how often it progresses to cancer. Thus, unlike in cancer of the cervix, the term **“Carcinoma in situ”** is not used for PIN. There are many other secrets about prostate cancer that have yet to be revealed.

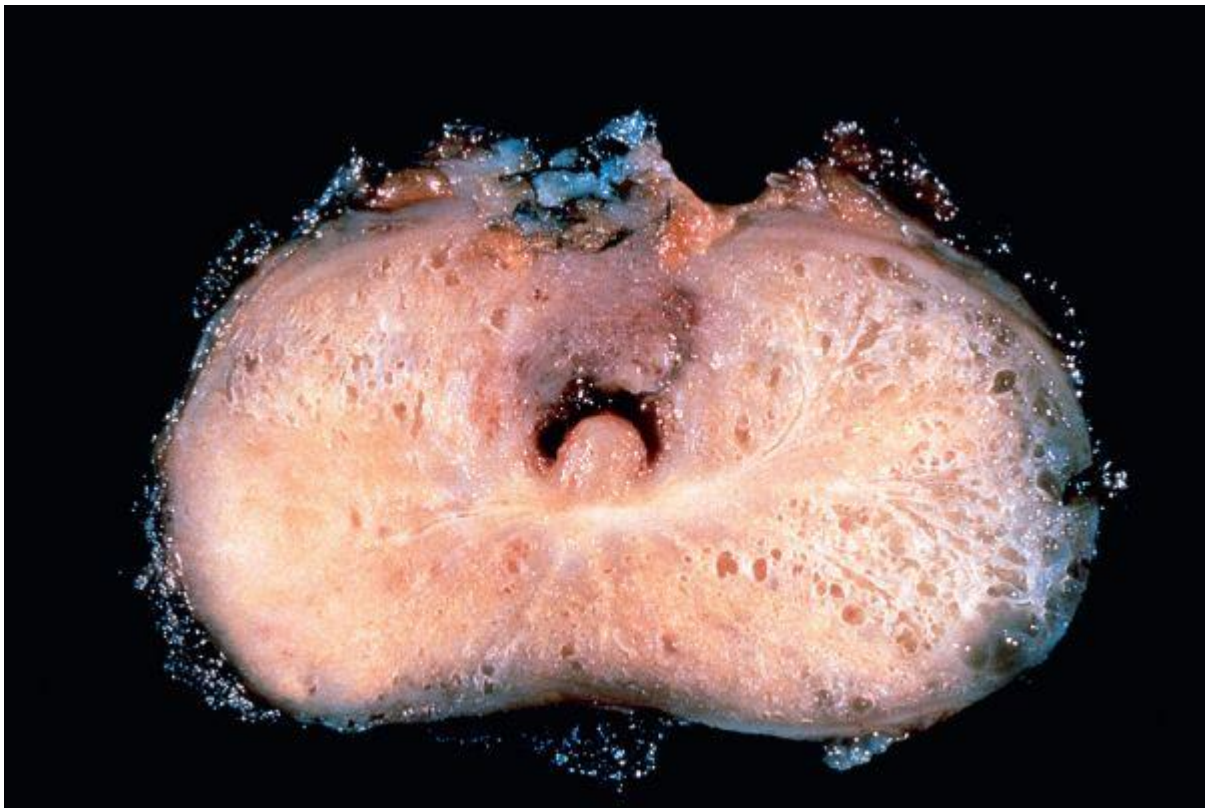

FIGURE 21-34 Adenocarcinoma of the prostate. Carcinomatous tissue is seen on the posterior aspect *(lower left)*. Note solid whiter tissue of cancer in contrast to spongy appearance of benign peripheral zone in the contralateral side.

FIGURE 21-35 Metastatic osteoblastic prostatic carcinoma within vertebral bodies.

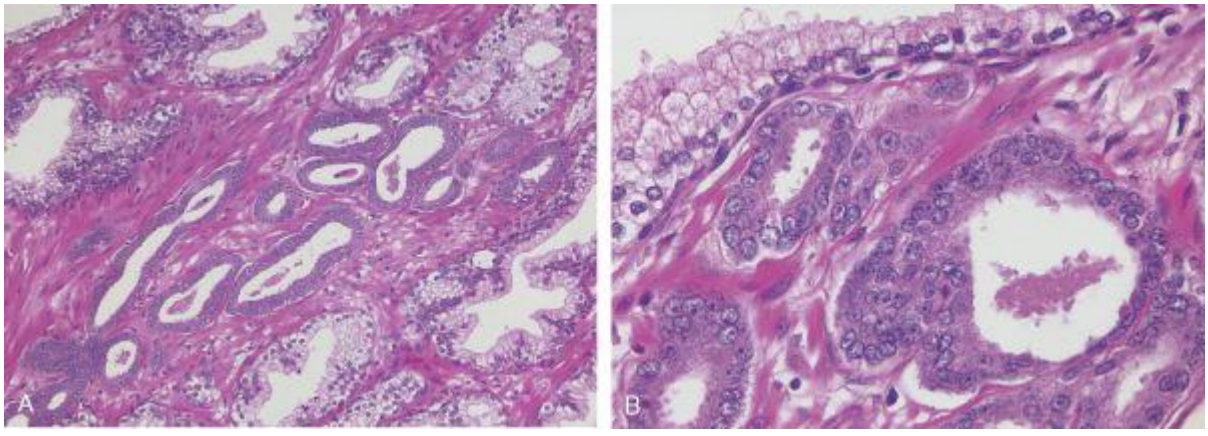

FIGURE 21-36 **A**, Photomicrograph of small focus of adenocarcinoma of the prostate demonstrating small glands crowded in between larger benign glands. **B**, Higher magnification shows several small malignant glands with enlarged nuclei, prominent nucleoli, and dark cytoplasm, as compared with larger benign gland *(top)*.

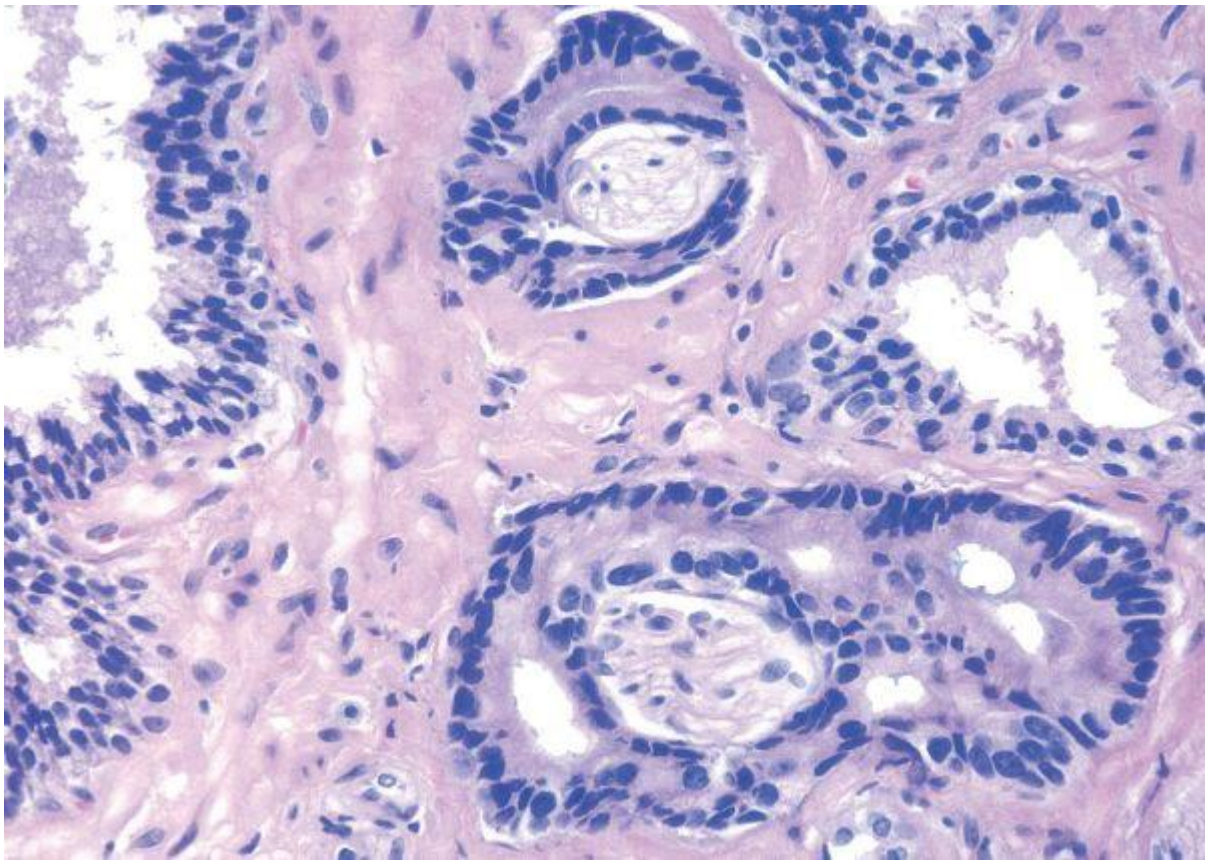

FIGURE 21-37 Carcinoma of prostate showing perineural invasion by malignant glands. Compare to benign gland *(left)*.

Grading and Staging.

The grading schema used for prostate cancer is the Gleason system.[129,][130] According to this system, prostate cancers are stratified into five grades on the basis of glandular patterns of differentiation. Grade 1 represents the most well-differentiated tumors, in which the neoplastic glands are uniform and round in appearance and are packed into well-circumscribed nodules (Fig. 21-38A). By contrast, grade 5 tumors show no glandular differentiation, and the tumor cells infiltrate the stroma in the form of cords, sheets, and nests (Fig. 21-38C). The other grades fall in between. Most tumors contain more than one pattern, where one assigns a primary grade to the dominant pattern and a secondary grade to the second most frequent pattern. The two numeric grades are then added to obtain a combined Gleason grade or score. Thus, for example, a tumor with a dominant grade 3 and a secondary grade 4 would achieve a Gleason score of 7. Tumors with only one pattern are treated as if their primary and secondary grades are the same, and hence, the number is doubled. An exception to the rule is if three patterns are present on biopsy, the most common and highest grades are added together to arrive at the Gleason score. Thus, under this schema the most well-differentiated tumors have a Gleason score of 2 (1 + 1), and the least-

differentiated tumors merit a score of 10 (5 + 5). Gleason scores are often combined into groups with similar biologic behavior, with grades 2 through 4 representing well-differentiated cancer, 5 and 6 intermediate-grade tumor, 7 moderate to poorly differentiated cancer, and 8 through 10 high-grade tumor. Gleason scores of 2 through 4 are typically found in small tumors within the transition zone. In surgical specimens, such low-grade cancer is typically an incidental finding on TURP performed for symptoms of BPH. The majority of potentially treatable cancers detected on needle biopsy as a result of screening have Gleason scores of 5 through 7. Tumors with Gleason scores 8 through 10 tend to be advanced cancers that are unlikely to be cured. Although there is some evidence that prostate cancers can become more aggressive with time, most commonly, the Gleason score remains stable over a period of several years. *Grading is of particular importance in prostatic cancer, because grade and stage are the best prognostic predictors*.

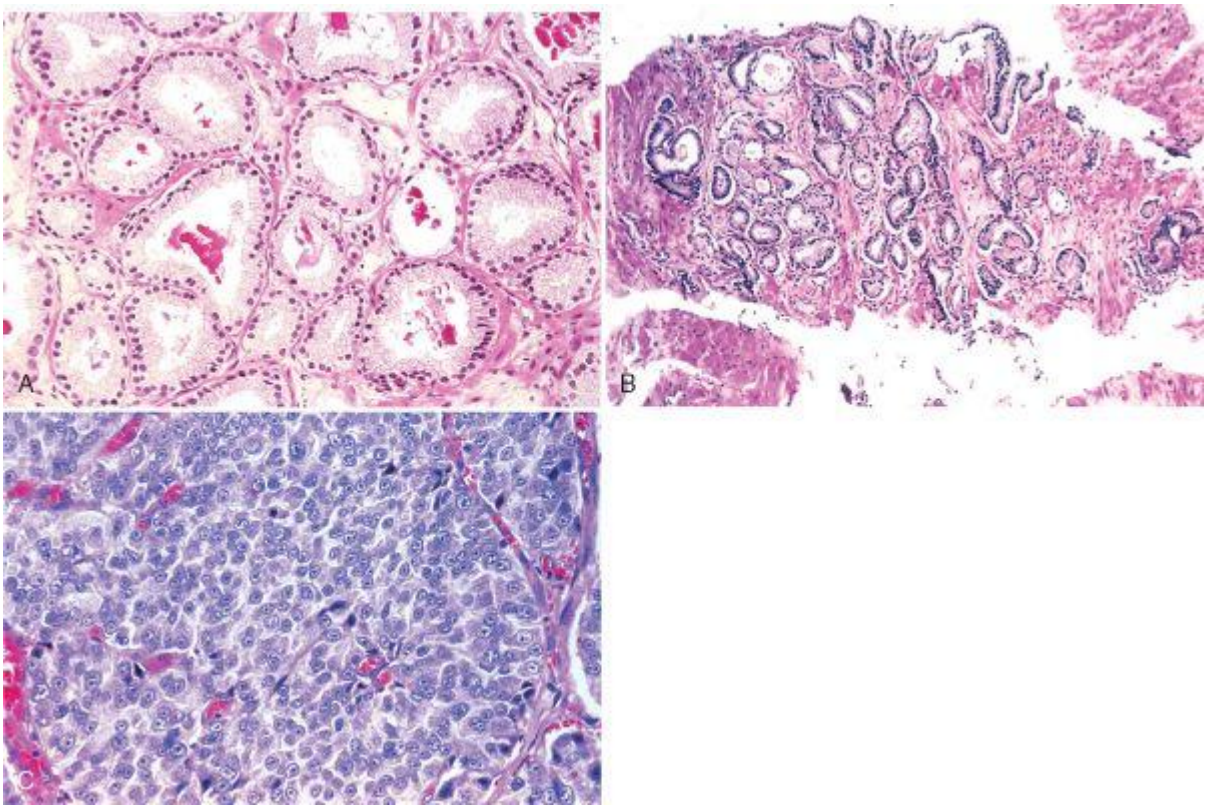

FIGURE 21-38 **A**, Low-grade (Gleason score 1 + 1 = 2) prostate cancer consisting of back-to-back uniform-sized malignant glands. Glands contain eosinophilic intraluminal prostatic crystalloids, a feature more commonly seen in cancer than benign glands and more frequently seen in lower grade than higher grade prostate cancer. **B**, Needle biopsy of the prostate with variably sized, more widely dispersed glands of moderately differentiated Gleason score 3 + 3 = 6) adenocarcinoma. **C**, Poorly differentiated (Gleason score 5 + 5 = 10) adenocarcinoma composed of sheets of malignant cells.

Staging of prostatic cancer is also important in the selection of the appropriate form of therapy (Table 21-6). Stage T1 refers to incidentally found cancer, either on TURP done for BPH symptoms (T1a and T1b depending on the extent and grade) or on needle biopsy typically performed for elevated serum prostate-specific antigen (PSA) levels (stage T1c). [131] [132] [133] Stage T2 is organ-confined cancer. Stage T3a and T3b tumors show extra-prostatic extension, with and without seminal vesicle invasion, respectively. Stage T4 reflects direct invasion of contiguous organs. Any spread of tumor to the lymph nodes regardless of extent is eventually associated with a fatal outcome, such that the staging system merely records the presence or absence of this finding (N0/N1).

TABLE 21-6 -- Staging of Prostatic Adenocarcinoma Using the TNM System

TNM Designation	Anatomic Findings
Extent of Primary Tumor (T)	
T1	**CLINICALLY INAPPARENT LESION (BY PALPATION/IMAGING STUDIES)**
T1a	Involvement of ≤5% of resected tissue
T1b	Involvement of >5% of resected tissue
T1c	Carcinoma present on needle biopsy (following elevated PSA)
T2	**PALPABLE OR VISIBLE CANCER CONFINED TO PROSTATE**
T2a	Involvement of ≤5% of one lobe
T2b	Involvement of >5% of one lobe, but unilateral
T2c	Involvement of both lobes
T3	**LOCAL EXTRAPROSTATIC EXTENSION**
T3a	Extracapsular extension
T3b	Seminal vesical invasion
T4	**INVASION OF CONTIGUOUS ORGANS AND/OR SUPPORTING STRUCTURES INCLUDING BLADDER NECK, RECTUM, EXTERNAL SPHINCTER, LEVATOR MUSCLES, OR PELVIC FLOOR**
Status of Regional Lymph Nodes (N)	
N0	**NO REGIONAL NODAL METASTASES**
N1	**METASTASIS IN REGIONAL LYMPH NODES**
Distant Metastases (M)	
M0	**NO DISTANT METASTASES**
M1	**DISTANT METASTASES PRESENT**
M1a	Metastases to distant lymph nodes
M1b	Bone metastases
M1c	Other distant sites

PSA, prostate-specific antigen.

Clinical Course.

It is generally accepted that most men with incidentally discovered focal (stage T1a) cancer found on TURP do not show evidence of progression when followed for 10 or more years. Older patients with stage T1a disease are typically followed, but younger men with a longer life expectancy may undergo needle biopsy to look for additional cancer in the peripheral zone of the prostate. Stage T1b lesions are more ominous and are treated the same as tumors that are found on needle biopsy, since they have a mortality of 20% if left untreated.

Localized prostate cancer is asymptomatic, and is usually discovered by the detection of a suspicious nodule on rectal examination or elevated serum PSA level (discussed later). Most prostatic cancers arise peripherally away from the urethra, and therefore urinary symptoms occur late. Patients with clinically advanced prostatic cancer may present with urinary symptoms, such as difficulty in starting or stopping

the stream, dysuria, frequency, or hematuria. Today it is uncommon for patients to come to attention because of back pain caused by vertebral metastases. *The finding of osteoblastic metastases by skeletal surveys or the much more sensitive radionuclide bone scanning is virtually diagnostic of this form of cancer in men*. These patients have a universally fatal outcome.

Digital rectal examination may detect some early prostatic carcinomas because of their posterior location, although the test suffers from both low sensitivity and specificity. Although there are characteristic findings of prostate cancer on transrectal ultrasonography and other imaging modalities, the poor sensitivity and specificity of these tests also limit their diagnostic utility. Typically a transrectal needle *biopsy is required to confirm the diagnosis*.

PSA is the most important test used in the diagnosis and management of prostate cancer.[134] PSA is a product of prostatic epithelium and is normally secreted in the semen. It is a serine protease whose function is to cleave and liquefy the seminal coagulum formed after ejaculation. In normal men, only minute amounts of PSA circulate in the serum. Elevated blood levels of PSA occur in association with localized as well as advanced cancer. In most laboratories a serum level of 4 ng/mL is used as a cutoff point between normal and abnormal. However, as discussed below, this simplified approach to serum PSA tests is not appropriate, and has led to the delay in diagnosis of many prostate cancers.

PSA is organ-specific, yet not cancer-specific. Although serum levels of PSA are elevated to a lesser extent in BPH, there is considerable overlap. Other factors such as prostatitis, infarct, instrumentation of the prostate, and ejaculation also increase serum PSA levels. Furthermore, 20% to 40% of patients with organ-confined prostate cancer have a PSA value of 4.0 ng/mL or less.

Whereas most readers of this text will not directly practice pathology, almost all will be confronted with evaluation of a serum PSA test, either as a treating primary care physician, in addressing the results of a family member's or friend's test, or for the male readers reviewing one's own test results. The widespread use of this test, along with its complexity and the corresponding increased risk of it being interpreted incorrectly, warrant a detailed discussion of this topic. This test differs from most other laboratory tests that a physician may order in that it is a cancer detection test. Consequently, physicians should ensure that tests come back from the laboratory, abnormal values are recorded, and patients are contacted for follow-up of elevated levels. Numerous medical malpractice cases result from the mishandling of serum PSA test results and the subsequent delay in diagnosis.

Several refinements in the estimation and interpretation of PSA values have been proposed. These include the ratio between the serum PSA value and volume of prostate gland (PSA density), the rate of change in PSA value with time (PSA velocity), the use of age-specific reference ranges, and the ratio of free and bound PSA in the serum. Men with enlarged hyperplastic prostate glands have higher total serum PSA levels than men with small glands. The measurement of serum *PSA density* factors out the contribution of benign prostatic tissue to serum PSA levels. It is calculated by dividing the total serum PSA level by the estimated gland volume (usually determined by transrectal ultrasound measurements) to estimate the PSA produced per gram of prostate tissue. As men age, their prostates tend to enlarge with BPH. One would then anticipate that overall older men would have higher serum PSA levels than younger men. The upper *age-specific PSA* reference ranges are 2.5 ng/mL for men 40 to 49 years of age, 3.5 ng/mL for men 50 to 59 years, 4.5 ng/mL for men 60 to 69 years, and 6.5 ng/mL for men 70 to 79 years. Consequently, a serum PSA value of 3.5, while it will appear as a normal value on a laboratory test, is a worrisome finding in a man in his 40s, warranting additional evaluation. Another means of interpreting serum PSA tests is by assessing *PSA velocity* or the rate of change of PSA. Men with prostate cancer demonstrate an increased rate of rise in PSA as compared with men who do not have prostate cancer. The rate of change in PSA that best distinguishes between men with and without prostate cancer is 0.75 ng/mL per year. If this test is to be valid, there must be at least three PSA

measurements available over a period of 1.5 to 2 years, as there is substantial short-term variability (up to 20%) between repeat PSA measurements. A man who has a significant rise in serum PSA levels even though the latest serum PSA test may be below the normal cutoff (<4 ng/mL), should undergo additional work-up. Studies have revealed that immunoreactive PSA (the form detected by the widely used antibody test) exists in two forms: a major fraction bound to α_1-antichymotrypsin and a minor free fraction. The *percentage of free PSA* (free PSA/total PSA × 100) is lower in men with prostate cancer than in men with benign prostatic diseases. Free PSA higher than 25% indicates a lower risk of cancer, as compared with free PSA values of less than 10%, which are of concern for cancer.

Because many small cancers localized to the prostate may never progress to clinically significant invasive cancers, there is considerable uncertainty regarding the management of small lesions that are detected because of an elevated PSA level. This has created some controversy about the role of widespread screening for prostate cancer. Much effort is therefore focused in devising criteria by which those localized lesions most likely to advance can be distinguished from those that may remain innocuous.

Serial measurements of PSA are of great value in assessing the response to therapy. For example, a rising PSA level after radical prostatectomy or radiotherapy for localized disease is indicative of recurrent or disseminated disease. Immunohistochemical localization of PSA on tissue sections can also help the pathologist to determine whether a metastatic tumor originated in the prostate.[135]

Cancer of the prostate is treated by surgery, radiation therapy, and hormonal manipulations. More than 90% of patients who receive such therapy can expect to live for 15 years. Currently, the most common treatment for clinically localized prostate cancer is radical prostatectomy. The prognosis following radical prostatectomy is based on the pathologic stage, margin status, and Gleason grade. Alternative treatments for localized prostate cancer are either external-beam radiation therapy or interstitial radiation therapy, the latter consisting of placing radioactive seeds throughout the prostate (brachytherapy). External-beam radiation therapy is also used to treat prostate cancer that is too locally advanced to be cured by surgery. Since some prostate cancers have a relatively indolent course, wherein it may take 10 years to see benefit from surgery or radiation therapy, active surveillance is appropriate for many older men or those with significant co-morbidity or even some younger men with low serum PSA values and limited lower grade cancer on biopsy. Advanced, metastatic carcinoma is treated by androgen deprivation either by orchiectomy or by administration of synthetic agonists of luteinizing hormone–releasing hormone (LHRH). Long-term administration of LHRH agonists suppresses normal LHRH, achieving in effect a pharmacologic orchiectomy. Although anti-androgen therapy induces remissions, eventually tumors develop testosterone-resistance, followed by a rapid progression of disease and death.

Miscellaneous Tumors and Tumor-like Conditions

Prostate adenocarcinomas may also arise from prostatic ducts. Ductal adenocarcinomas arising in peripheral ducts may present in a similar fashion to ordinary prostate cancer, whereas those arising in the larger periurethral ducts may show signs and symptoms similar to urothelial cancer, causing hematuria and urinary obstructive symptoms.[136,][137] Ductal adenocarcinomas are associated with a relatively poor prognosis. Prostate cancer may show squamous differentiation, either following hormone therapy or de novo, resulting in either adenosquamous or pure squamous cancer. Prostate cancer that reveal abundant mucinous secretions are termed *colloid carcinoma of the prostate*.[138] The most aggressive variant of prostate cancer is small-cell cancer.[139] Almost all cases are rapidly fatal, only a few surviving with aggressive combination chemotherapy.

The most common tumor to secondarily involve the prostate is urothelial cancer.[139] Two distinct patterns of involvement exist. Large invasive urothelial cancers can directly invade from the bladder

into the prostate. Alternatively, CIS of the bladder can extend into the prostatic urethra and down into the prostatic ducts and acini.

The same mesenchymal tumors described earlier that involve the bladder may also manifest in the prostate.[140] [141] [142] In addition, there exist unique mesenchymal tumors of the prostate derived from the prostatic stroma.[143] Although lymphomas may appear to first arise in the prostate, most patients shortly thereafter demonstrate systemic disease.[144]

3.12 22. The Female Genital Tract

3.12.1 Development

LORA HEDRICK ELLENSON,
EDYTA C. PIROG

* The contributions of Dr. Christopher Crum to this chapter over the past many editions are gratefully acknowledged.

Development

The development of the female genital tract is relevant to both anomalies in this region and the histogenesis of various tumors. The primordial germ cells arise in the wall of the yolk sac by the fourth week of gestation; by the fifth or sixth week they migrate into the urogenital ridge. The mesodermal epithelium of the urogenital ridge then proliferates, to eventually produce the epithelium and stroma of the gonad. The dividing germ cells, which are of endodermal origin, are incorporated into the proliferating mesodermal epithelium to form the ovary.[1]

A second component of female genital development is the *müllerian duct*. At about the sixth week, invagination and subsequent fusion of the coelomic lining epithelium forms the lateral müllerian (or paramesonephric) ducts. Müllerian ducts progressively grow caudally to enter the pelvis, where they swing medially to fuse with the urogenital sinus at the müllerian tubercle (Fig. 22-1A). Further caudal growth brings these fused ducts into contact with the urogenital sinus, formed when the cloaca is subdivided by the urorectal septum. The urogenital sinus eventually becomes the vestibule of the external genitalia (Fig. 22-1B). Normally the unfused portions mature into the fallopian tubes, the fused caudal portion develop into the uterus and upper vagina, and the urogenital sinus forms the lower vagina and vestibule. Consequently, the entire lining of the uterus and tubes as well as the ovarian surface is ultimately derived from coelomic epithelium (mesothelium). This close embryologic relationship between the mesothelium and müllerian system may be reflected in adult life in the form of benign (endometriosis) and malignant (endometrioid and serous neoplasia) lesions, which may arise in both the surface of the ovaries and the peritoneal surfaces. In addition, it explains the morphologic overlap of tumors arising in the various parts of the female genital tract (e.g., serous, endometrioid, clear cell).

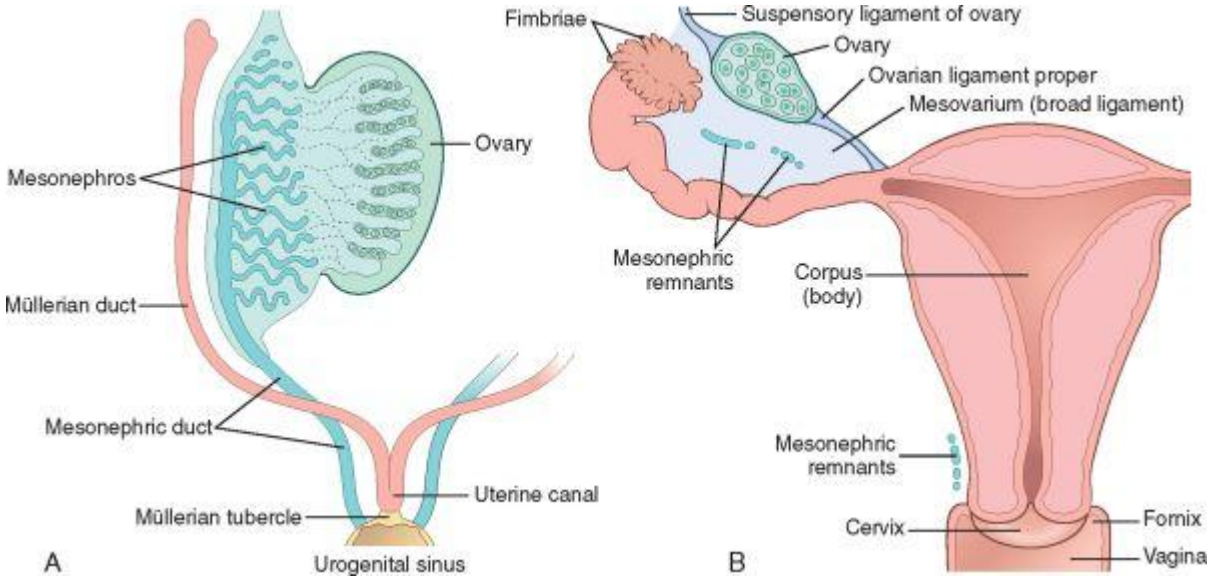

FIGURE 22-1 Embryology and anatomy of the female genital tract. **A**, Early in development the mesonephric *(blue)* and müllerian *(red)* ducts merge at the urogenital sinus to form the müllerian tubercle. **B**, By birth the müllerian ducts have fused to form the fallopian tubes, uterus, and endocervix *(red)*, merging with the vaginal squamous mucosa. The mesonephric ducts regress but may be found as a remnant in the ovary, adnexa, and cervix (Gartner duct). *(Adapted from Langman J: Medical Embryology. Baltimore, Williams and Wilkins, 1981.)*

The epithelium of the vagina, cervix, and urinary tract is formed by induction of basal cells from the underlying stroma, which undergo squamous and urothelial differentiation.[2] A portion of these cells remains uncommitted, forming the reserve cells of the cervix. The latter are capable of both squamous and columnar cell differentiation.[3]

In males, müllerian inhibitory substance[4] from the developing testis causes regression of the müllerian ducts, and the paired wolffian (or mesonephric) ducts form the epididymis and the vas deferens. Normally the mesonephric duct regresses in the female, but remnants may persist into adult life as epithelial inclusions adjacent to the ovaries, tubes, and uterus. In the cervix and vagina these rests may be cystic and are termed *Gartner duct cysts*. Many of the events in the formation of the internal and external genitalia and their epithelial coverings result from reciprocal epithelial-stromal signaling, leading to mesenchymal remodeling and changes in epithelial cell fate.[2,][5]

3.12.2 Anatomy

During active reproductive life, the ovaries measure about 4 × 2.5 × 1.5 cm in dimension. The ovary is divided into a cortex and a medulla. The cortex consists of a layer of closely packed stromal cells and a thin covering of relatively acellular collagenous connective tissue. Follicles in varying stages of maturation are found within the outer cortex. With each menstrual cycle, one follicle develops into a graafian follicle, which is transformed into a corpus luteum following ovulation. Corpora lutea ranging from recent to senescent (corpora albicans) may be found in the cortex of the adult ovary.

The medulla of the ovary consists of loosely arranged mesenchymal tissue and contains remnants of the mesonephric duct (rete ovarii) and small clusters of round to polygonal, epithelioid cells (hilus cells) around vessels and nerves. These hilus cells are vestigial remains of the gonad from its primitive

“ambisexual” phase, are steroid producing, and resemble the interstitial cells of the testis. Rarely, these cells give rise to masculinizing tumors (hilar cell tumors).

The fallopian tube mucosa is composed of numerous delicate papillary folds (plica) consisting of three cell types: ciliated columnar cells; nonciliated, columnar secretory cells; and so-called intercalated cells, which may simply represent inactive secretory cells.

The uterus varies in size depending on the age and parity of the individual. It weighs about 50 gm and measures about 8.0 × 6.0 × 3.0 cm in nulliparous reproductive age women. Following pregnancies, uteri are slightly larger (up to 70 gm in weight), then diminish to half their weight and dimension following menopause.

The uterus has three distinctive anatomic and functional regions: the cervix, the lower uterine segment, and the corpus. The cervix is further divided into the vaginal portio (ectocervix) and the endocervix. The portio is visible to the naked eye on vaginal examination and is covered by a stratified nonkeratinizing squamous epithelium continuous with the vaginal vault. The squamous epithelium converges centrally at a small opening termed the *external os*. In the nulliparous woman, this os is virtually closed. Just cephalad from the os is the endocervix, which is lined by columnar, mucus-secreting epithelium that dips down into the underlying stroma to produce endocervical glands. The point at which the squamous and endocervical mucinous columnar epithelium meet is termed the *squamocolumnar junction* (Fig. 22-2). The position of the junction is variable because of both the cervical anatomy and age-related hormonal influences. The differentiation of basal/reserve cells at the squamocolumnar junction into either squamous or glandular cell type governs the microanatomy of this region and results in a progressive upward migration of the squamocolumnar junction with age. The area of the cervix where the columnar epithelium is ultimately replaced by squamous epithelium is termed the *transformation zon* (see Fig. 22-2). Metaplasia of glandular epithelium to squamous epithelium at the squamocolumnar junction produces multilayered, initially immature, squamous epithelium known as “squamous metaplasia.” These immature squamous cells are susceptible to human papillomavirus (HPV) infection and, as discussed below, it is at the squamocolumnar junction where precancerous lesions and cervical carcinomas develop.[6]

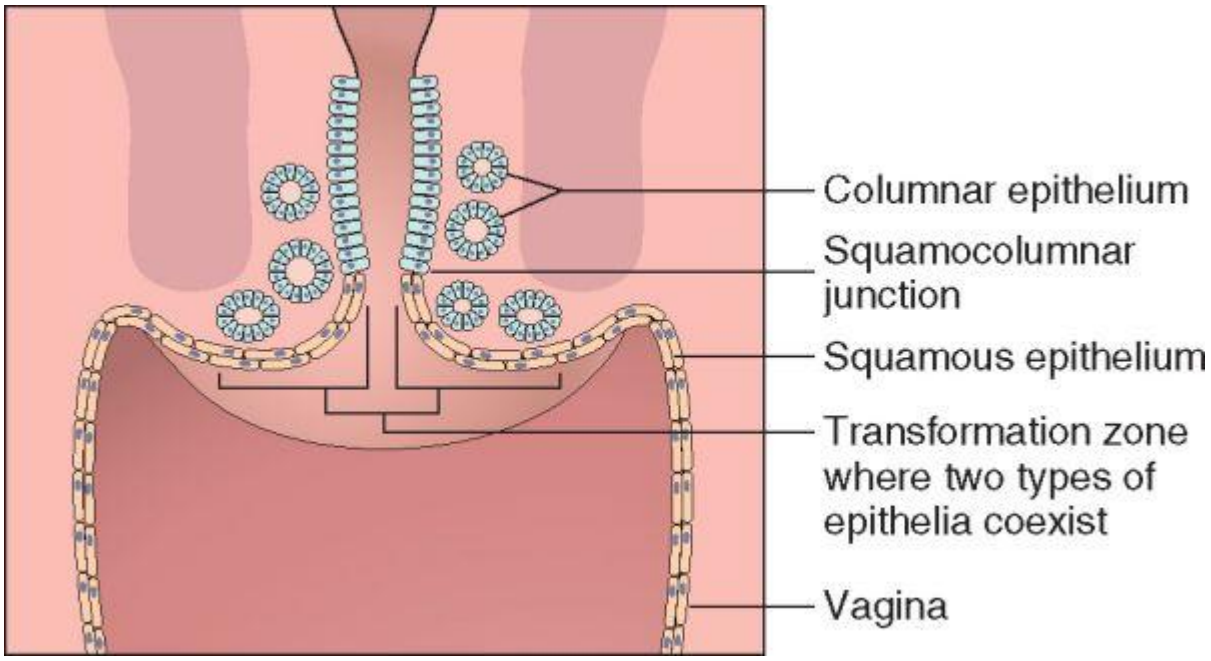

FIGURE 22-2 Schematic of the cervical transformation zone where squamous and endocervical columnar epithelia coexist undergoing

metaplasia (“transformation”) from glandular to squamous differentiation.

The corpus consists of the endometrium surrounded by the myometrium. Changes in the endometrium that occur during the menstrual cycle (discussed below) are keyed to the rise and fall in the levels of ovarian hormones, and the reader should be familiar with the complex but fascinating interactions among hypothalamic, pituitary, and ovarian factors underlying maturation of ovarian follicles, ovulation, and the menstrual cycle.

Diseases of the female genital tract are extremely common and include complications of pregnancy, infections, tumors, and hormonally induced effects. The following discussion presents the pathology of the major diseases that result in clinical problems. Details can be found in current textbooks of gynecologic pathology and clinical obstetrics and gynecology.[7,][8] The pathologic conditions peculiar to each segment of the female genital tract are discussed separately, but first we briefly review infections and pelvic inflammatory disease because they can affect many of the various anatomic structures concomitantly.

3.12.3 Infections of the Female Genital Tract

A large variety of organisms can infect the female genital tract. Infections with some microorganisms, such as *Candida*, *Trichomonas*, and *Gardnerella*, are extremely common and may cause significant discomfort with no serious sequelae. Others, such as *Neisseria gonorrhoeae* and *Chlamydia* infections, are major causes of female infertility, and others still, such as *Ureaplasma urealyticum* and *Mycoplasma hominis* infections, are implicated in preterm deliveries. Viruses, especially herpes simplex viruses (HSVs) and human papillomaviruses (HPVs), also account for considerable morbidity; HSVs cause painful genital ulcerations, whereas HPVs are involved in the pathogenesis of cervical, vaginal, and vulvar cancers.

Many of these infections are sexually transmitted, including trichomoniasis, gonorrhea, chancroid, granuloma inguinale, lymphogranuloma venereum, syphilis, mycoplasma, chlamydia, HSV, and HPV.[9] Most of these conditions have been considered in Chapter 8 . Here we touch only on selected aspects relevant to the female genital tract, including pathogens confined to the lower genital tract (vulva, vagina, and cervix) and those that involve the entire genital tract and are implicated in pelvic inflamatory disease. Papillomaviruses are also discussed in Chapter 7 .

Infections of the Lower Genital Tract

Genital *herpes simplex virus* infection is common and involves, in the order of frequency, the cervix, vagina, and vulva. HSVs are DNA viruses that include two serotypes, HSV-1 and HSV-2. *HSV-1 typically results in oropharyngeal infection, whereas HSV-2 usually involves genital mucosa and skin*; however, depending on the sexual practices HSV-1 may be detected in the genital region and HSV-2 may cause oral infections as well (see also Chapter 8). The frequency of genital herpes has increased dramatically in the past decades, particularly in teenagers and young women. *By the age of 40, 20% of women are seropositive for antibodies against HSV-2*.[10]

Clinical symptoms are seen in about one third of infected individuals. The initial lesions typically develop 3 to 7 days after sexual transmission and consist of red papules that progress to vesicles and then to painful coalescent ulcers. Such lesions are clinically apparent on vulvar skin and mucosa, while cervical or vaginal lesions present with severe purulent discharge and pelvic pain. Lesions around the urethra may cause painful urination and urine retention. The initial infection typically produces systemic symptoms such as fever, malaise, and tender inguinal lymph nodes. The vesicles and ulcers contain

numerous viral particles, accounting for the high transmission rate during active infection. The mucosal and skin lesions heal spontaneously in 1 to 3 weeks, but as with herpetic infections elsewhere, the virus migrates to the regional lumbosacral nerve ganglia establishing a latent infection. Because of viral latency, HSV infections persist indefinitely and any decrease in immune system surveillance, as well as stress, trauma, ultraviolet radiation, and hormonal changes, can trigger reactivation of the virus and recurrence of the skin and mucosal lesions.[9] As expected, recurrences are much more common in immunosuppressed individuals. In addition, *HSV-2 infections are more likely to recur than HSV-1 infections*.

Transmission of HSV may occur during both the active and latent phases (subclinical virus shedding), although it is much less likely in asymptomatic carriers. Condoms offer limited protection against HSV infection, since a large genital area may be affected by the virus. As with other sexually transmitted diseases, women are more susceptible to transmission than men. Previous infection with HSV-1 seems to reduce susceptibility to HSV-2 infection. The gravest consequence of HSV infection is transmission to the neonate during birth. This risk is highest if the infection is active during delivery and particularly if it is a primary (initial) infection in the mother. Cesarian section is warranted in such cases.

The diagnosis is based on typical clinical findings and HSV detection. For diagnosis the purulent exudate is aspirated from the lesions and inoculated into a tissue culture. After 48 to 72 hours the *viral cytopathic effect* can be seen, and the virus may then be isolated and serotyped. In addition, some laboratories offer more sensitive *polymerase chain reaction*, enzyme-linked immunosorbent assays, and direct immunofluorescent antibody tests for detection of HSV in the lesional secretions. Individuals with primary, acute-phase HSV infection do not have serum anti-HSV antibodies. Detection of *anti-HSV antibodies in the serum is indicative of recurrent/latent infection*.

There is no effective treatment for latent HSV; however, antiviral agents like acyclovir or famciclovir may shorten the length of the initial and recurrent symptomatic phase. Several prophylactic and therapeutic vaccine strategies have been developed using animal models, and several clinical trials are currently underway.[11]

Molluscum contagiosum is a poxvirus infection of the skin and the mucous membranes. There are four types of *molluscum contagiosum viruses* (MCVs), MCV-1 to -4, with MCV-1 being the most prevalent and MCV-2 being most often sexually transmitted. The infections are common in young children between 2 and 12 years of age and are transmitted through direct contact or shared articles (e.g., towels). Molluscum may affect any area of the skin but is most common on the trunk, arms, and legs. In adults, molluscum infections are typically sexually transmitted and affect the genitals, lower abdomen, buttocks, and inner thighs. The average incubation period is 6 weeks. Diagnosis is based on the characteristic clinical appearance of pearly, dome-shaped papules with a dimpled center. The papules measure 1 to 5 mm in diameter, and their central waxy core contains cells with *intracytoplasmic viral inclusions* (Fig. 22-3).

FIGURE 22-3 Lesion caused by molluscum contagiosum infection. *Arrow* points to intracytoplasmic viral inclusions.

Fungal infections, especially those caused by yeasts (*Candida*), are extremely common; in fact, yeasts are part of many women's normal vaginal microflora and the development of symptomatic candidiasis is typically a result of a disturbance in the patient's vaginal microbial ecosystem. *Diabetes mellitus, antibiotics, pregnancy, and conditions resulting in compromised cell-mediated immunity are permissive to symptomatic infection*, which manifests itself by marked vulvovaginal pruritus, erythema, swelling, and curdlike vaginal discharge. Severe infection may result in mucosal ulcerations. The diagnosis is made by finding the pseudospores or filamentous fungal hyphae in wet KOH mounts of the discharge or on Pap smear. Even though sexual transmission of yeast infection has been documented, candidiasis is not considered a sexually transmitted disease.

Trichomonas vaginalis is a large, flagellated ovoid protozoan that can be readily identified in wet mounts of vaginal discharge or Pap smear of infected patients. The infection is usually transmitted by sexual contact and develops within 4 days to 4 weeks. The patients may be asymptomatic or may complain of yellow, frothy vaginal discharge, vulvovaginal discomfort, dysuria (painful urination), and dyspareunia (painful intercourse). The vaginal and cervical mucosa typically has a fiery-red appearance, with marked dilatation of cervical mucosal vessels resulting in characteristic colposcopic appearance of "strawberry cervix."

Gardnerella vaginalis is a gram-negative bacillus that is implicated as the main cause of bacterial vaginosis (vaginitis). Patients typically present with thin, green-gray, malodorous (fishy) vaginal

discharge. Pap smears reveal superficial and intermediate squamous cells covered by a shaggy coat of multiple coccobacilli. Bacterial cultures in such cases reveal *G. vaginalis* and other bacteria including anaerobic peptostreptococci and aerobic α-hemolytic streptococci. In pregnant patients, bacterial vaginosis has been implicated in premature labor.

Ureaplasma urealyticum and *Mycoplasma hominis* species account for some cases of vaginitis and cervicitis, and have been implicated in chorioamnionitis and premature delivery in pregnant patients.[12]

Most *Chlamydia trachomatis* infections take the form of cervicitis. However, in some patients it ascends to the uterus and fallopian tubes, resulting in endometritis and salpingitis, and thus is one of the causes of pelvic inflammatory disease, as discussed below.

For description of genital lesions caused by *Treponema pallidium*, see Chapter 8 . Description of HPV infections is presented in this chapter under "Cervix", and gonorrhea infections are described below.

Infections Involving The Lower and Upper Genital Tract

Pelvic Inflammatory Disease (PID)

PID is an ascending infection that begins in the vulva or vagina and spreads upward to involve most of the structures in the female genital system, resulting in pelvic pain, adnexal tenderness, fever, and vaginal discharge. Gonococcus continues to be a common cause of PID, the most serious complication of gonorrhea in women. *Chlamydia* infection is another well-recognized cause of PID. Besides these two organisms, infections after spontaneous or induced abortions and normal or abnormal deliveries (called puerperal infections) are important causes of PID. In these situations the infections are typically polymicrobial and may be caused by staphylococci, streptococci, coliform bacteria, and *Clostridium perfringens*.

With gonococcus, inflammatory changes start to appear approximately 2 to 7 days after inoculation. Endocervical mucosa is the most common site of initial involvement. Gonococcal inflammation may also begin in the Bartholin gland and other vestibular, or periurethral, glands. From any of these sites, the organisms may spread upward to involve the fallopian tubes and tubo-ovarian region. The non-gonococcal bacterial infections that follow induced abortion, dilation and curettage of the uterus, and other surgical procedures of the female genital tract are thought to spread from the uterus upward through the lymphatics or venous channels rather than on the mucosal surfaces. Therefore, these infections tend to produce less mucosal involvement but more reaction within the deeper layers of the organs.

Morphology. Wherever it occurs, gonococcal disease is characterized by marked acute inflammation largely confined to the superficial mucosa. Smears of the inflammatory exudate disclose the intracellular gram-negative diplococcus; however, definitive diagnosis requires culture, or detection of gonoccocal RNA or DNA. If spread occurs, the endometrium is usually spared for unclear reasons. Once the infection reaches the tubes, an **acute suppurative salpingitis** ensues. The tubal mucosa becomes congested and diffusely infiltrated by neutrophils, plasma cells, and lymphocytes. Gonococcal lipopolysaccharide and inflammatory mediators such as TNF cause epithelial injury and sloughing of the plicae. The tubal lumen fills with purulent exudate that may leak out of the fimbriated end. The infection may further spill over to the ovary to create a **salpingo-oophoritis**. Collections of pus within the ovary and tube **(tubo-ovarian abscesses)** or tubal lumen **(pyosalpinx)** may occur (Fig. 22-4). In the course of time the infecting organisms may disappear, leaving the sequelae of **chronic follicular salpingitis** and **hydrosalpinx** (dilated, fluid-filled fallopian tube). The tubal plicae, denuded of epithelium, adhere to one another and slowly fuse in a reparative, scarring

process that forms glandlike spaces and blind pouches, referred to as chronic follicular salpingitis. The lumen of such tubes may be impenetrable for the oocyte, resulting in infertility or ectopic pregnancy. Hydrosalpinx develops as a consequence of the fusion of the fimbriae and the subsequent accumulation of the tubal secretions and tubal distention. Hydrosalpinx is another cause of post-PID infertility, since lack of flexible tubal fimbriae prevents uptake of the oocyte after ovulation.

PID caused by staphylococci, streptococci, and the other puerperal invaders tends to have less exudation within the lumen of the tube and less involvement of the mucosa, but a greater inflammatory response within the deeper tissue layers. These infections often spread throughout the wall to involve the serosa and the broad ligaments, pelvic structures, and peritoneum. Bacteremia is a more frequent complication of streptococcal or staphylococcal PID than of gonococcal infections.

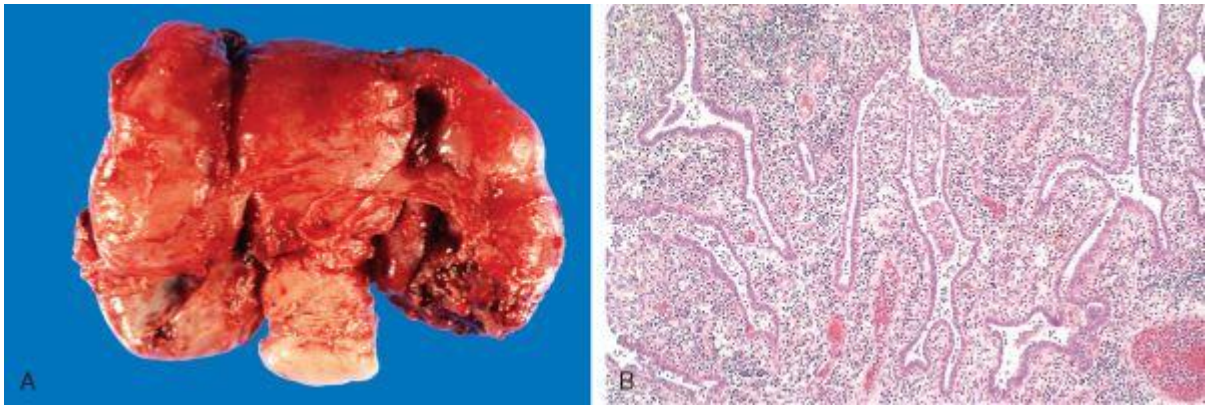

FIGURE 22-4 **A**, Acute salpingo-oophoritis, with tubo-ovarian abscess. The fallopian tubes and ovaries have coalesced into an inflammatory mass adherent to the uterus. **B**, Salpingitis with edematous tubal plicae expanded by inflammatory cell infiltrates.

The acute complications of PID include peritonitis and bacteremia, which in turn may result in endocarditis, meningitis, and suppurative arthritis. The remote sequelae of PID include infertility and tubal obstruction, increased risk of ectopic pregnancy, pelvic pain, as well as intestinal obstruction due to adhesions between the bowel and pelvic organs.

In the early stages, gonococcal infections are readily controlled with antibiotics, although penicillin-resistant strains have regrettably emerged. When the infection becomes walled off in tubo-ovarian abscesses, it is difficult to achieve sufficient levels of antibiotics within such infectious foci and it sometimes becomes necessary to remove the organs surgically. Postabortion and postpartum PIDs are also amenable to treatment with antibiotics but are far more difficult to control than the gonococcal infections because of the broad spectrum of pathogens that may be involved.

3.12.4 Vulva

Diseases of the vulva in the aggregate constitute only a small fraction of gynecologic practice. Many inflammatory dermatologic diseases that affect skin elsewhere on the body may also occur on the vulva, such as psoriasis, eczema, and allergic dermatitis. The vulva is more prone to skin infections, because it is constantly exposed to secretions and moisture. Nonspecific vulvitis is particularly likely to occur in the setting of immunosuppression. Most skin cysts (epidermal inclusion cysts) and skin tumors can also occur in the vulva. Here we discuss disorders particular to the vulva, including Bartholin cyst, non-neoplastic epithelial disorders, benign exophytic lesions, and tumors of the vulva.

3.12.4.1 Bartholin Cyst

Infection of the Bartholin gland produces an acute inflammation within the gland (adenitis) and may result in an abscess. Bartholin duct cysts are relatively common, occur at all ages, and result from obstruction of the duct by an inflammatory process. The resulting cysts are lined by the ductal squamous metaplastic and/or epithelium. They may become large, up to 3 to 5 cm in diameter, and produce pain and local discomfort. Bartholin duct cysts are either excised or opened permanently (marsupialization).

3.12.4.2 Non-Neoplastic Epithelial Disorders

A heterogeneous group of lesions of the vulva presents as opaque, white, plaquelike mucosal thickening that may produce itching (pruritus) and scaling. Because of their appearance, these disorders have traditionally been termed *leukoplakia* by clinicians. This is a non-specific descriptive term, as *white plaques may represent a variety of benign, premalignant, or malignant lesions* including (1) inflammatory dermatoses (e.g., psoriasis, chronic dermatitis); (2) vulvar intraepithelial neoplasia, Paget disease, or even invasive carcinoma; and (3) epithelial disorders of unknown etiology. Excluding neoplasms and specific disease entities, nonneoplastic epithelial disorders of unknown etiology are classified into two categories: (1) *lichen sclerosus* and (2) *squamous cell hyperplasia (also known as lichen simplex chronicus)*. The two disorders may coexist and the lesions are often multiple, making their clinical management particularly difficult.

LICHEN SCLEROSUS

This lesion is characterized by thinning of the epidermis and disappearance of rete pegs, hydropic degeneration of the basal cells, superficial hyperkeratosis, and dermal fibrosis with a scant perivascular, mononuclear inflammatory cell infiltrate (Fig. 22-5). The lesions appear clinically as smooth, white plaques or papules that in time may extend and coalesce. The surface is smoothed out and sometimes resembles parchment. When the entire vulva is affected, the labia become somewhat atrophic and stiffened, and the vaginal orifice is constricted. It occurs in all age groups but is most common in postmenopausal women. It may also be encountered elsewhere on the skin. The pathogenesis is uncertain, but the presence of activated T cells in the subepithelial inflammatory infiltrate and the increased frequency of autoimmune disorders in these women suggests an autoimmune reaction may be involved. Although the lesion in lichen sclerosus is not pre-malignant by itself, women with symptomatic lichen sclerosus have a somewhat increased chance of developing squamous cell carcinoma in their lifetime.[13]

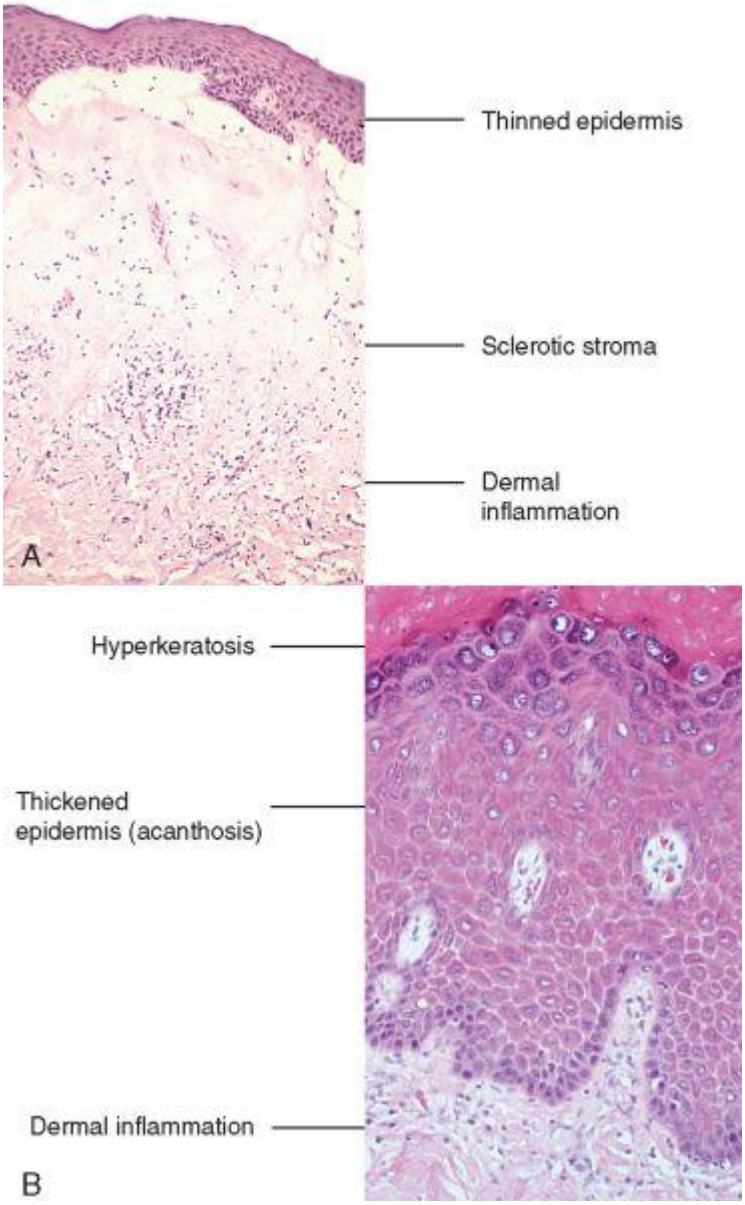

FIGURE 22-5 Non-neoplastic epithelial vulvar disorders. **A**, Lichen sclerosus. **B**, Squamous cell hyperplasia. The main features of the lesions are indicated in the figures.

SQUAMOUS CELL HYPERPLASIA

Previously called hyperplastic dystrophy, or *lichen simplex chronicus*, squamous cell hyperplasia is a nonspecific condition resulting from rubbing or scratching of the skin to relieve pruritus. It is marked by epithelial thickening, expansion of the stratum granulosum, and significant surface hyperkeratosis. It appears clinically as an area of leukoplakia. The epithelium may show increased mitotic activity in both the stratum basalis and spinosum. Leukocytic infiltration of the dermis is sometimes pronounced. The hyperplastic epithelial changes show no atypia (see Fig. 22-5B). There is generally no increased predisposition to cancer, but suspiciously, lichen simplex chronicus is often present at the margins of established cancer of the vulva.

3.12.4.3 Benign Exophytic Lesions

Benign raised (exophytic) or wartlike conditions of the vulva may be caused by an infection or are of unknown etiology. *Condyloma acuminatum,* a papillomavirus-induced lesion, also called a genital wart, and syphilitic *condyloma latum* (described in Chapter 8) are consequences of sexually transmitted infections. Vulvar *fibroepithelial polyps*, or skin tags, are similar to skin tags occurring elsewhere on the skin. Vulvar *squamous papillomas* are benign exophytic proliferations covered by nonkeratinized squamous epithelium, which develop on vulvar mucosal surfaces and may be single or numerous (vulvar papillomatosis). The etiology of *fibroepithelial polyps* and *squamous papillomas* is unknown; however, these lesions are not related to any known infectious agent.

CONDYLOMA ACUMINATUM

Condylomata acuminata are sexually transmitted, benign lesions that have a distinct *verrucous gross appearance* (Fig. 22-6A). Although they may be solitary, they are more frequently multifocal: they may involve vulvar, perineal, and perianal regions as well as the vagina and, less commonly, the cervix. The lesions are identical to those found on the penis and around the anus in males (Chapter 21). On histologic examination, they consist of branching, treelike cores of stroma covered by squamous epithelium with characteristic viral cytopathic changes referred to as *koilocytic atypia* (Fig. 22-6B). Condylomata acuminata are caused by low oncogenic risk HPVs, principally types 6 and 11, and represent productive viral infection in which HPV replicates in the squamous cells. The virus life cycle is completed in the mature superficial cells, resulting in distinct cytologic changes—*koilocytotic atypia*—characterized by nuclear enlargement and atypia as well as a cytoplasmic perinuclear halo (see also “Cervix”). Condylomata acuminata are not considered precancerous lesions.

3.12.4.4 Squamous Neoplastic Lesions

VULVAR INTRAEPITHELIAL NEOPLASIA AND VULVAR CARCINOMA

Carcinoma of the vulva is an uncommon malignant neoplasm (approximately one eighth as frequent as cervical cancer) representing about 3% of all genital cancers in the female; approximately two thirds occur in women older than 60 years. Squamous cell carcinoma is the most common histologic type of vulvar cancer. In terms of etiology, pathogenesis, and histologic features, vulvar squamous cell carcinomas are divided into two groups: *basaloid and warty carcinomas* related to infection with high oncogenic risk HPVs (30% of cases) and *keratinizing squamous cell carcinomas*, not related to HPV infection (70% of cases).[14]

Invasive *basaloid and warty carcinomas* develop from a precancerous in situ lesion called *classic vulvar intraepithelial neoplasia* (classic VIN). This form of VIN includes lesions designated formerly as carcinoma in situ or Bowen disease. Classic VIN is characterized by nuclear atypia of the squamous cells, increased mitoses, and lack of cellular maturation (Fig. 22-7A). It is analogous to cervical squamous intraepithelial lesions (SILs, see under "Cervix"). It most commonly occurs in reproductive-age women, and the risk factors are the same as those associated with cervical squamous intraepithelial lesions (e.g., young age at first intercourse, multiple sexual partners, male partner with multiple sexual partners), since both cervical squamous intraepithelial lesions and classic VIN are related to HPV infection. VIN is frequently multicentric in the vulva, and 10% to 30% of patients with VIN also have vaginal or cervical HPV-related lesions. The majority of cases of classic VIN are positive for HPV 16, and less frequently for other high-risk HPV types, like HPV 18 or 31. Spontaneous regression of VIN lesions has been reported, usually in younger women; the risk of progression to invasive carcinoma is higher in women older than 45 years of age or in women with immunosuppression.

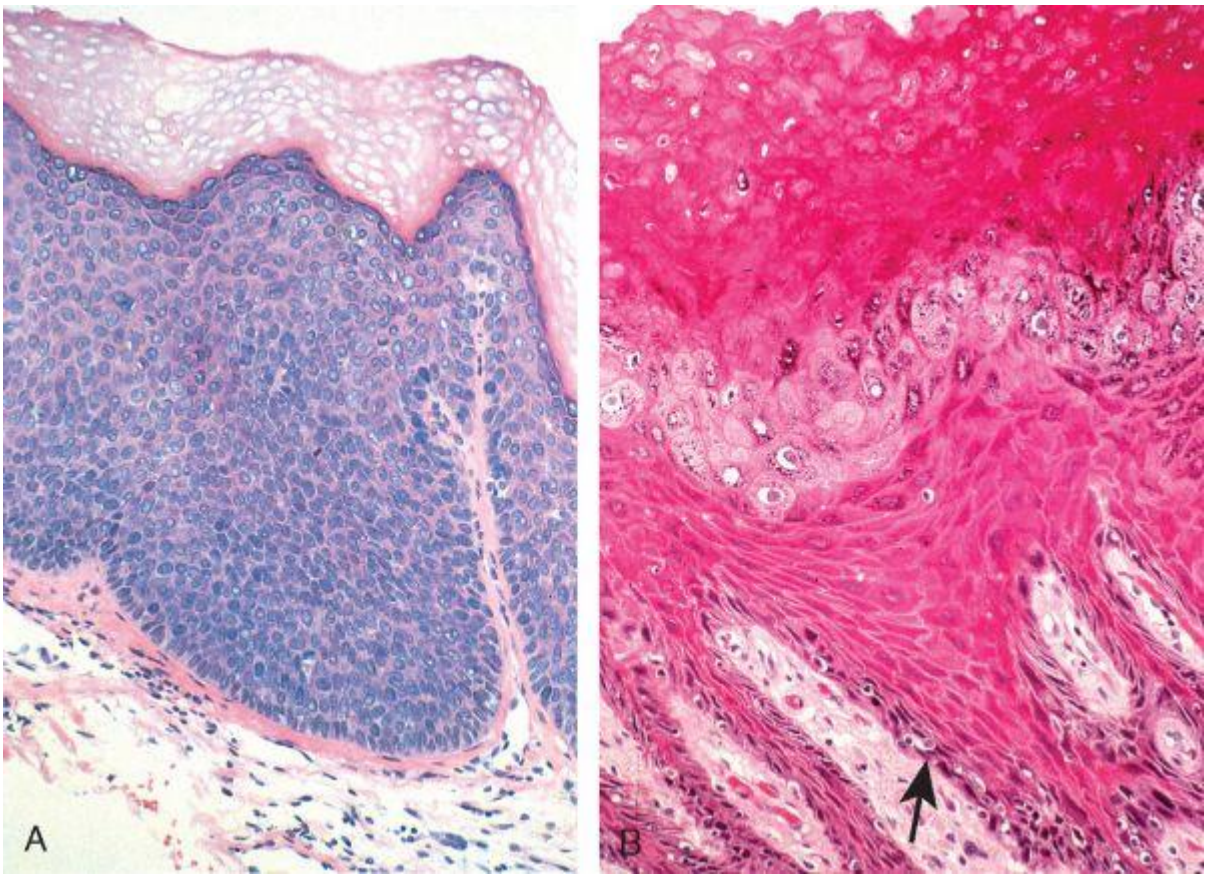

FIGURE 22-7 A, Histopathology of classic vulvar intraepithelial neoplasia (HPV positive) with diffuse cellular atypia, immaturity, nuclear crowding, and increased mitotic activity. **B**, Differentiated VIN (HPV negative), showing maturation of the superficial layers, hyperkeratosis, and basal cell atypia *(arrow)*.

Morphology. HPV-associated vulvar squamous cell carcinomas begin as classic VIN lesions, which present as discrete white (hyperkeratotic), flesh-colored or pigmented, slightly raised lesions. Coexisting carcinomas may be exophytic or indurated, frequently with ulceration. On histologic examination, basaloid carcinoma (Fig. 22-8A) shows an infiltrating tumor characterized by nests and cords of small, tightly packed malignant squamous cells lacking maturation that resemble immature

cells from the basal layer of the normal epithelium. The tumor may have foci of central necrosis.

Warty carcinoma is characterized by exophytic, papillary architecture and prominent koilocytic atypia (Fig. 22-8B).

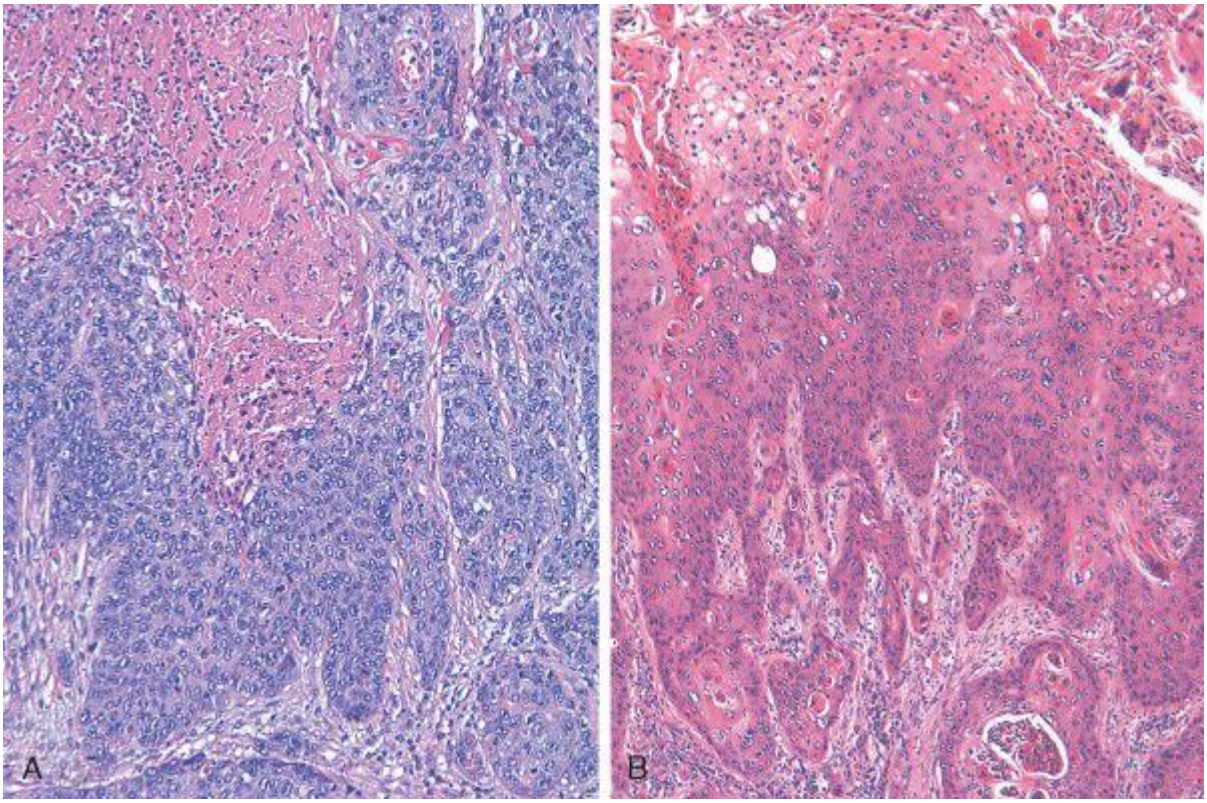

FIGURE 22-8 **A**, Basaloid vulvar carcinoma (HPV positive). **B**, Warty vulvar carcinoma (HPV positive).

Non-HPV-related *keratinizing squamous cell carcinomas* frequently arise in individuals with long-standing lichen sclerosus or squamous cell hyperplasia. The mean age of the patients is 76 years. The immediate premalignant lesion is referred to as *differentiated vulvar intraepithelial neoplasia* (differentiated VIN) or VIN *simplex* (see Fig. 22-7B).[14] Differentiated VIN is characterized by marked atypia of the basal layer of the squamous epithelium with apparently normal epithelial maturation and differentiation in the superfical layers, thus the designation "differentiated VIN." The etiology of differentiated VIN is unknown, but it is postulated that chronic epithelial irritation in lichen sclerosus or squamous cell hyperplasia may contribute to a gradual evolution of the malignant phenotype. The putative molecular events leading to malignant transformation in lichen sclerosus, squamous cell hyperplasia, and differentiated VIN are under investigation. A report of allelic imbalance in lichen sclerosus and squamous cell hyperplasia supports the hypothesis that both conditions pose a risk for neoplasia despite the lack of morphologic evidence of atypia. Rare cases of lichen sclerosus, differentiated VIN, and adjacent carcinoma with identical *p53* gene mutations have been reported. Overall, however, *p53* gene mutation is an infrequent and rather late event in vulvar carcinogenesis.[15]

Morphology. Carcinomas associated with lichen sclerosus, squamous cell hyperplasia, and differentiated VIN may develop as nodules in a background of vulvar inflammation. The often-subtle

emergence of cancer may be misinterpreted as dermatitis, eczema, or leukoplakia for long periods. The clinical manifestations are nonspecific, including local discomfort, itching, and exudation because of superficial secondary infection, and underscore the importance of repeated examination in women with vulvar inflammatory disorders. Histologic examination reveals infiltrating tumor characterized by nests and tongues of malignant squamous epithelium with prominent central keratin pearls (Fig. 22-9A).

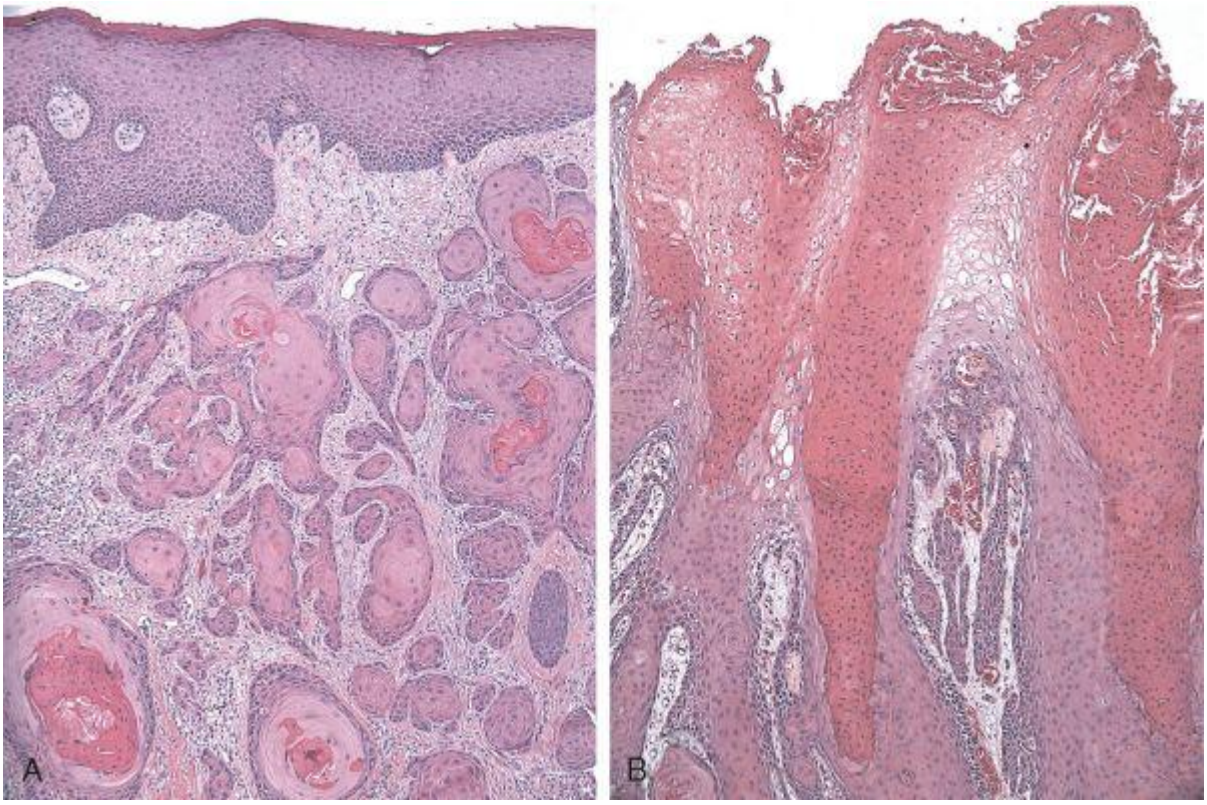

FIGURE 22-9 **A**, Well-differentiated, keratinizing squamous cell carcinoma of the vulva (HPV negative). **B**, Verrucous carcinoma of the vulva (HPV negative).

Risk of cancer development in VIN is principally a function of age, extent, and immune status.[16] Once invasive cancer develops, metastatic spread is linked to the size of tumor, depth of invasion, and involvement of lymphatic vessels. The initial spread is to inguinal, pelvic, iliac, and periaortic lymph nodes. Ultimately, lymphohematogenous dissemination to the lungs, liver, and other internal organs may occur. Patients with lesions less than 2 cm in diameter have a 60% to 80% 5-year survival after treatment with vulvectomy and lymphadenectomy; however, larger lesions with lymph node involvement have a 5-year survival rate of less than 10%.

Rare variants of squamous cell carcinoma include *verrucous carcinomas* (Fig. 22-9B), which are fungating tumors resembling condyloma acuminatum, and *basal cell carcinomas*, which are identical to their counterparts in the skin. Neither tumor is associated with papillomaviruses. Both tumors rarely metastasize and are successfully cured by wide excision.

3.12.4.5 Glandular Neoplastic Lesions

PAPILLARY HIDRADENOMA

Like the breast, the vulva contains modified apocrine sweat glands. In fact, the vulva may contain tissue closely resembling breast ("ectopic breast") and develop two tumors with counterparts in the breast, namely papillary hidradenoma and extramammary Paget disease. Papillary hidradenoma presents as a sharply circumscribed nodule, most commonly on the labia majora or interlabial folds, and may be confused clinically with carcinoma because of its tendency to ulcerate.

Morphology. On histologic examination hidradenoma is identical in appearance to intraductal papillomas of the breast and consists of papillary projections covered with two layers of cells: the top columnar, secretory cells and an underlying layer of flattened "myoepithelial cells." These myoepithelial elements are characteristic of sweat glands and sweat gland tumors (Fig. 22-10).

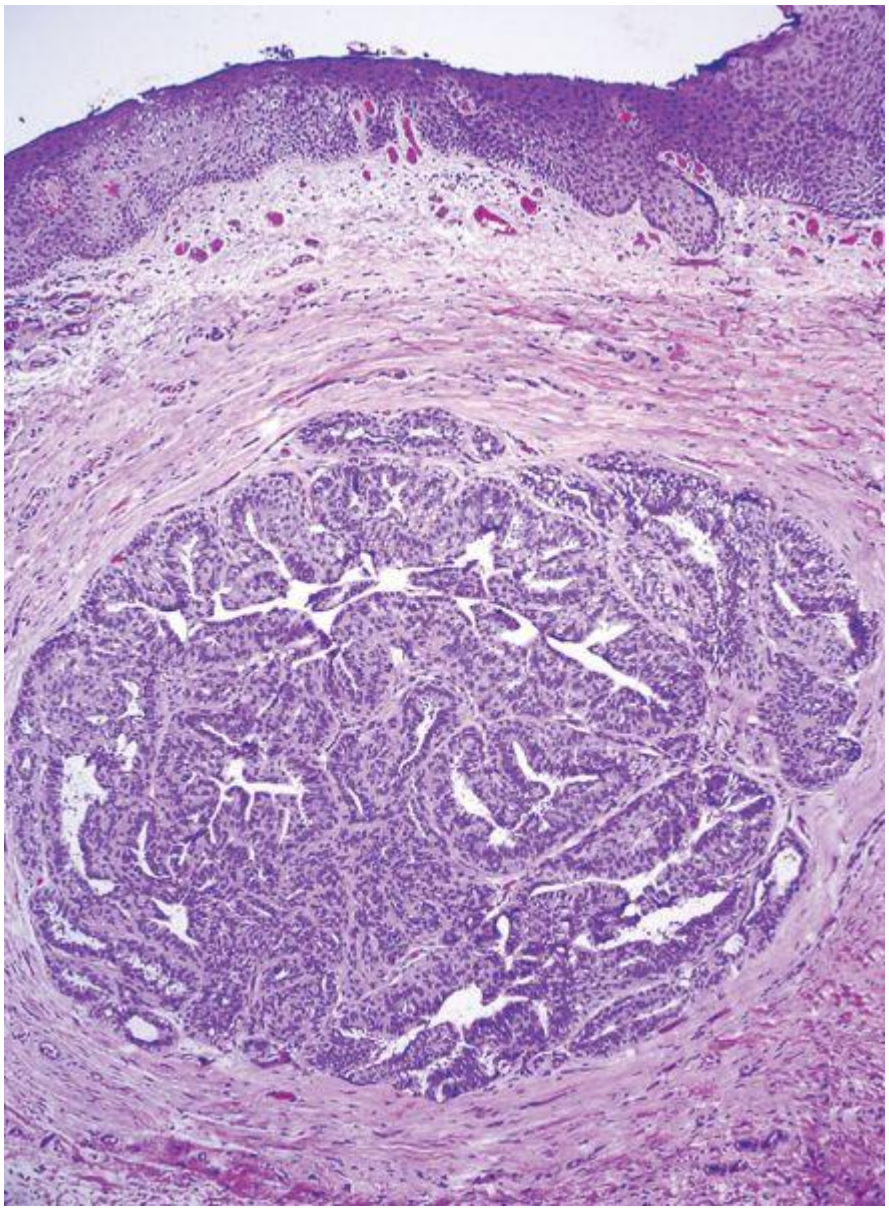

FIGURE 22-10 Papillary hidradenoma of the vulva, a well-circumscribed tumor nodule composed of benign papillary projections covered with columnar secretory epithelium and underlying myoepithelial cells.

EXTRAMAMMARY PAGET DISEASE

This curious and rare lesion of the vulva, and sometimes the perianal region, is similar in its manifestations to Paget disease of the breast (Chapter 23). As a vulvar neoplasm, it presents as a pruritic, red, crusted, sharply demarcated, maplike area, occurring usually on the labia majora. It may be accompanied by a palpable submucosal thickening or nodule.

Morphology. Paget disease is a distinctive intraepithelial proliferation of malignant cells. The diagnostic microscopic feature is the presence of large tumor cells lying singly or in small clusters within the epidermis and its appendages. These cells are distinguished by a clear separation ("halo") from the surrounding epithelial cells (Fig. 22-11) and a finely granular cytoplasm containing mucopolysaccharide that stains with periodic acid–Schiff (PAS), Alcian blue, or mucicarmine stains. Ultrastructurally, Paget cells display apocrine, eccrine, and keratinocyte differentiation and presumably arise from primitive germinal cells of the mammary-like gland ducts of the vulvar skin.[17,][18]

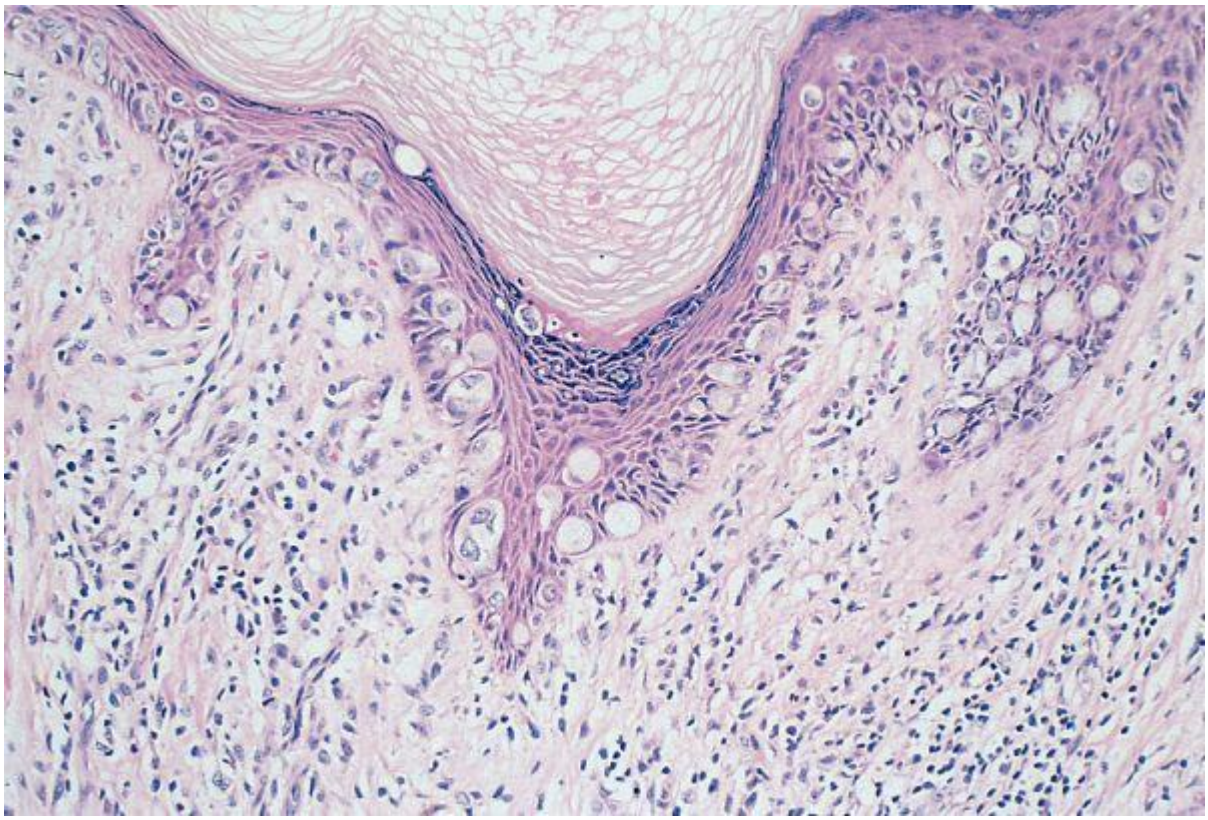

FIGURE 22-11 Paget disease of the vulva with clusters and single pale tumor cells spreading along the basal portion of the squamous epithelium. There is inflammation in the underlying dermis.

In contrast to Paget disease of the nipple, in which 100% of patients show an underlying ductal breast carcinoma, vulvar lesions are most frequently confined to the epidermis of the skin and adjacent hair follicles and sweat glands. Paget disease is treated with wide local excision and shows a high recurrence

rate. Typically, Paget cells spread beyond the confines of the grossly visible lesion, and therefore are frequently present beyond the margins of surgical excision. Intraepidermal Paget disease may persist for many years, even decades, without invasion or metastases. Invasion develops rarely, and in such patients the prognosis is poor.

3.12.4.6 Malignant Melanoma

Melanomas of the vulva are rare, representing less than 5% of all vulvar cancers and 2% of all melanomas in women. Their peak incidence is in the sixth or seventh decade; they tend to have the same biologic and histologic characteristics as melanomas occurring elsewhere in the skin and are capable of widespread metastatic dissemination. The 5-year survival rate is less than 32%, presumably because of delays in detection and because the majority of these tumors rapidly enter a vertical growth phase following inception (Chapter 25). Prognosis is linked principally to depth of invasion, with greater than 60% mortality for lesions invading deeper than 1 mm.

Because it is initially confined to the epithelium, melanoma may resemble Paget disease, both grossly and histologically. It can usually be differentiated by its uniform reactivity with antibodies to S100 protein, absence of reactivity with antibodies to cytokeratin, and lack of mucopolysaccharides, both of which are present in Paget disease.

3.12.5 Vagina

The vagina is a portion of the female genital tract that is remarkably free from primary disease. In the adult, inflammations often affect the vulva and perivulvar structures and spread to the cervix without significant involvement of the vagina. Primary lesions of the vagina are rare; the most serious of which is primary vaginal carcinoma. Thus, they are discussed only briefly.

3.12.5.1 Developmental Anomalies

Septate, or double, vagina is an uncommon anomaly that arises from failure of total fusion of the müllerian ducts and accompanies a double uterus (uterus didelphys). These and other anomalies of the external genitalia may be the manifestations of genetic syndromes, in utero exposure to diethylstilbestrol (DES) used to prevent threatened abortions in the 1940s through 1960s, or other disturbances associated with abnormalities in reciprocal epithelial-stromal signaling during fetal development.[19]

Vaginal adenosis is a remnant of columnar, endocervical-type epithelium that during embryonal development extends from the endocervix and covers the ectocervix as well as the upper vagina and is subsequently replaced by the squamous epithelium advancing upwardly from the urogenital sinus. Small patches of unreplaced glandular epithelium may persist focally into adult life. Adenosis presents clinically as red, granular areas contrasting with the normal pale-pink vaginal mucosa. On microscopic examination, adenosis consists of columnar mucinous epithelium indistinguishable from endocervical epithelium. Adenosis, while normally present in a small percentage of adult women, has been reported in 35% to 90% of women exposed to DES in utero. Rare cases of clear cell carcinoma (Fig. 22-12) arising in DES-related adenosis were recorded in teens and young women in the 1970s and 1980s, resulting in discontinuation of DES treatment.

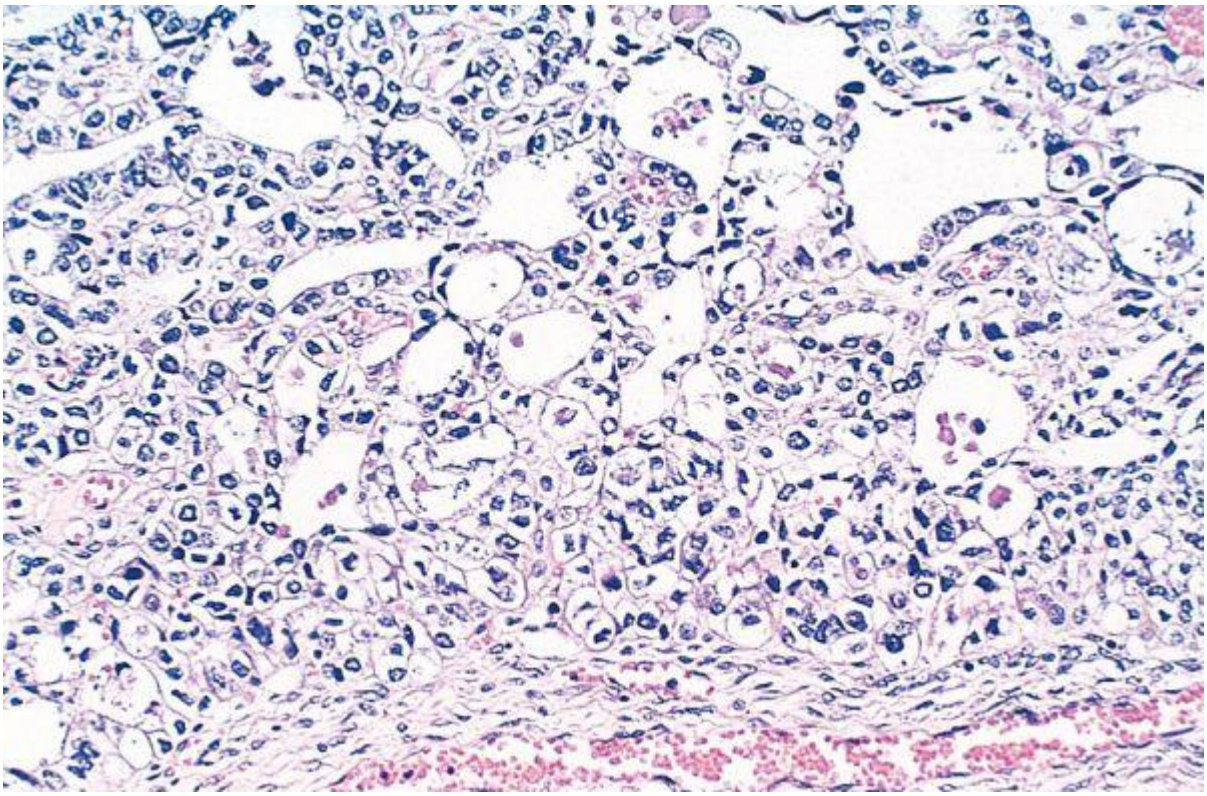

FIGURE 22-12 Clear cell adenocarcinoma of the vagina showing vacuolated tumor cells in clusters and glandlike structures.

Gartner duct cysts are relatively common lesions found along the lateral walls of the vagina and derived from wolffian (mesonephric) duct rests. They are 1- to 2-cm fluid-filled cysts that occur in the submucosal location. Other cysts, including mucus cysts, which occur in the proximal vagina, are derived from müllerian epithelium. Another müllerian-derived lesion, endometriosis (described later), may occur in the vagina and simulate a neoplasm.

3.12.5.2 Premalignant & Malignant Neoplasms

Most of the benign tumors of the vagina occur in reproductive-age women and include stromal tumors (stromal polyps), leiomyomas, and hemangiomas. The most common malignant tumor of the vagina is carcinoma metastatic from the cervix, followed by a primary squamous cell carcinoma of the vagina. Infants may develop a unique, rare malignancy—embryonal rhabdomyosarcoma (sarcoma botryoides).

VAGINAL INTRAEPITHELIAL NEOPLASIA AND SQUAMOUS CELL CARCINOMA

Primary carcinoma of the vagina is an extremely uncommon cancer (about 0.6 per 100,000 women yearly) accounting for about 1% of malignant neoplasms in the female genital tract. Almost all of these tumors are squamous cell carcinomas associated with *high oncogenic risk HPVs*. The greatest risk factor is a previous carcinoma of the cervix or vulva; 1% to 2% of women with an invasive cervical carcinoma eventually develop a vaginal squamous cell carcinoma. Squamous cell carcinoma of the vagina arises from a premalignant lesion, *vaginal intraepithelial neoplasia*, analogous to cervical squamous intraepithelial lesions (SILs, see under “Cervix”). Most often the invasive tumor affects the upper posterior vagina, particularly along the posterior wall at the junction with the ectocervix. The lesions in the lower two thirds of the vagina metastasize to the inguinal nodes, whereas upper lesions tend to involve the regional iliac nodes.

EMBRYONAL RHABDOMYOSARCOMA

Also called *sarcoma botryoides*, this uncommon vaginal tumor is most frequently found in infants and in children younger than 5 years of age and consists predominantly of malignant embryonal rhabdomyoblasts.[20] These tumors tend to grow as *polypoid, rounded, bulky masses that sometimes fill and project out of the vagina*; they have the appearance and consistency of grapelike clusters (hence the designation botryoides = grapelike) (Fig. 22-13). On histologic examination, the tumor cells are small and have oval nuclei, with small protrusions of cytoplasm from one end, resembling a tennis racket. Rarely, striations can be seen within the cytoplasm. Beneath the vaginal epithelium, the tumor cells are crowded in a so-called cambium layer, but in the deep regions they lie within a loose fibromyxomatous stroma that is edematous and may contain many inflammatory cells. For this reason the lesions can be mistaken for benign inflammatory polyps, leading to unfortunate delays in diagnosis and treatment. These tumors tend to invade locally and cause death by penetration into the peritoneal cavity or by obstruction of the urinary tract. Conservative surgery, coupled with chemotherapy, seems to offer the best results in cases diagnosed sufficiently early.

FIGURE 22-13 Sarcoma botryoides (embryonal rhabdomyosarcoma) of the vagina appearing as a polypoid mass protruding from the vagina. *(Courtesy of Dr. Michael Donovan, Children's Hospital, Boston, MA.)*

3.12.6 Cervix

The cervix is both a sentinel for potentially serious upper genital tract infections and a target for viruses and other carcinogens, which may lead to invasive carcinoma. Worldwide, cervical carcinoma is the second most common cancer in women, with an estimated 493,000 new cases each year, over half of which are fatal. In the United States, 11,150 women were diagnosed with cervical cancer and 3670 women died from this disease in 2007. The potential threat of cancer is central to Papanicolaou (Pap) smear screening programs and histologic interpretation of biopsy specimens by the pathologist.

3.12.6.1 Inflammations

At the onset of menarche, the production of estrogens by the ovary stimulates maturation of the cervical and vaginal squamous mucosa and formation of intracellular glycogen vacuoles in the squamous cells. As these cells are shed, the glycogen provides a substrate for endogenous vaginal aerobes and anaerobes, including streptococci, enterococci, *Escherichia coli*, and staphylococci; however, the normal vaginal and cervical flora is largely dominated by lactobacilli. Lactobacilli produce lactic acid that maintains the vaginal pH below 4.5, suppressing the growth of other saprophytic and pathogenic organisms. In addition, at low pH, lactobacilli produce bacteriotoxic hydrogen peroxide (H_2O_2).[21] At higher, more alkaline pH caused by bleeding, sexual intercourse, vaginal douching as well as during antibiotic treatment, lactobacilli decrease H_2O_2 production, permitting the overgrowth of other microorganisms, which may result in clinically apparent cervicitis or vaginitis. Some degree of cervical inflammation may be found in virtually all women, and it is usually of little clinical consequence. However, infections by *gonococci*, *chlamydiae*, *mycoplasmas*, and *herpes simplex virus* may produce significant acute or chronic cervicitis and are important to identify due to their association with upper genital tract disease, complications during pregnancy, and sexual transmission. Marked cervical inflammation produces reparative and reactive changes of the epithelium and shedding of atypical-appearing squamous cells, and therefore may cause a nonspecific, abnormal Pap test result.

3.12.6.2 Endocervical Polyps

Endocervical polyps are benign exophytic growths that occur in 2% to 5% of adult women. Perhaps the major significance of polyps lies in their production of irregular vaginal “spotting” or bleeding that arouses suspicion of some more ominous lesion. Most polyps arise within the endocervical canal and vary from small and sessile to large, 5-cm masses that may protrude through the cervical os. All are soft, almost mucoid, lesions composed of a loose fibromyxomatous stroma harboring dilated, mucus-secreting endocervical glands, often accompanied by inflammation (Fig. 22-14). Simple curettage or surgical excision effects a cure.

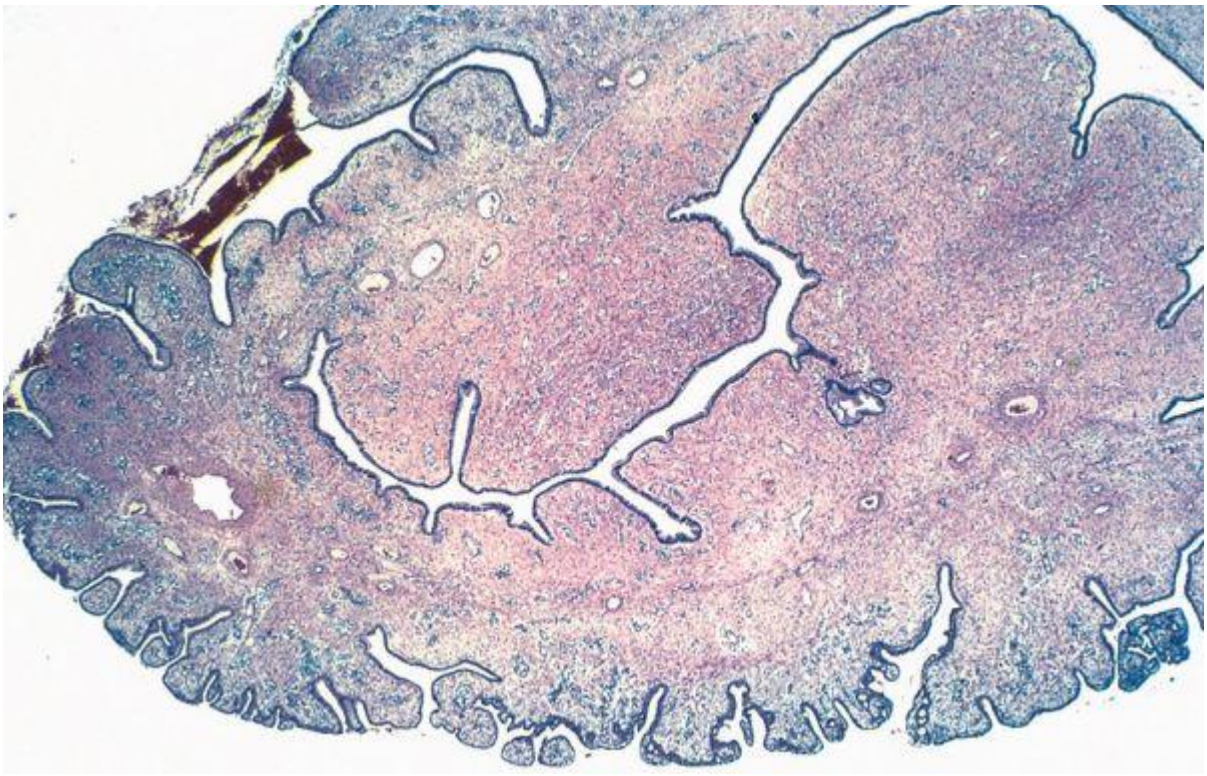

FIGURE 22-14 Endocervical polyp composed of a dense fibrous stroma covered with endocervical columnar epithelium.

3.12.6.3 Premalignant & Malignant Neoplasms

No form of cancer better documents the remarkable effects of screening, early diagnosis, and curative therapy on the mortality rate than does cancer of the cervix. Fifty years ago, carcinoma of the cervix was the leading cause of cancer deaths in women in the United States, but the death rate has declined by two thirds to its present rank as the eighth leading cause of cancer mortality. In sharp contrast to this reduced mortality, the detection frequency of early cancers and precancerous lesions is high. Much credit for these dramatic gains belongs to the effectiveness of the Pap test in detecting cervical precancers and to the accessibility of the cervix to colposcopy (visual examination of the cervix with a magnifying glass) and biopsy. While there are an estimated 11,000 new cases of invasive cervical cancer in the United States annually, there are nearly 1 million precancerous lesions of varying grade that are discovered yearly by cytologic examinations. Thus, it is evident that Pap smear screening not only has increased the detection of potentially curable, low-stage cancers but has also allowed the detection and eradication of preinvasive lesions, some of which would have progressed to cancer if not discovered and treated.

Pathogenesis.

The pathogenesis of cervical carcinoma has been delineated by a series of epidemiologic, clinicopathologic, and molecular genetic studies. Epidemiologic data have long implicated a sexually transmitted agent, which is now established to be HPV. For his discovery of HPV as a cause of cervical cancer, Harald zur Hausen was awarded the Nobel Prize in 2008. HPVs are DNA viruses that are typed based on their DNA sequence and subgrouped into high and low oncogenic risk. *High oncogenic risk HPVs are currently considered to be the single most important factor in cervical oncogenesis*. High oncogenic risk HPVs have also been detected in vaginal squamous cell carcinomas and in a subset of vulvar, penile, anal, tonsillar, and other oropharyngeal carcinomas, as detailed in Chapter 7 . As noted

earlier, low oncogenic risk HPVs are the cause of the sexually transmitted vulvar, perineal, and perianal condyloma acuminatum. There are 15 high oncogenic risk HPVs that are currently identified. From the point of view of cervical pathology, HPV 16 and HPV 18 are the most important. HPV 16 alone accounts for almost 60% of cervical cancer cases, and HPV 18 accounts for another 10% of cases; other HPV types contribute to less than 5% of cases, individually.[22] The risk factors for cervical cancer are related to both host and viral characteristics such as HPV exposure, viral oncogenicity, inefficiency of immune response, and presence of co-carcinogens.[23] These include:

1. Multiple sexual partners
2. A male partner with multiple previous or current sexual partners
3. Young age at first intercourse
4. High parity
5. Persistent infection with a high oncogenic risk HPV, e.g., HPV 16 or HPV18
6. Immunosuppression
7. Certain HLA subtypes
8. Use of oral contraceptives
9. Use of nicotine

Genital HPV infections are extremely common; most of them are asymptomatic, do not cause any tissue changes, and therefore are not detected on Pap test. Figure 22-15 shows age-dependent prevalence of HPVs in cervical smears in women with normal Pap test results. The high peak of HPV prevalence in 20-year-olds is related to sexual début, while the subsequent decrease in prevalence reflects acquisition of immunity and monogamous relationships. Most HPV infections are transient and are eliminated by the immune response in the course of months. On average, 50% of HPV infections are cleared within 8 months, and 90% of infections are cleared within 2 years. The duration of the infection is related to HPV type; on average, infections with high oncogenic risk HPVs last longer than infections with low oncogenic risk HPVs, 13 months versus 8 months, respectively.[24] Persistent infection increases the risk of the development of cervical precancer and subsequent carcinoma.

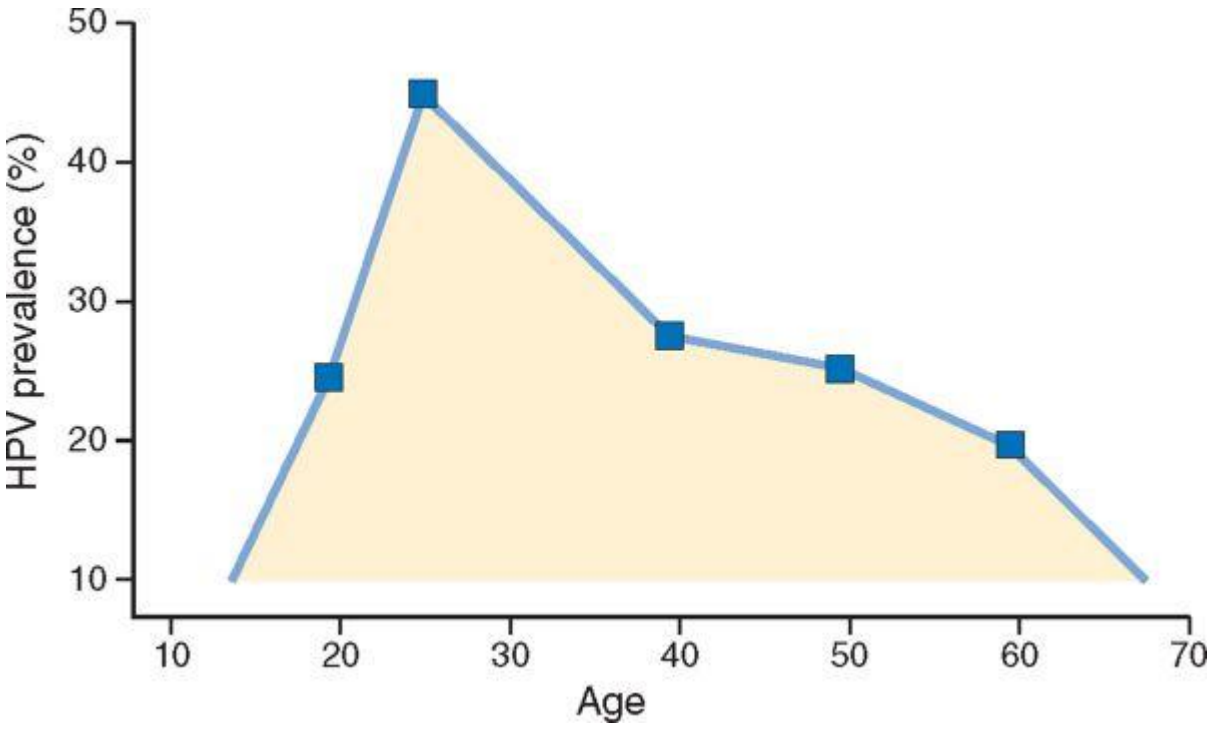

FIGURE 22-15 Age-dependent prevalence of HPVs in cervical smears in women with normal Pap test results in the US population. *(Adapted from Dunne EF et al.: Prevalence of HPV infection among females in the United States. JAMA 297:813, 2007.)*

HPVs infect immature basal cells of the squamous epithelium in areas of epithelial breaks, or immature metaplastic squamous cells present at the squamocolumnar junction (Fig. 22-16). HPVs cannot infect the mature superficial squamous cells that cover the ectocervix, vagina, or vulva. Establishing HPV infection in these sites requires damage to the surface epithelium, which gives the virus access to the immature cells in the basal layer of the epithelium. The cervix, with its relatively large areas of immature squamous metaplastic epithelium, is particularly vulnerable to HPV infection as compared, for example, with vulvar skin and mucosa that are covered by mature squamous cells. This difference in epithelial susceptibility to HPV infection accounts for the marked difference in incidence of HPV-related cancers arising in different sites, and explains the high frequency of cervical cancer in women or anal cancer in homosexual men and a relatively low frequency of vulvar and penile cancer.

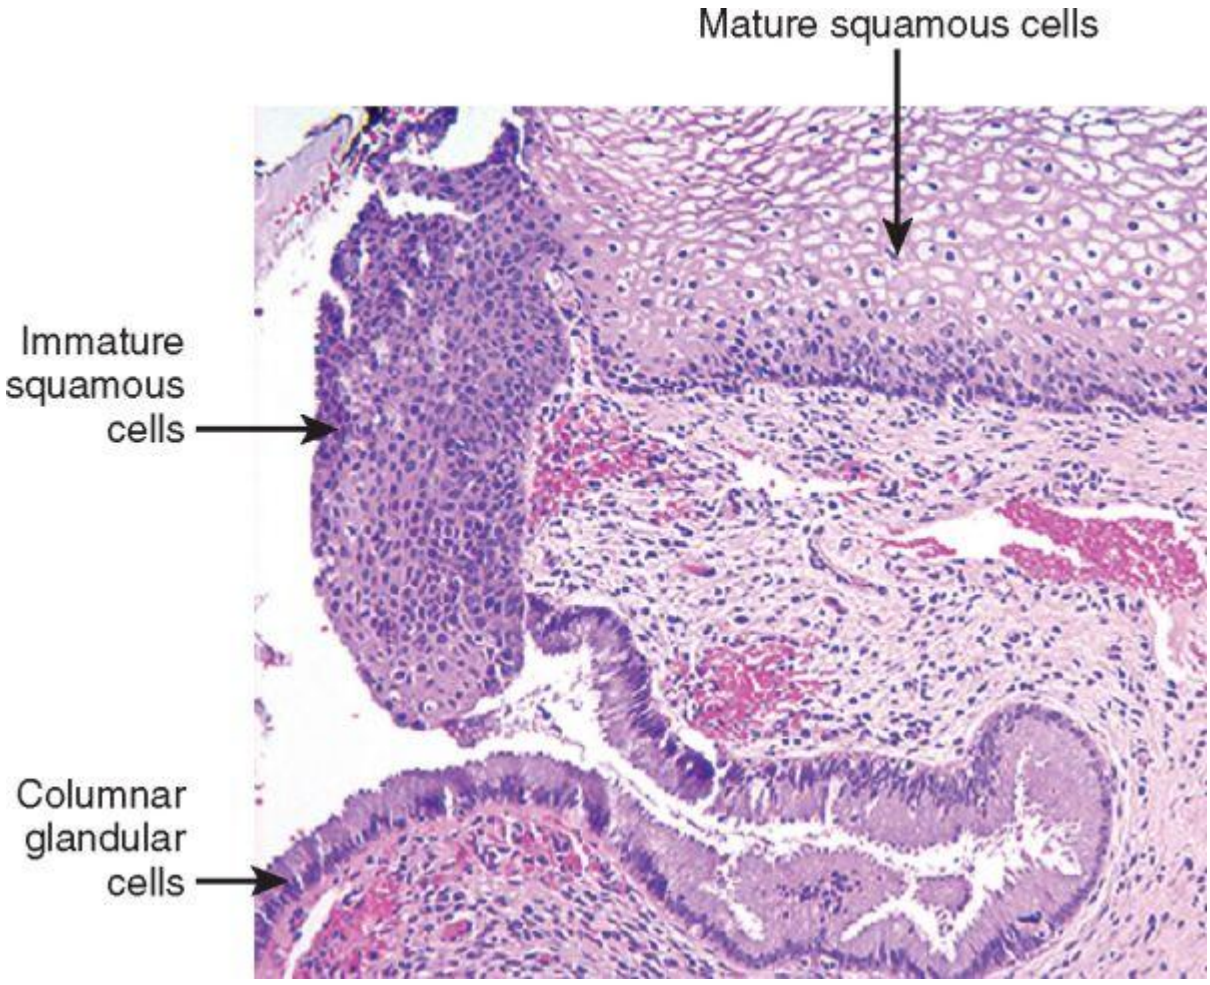

FIGURE 22-16 Cervical squamocolumnar junction showing mature, glycogenized *(pale)* squamous epithelium, immature *(dark pink)* squamous metaplastic cells, and columnar endocervical glandular epithelium.

Although the virus can *infect* only the immature squamous cells, *replication* of HPV occurs in the maturing squamous cells and results in a cytopathic effect, "*koilocytic atypia*," consisting of nuclear atypia and a cytoplasmic perinuclear halo. To replicate, HPV has to induce DNA synthesis in the host cells. Since HPV replicates in maturing, nonproliferating squamous cells, it must reactivate the mitotic cycle in such cells. Experimental studies have shown that HPV activates the cell cycle by interfering with the function of *Rb* and *p53*, two important tumor suppressor genes (Chapter 7).

Viral E6 and E7 proteins are critical for the oncogenic effects of HPV. They can promote cell cycle by binding to RB and up-regulation of cyclin E (E7); interrupt cell death pathways by binding to p53 (E6); induce centrosome duplication and genomic instability (E6, E7); and prevent replicative senescence by up-regulation of telomerase (E6) (Chapter 7). HPV E6 induces rapid degradation of p53 via ubiquitin-dependent proteolysis, reducing p53 levels by two- to three-fold. E7 complexes with the hypophosphorylated (active) form of RB, promoting its proteolysis via the proteosome pathway. Because hypophosphorylated RB normally inhibits S-phase entry via binding to the E2F transcription factor, the two viral oncogenes cooperate to promote DNA synthesis while interrupting p53-mediated growth arrest and apoptosis of genetically altered cells. Thus, the viral oncogenes are critical in extending the life span of epithelial cells—a necessary component of tumor development.

The physical state of the virus differs in different lesions, being integrated into the host DNA in cancers, and present as free (episomal) viral DNA in condylomata and most precancerous lesions. Certain chromosome abnormalities, including deletions at 3p and amplifications of 3q, have been associated with cancers containing specific (HPV-16) papillomaviruses.

Even though HPV has been firmly established as a causative factor for cancer of the cervix, the evidence does not implicate HPV as the only factor. A high percentage of young women are infected with one or more HPV types during their reproductive years, and only a few develop cancer. Other cocarcinogens, the immune status of the individual, and hormonal and other factors influence whether the HPV infection will regress or persist and eventually progress to cancer.[23]

In addition to infecting squamous cells, HPVs may also infect glandular cells or neuroendocrine cells present in the cervical mucosa and cause malignant transformation, resulting in adenocarcinomas, and adenosquamous and neuroendocrine carcinomas; these tumor subtypes, however, are less common since glandular and neuroendocrine cells do not support effective HPV replication.

CERVICAL INTRAEPITHELIAL NEOPLASIA

The classification of cervical precancerous lesions has evolved over time and the terms from the different classification systems are currently used interchangeably. Hence a brief review of the terminology is warranted. The oldest classification system classified lesions as having mild dysplasia on one end and severe dysplasia/carcinoma in situ on the other. This was followed by *cervical intraepithelial neoplasia* (CIN) classification, with mild dysplasia termed *CIN I*, moderate dysplasia *CIN II*, and severe dysplasia termed *CIN III*. Because the decision with regard to patient management is two-tiered (observation versus surgical treatment), the three-tier classification system has been recently simplified to a two-tiered system, with CIN I renamed low-grade squamous intraepithelial lesion (LSIL) and CIN II and CIN III combined into one category referred to as high-grade squamous intraepithelial lesion (HSIL) (Table 22-1).

TABLE 22-1 -- Classification Systems for Premalignant Squamous Cervical Lesions

Dysplasia/Carcinoma in Situ	Cervical Intraepithelial Neoplasia (CIN)	Squamous Intraepithelial Lesion (SIL), Current Classification
Mild dysplasia	CIN I	Low-grade SIL (LSIL)
Moderate dysplasia	CIN II	High-grade SIL (HSIL)
Severe dysplasia	CIN III	High-grade SIL (HSIL)
Carcinoma in situ	CIN III	High-grade SIL (HSIL)

LSILs are associated with productive HPV infection, but show no significant disruption or alteration of the host cell cycle. Most LSILs regress spontaneously, with only a small percentage progressing to HSIL. LSIL does not progress directly to invasive carcinoma. For these reasons LSIL is not treated like a premalignant lesion. In HSIL, there is a progressive deregulation of the cell cycle by HPV, which results in increased cellular proliferation, decreased or arrested epithelial maturation, and a lower rate of viral replication, as compared with LSIL. HSILs are one tenth as common as LSILs.

Morphology. Figure 22-17 illustrates a spectrum of morphologic alterations that range from normal to high grade dysplasia. The diagnosis of SIL is based on identification of nuclear atypia characterized by nuclear enlargement, hyperchromasia (dark staining), presence of coarse chromatin granules, and variation of nuclear sizes and shapes. The nuclear changes may be accompanied by cytoplasmic halos indicating disruption of the cytoskeleton before release of the virus into the environment. Nuclear alterations and perinuclear halo are termed *koilocytic atypia*. The grading of SIL into low or high grade is based on expansion of the immature cell layer from its normal, basal location. If the atypical, immature squamous cells are confined to the lower one third of the epithelium, the lesion is graded as LSIL; if they expand to two thirds of the epithelial thickness, it is graded as HSIL.

Figure 22-18A illustrates the histologic features of LSIL. The adjacent panel, Figure 22-18B , shows detection of HPV DNA using an in situ hybridization test. The staining is most intense in the superficial layers of the epithelium, which contain the highest viral load. Figures 22-18C and D show immunostaining for Ki-67 and p16. Ki-67 is a marker of cellular proliferation, and in normal squamous mucosa is confined to the basal layer of the epithelium. In contrast, in SILs, Ki-67 positivity is seen throughout the entire thickness of epithelium, indicating abnormal expansion of the epithelial proliferative zone (see Fig. 22-18C). p16, a cyclin kinase inhibitor, is a cell cycle–regulatory protein, which inhibits the cell cycle by preventing the phosphorylation of RB. It has been shown that in cells infected with oncogenic HPVs, there is overexpression of p16 (see Fig. 22-18D). Despite high levels of p16, however, the HPV-infected cells continue to proliferate because RB, the target of p16 inhibitory activity, is inactivated by the E7 HPV oncoprotein. Both Ki-67 and p16 staining are highly correlated with HPV infection and are useful for confirmation of the diagnosis in equivocal cases of SIL.

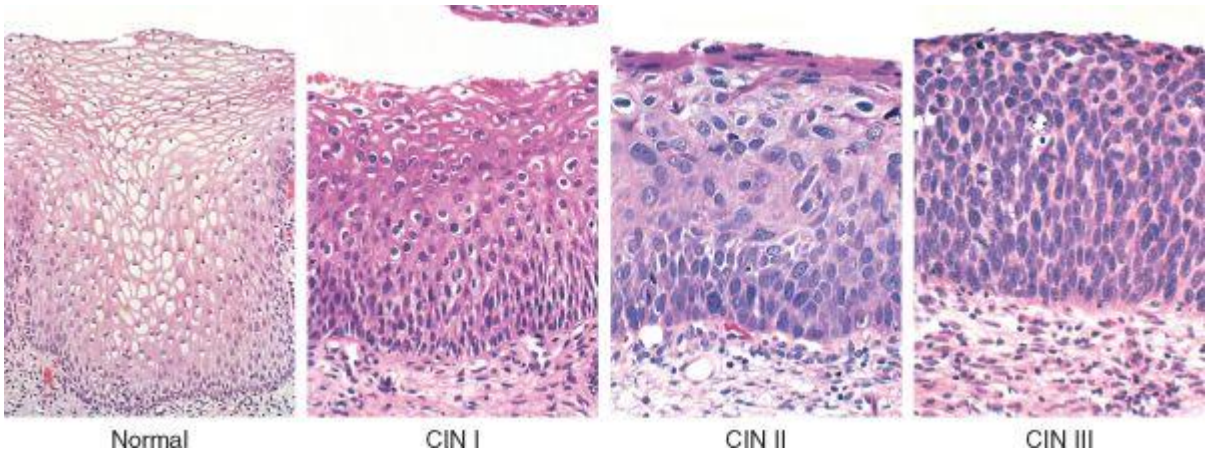

FIGURE 22-17 Spectrum of cervical intraepithelial neoplasia: normal squamous epithelium for comparison; LSIL (CIN I) with koilocytic atypia; HSIL (CIN II) with progressive atypia and expansion of the immature basal cells above the lower third of the epithelial thickness; HSIL (CIN III) with diffuse atypia, loss of maturation, and expansion of the immature basal cells to the epithelial surface.

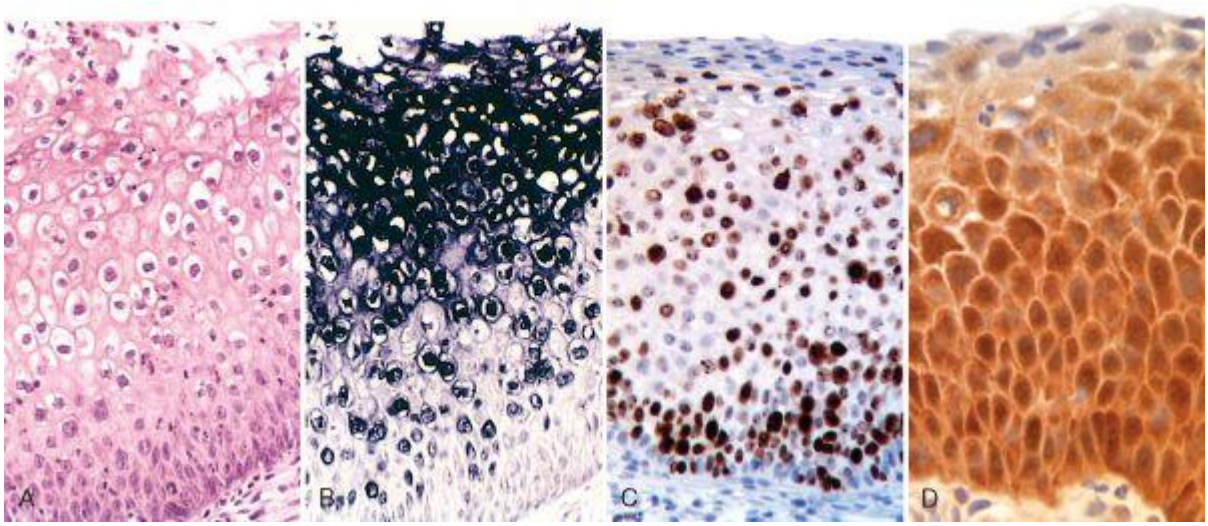

FIGURE 22-18 **A**, LSIL—routine H&E staining. **B**, In situ hybridization test for HPV DNA. The dark granular staining denotes HPV DNA, which is typically most abundant in the koilocytes. **C**, Diffuse immunostaining for the proliferation marker Ki-67, illustrating abnormal expansion of the proliferating cells from the normal basal location to the superficial layers of the epithelium. **D**, Up-regulation of p16INK4 (seen as intense brown immunostaining) characterizes high oncogenic risk HPV infections.

More than 80% of LSILs and 100% of HSILs are associated with high oncogenic risk HPVs. HPV 16 is the single most common HPV type detected in both categories of lesions. Table 22-2 shows rates of regression and progression of SILs within 2-year follow-up.[25] Although the majority of HSILs develop from LSILs, approximately 20% of cases of HSIL develop de novo, without the preexisting LSIL.[26] The rates of progression are by no means uniform, and although HPV type—especially HPV 16—is associated with increased risk, it is difficult to predict the outcome in an individual patient. These findings underscore that the *risk of developing precancer and cancer is conferred only in part by HPV*

type, and depends also on immune status and environmental factors. Progression to invasive carcinoma, when it occurs, may take place in a few months to more than a decade.

TABLE 22-2 -- Natural History of Squamous Intraepithelial Lesions (SILs) with Approximate 2-Year Follow-up

Lesion	Regress	Persist	Progress
LSIL	60%	30%	10% to HSIL
HSIL	30%	60%	10% to carcinoma[*]

HSIL, high-grade SIL; LSIL, low-grade SIL.

* Progression within 2–10 years.

CERVICAL CARCINOMA

Squamous cell carcinoma is the most common histologic subtype of cervical cancer, accounting for approximately 80% of cases. As outlined above, HSIL is an immediate precursor of cervical squamous cell carcinoma. The second most common tumor type is cervical adenocarcinoma, which constitutes about 15% of cervical cancer cases and develops from a precursor lesion called adenocarcinoma in situ. Adenosquamous and neuroendocrine carcinomas are rare cervical tumors that account for the remaining 5% of cases. All of the above tumor types are caused by high oncogenic risk HPVs. The clinical characteristics and risk factors are the same for each tumor type, with the exception that adenocarcinomas and adenosquamous and neuroendocrine carcinomas typically present with advanced-stage disease. This unfortunate outcome occurs because Pap screening is less effective in detecting these cancers. Patients with adenosquamous and neuroendocrine carcinomas, therefore, have a less favorable prognosis than patients with squamous cell carcinomas or adenocarcinomas. The peak incidence of invasive cervical carcinoma is 45 years. With the advent of widespread screening, many cervical carcinomas are detected at a subclinical stage, during evaluation of an abnormal Pap smear.

Morphology. Invasive cervical carcinoma may manifest as either fungating (exophytic) or infiltrative cancers.

On histologic examination, squamous cell carcinomas are composed of nests and tongues of malignant squamous epithelium, either keratinizing or nonkeratinizing, invading the underlying cervical stroma (Fig. 22-19). Adenocarcinomas are characterized by proliferation of glandular epithelium composed of malignant endocervical cells with large, hyperchromatic nuclei and relatively mucin-depleted cytoplasm, resulting in dark appearance of the glands, as compared with the normal endocervical epithelium (Fig. 22-20A). Adenosquamous carcinomas are tumors composed of intermixed malignant glandular and malignant squamous epithelium. Neuroendocrine cervical carcinomas typically have an appearance similar to small-cell carcinoma of the lung (see Chapter 15); however, in contrast to the lung tumor, which is not related to HPV infection, cervical small-cell carcinomas are positive for high oncogenic risk HPVs.

Advanced cervical carcinoma extends by direct spread to involve contiguous tissues, including the paracervical tissues, urinary bladder, ureters, rectum, and vagina. Local and distant lymph nodes are also involved. Distant metastases may be found in the liver, lungs, bone marrow, and other structures.

Cervical cancer is staged as follows:

Stage 0.	Carcinoma in situ (CIN III, HSIL)
Stage I.	Carcinoma confined to the cervix
	Ia. Preclinical carcinoma, that is, diagnosed only by microscopy
	Ia1. Stromal invasion no deeper than 3 mm and no wider than 7 mm (so-called **microinvasive carcinoma**) (see Fig. 22-19A)
	Ia2. Maximum depth of invasion of stroma deeper than 3 mm and no deeper than 5 mm taken from base of epithelium; horizontal invasion not more than 7 mm
	Ib. Histologically invasive carcinoma confined to the cervix and greater than stage Ia2
Stage II.	Carcinoma extends beyond the cervix but not to the pelvic wall. Carcinoma involves the vagina but not the lower third.
Stage III.	Carcinoma has extended to the pelvic wall. On rectal examination there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina.
Stage IV.	Carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum. This stage also includes cancers with metastatic dissemination.

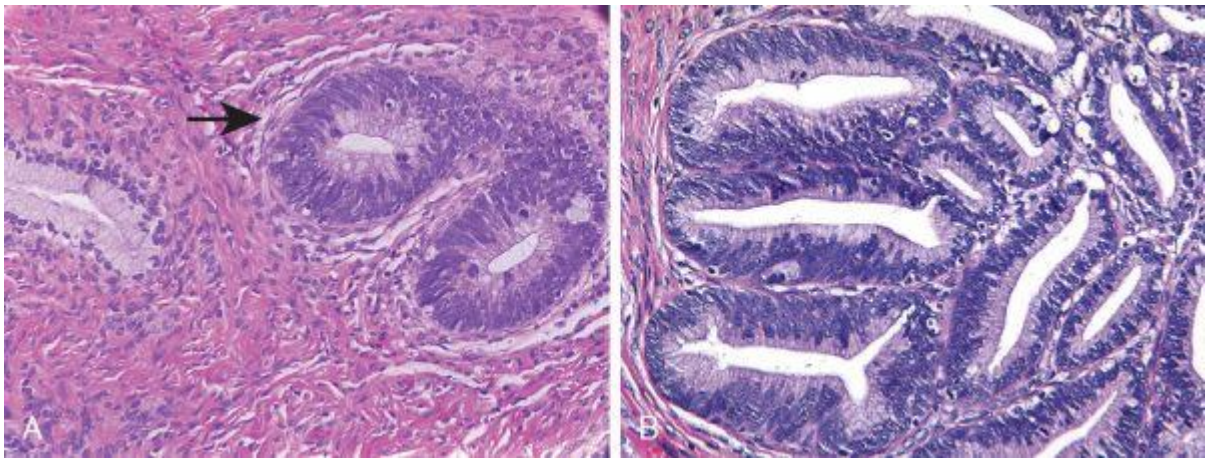

FIGURE 22-20 Adenocarcinoma of the cervix. **A**, Adenocarcinoma in situ *(arrow)* showing dark glands adjacent to normal, pale endocervcial glands. **B**, Invasive adenocarcinoma.

Clinical Features.

More than half of invasive cervical cancers are detected in women who did not participate in regular screening. While early invasive cancers of the cervix (microinvasive carcinomas) may be treated by cone biopsy alone, most invasive cancers are managed by hysterectomy with lymph node dissection and, for advanced lesions, irradiation. The prognosis and survival for invasive carcinomas depend largely on the stage at which cancer is first discovered and to some degree on the cell type, with small-cell neuroendocrine tumors having a very poor prognosis. With current methods of treatment there is a 5-year survival rate of at least 95% for stage Ia (including microinvasive) carcinomas, about 80% to 90% with stage Ib, 75% with stage II, and less than 50% for stage III and higher. Most patients with stage IV cancer die as a consequence of local extension of the tumor (e.g., into and about the urinary bladder and ureters, leading to ureteral obstruction, pyelonephritis, and uremia) rather than distant metastases. However, as mentioned above, early detection has reduced the number of patients with stage IV cancer by more than two thirds in the past 50 years.

Cervical Cancer Screening and Prevention

Cervical cancer prevention and control can be divided into several components. One includes cytologic screening and management of Pap smear abnormalities. Another is the histologic diagnosis and removal of precancerous lesions. Still another component is surgical removal of invasive cancers, with adjunctive radiation therapy and chemotherapy. A new aspect is an HPV vaccination program, approved by the US Food and Drug Administration (FDA) for preventing HPV infection. HPV vaccines are also being evaluated for effectiveness as a therapeutic tool in cervical precancers.

The reason that cytologic screening is so effective in preventing cervical cancer is that the majority of cancers are preceded by a long-standing precancerous lesion. This lesion may exist in the noninvasive stage for years and shed abnormal cells that can be detected on cytologic examination. Pap tests are cytologic preparations of exfoliated cells from the cervical transformation zone that are stained with the Papanicolaou method. Using a spatula or brush, the transformation zone of the cervix is circumferentially scraped and the cells are smeared or spun down onto a slide. Following fixation and staining, the cytotechnologist, a person specifically trained to identify cytologic abnormalities, screens

the smears. The cellular changes on Pap test illustrating the spectrum from normal, through LSIL to HSIL, are shown in Figure 22-21 .

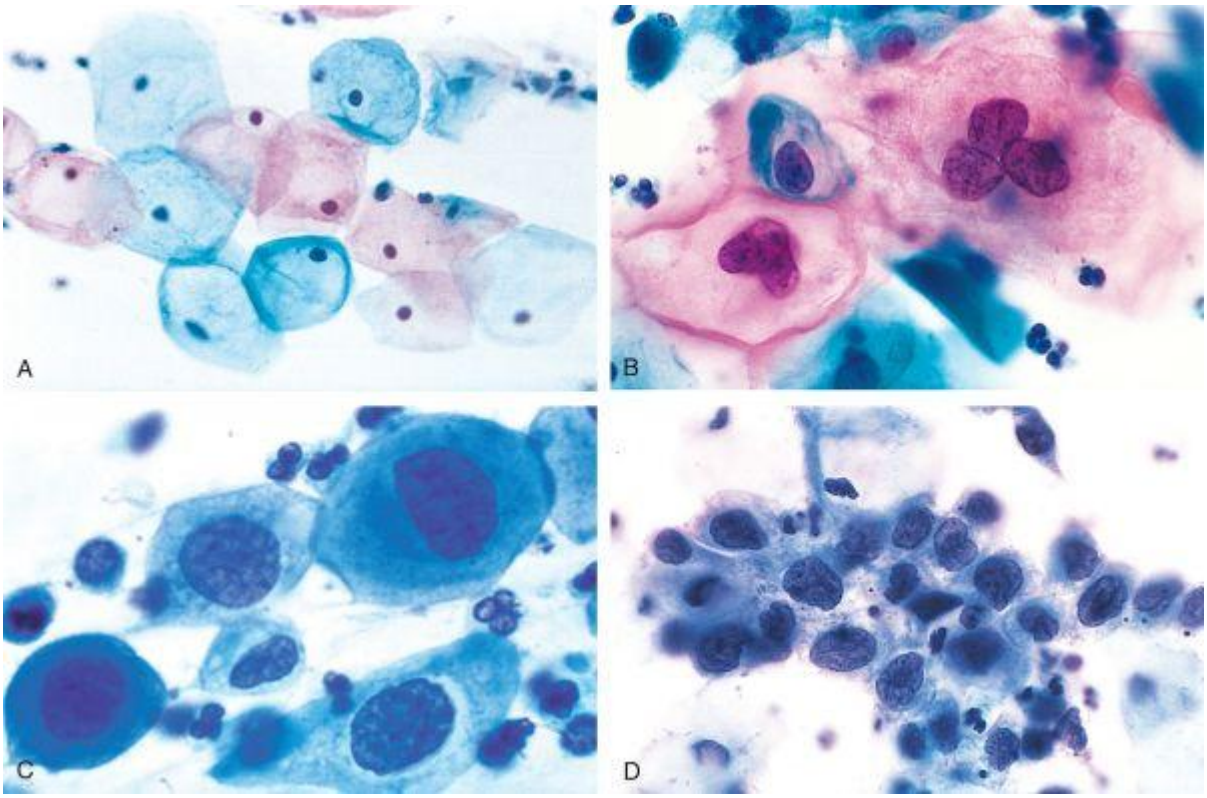

FIGURE 22-21 The cytology of cervical intraepithelial neoplasia as seen on the Papanicolaou smear. Normal cytoplasmic staining in superficial cells (***A*** and ***B***) may be either red or blue. **A**, Normal exfoliated superficial squamous cells. **B**, LSIL—koilocytes. **C**, HSIL (CIN II). **D**, HSIL (CIN III). Note the reduction in cytoplasm and the increase in the nucleus-to-cytoplasm ratio, which occurs as the grade of the lesion increases. This reflects the progressive loss of cellular differentiation on the surface of the lesions from which these cells are exfoliated. *(Courtesy of Dr. Edmund S. Cibas, Brigham and Women's Hospital, Boston, MA.)*

The false-negative error rate of the Pap test is around 10% to 20%. Most of these false-negative tests stem from sampling errors. Recommendations for the frequency of Pap screening vary, but in general the first smear should be at age 21 years or within 3 years of onset of sexual activity, and thereafter on an annual basis. After age 30, women who have had three consecutive normal cytology results may be screened every 2 to 3 years.[27]

As an adjunct to cytology, HPV DNA testing may be added to cervical cytology for screening in women aged 30 years or older. Women with normal cytology result and negative HPV DNA testing may be rescreened every 3 years. Women with a normal cytology result, but who are high-risk HPV DNA–positive, should have cervical cytology repeated at 6 to 12 months.[28] HPV testing of women younger than 30 is not recommended because of the high prevalence of HPV infection in this age group and the low specificity of the positive result (see Fig. 22-15).

When the Pap test is abnormal, a colposcopic examination of the cervix and vagina is performed to delineate the extent of the lesion and to target the areas to be biopsied. Application of acetic acid to the cervix highlights abnormal areas. After confirmation by tissue biopsy, women with LSIL can be

followed in a conservative fashion with repeat smears and close follow-up. Some gynecologists use local ablative measures based upon their experience with the disease and reliability of patient follow-up. HSILs are treated with cervical conization (excision).[29] Follow-up smears and clinical examinations should continue for life, since vaginal, vulvar, or cervical precancers and cancers may later develop.

In 2006 the FDA licensed a quadrivalent, prophylactic HPV vaccine for HPV types 6, 11, 16, and 18. This vaccine is designed to reduce the incidence of cervical cancer caused by HPV 16 and HPV 18 (together accounting for approximately 70% of cervical cancer cases[22]) and vulvar condylomas (HPV 6 and 11). In phase III trials the vaccine prevented 100% of HPV 16/18–associated HSILs. The vaccine is prepared from noninfectious, DNA-free virus-like particles produced by recombinant technology. It induces high levels of serum antibodies in all vaccinated individuals. In women who have no evidence of past or current infection with the HPV genotypes included in the vaccine, there is protection from HPV infection for up to 5 years after vaccination; longer follow-up studies are still pending. Since the HPV vaccine does not eliminate the risk of cervical cancer due to other oncogenic HPV types, cervical cancer screening should still continue according to past guidelines to minimize cancer incidence.[30]

3.12.7 Body of Uterus & Endometrium

The uterus has two major components: the myometrium and the endometrium. The myometrium is composed of tightly interwoven bundles of smooth muscle that form the wall of the uterus. The internal cavity of the uterus is lined by the endometrium composed of glands embedded in a cellular stroma. The uterus is subject to a variety of disorders, the most common of which result from endocrine imbalances, complications of pregnancy, and neoplastic proliferation. Together with the lesions that affect the cervix (causing abnormal Pap smears), the lesions of the corpus of the uterus and the endometrium (causing abnormal vaginal bleeding) account for most patient visits to gynecologic practices.

3.12.7.1 Endometrial Histology in the Menstrual Cycle

The endometrium is a dynamic tissue that undergoes physiologic and characteristic morphologic changes during the menstrual cycle as a result of the effect of sex steroid hormones coordinately produced in the ovary. The ovary, in turn, is influenced by hormones produced by the pituitary. Together the hypothalamic, pituitary, and ovarian factors and their interactions regulate maturation of ovarian follicles, ovulation, and menstruation.

“Dating” the endometrium by its histologic appearance is often used clinically to assess hormonal status, document ovulation, and determine causes of endometrial bleeding and infertility (Fig. 22-22). The cycle begins with the shedding of the upper half to two thirds of the endometrium, referred to as the functionalis (the hormonally responsive upper zone), during menses. Under the influence of estrogen, produced by the granulosa cells of the developing follicle in the ovary, the remaining third (basalis) of the endometrium undergoes extremely rapid growth of both glands and stroma *(proliferative phase).* During the proliferative phase the glands are straight, tubular structures lined by regular, tall, pseudostratified columnar cells. Mitotic figures are numerous, and there is no evidence of mucus secretion or vacuolation. The endometrial stroma is composed of thickly compacted spindle cells that have scant cytoplasm but abundant mitotic activity (Fig. 22-22A).

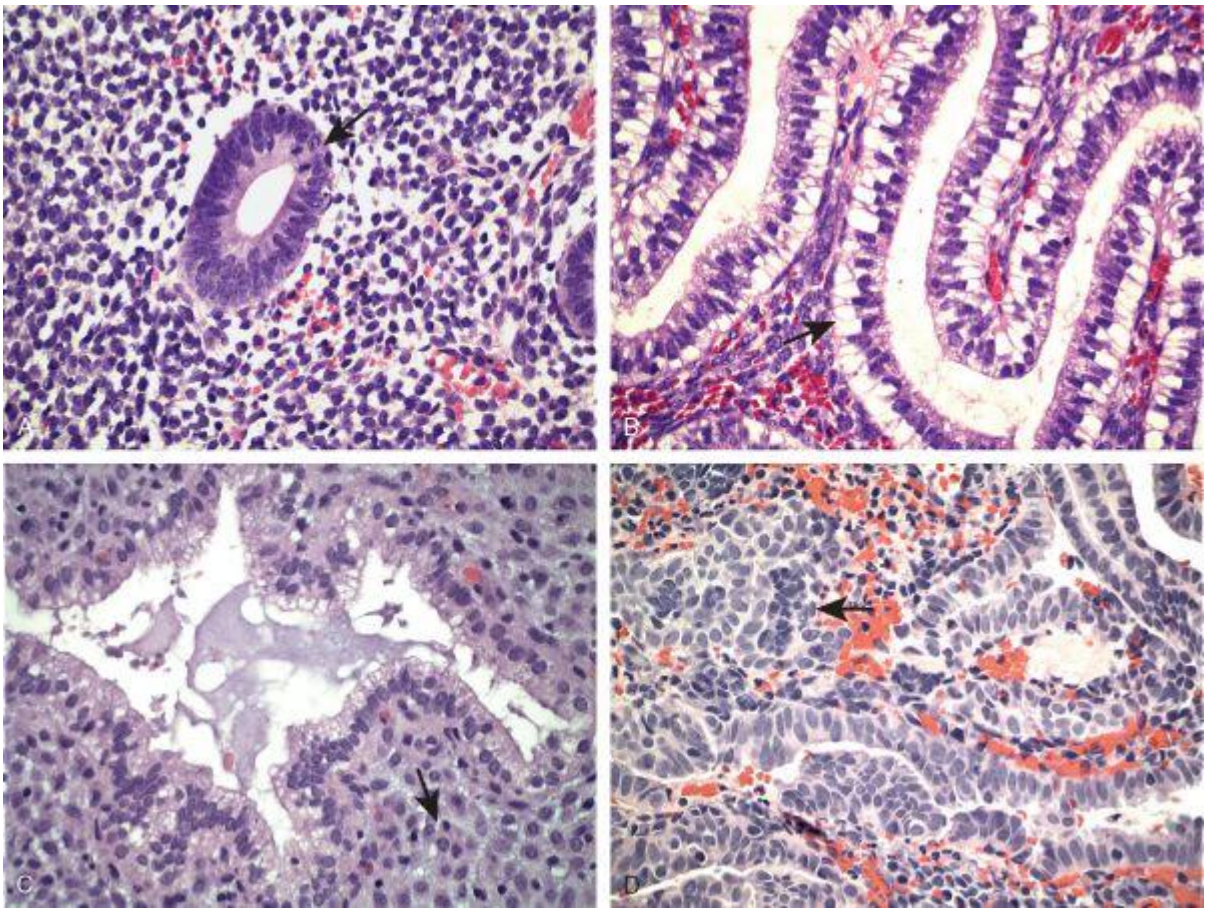

FIGURE 22-22 Histology of the menstrual cycle. **A**, Proliferative phase with mitoses *(arrow)*. **B**, Early secretory phase with subnuclear vacuoles *(arrow)*. **C**, Late secretory exhaustion and predecidual changes *(arrow)*. **D**, Menstrual endometrium with stromal breakdown *(arrow)* (see text).

At the time of ovulation the endometrium slows in its growth, and it ceases mitotic activity within days after ovulation, at which time the corpus luteum is producing progesterone in addition to estrogen. The postovulatory endometrium is initially marked by secretory vacuoles beneath the nuclei in the glandular epithelium (Fig. 22-22B). This *secretory activity* is most prominent during the third week of the menstrual cycle, when the basal vacuoles progressively push past the nuclei. By the fourth week, the secretions are discharged into the gland lumens. When secretion is maximal, between 18 and 24 days, the glands are dilated. By the fourth week the glands are tortuous, producing a serrated appearance when they are cut in their long axis. This serrated or "saw-toothed" appearance is accentuated by secretory exhaustion and shrinking of the glands.

The stromal changes in late secretory phase, due predominantly to progesterone, are important for dating the endometrium and consist of the development of prominent spiral arterioles by days 21 to 22. A considerable increase in ground substance and edema between the stromal cells occurs and is followed in days 23 to 24 by stromal cell hypertrophy with accumulation of cytoplasmic eosinophilia (predecidual change) and resurgence of stromal mitoses (Fig. 22-22C). Predecidual changes spread throughout the functionalis during days 24 to 28 and are accompanied by scattered neutrophils and occasional lymphocytes, which in this context do not imply inflammation. With the dissolution of the corpus luteum and the subsequent lack of progesterone, the disintegration of the functionalis begins with the escape of blood into the stroma, marking the beginning of menstrual shedding (Fig. 22-22D).

Although the molecular mechanism(s) by which estrogen and progesterone cause these profound changes in the endometrium are not well understood, it is known that these hormones induce local production of molecules that act in an autocrine and paracrine fashion.[31] Much of the hormonal action occurs through their cognate nuclear receptors (estrogen receptor α, progesterone receptor A, and progesterone receptor B). However, they may also act through alternate receptors or perhaps even by receptor-independent pathways.[32] In addition, there is considerable cross-talk between the glands and stroma. For example, much of the effect of estrogen on glandular proliferation occurs via stromal cells, which in response to estrogen produce growth factors (e.g., insulin-like growth factor 1 and epidermal growth factor) that bind receptors expressed on the epithelial cells. In the secretory phase, progesterone initially inhibits proliferation in both the glands and the stroma. It also promotes differentiation of the glands and causes profound alterations of the stroma. Interestingly, progesterone secretion leads to a decrease in estrogen receptor expression in both the glands and stroma, making the endometrium relatively unresponsive to estrogen still being produced by the ovary. To further elucidate the mechanisms responsible for the hormonal effects, global gene expression studies are being used.[33] It is thought that such information will aid in the treatment of women with disorders of the endometrium that range from infertility to cancer, as discussed below.

3.12.7.2 Functional Endometrial Disorders (Dysfunctional Uterine Bleeding)

During active reproductive life, the endometrium is in a dynamic state of proliferation, differentiation, and shedding, in preparation for implantation of an embryo. As discussed above, this cycle is exquisitely controlled by the rise and fall of pituitary and ovarian hormones, which is executed by proper timing of hormone release in both absolute and relative amounts. Abnormalities in this system result in abnormal uterine bleeding.

Although abnormal uterine bleeding can be caused by well-defined organic pathologic conditions, such as chronic endometritis, endometrial polyp (see Fig. 22-23C), submucosal leiomyomas (see Fig. 22-23D), or endometrial neoplasms, the largest single group encompasses functional disturbances, referred to as dysfunctional uterine bleeding (DUB; Table 22-3). DUB is a clinical term for uterine bleeding not caused by any underlying organic (structural) abnormality. The most common causes of DUB are discussed.

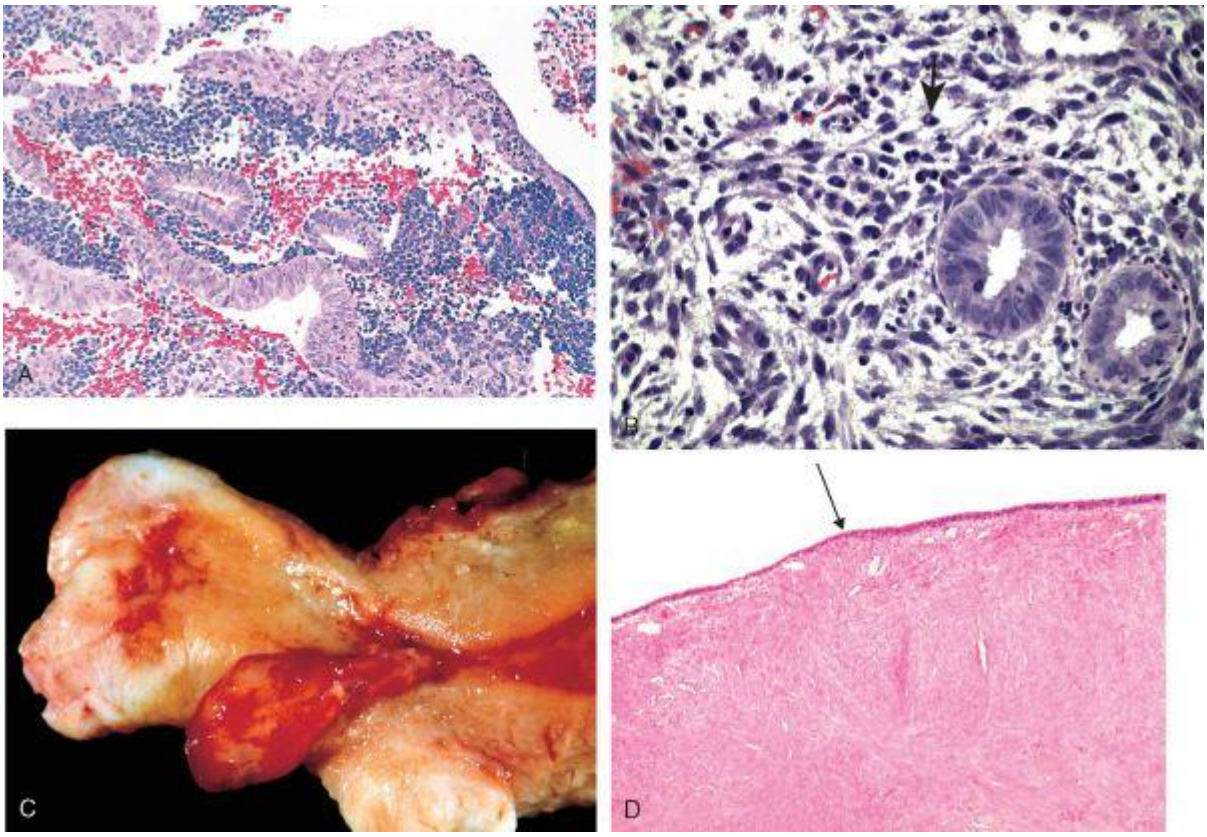

FIGURE 22-23 Common causes of abnormal uterine bleeding. **A**, The most common is dysfunctional uterine bleeding, seen here as anovulatory endometrium with stromal breakdown. Note breakdown associated with proliferative glands. **B**, Chronic endometritis with numerous plasma cells *(arrow)*. **C**, Endometrial polyp. **D**, Submucosal leiomyoma with attenuation of the endometrial lining *(arrow)*.

TABLE 22-3 -- Causes of Abnormal Uterine Bleeding by Age Group

Age Group	Causes
Prepuberty	Precocious puberty (hypothalamic, pituitary, or ovarian origin)
Adolescence	Anovulatory cycle, coagulation disorders
Reproductive age	Complications of pregnancy (abortion, trophoblastic disease, ectopic pregnancy) Organic lesions (leiomyoma, adenomyosis, polyps, endometrial hyperplasia, carcinoma) Dysfunctional uterine bleeding Anovulatory cycle Ovulatory dysfunctional bleeding (e.g., inadequate luteal phase)
Perimenopausal	Dysfunctional uterine bleeding Anovulatory cycle Irregular shedding Organic lesions (carcinoma, hyperplasia, polyps)
Postmenopausal	Endometrial atrophy

Age Group	Causes
	Organic lesions (carcinoma, hyperplasia, polyps)

ANOVULATORY CYCLE

In most instances, dysfunctional bleeding is due to the occurrence of an anovulatory cycle. Anovulation results in excessive and prolonged estrogenic stimulation without the counteractive effect of the progestational phase that regularly follows ovulation. In most women anovulatory cycles have no obvious cause, occurring most likely due to subtle hormonal imbalances. Anovulatory cycles are most common at menarche and in the perimenopausal period. Less commonly, lack of ovulation is the result of (1) an endocrine disorder, such as thyroid disease, adrenal disease, or pituitary tumors; (2) a primary lesion of the ovary, such as a functioning ovarian tumor (granulosa-theca cell tumors) or polycystic ovaries (see “Ovaries”); or (3) a generalized metabolic disturbance, such as marked obesity, severe malnutrition, or any chronic systemic disease.

Failure of ovulation results in prolonged, excessive endometrial stimulation by estrogens. Under these circumstances the endometrial glands undergo mild architectural changes, including cystic dilation, that are usually selflimited by the occurrence of the next ovulatory cycle. Unscheduled breakdown of the stroma may also occur (“anovulatory menstruation”), with no evidence of endometrial secretory activity (see Fig. 22-23A). More severe consequences of repeated anovulation are discussed under “Endometrial Hyperplasia.”

INADEQUATE LUTEAL PHASE

This term refers to a condition that is thought to stem from inadequate corpus luteum function resulting in low progesterone output, with subsequent early menses. The condition often manifests clinically as infertility, with either increased bleeding or amenorrhea. Endometrial biopsy performed at an estimated postovulatory date shows secretory endometrium, which, however, lags in its secretory characteristics expected at that date.

ENDOMETRIAL CHANGES INDUCED BY ORAL CONTRACEPTIVES

As might be suspected, oral contraceptives containing synthetic or derivative ovarian steroids induce a wide variety of endometrial changes, depending on the steroids used, the method of administration (combined or sequential regimen), and the dose. A common response pattern is a discordant appearance between glands and stroma, usually with inactive glands amid a stroma showing large cells with abundant cytoplasm reminiscent of the decidua of pregnancy. When such therapy is discontinued, the endometrium reverts to normal. All these changes have been minimized with newer low-dose contraceptives.

MENOPAUSAL AND POSTMENOPAUSAL CHANGES

Because the menopause is characterized by anovulatory cycles, architectural alterations in the endometrial glands may be present transiently, followed by ovarian failure and atrophy of the endometrium. As discussed later in this chapter, anovulatory cycles and uninterrupted estrogen production can induce mild hyperplasias with cystic dilation of glands. If this is followed by complete ovarian atrophy and loss of stimulus, the cystic dilation may remain, while the ovarian stroma and gland epithelium undergo atrophy. In this case, so-called cystic atrophy results. Such cystic changes should not be confused with simple hyperplasia, which shows evidence of glandular and stromal proliferation.

3.12.7.3 Inflammation

The endometrium and myometrium are relatively resistant to infections, primarily because the endocervix normally forms a barrier to ascending infection. Thus, although chronic inflammation in the cervix is an expected and frequently insignificant finding, it is of concern in the endometrium, excluding the menstrual phase.

ACUTE ENDOMETRITIS

Acute endometritis is uncommon and limited to bacterial infections that arise after delivery or miscarriage. Retained products of conception are the usual predisposing influence; the causative agents include group A hemolytic streptococci, staphylococci, and other bacteria. The inflammatory response is chiefly limited to the interstitium and is entirely nonspecific. Removal of the retained gestational fragments by curettage, accompanied by antibiotic therapy, is promptly followed by remission of the infection.

CHRONIC ENDOMETRITIS

Chronic inflammation of the endometrium occurs in the following settings: (1) in patients suffering from chronic PID; (2) in postpartum or post-abortion patients with retained gestational tissue; (3) in women with intrauterine contraceptive devices; and (4) in women with tuberculosis, either from miliary spread or, more commonly, from drainage of tuberculous salpingitis. The last is distinctly rare in Western countries. The chronic endometritis in all these cases is secondary to another underlying cause.

In about 15% of cases no cause is obvious, yet plasma cells (which are not present in normal endometrium) are seen together with macrophages and lymphocytes (see Fig. 22-23B). Some women with this so-called nonspecific chronic endometritis have gynecologic complaints such as abnormal bleeding, pain, discharge, and infertility. *Chlamydia* may be involved and is commonly associated with both acute (e.g., polymorphonuclear leukocytes) and chronic (e.g., lymphocytes, plasma cells) inflammatory cell infiltrates. The organisms may or may not be successfully cultured.[34] Importantly, antibiotic therapy is indicated because it may prevent other sequelae (e.g., salpingitis).

3.12.7.4 Endometriosis & Adenomyosis

Endometriosis is the presence of endometrial tissue outside of the uterus. It most commonly consists of both endometrial glands and stroma, but rarely consists only of endometrial stroma. It occurs in the following sites, in descending order of frequency: (1) ovaries; (2) uterine ligaments; (3) rectovaginal septum; (4) cul de sac; (5) pelvic peritoneum; (6) large and small bowel and appendix; (7) mucosa of the cervix, vagina, and fallopian tubes; and (8) laparotomy scars.

Endometriosis is an important clinical condition; it often causes *infertility*, *dysmenorrhea (painful menstruation)*, *pelvic pain*, and other problems. The disorder is principally a disease of women in active reproductive life, most often in the third and fourth decades, affecting approximately 10% of women. Uncommonly, endometriosis can show features (metastasis and invasion) similar to malignant tumors. When these features are present they often contribute to significant complications. For example, invasion of the muscular wall of the bowel can result in intestinal symptoms (Fig. 22-24).

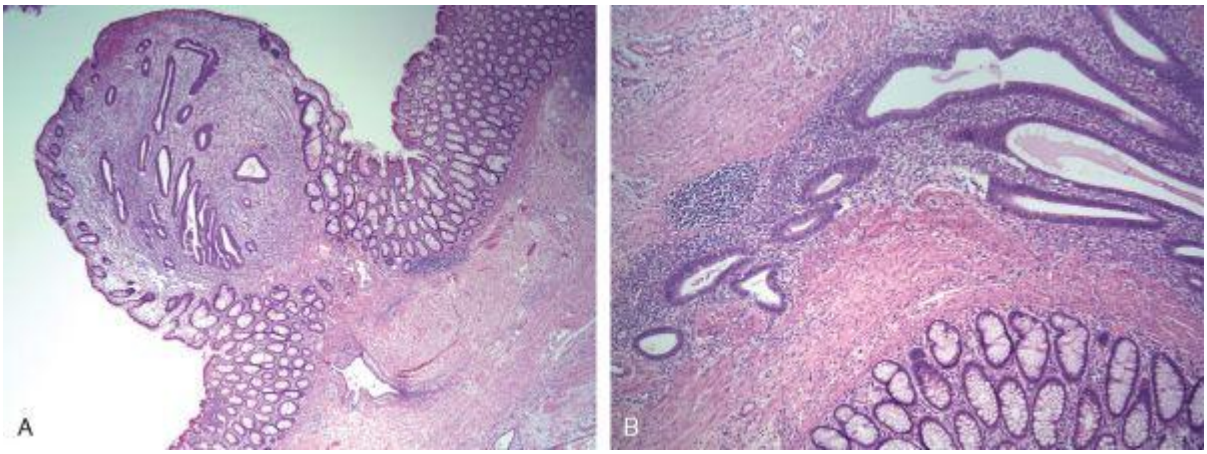

FIGURE 22-24 Endometriosis. **A**, Endometriosis is present in the mucosa of the colon. **B**, Higher magnification reveals the presence of both endometrial glands and stroma.

Two major theories for the development of endometriosis have been proposed.[7]

1. *The metastatic theory*. According to this, endometrial tissue is implanted at abnormal locations. Retrograde menstruation through the fallopian tubes occurs regularly even in normal women and could mediate spread of endometrial tissue to the peritoneal cavity. Endometriosis is also found in cervical mucosa, particularly following surgical procedures, supporting implantation from above. In addition, this theory can explain the "spread" of endometriosis to distant sites via hematogenous and lymphatic "metastases." In the context of endometriosis, the term *metastatic* simply refers to the appearance of endometrial tissue in extrauterine locations but does not imply an underlying mechanism.
2. *The metaplastic theory*. Endometrium could arise directly from coelomic epithelium (mesothelium of pelvis or abdomen), from which the müllerian ducts and ultimately the endometrium itself originate during embryonic development.

The metastatic theory is most widely accepted and provides a plausible explanation for the majority of cases of endometriosis. However, it fails to explain some situations in which endometriosis arises. For example, the presence of endometriosis in women who are amenorrheic because of a variety of underlying etiologies (e.g., gonadal dysgenesis) cannot be due to displaced menstrual endometrium. In addition, the relatively low incidence of endometriosis despite the common occurrence of retrograde menstruation (76% to 90% of women) suggests that specific individual factors must predispose women. Other factors that have been postulated include genetic, hormonal, and immune factors.[35] Molecular analysis, including gene expression profiling, have provided novel insights into pathogenesis of endometriosis. Some of the specific abnormalities that distinguish normal endometrium from endometriotic tissue are highlighted below[35]:

- There is a profound activation of the *inflammatory cascade* in endometriosis, characterized by high levels of prostaglandin E2, IL-1β, TNF and IL-6. The key role played by prostaglandins in endometriosis is supported by the beneficial effects of COX-2 inhibitors on pelvic pain, an important clinical feature of this disorder.
- *Estrogen production* by endometriotic stromal cells is markedly upregulated, due in large part to high levels of the key steroidogenic enzyme aromatase.[36] This enzyme is absent in normal endometrial stroma. Estrogen enhances the survival and persistence of endometriotic tissue; in keeping with this, inhibitors of aromatase are beneficial in the treatment of endometriosis. A linkage between activation of inflammation and estrogen production is suggested by the ability of prostaglandin E_2 to stimulate local synthesis of estrogen. Interestingly, endometriotic tissue is resistant to the anti-estrogenic effect of progesterone,[37]

suggesting that progesterone resistance also plays a role in endometriosis.

These abnormalities seem related to epigenetic changes in key genes that encode two nuclear receptors: steroidogenic factor-1, and estrogen receptor-β. Substantially decreased methylation of the promoters of these genes cause their pathologic overexpression leading to activation of a downstream molecular cascade favoring overproduction of estrogen and prostaglandin and resistance to progesterone action. These defects are present not only in ectopic endometriotic tissue, but, to a lesser degree, also in the endometrium lining the uterus in patients with endometriosis suggesting that they are not secondary to abnormal location.

Some studies have suggested that endometriosis is clonal, yet other studies have demonstrated polyclonality.[38,][39] Moreover, recent studies have detected mutations in endometriotic cysts that are similar to those found in ovarian endometrioid adenocarcinoma,[40] and clinicopathologic studies have long reported an association between the two. Collectively, these findings suggest that endometriosis can give rise to carcinoma.

Morphology. The foci of endometriosis respond to both extrinsic cyclic (ovarian) and intrinsic hormonal stimulation with periodic bleeding. This produces nodules with a red-blue to yellow-brown appearance on or just beneath the mucosal and/or serosal surfaces in the site of involvement. When the disease is extensive, organizing hemorrhage causes extensive fibrous adhesions between tubes, ovaries, and other structures and obliterates the pouch of Douglas. The ovaries may become markedly distorted by large cystic masses (3 to 5 cm in diameter) filled with brown fluid resulting from previous hemorrhage; these are often referred to clinically as chocolate cysts or endometriomas. Aggressive forms of endometriosis can infiltrate tissues and cause fibrosis and subsequent adhesions.

The histologic diagnosis of endometriosis is usually straightforward but may be difficult in long-standing cases in which the endometrial tissue is obscured by the secondary fibrosis. A histologic diagnosis of endometriosis is readily made when both endometrial glands and stroma are present (Fig. 22-24B), with or without the presence of hemosiderin. In rare cases only stroma is identified; however, if only glands are present it must be distinguished from other entities, such as endosalpingiosis, that have different clinical ramifications.

Clinical Features.

Clinical signs and symptoms usually consist of severe dysmenorrhea, dyspareunia (pain with intercourse), and pelvic pain due to the intrapelvic bleeding and periuterine adhesions. Pain on defecation indicates rectal wall involvement, and dysuria results from involvement of the serosa of the bladder. Intestinal disturbances may appear when the small intestine is affected. Menstrual irregularities are common, and infertility is the presenting complaint in 30% to 40% of women. In addition, though uncommon, malignancies can develop in this setting, suggesting that endometriosis contains “at-risk” epithelium.

A closely related disorder, *adenomyosis*, is defined as the *presence of endometrial tissue within the uterine wall* (myometrium). Adenomyosis remains in continuity with the endometrium, presumably signifying downgrowth of endometrial tissue into and between the smooth muscle fascicles of the myometrium. Adenomyosis occurs in up to 20% of uteri (Fig. 22-25). On microscopic examination, irregular nests of endometrial stroma, with or without glands, are arranged within the myometrium, separated from the basalis by at least 2 to 3 mm. Like endometriosis, the clinical symptoms of adenomyosis include menometrorrhagia (irregular and heavy menses), colicky dysmenorrhea, dyspareunia, and pelvic pain, particularly during the premenstrual period.

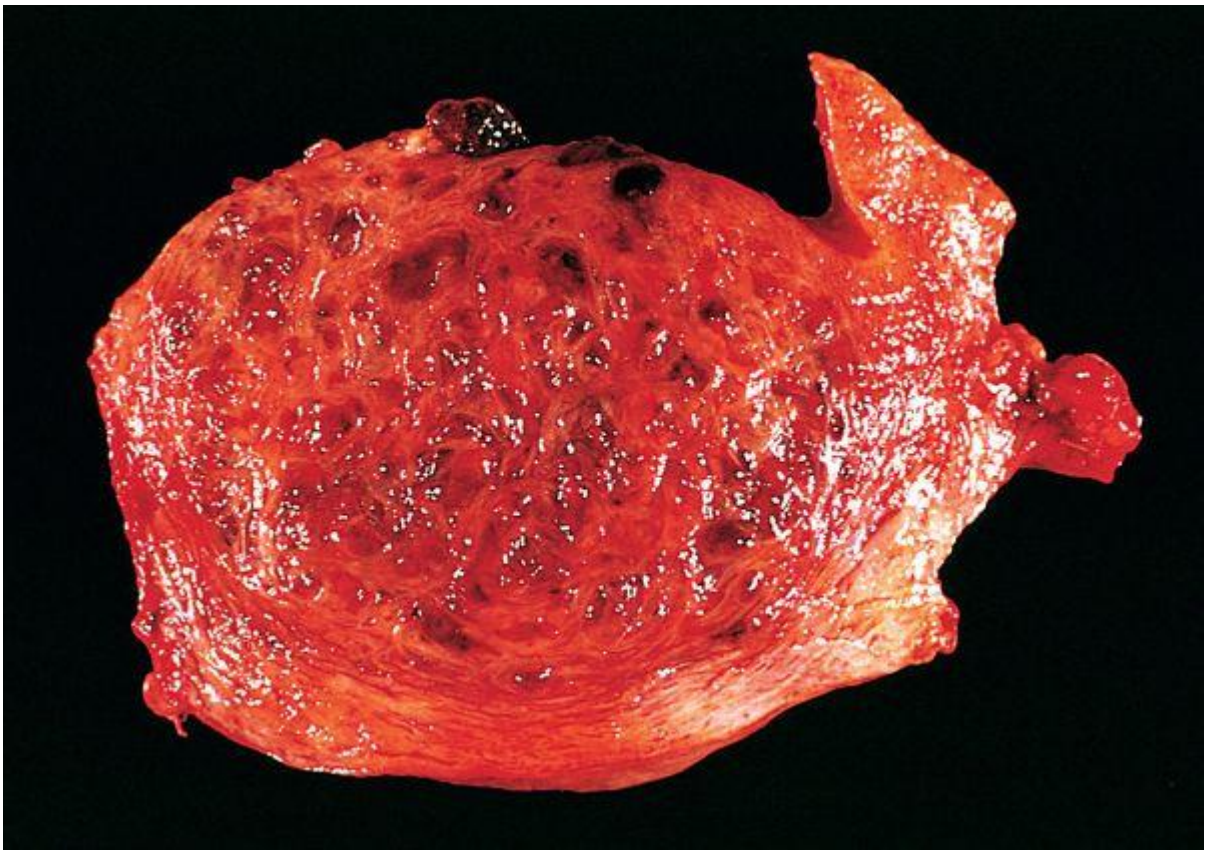

FIGURE 22-25 Adenomyosis. This disorder is characterized by functional endometrial nests within the myometrium, producing foci of hemorrhagic cysts within the uterine wall.

3.12.7.5 Endometrial Polyps

Endometrial polyps are exophytic masses of variable size that project into the endometrial cavity. They may be single or multiple and are usually sessile, measuring from 0.5 to 3 cm in diameter, but are occasionally large and pedunculated. Polyps may be asymptomatic or may cause abnormal bleeding (intramenstrual, menometrorrhagia, or postmenopausal) if they ulcerate or undergo necrosis. Most commonly the glands within polyps are hyperplastic or atrophic, but they can occasionally demonstrate secretory changes (functional polyps). Hyperplastic polyps may develop in association with generalized endometrial hyperplasia and are responsive to the growth effect of estrogen but show little or no progesterone response (see Fig. 22-23C). Atrophic polyps, which largely occur in postmenopausal women, most likely represent atrophy of a hyperplastic polyp. Rarely, adenocarcinomas arise within endometrial polyps. Endometrial polyps have been observed in association with the administration of tamoxifen. This drug is often used in the therapy of breast cancer due to its anti-estrogenic activity on the breast.[41] However, tamoxifen has weak estrogenic effects in the endometrium. Cytogenetic studies indicate that the stromal cells in endometrial polyps contain chromosome (6p21) rearrangements involving the *HMGIY* gene, which is also rearranged in a variety of other benign mesenchymal tumors.[42]

3.12.7.6 Endometrial Hyperplasia

Endometrial hyperplasia, an important cause of abnormal bleeding, is defined as an increased proliferation of the endometrial glands relative to the stroma, resulting in an increased gland-to-stroma

ratio when compared with normal proliferative endometrium. Endometrial hyperplasia deserves special attention because of its *relationship with endometrial carcinoma*. Clinicopathologic and epidemiologic studies have supported the malignant potential of endometrial hyperplasia and the concept of a continuum of proliferative glandular lesions culminating, in some cases, in carcinoma.[43] Molecular studies have confirmed this relationship, since endometrial hyperplasia and carcinoma share specific molecular genetic alterations.

Endometrial hyperplasia is associated with *prolonged estrogen stimulation of the endometrium*, which can be due to anovulation, increased estrogen production from endogenous sources, or exogenous estrogen. Thus, conditions associated with hyperplasia include obesity, menopause, polycystic ovarian disease (including Stein-Leventhal syndrome), functioning granulosa cell tumors of the ovary, excessive cortical function (cortical stromal hyperplasia), and prolonged administration of estrogenic substances (estrogen replacement therapy). These are the same influences postulated to be of pathogenetic significance in some endometrial carcinomas, discussed later.

A common genetic alteration found in a significant number of hyperplasias and related endometrial carcinomas is *inactivation of the PTEN tumor suppressor gene*.[44] *PTEN* is located on chromosome 10q23.3 and encodes a dual-specificity phosphatase capable of dephosphorylating both lipid and protein molecules. Its main function in tumorigenesis, as presently understood, is dephosphorylation of the lipid molecule phosphatidylinositol (3,4,5)-trisphosphate (PIP_3), which blocks the phosphorylation of AKT, a central factor in the phosphatidylinositol 3-kinase (PI3K) growth-regulatory pathway. When PTEN is inactive, AKT phosphorylation is enhanced, and it stimulates protein synthesis and cell proliferation and inhibits apoptosis. Mutations in *PTEN* have been found in more than 20% of hyperplasias, both with and without atypia, and in 30% to 80% of endometrial carcinomas, suggesting that alterations in *PTEN* occur at a relatively early stage in endometrial tumorigenesis.[45,][46] You will also recall that patients with Cowden syndrome, which is caused by germline mutations in PTEN, have a high incidence of endometrial carcinoma. Although it is clear that PTEN plays a central role in the development of hyperplasia and carcinoma, the mechanism by which its loss contributes to endometrial tumorigenesis is not yet well understood. It has been shown that loss of PTEN, resulting in the activation of AKT, can lead to phosphorylation of the estrogen receptor in a ligand (estrogen)-independent manner.[47] Thus, loss of PTEN function may activate pathways normally activated by estrogen.

Morphology. Based on architectural and cytologic features, endometrial hyperplasia is divided into four major categories:

Simple hyperplasia without atypia, also known as cystic or mild hyperplasia, is characterized by glands of various sizes and irregular shapes with cystic dilatation. There is a mild increase in the gland-to-stroma ratio. The epithelial growth pattern and cytology are similar to those of proliferative endometrium, although mitoses are not as prominent (Fig. 22-26A). These lesions uncommonly progress to adenocarcinoma (approximately 1%) and largely reflect a response to persistent estrogen stimulation. Simple hyperplasia may evolve into cystic atrophy when the estrogen stimulation is withdrawn.

Simple hyperplasia with atypia is uncommon. Architecturally it has the appearance of simple hyperplasia, but there is cytologic atypia within the glandular epithelial cells, as defined by loss of polarity, vesicular nuclei, and prominent nucleoli. Morphologically the cells become rounded and lose the normal perpendicular orientation to the basement membrane. In addition, the nuclei have an open chromatin pattern and conspicuous nucleoli. Approximately 8% of such lesions progress to carcinoma.

Complex hyperplasia without atypia shows an increase in the number and size of endometrial glands, marked gland crowding, and branching of glands. As a result, the glands may be crowded back-to-back with little intervening stroma and abundant mitotic figures (Fig. 22-26B). However, the glands remain distinct and nonconfluent, and the epithelial cells remain cytologically normal. This class of lesions has about a 3% progression to carcinoma, lower than that of simple hyperplasia with atypia.

Complex hyperplasia with atypia has considerable morphologic overlap with well-differentiated endometrioid adenocarcinoma (as discussed below), and an accurate distinction between complex hyperplasia with atypia and cancer may not be possible without hysterectomy (Fig. 22-26C and D).[48] It has been found that approximately 23% to 48% of women with a diagnosis of complex hyperplasia with atypia have carcinoma when a hysterectomy is performed shortly after the endometrial biopsy or curettage.[49] In one study, in which women with complex hyperplasia with atypia were treated with progestin therapy alone, 50% had persistent disease, 25% recurred, and 25% progressed to carcinoma.[50] Currently, complex hyperplasia with atypia is managed by hysterectomy or, in young women, a trial of progestin therapy and close follow-up. The low rate of regression usually requires the removal of the uterus.

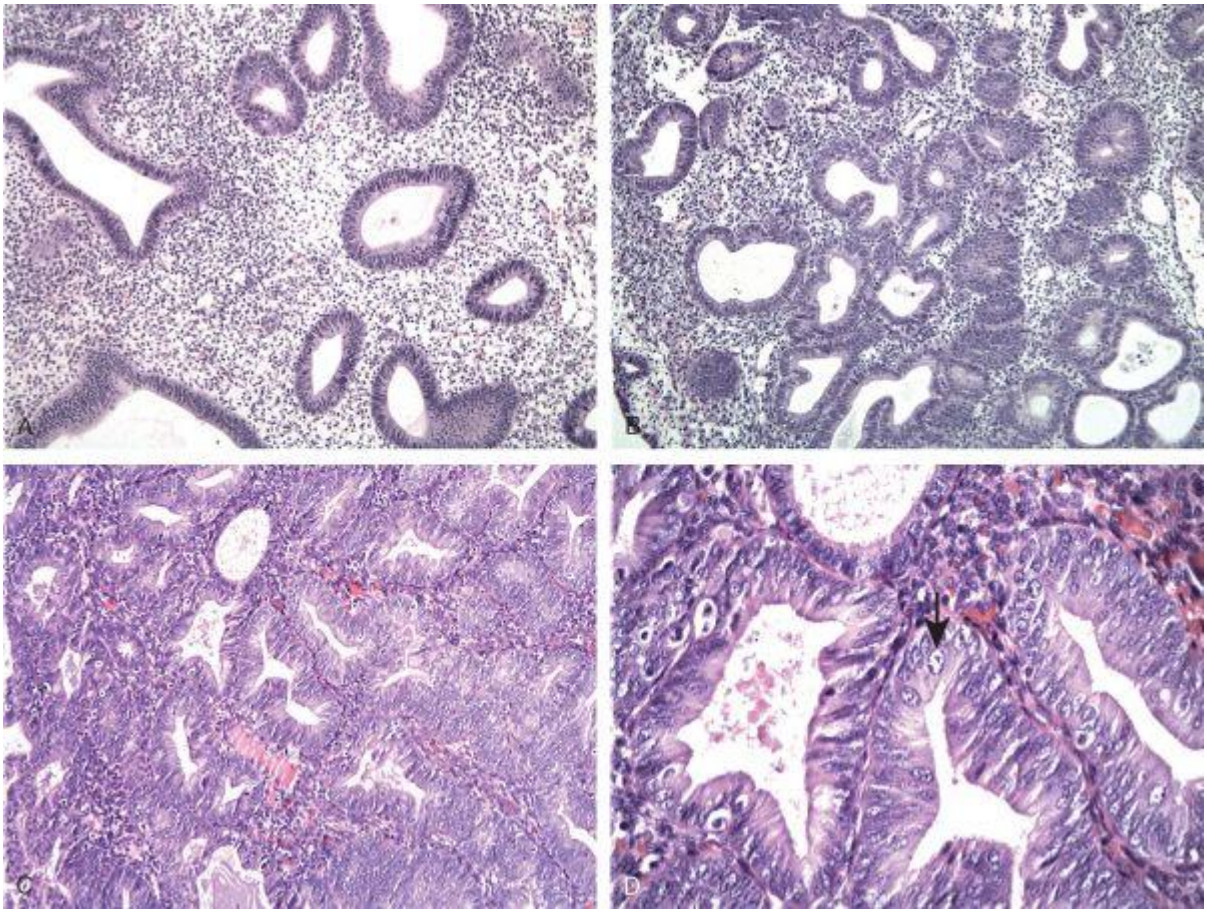

FIGURE 22-26 **A**, Simple hyperplasia without atypia with architectural abnormalities including mild glandular crowding and cystic glandular dilatation. **B**, Complex hyperplasia without atypia demonstrates increased glandular crowding with areas of back-to-back glands with cytologic features similar to proliferative endometrium. **C**, Complex hyperplasia with atypia has architectural features similar to complex hyperplasia without atypia, but the cytologic features have changed. **D**, High magnification of complex hyperplasia with atypia showing rounded, vesicular nuclei with prominent nucleoli *(arrow)*.

A proportion of endometrial hyperplasias are less easily classified, including complex lesions without cellular atypia (uncommon) and those with altered cellular differentiation (metaplasia), such as squamous, ciliated cell, and mucinous metaplasia. The latter may result from alterations in epithelial-stromal interactions inducing the basal endometrial cells to follow different differentiation pathways.[51] Because of these nuances of cell growth and differentiation, interpretation of endometrial hyperplasia may be highly subjective, and thus precise classification of every change is not possible. Any assessment of a suspected hyperplasia should include the degree of atypia in a manner clearly understandable by the clinician because the impact on therapy is great. For the patient it may mean the difference between cyclic progestin therapy on one hand and continuous high-dose progestin therapy or hysterectomy (or both) on the other.

3.12.7.7 Malignant Tumors of the Endometrium

CARCINOMA OF THE ENDOMETRIUM

Endometrial carcinoma is the most common invasive cancer of the female genital tract and accounts for 7% of all invasive cancer in women, excluding skin cancer. At one time, it was far less common than cancer of the cervix, but earlier detection and eradication of squamous intraepithelial lesions and an increase in endometrial carcinomas in younger age groups have reversed this ratio. There are now 39,000 new endometrial cancers per year, compared with 11,000 new invasive cervical cancers. Although they occur at a high frequency, endometrial cancers arise mainly in postmenopausal women. Because they cause abnormal (postmenopausal) bleeding, early detection and cures are possible.

Molecular Pathogenesis.

Carcinoma of the endometrium is uncommon in women younger than 40 years of age. The peak incidence is in 55- to 65-year-old women. Clinicopathologic studies and molecular analyses support the classification of endometrial carcinoma into two broad categories, referred to as type I and type II, as summarized in Table 22-4 .[52] Because of their distinct pathogenesis they will be discussed separately.

TABLE 22-4 -- Characteristics of Type I and Type II Endometrial Carcinoma

Characteristics	Type I	Type II
Age	55–65 yr	65–75 yr
Clinical setting	Unopposed estrogen Obesity Hypertension Diabetes	Atrophy Thin physique
Morphology	Endometrioid	Serous Clear cell Mixed müllerian tumor
Precursor	Hyperplasia	Endometrial intraepithelial carcinoma
Molecular genetics	*PTEN* *PIK3CA* *KRAS* MSI[*] β-*catenin*	*p53* Aneuploidy *PIK3CA*

Characteristics	Type I	Type II
	p53	
Behavior	Indolent Spreads via lymphatics	Aggressive Intraperitoneal and lymphatic spread

* MSI, microsatellite instability.

Type I carcinomas.

These are the most common type, accounting for greater than 80% of all cases. The majority are well differentiated and mimic proliferative endometrial glands and, as such, are referred to as *endometrioid carcinoma*. As discussed above, they typically arise in the setting of endometrial hyperplasia and like endometrial hyperplasia they are associated with (1) obesity, (2) diabetes (abnormal glucose tolerance is found in more than 60%), (3) hypertension, (4) infertility (women who develop cancer of the endometrium tend to be nulliparous and have a history of functional menstrual irregularities consistent with anovulatory cycles), and (5) unopposed estrogen stimulation. Recent molecular studies have provided further evidence that endometrial hyperplasia is a precursor to endometrioid carcinoma (Fig. 22-27).[53]

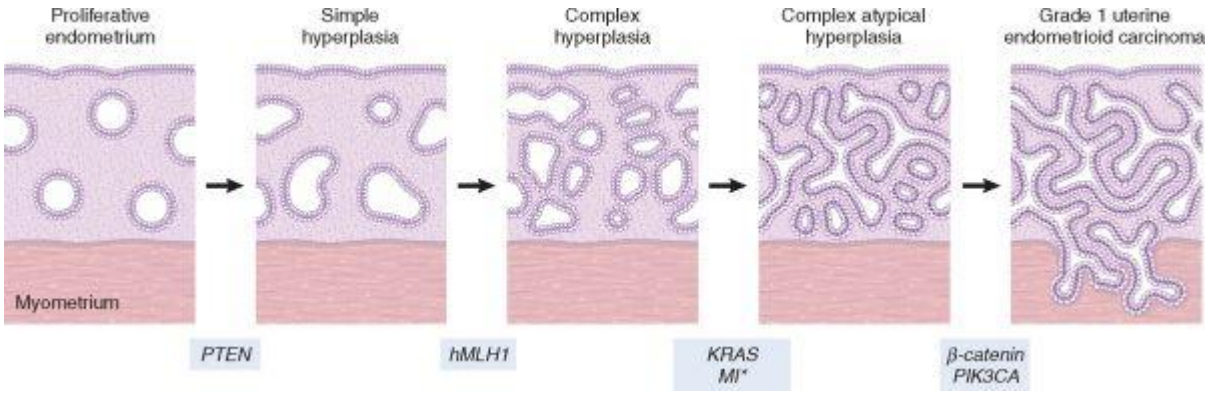

FIGURE 22-27 Schematic diagram depicting the development of type I endometrial carcinoma arising in the setting of hyperplasia. The most common molecular genetic alterations are shown at the time they are most likely to occur during the progression of the disease. *MI, microsatellite instability.

As mentioned earlier, *mutations in the PTEN tumor suppressor gene have been identified in 30% to 80% of endometrioid carcinomas and in approximately 20% of endometrial hyperplasias*, both with and without atypia. In hysterectomy specimens containing complex hyperplasia with atypia and carcinoma, identical *PTEN* mutations have been identified in each component.[54] These findings support complex hyperplasia with atypia as a precursor to carcinoma and demonstrate that *PTEN* mutations occur before the development of invasion. Of interest, *PIK3CA* mutations have recently been reported in approximately 39% of endometrioid carcinomas, and they have been found in tumors with and without *PTEN* mutations.[55] PIK3CA is the catalytic subunit of PI3K, a lipid kinase that phosphorylates PIP_2 to PIP_3, directly antagonizing the action of *PTEN*. However, in contrast to *PTEN* mutations, *PIK3CA* mutations rarely occur in complex hyperplasia with atypia, suggesting that mutations in *PIK3CA* play a role in invasion.[56] Additional molecular changes that are common in type I carcinomas include microsatellite instability and mutations in the *KRAS* and β-catenin oncogenes. Microsatellite instability

occurs in about 20% of sporadic tumors but is also found in tumors in women from families with hereditary non-polyposis colorectal carcinoma (HNPCC), as discussed in Chapter 17 . While microsatellite instability in HNPCC-related carcinomas is caused by germline mutations, in sporadic endometrioid carcinomas it is most commonly due to epigenetic silencing (via promoter hypermethylation) of one of the DNA mismatch repair genes. Mutations in *KRAS* are found in approximately 25% of cases and have also, but less commonly, been found in complex atypical hyperplasia. These molecular genetic alterations in endometrioid carcinoma, are rarely, if ever, found in type II carcinomas. One of the genes altered in both tumor types is *p53*. In the more poorly differentiated endometrioid carcinomas, mutations in *p53* can be found in up to 50% of cases. They are not identified in well-differentiated tumors or in complex atypical hyperplasias. Thus, it is thought that *p53* mutations are a late-occurring event in endometrioid carcinoma, in contrast to what is seen in serous endometrial carcinoma, as discussed below.

Morphology. On gross inspection, endometrial carcinoma can be either a localized polypoid tumor or a diffuse tumor involving the endometrial surface (Fig. 22-28A). Spread generally occurs by direct myometrial invasion with eventual extension to the periuterine structures by direct continuity. Spread into the broad ligaments may create a palpable mass. Dissemination to the regional lymph nodes eventually occurs, and in the late stages, the tumor may metastasize to the lungs, liver, bones, and other organs.

On histologic examination, most endometrial carcinomas (about 85%) are **endometrioid adenocarcinomas** characterized by gland patterns resembling normal endometrial epithelium. A three-step grading system is applied to endometrioid tumors and includes well differentiated (grade 1) (Fig. 22-28B), with easily recognizable glandular patterns; moderately differentiated (grade 2) (Fig. 22-28C), showing well-formed glands mixed with solid sheets of malignant cells; or poorly differentiated (grade 3) (Fig. 22-28D), characterized by solid sheets of cells with barely recognizable glands and a greater degree of nuclear atypia and mitotic activity (see below).

G1. Well-differentiated adenocarcinoma, less than 5% solid growth

G2. Moderately differentiated adenocarcinoma with partly (less than 50%) solid growth

G3. Poorly differentiated adenocarcinoma with predominantly solid growth (greater than 50%)

Up to 20% of endometrioid carcinomas contain foci of squamous differentiation. Squamous elements may be histologically benign-appearing when they are associated with well-differentiated adenocarcinomas. Less commonly, moderately or poorly differentiated endometrioid carcinomas contain squamous elements that appear frankly malignant. Current classification systems grade the carcinomas based on glandular differentiation alone and do not include areas of solid squamous differentiation when considering grading.

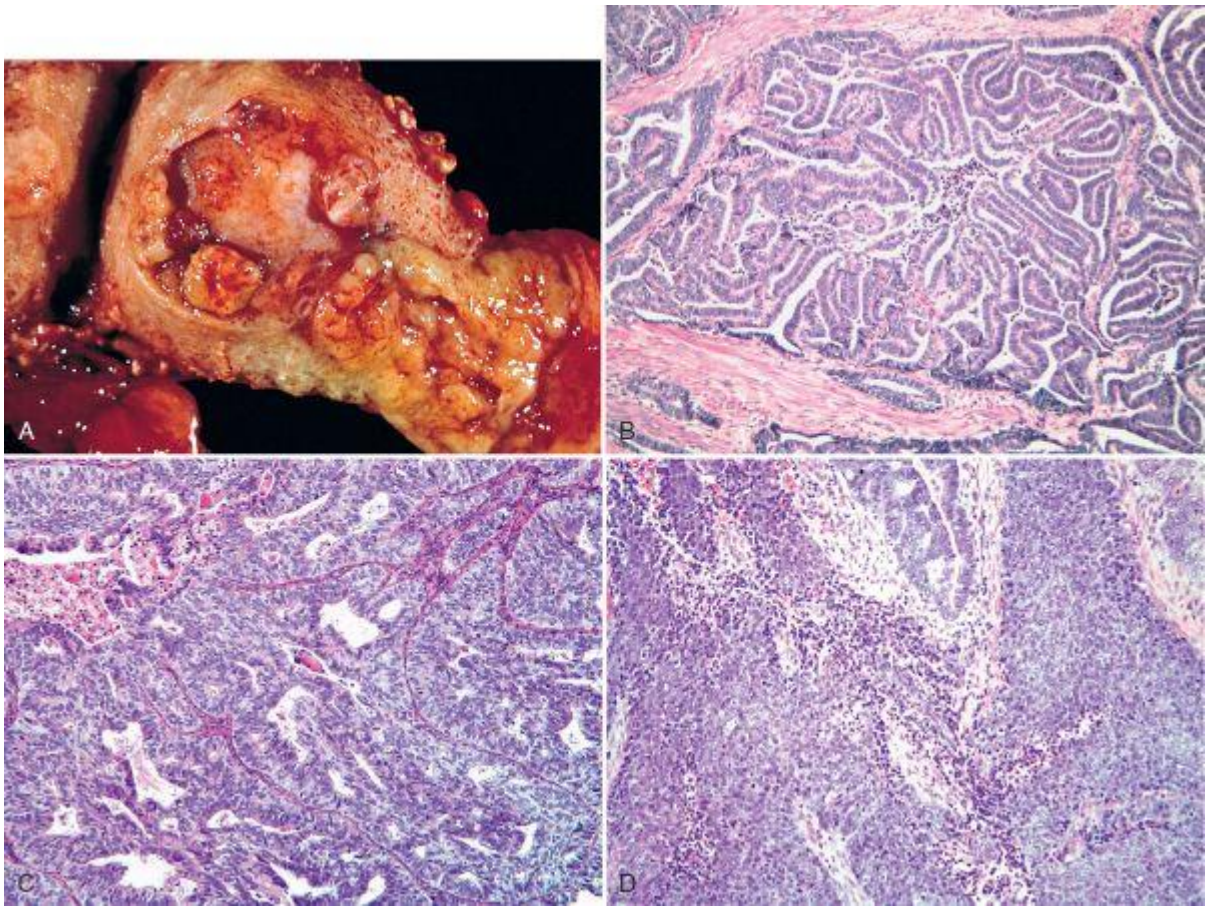

FIGURE 22-28 Type I carcinoma. **A**, Endometrial adenocarcinoma presenting as a fungating mass in the fundus of the uterus. **B**, Well-differentiated (grade 1) endometrioid adenocarcinoma with preserved glandular architecture but lack of intervening stroma, distinguishing it from hyperplasia. **C**, Moderately differentiated (grade 2) endometrioid adenocarcinoma with glandular architecture admixed with solid areas. **D**, Poorly differentiated (grade 3) endometrioid adenocarcinoma with predominantly solid growth.

Type II carcinomas.

These generally occur in women a decade later than type I carcinoma, and in contrast to type I carcinoma they *usually arise in the setting of endometrial atrophy* (Fig. 22-29). Type II tumors are by definition poorly differentiated (grade 3) tumors and account for approximately 15% of cases of endometrial carcinoma. The most common subtype is serous carcinoma, referred to as such because of morphologic and biologic overlap with ovarian serous carcinoma. There are less common histologic subtypes (clear cell carcinoma and malignant mixed müllerian tumor) within this category, but very little is known about their pathogenesis. The most frequent alteration described thus far in serous endometrial carcinoma is mutation of the *p53* tumor suppressor gene. Alterations in other genes have been described, but at much lower frequency. Mutations in *p53* are present in at least 90% of serous endometrial carcinoma.[57] The majority of mutations are missense mutations that result in an accumulation of the altered protein that can be detected with immunohistochemistry as strong, diffuse staining of the tumor cell nuclei (Fig. 22-30B and D).

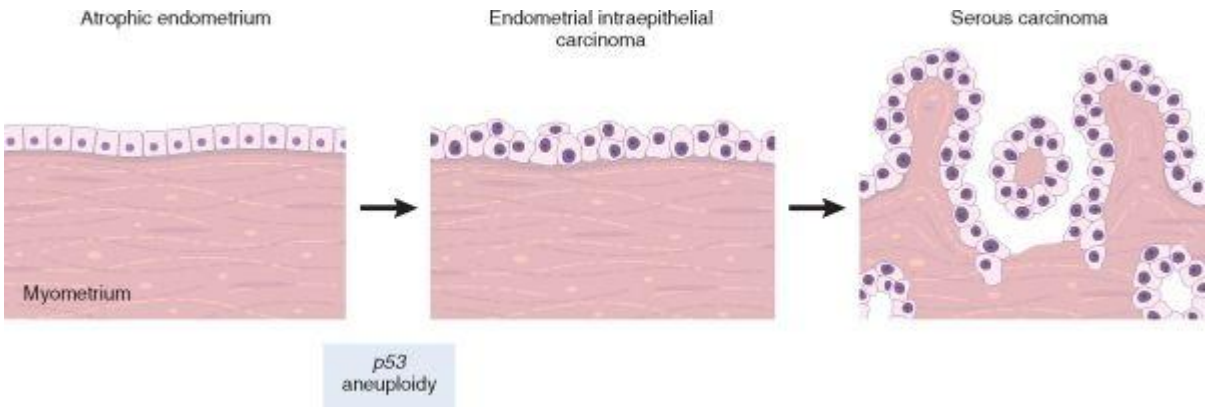

FIGURE 22-29 Schematic diagram of the development of type II endometrial carcinoma.

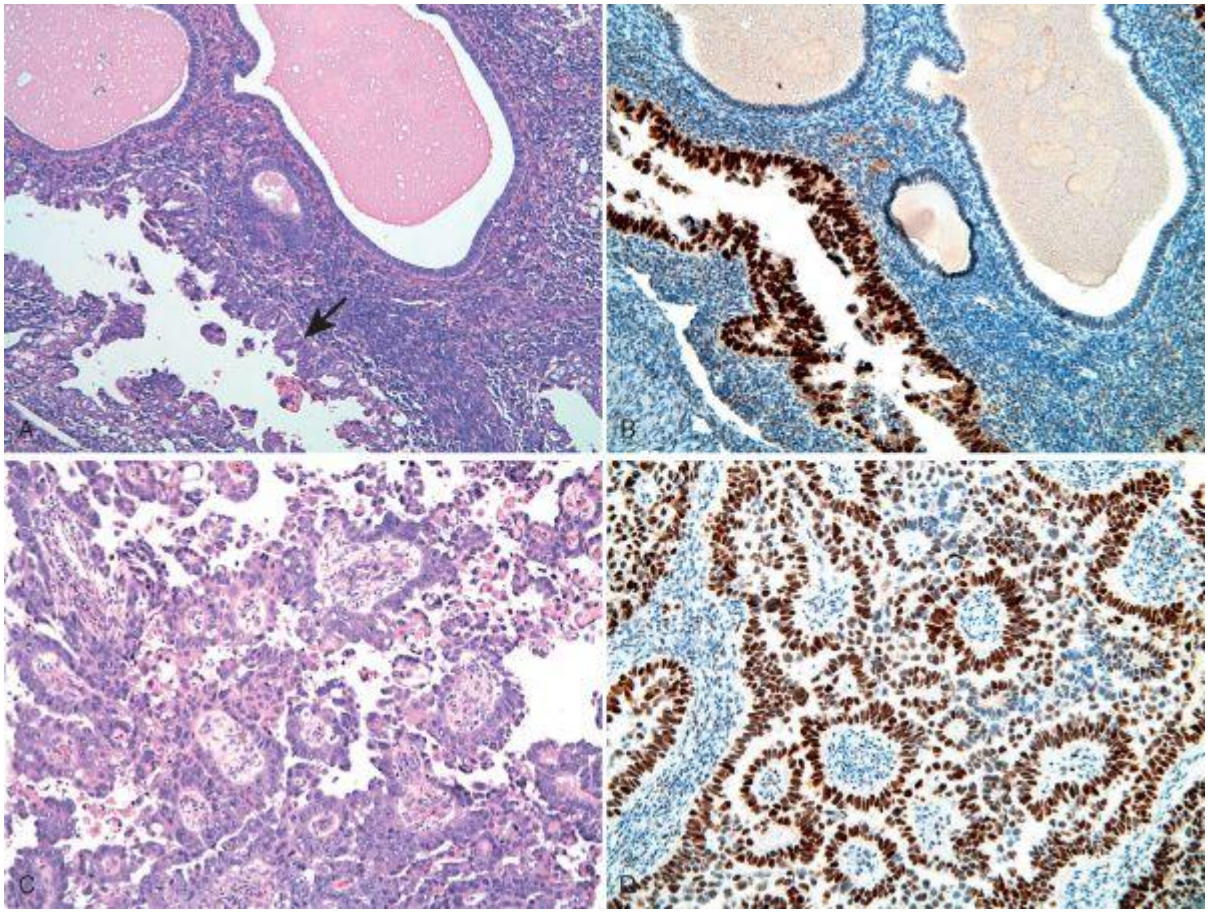

FIGURE 22-30 Type II carcinoma. **A**, Endometrial intraepithelial carcinoma, the precursor to serous carcinoma showing malignant cells *(arrow)* with morphologic features identical to serous carcinoma lining the surfaces of the endometrial glands without obvious stromal invasion. **B**, Strong, diffuse expression of p53 as detected by immunohistochemistry in endometrial intraepithelial carcinoma. **C**, Serous carcinoma of the endometrium with papillary growth pattern consisting of malignant cells with marked cytologic atypia including high nuclear-to-cytoplasmic ratio, atypical mitotic figures, and hyperchromasia. **D**, As with the previous lesion, there is an accumulation of p53 protein in the nucleus.

The precursor of serous carcinoma, endometrial intraepithelial carcinoma (EIC), consists of cells identical to those of serous carcinoma but lacks identifiable stromal invasion. Mutations in *p53* are found in approximately 75% of these lesions, suggesting that *mutation of p53 is an early event in serous endometrial carcinoma*. Thus, serous carcinoma presumably begins as a surface epithelial neoplasm that extends into adjacent gland structures and later invades endometrial stroma. Their generally poorer prognosis is thought to be a consequence of a propensity to exfoliate, undergo transtubal spread, and implant on peritoneal surfaces like their ovarian counterparts. They have often spread outside of the uterus at the time of diagnosis.

Morphology. Generally, serous carcinomas arise in small atrophic uteri and are often large bulky tumors or deeply invasive into the myometrium. The precursor lesion, endometrial intraepithelial carcinoma, consists of malignant cells identical to those of serous carcinoma but they remain contained to the gland surface without identifiable stromal invasion (see Fig. 22-30A and B). The invasive lesions may have a papillary growth pattern composed of cells with marked cytologic atypia including high nuclear-to-cytoplasmic ratio, atypical mitotic figures, heterochromasia, and prominent nucleoli (see Fig. 22-30C and D). However, they can also have a predominantly glandular growth pattern that can be distinguished from endometroid carcinoma by the marked cytologic atypia. All of the non-endometrioid carcinomas are classified as grade 3 irrespective of histologic pattern. Serous carcinoma, despite relatively superficial endometrial involvement, may be associated with extensive peritoneal disease, suggesting spread by routes (i.e., tubal or lymphatic transmission) other than direct invasion.

Clinical Course.

There is no currently available screening test for carcinoma of the endometrium. Although it may be asymptomatic for a period of time, it usually produces irregular or postmenopausal vaginal bleeding with excessive leukorrhea. Uterine enlargement may be absent in the early stages. The diagnosis of endometrial cancer must ultimately be established by biopsy or curettage and histologic examination of the tissue.

As would be anticipated, the prognosis depends heavily on the clinical stage of the disease when it is discovered, and its histologic grade and type. In the United States, most women (about 80%) present in stage I and have well-differentiated or moderately differentiated endometrioid carcinomas. Surgery, alone or in combination with irradiation, gives about 90% 5-year survival in stage I (grade 1 or 2) disease. This rate drops to approximately 75% for grade 3/stage I and to 50% or less for stage II and III endometrial carcinomas.

As mentioned, serous carcinoma has a propensity for extrauterine (lymphatic or transtubal) spread, even when apparently confined to the endometrium or its surface epithelium. Overall, fewer than 50% of patients with these tumors are alive 3 years after diagnosis and 35% after 5 years. If peritoneal cytology and adnexal histologic exam are negative, the 5-year survival of those with stage I disease is approximately 80% to 85%.[58] The additional advantage of prophylactic radiation or chemotherapy in early-stage disease is unclear.[59,][60]

MALIGNANT MIXED MÜLLERIAN TUMORS

MMMTs (previously referred to as carcinosarcomas) consist of endometrial adenocarcinomas with malignant changes in the stroma.[61] The stroma tends to differentiate into a variety of malignant mesodermal components, including muscle, cartilage, and even osteoid. The epithelial and stromal components are presumably derived from the same cell, a concept supported by immunohistochemical

and molecular studies.[62] Both clinicopathologic and molecular studies suggest that the vast majority of these tumors are carcinomas with sarcomatous differentiation. The mechanisms underlying the sarcomatous transformation are unknown. MMMTs occur in postmenopausal women and present with postmenopausal bleeding.

Morphology. In gross appearance, MMMTs are fleshier than adenocarcinomas, may be bulky and polypoid, and sometimes protrude through the cervical os. On histology, the tumors consist of adenocarcinoma (endometrioid, serous, or clear cell) mixed with the malignant mesenchymal (sarcoma) elements (Fig. 22-31A); alternatively, the tumor may contain two distinct and separate epithelial and mesenchymal components. Sarcomatous components may also mimic extrauterine tissues (e.g., striated muscle, cartilage, adipose tissue, and bone). Metastases usually contain only epithelial components (Fig. 22-31B).

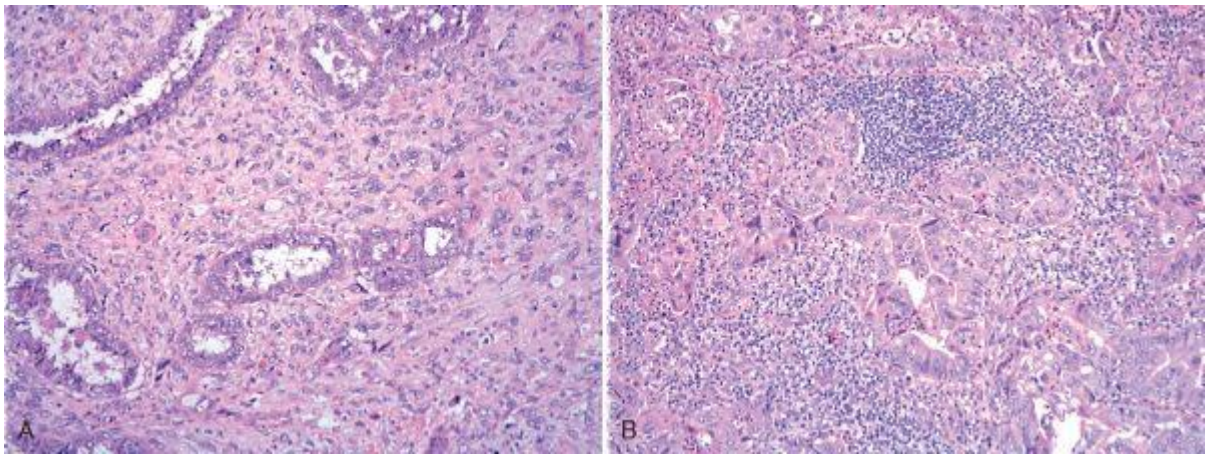

FIGURE 22-31 **A**, Malignant mixed müllerian tumor (MMMT), showing both malignant epithelial and stromal components. **B**, Lymph node metastasis from a MMMT showing only the epithelial component as is typically seen.

Outcome of MMMTs is determined primarily by depth of invasion and stage. As with endometrial carcinomas, the prognosis is influenced by the grade and type of the adenocarcinoma, being poorest with serous differentiation. These tumors are highly malignant, with 5-year survival rate of 25% to 30%.[61]

Staging of types I and II of endometrial adenocarcinoma and MMMTs is as follows:

Stage I.	Carcinoma is confined to the corpus uteri itself.
Stage II.	Carcinoma involves the corpus and the cervix.
Stage III.	Carcinoma extends outside the uterus but not outside the true pelvis.
Stage IV.	Carcinoma extends outside the true pelvis or involves the mucosa of the bladder or the rectum.

3.12.7.8 Tumors of the Endometrium with Stromal Differentiation

These are relatively uncommon tumors and comprise less than 5% of endometrial cancers. One group is composed of stromal neoplasias in association with benign glands (adenosarcomas). The other group

consists of pure stromal neoplasms, ranging from benign (stromal nodule) to malignant (stromal sarcoma).

ADENOSARCOMAS

Adenosarcomas present most commonly as large broad-based endometrial polypoid growths that may prolapse through the cervical os. The diagnosis is based on malignant-appearing stroma, which coexists with benign but abnormally shaped endometrial glands. These tumors predominate in women between the fourth and fifth decades and are generally considered to be a low-grade malignancy; recurrences develop in one fourth and are nearly always confined to the pelvis.[63] The principal diagnostic dilemma is distinguishing these tumors from large benign polyps. The distinction is important, because oophorectomy is typically performed in cases of adenosarcoma, since they are estrogen-sensitive.

STROMAL TUMORS

The endometrial stroma occasionally gives rise to neoplasms that may resemble normal stromal cells. Similar to most neoplasms, they may be well or poorly differentiated. Stromal neoplasms are divided into two categories: (1) benign stromal nodules and (2) endometrial stromal sarcomas.

Morphology. Stromal nodule is a well-circumscribed aggregate of endometrial stromal cells in the myometrium that does not penetrate the myometrium and is of little consequence. **Stromal sarcoma** consists of neoplastic endometrial stroma lying between muscle bundles of the myometrium and is distinguished from stromal nodules by either diffuse infiltration of myometrial tissue or the invasion of lymphatic channels (previously termed **endolymphatic stromal myosis**).

About half of stromal sarcomas recur, with relapse rates of 36% to over 80% for stage I and stage III/IV tumor, respectively; relapse cannot be predicted by either mitotic index or degree of cytologic atypia.[64] Distant metastases may occur decades after initial diagnosis, and death from metastatic tumor occurs in about 15% of cases. Five-year survival rates average 50%. A recurrent chromosomal translocation, t(7;17)(p15;q21), occurs in endometrial stromal sarcoma. This translocation leads to the fusion of two polycomb group genes, *JAZF1* and *JJAZ1*, with production of a fusion transcript with anti-apoptotic properties.[65] Interestingly, even normal endometrial stromal cells express the fusion gene, derived not by translocation, but by the "stitching" together of m-RNAs. Thus, it appears that a pro-survival gene in the normal endometrium is somehow subverted to become pro-neoplastic.

3.12.7.9 Tumors of the Myometrium

LEIOMYOMAS

Uterine leiomyomas (commonly called *fibroids*) are perhaps the most common tumor in women. They are benign smooth muscle neoplasms that may occur singly, but most often are multiple. Most leiomyomas have normal karyotypes, but approximately 40% have a simple chromosomal abnormality. Several cytogenetic subgroups have been recognized: a balanced translocation between chromosomes 12 and 14 (i.e., t(12;14)(q14–q15;q23–q24)), partial deletions of the long arm of chromosome 7 (i.e., del(7)(q22–q32)), trisomy 12, and rearrangements of 6p, 3q, and 10q. The rearrangements of 12q14 and 6p involving the *HMGIC* and *HMGIY* genes, respectively, which are also implicated in a variety of other benign neoplasms. Both genes encode closely related DNA-binding factors that regulate chromatin structure.[66,][67]

Morphology. Leiomyomas are sharply circumscribed, discrete, round, firm, gray-white tumors

varying in size from small, barely visible nodules to massive tumors that fill the pelvis. Except in rare instances, they are found within the myometrium of the corpus. Only infrequently do they involve the uterine ligaments, lower uterine segment, or cervix. They can occur within the myometrium (intramural), just beneath the endometrium (submucosal) (Fig. 22-32A ; see also Fig. 22-23D), or beneath the serosa (subserosal).

Whatever their size, the characteristic whorled pattern of smooth muscle bundles on cut section usually makes these lesions readily identifiable on gross inspection. Large tumors may develop areas of yellow-brown to red softening (red degeneration).

On histologic examination, the leiomyoma is composed of whorled bundles of smooth muscle cells that resemble the uninvolved myometrium (Fig. 22-32B). Usually, the individual muscle cells are uniform in size and shape and have the characteristic oval nucleus and long, slender bipolar cytoplasmic processes. Mitotic figures are scarce. Benign variants of leiomyoma include atypical or bizarre (symplastic) tumors with nuclear atypia and giant cells, and cellular leiomyomas. Importantly, both have a low mitotic index. An extremely rare variant, **benign metastasizing leiomyoma**, consists of a uterine tumor that extends into vessels and migrates to other sites, most commonly the lung. Another variant, **disseminated peritoneal leiomyomatosis**, presents as multiple small nodules on the peritoneum. Both are considered benign despite their unusual behavior.

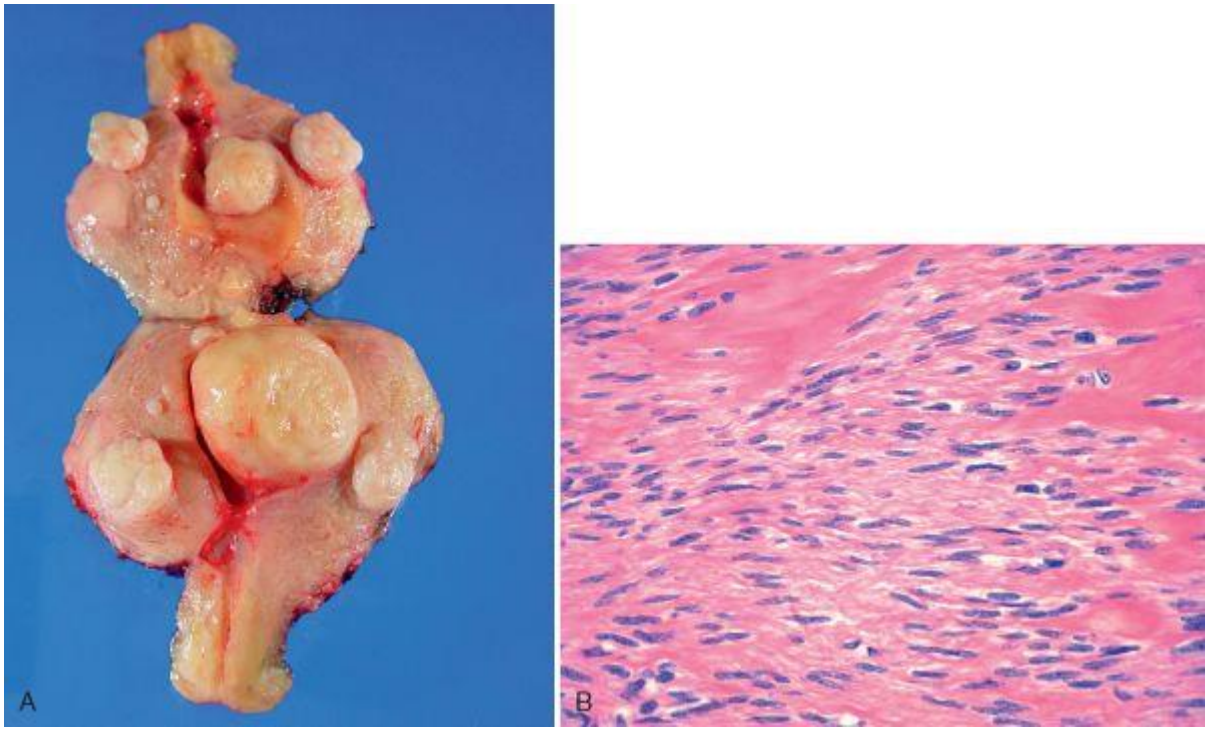

FIGURE 22-32 **A**, Leiomyomas of the myometrium. The uterus is opened to reveal multiple tumors in submucosal (bulging into the endometrial cavity), intramural, and subserosal locations that display a firm white appearance on sectioning. **B**, Leiomyoma showing well-differentiated, regular, spindle-shaped smooth muscle cells associated with hyalinization.

Leiomyomas of the uterus, even when they are extensive, may be asymptomatic. The most important symptoms are abnormal bleeding, compression of the bladder (urinary frequency), sudden pain if disruption of blood supply occurs, and impaired fertility. Myomas in pregnant women increase the

frequency of spontaneous abortion, fetal malpresentation, uterine inertia, and postpartum hemorrhage. Malignant transformation (leiomyosarcoma) within a leiomyoma is extremely rare.

LEIOMYOSARCOMAS

These uncommon malignant neoplasms arise de novo from the myometrium or endometrial stromal precursor cells. In contrast to leiomyomas, leiomyosarcomas have complex, highly variable karyotypes that frequently include deletions.[68]

Morphology. Leiomyosarcomas grow within the uterus in two somewhat distinctive patterns: bulky, fleshy masses that invade the uterine wall, or polypoid masses that project into the uterine lumen (Fig. 22-33A). On histologic examination, they contain a wide range of atypia, from those that are extremely well differentiated to highly anaplastic, pleomorphic lesions (Fig. 22-33B). The distinction from leiomyomas is based on nuclear atypia, mitotic index, and zonal necrosis. With few exceptions, the presence of 10 or more mitoses per 10 high-power (400×) fields indicates malignancy, particularly if accompanied by cytologic atypia and/or necrosis. If the tumor contains nuclear atypia or large (epithelioid) cells, 5 mitoses per 10 high-power (400×) fields are sufficient to justify a diagnosis of malignancy.[69] Rare exceptions include mitotically active leiomyomas in young or pregnant women, and caution should be exercised in interpreting such neoplasms as malignant. A proportion of smooth muscle neoplasms may be impossible to classify and are called smooth muscle tumors of "uncertain malignant potential."[69]

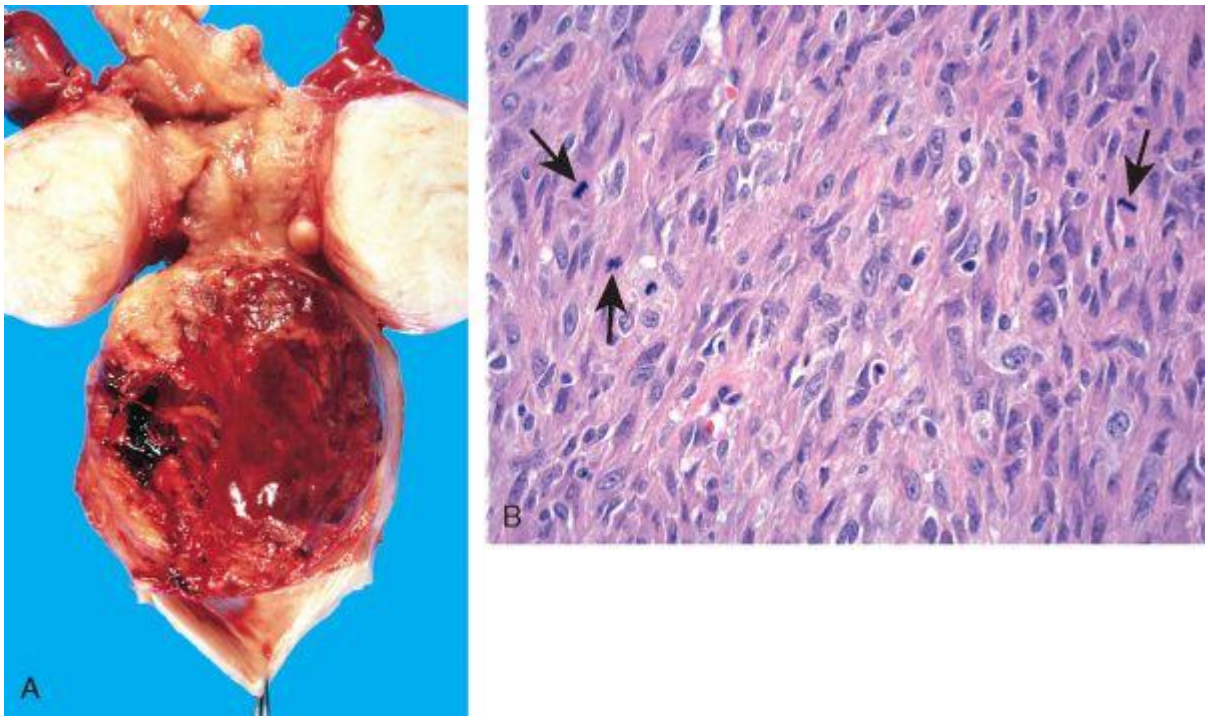

FIGURE 22-33 Leiomyosarcoma. **A**, A large hemorrhagic tumor mass distends the lower corpus and is flanked by two leiomyomas. **B**, The tumor cells are irregular in size and have hyperchromatic nuclei with numerous mitotic figures *(arrows)*.

Leiomyosarcomas are equally common before and after menopause, and have a peak incidence at 40 to 60 years of age. These tumors have a striking tendency to recur after removal, and more than half eventually metastasize through the bloodstream to distant organs, such as lungs, bone, and brain. Dissemination throughout the abdominal cavity is also encountered. The 5-year survival rate averages about 40%. The welldifferentiated lesions have a better prognosis than the anaplastic lesions, which have a 5-year survival rate of only 10% to 15%.[69]

3.12.8 Fallopian Tubes

The most common disorders in these structures are infections leading to inflammatory conditions, followed in frequency by ectopic (tubal) pregnancy (see discussion later in this chapter) and endometriosis.

3.12.8.1 Inflammations

Suppurative salpingitis may be caused by any of the pyogenic organisms; often more than one is involved. The gonococcus still accounts for more than 60% of cases of suppurative salpingitis, with chlamydiae less often a factor. These tubal infections are a part of pelvic inflammatory disease, described earlier in this chapter.

Tuberculous salpingitis is extremely uncommon in the United States and accounts for probably not more than 1% to 2% of all forms of salpingitis. It is more common, however, in parts of the world where tuberculosis is prevalent and is an important cause of infertility in these areas.

3.12.8.2 Tumors & Cysts

The most common primary lesions of the fallopian tube (excluding endometriosis) are minute, 0.1- to 2-cm translucent cysts filled with clear serous fluid, called *paratubal cysts*. Larger varieties are found near the fimbriated end of the tube or in the broad ligaments and are referred to as *hydatids of Morgagni*. These cysts are presumed to arise in remnants of the müllerian duct and are of little significance.

Tumors of the fallopian tube are uncommon. Benign tumors include *adenomatoid tumors* (mesotheliomas), which occur subserosally on the tube or sometimes in the mesosalpinx. These small nodules are the exact counterparts of those already described in relation to the testes or epididymus (Chapter 21) and are benign. Primary *adenocarcinoma* of the fallopian tubes is rare and is defined as an adenocarcinoma with a dominant tubal mass and luminal and mucosal involvement. These tumors are detected by pelvic examination, abnormal discharge, or bleeding, and occasionally, cervical cytology. Approximately one half are stage I at diagnosis, but nearly 40% of these patients do not survive 5 years. Higher stage tumors have a poorer prognosis.[70] Patients are typically managed with ovarian cancer chemotherapy protocols. Recently, occult carcinoma of the fallopian tube has been associated with germline *BRCA* mutations, as discussed below.[71]

3.12.9 Ovaries

The most common types of lesions encountered in the ovary include functional or benign cysts and tumors. Intrinsic inflammations of the ovary (oophoritis) are uncommon, and usually accompany tubal inflammation. Rarely, a primary inflammatory disorder involving ovarian follicles (autoimmune oophoritis) occurs and is associated with infertility. The ovary has three main histologic compartments: (1) the surface müllerian epithelium, (2) the germ cells, and (3) the sex cord–stromal cells. Each compartment gives rise to distinct non-neoplastic and neoplastic entities, as discussed below.

3.12.9.1 Non-Neoplastic & Functional Cysts

FOLLICLE AND LUTEAL CYSTS

Cystic follicles in the ovary are so common that they are considered virtually normal. They originate in unruptured graafian follicles or in follicles that have ruptured and immediately sealed.

Morphology. These cysts are usually multiple. They range in size up to 2 cm in diameter, are filled with a clear serous fluid, and are lined by a gray, glistening membrane. On occasion, larger cysts exceeding 2 cm (follicle cysts) may be diagnosed by palpation or ultrasonography; these may cause pelvic pain. Granulosa lining cells can be identified histologically if the intraluminal pressure has not been too great. The outer theca cells may be conspicuous due to increased amounts of pale cytoplasm (luteinized). As discussed subsequently, when this alteration is pronounced (hyperthecosis), it may be associated with increased estrogen production and endometrial abnormalities.

Granulosa **luteal cysts** (corpora lutea) are normally present in the ovary. These cysts are lined by a rim of bright yellow tissue containing luteinized granulosa cells. They occasionally rupture and cause a peritoneal reaction. Sometimes the combination of old hemorrhage and fibrosis may make their distinction from endometriotic cysts difficult.

POLYCYSTIC OVARIES AND STROMAL HYPERTHECOSIS

Polycystic ovarian disease (PCOD; formerly termed *SteinLeventhal syndrome*) affects 3% to 6% of reproductive-age women. The central pathologic abnormality is numerous cystic follicles or follicle cysts, often associated with oligomenorrhea. Women with PCOD have persistent anovulation, obesity (40%), hirsutism (50%), and, rarely, virilism.[72,][73]

Morphology. The ovaries are usually twice normal size and have a smooth, gray-white outer cortex studded with subcortical cysts 0.5 to 1.5 cm in diameter. On histologic examination, there is a thickened, fibrotic superficial cortex beneath which are innumerable follicle cysts associated with hyperplasia of the theca interna (follicular hyperthecosis) (Fig. 22-34). Corpora lutea are frequently but not invariably absent.

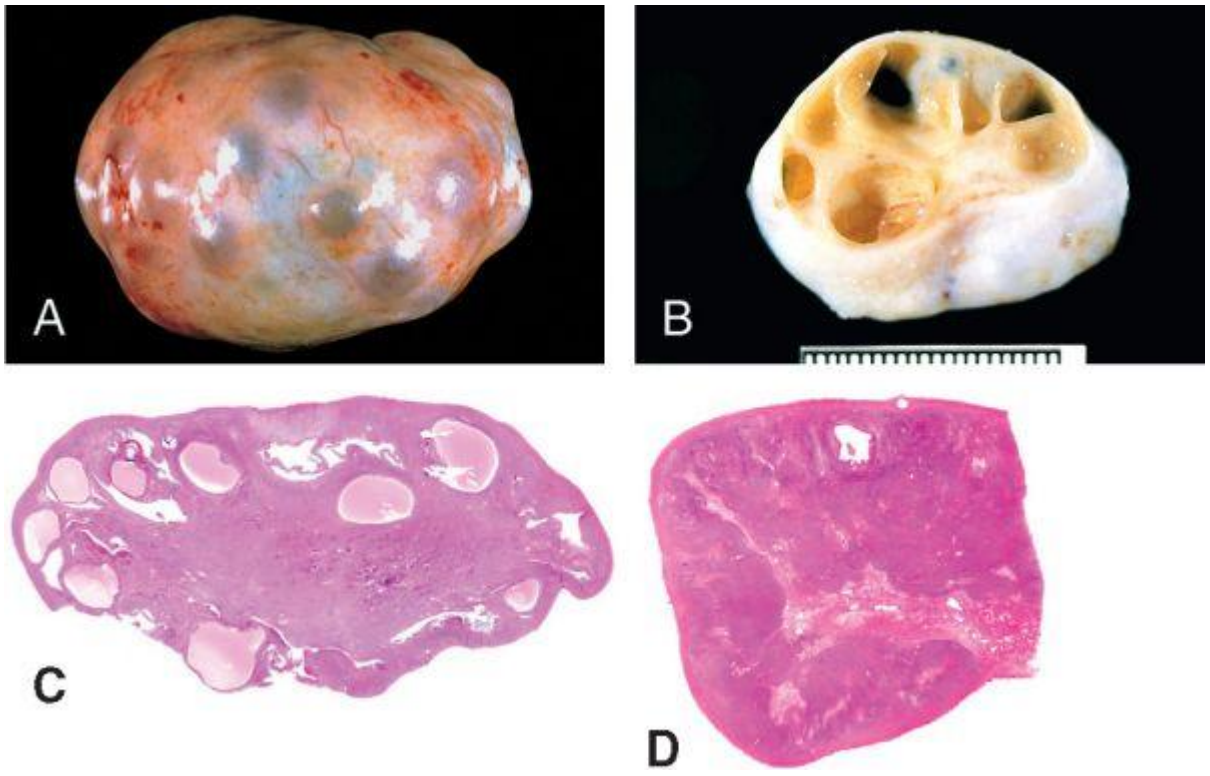

FIGURE 22-34 Polycystic ovarian disease and cortical stromal hyperplasia. **A**, The ovarian cortex reveals numerous clear cysts. **B**, Sectioning of the cortex reveals several subcortical cystic follicles. **C**, Cystic follicles seen in a low-power microphotograph. **D**, Cortical stromal hyperplasia manifests as diffuse stromal proliferation with symmetric enlargement of the ovary.

The initiating event in PCOD is not clear. Increased secretion of luteinizing hormone may stimulate the theca-lutein cells of the follicles, to produce excessive androgen (androstenedione), which is converted to estrone. For years, these endocrine abnormalities were attributed to primary ovarian dysfunction because large wedge resections of the ovaries sometimes restored fertility. It is now believed that *a variety of enzymes involved in androgen biosynthesis are poorly regulated in PCOD*. Recent studies link PCOD, like type 2 diabetes, to insulin resistance. Treatment of the insulin resistance sometimes results in resumption of ovulation.[74]

Stromal hyperthecosis, also called cortical stromal hyperplasia, is a disorder of ovarian stroma most commonly seen in postmenopausal women, but it may blend with PCOD in younger women. The disorder is characterized by uniform enlargement of the ovary (up to 7 cm), which has a white to tan appearance on sectioning. The involvement is usually bilateral and microscopically shows hypercellular stroma and luteinization of the stromal cells, which are visible as discrete nests of cells with vacuolated cytoplasm. The clinical presentation and effects on the endometrium are similar to those of PCOD, although virilization may be striking.[72]

A physiologic condition mimicking the above syndromes is *theca lutein hyperplasia of pregnancy*. In response to pregnancy hormones (gonadotropins), proliferation of theca cells and expansion of the perifollicular zone occurs. As the follicles regress, the concentric theca-lutein hyperplasia may appear nodular. This change is not to be confused with true luteomas of pregnancy (see below).

3.12.9.2 Ovarian Tumors

There are numerous types of ovarian tumors, and overall they fall into benign, borderline, and malignant categories. About 80% are benign, and these occur mostly in young women between the ages of 20 and 45 years. Borderline tumors occur at slightly older ages. Malignant tumors are more common in older women, between the ages of 45 and 65 years. Ovarian cancer accounts for 3% of all cancers in females and is the fifth most common cause of death due to cancer in women in the United States. Among cancers of the female genital tract, the incidence of ovarian cancer ranks below only carcinoma of the cervix and the endometrium. In addition, because *most ovarian cancers are detected when they have spread beyond the ovary, they account for a disproportionate number of deaths from cancer of the female genital tract*.

Classification.

The classification of ovarian tumors given in Table 22-5 and Figure 22-35 is a simplified version of the World Health Organization Histological Classification, which separates ovarian neoplasms according to the most probable tissue of origin. It is now believed that tumors of the ovary arise ultimately from one of three ovarian components: (1) surface epithelium derived from the coelomic epithelium; (2) the germ cells, which migrate to the ovary from the yolk sac and are pluripotent; and (3) the stroma of the ovary, including the sex cords, which are forerunners of the endocrine apparatus of the postnatal ovary. There is also a group of tumors that defy classification, and finally there are secondary or metastatic tumors to the ovary.

TABLE 22-5 -- WHO Classification of Ovarian Neoplasms

SURFACE EPITHELIAL-STROMAL TUMORS
Serous tumors
Benign (cystadenoma)
Borderline tumors (serous borderline tumor)
Malignant (serous adenocarcinoma)
Mucinous tumors, endocervical-like and intestinal type
Benign (cystadenoma)
Borderline tumors (mucinous borderline tumor)
Malignant (mucinous adenocarcinoma)
Endometrioid tumors
Benign (cystadenoma)
Borderline tumors (endometrioid borderline tumor)
Malignant (endometrioid adenocarcinoma)
Clear cell tumors
Benign
Borderline tumors
Malignant (clear cell adenocarcinoma)
Transitional cell tumors
Brenner tumor
Brenner tumor of borderline malignancy

- Malignant Brenner tumor
- Transitional cell carcinoma (non-Brenner type)
- Epithelial-stromal
  - Adenosarcoma
  - Malignant mixed müllerian tumor

SEX CORD–STROMAL TUMORS

- Granulosa tumors
- Fibromas
- Fibrothecomas
- Thecomas
- Sertoli cell tumors
- Leydig cell tumors
- Sex cord tumor with annular tubules
- Gynandroblastoma
- Steroid (lipid) cell tumors

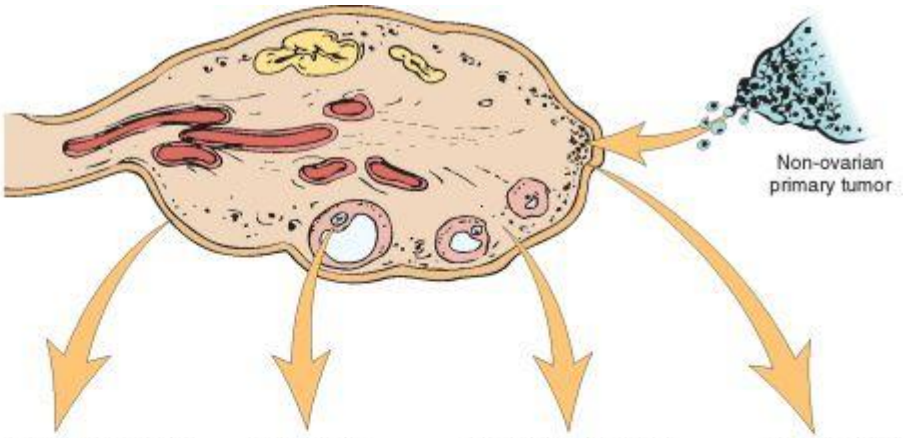
GERM CELL TUMORS

- Teratoma
  - Immature
  - Mature
    - Solid
    - Cystic (dermoid cyst)
  - Monodermal (e.g., struma ovarii, carcinoid)
- Dysgerminoma
- Yolk sac tumor (endodermal sinus tumor)
- Mixed germ cell tumors

MALIGNANT, NOT OTHERWISE SPECIFIED

METASTATIC CANCER FROM NONOVARIAN PRIMARY

- Colonic, appendiceal
- Gastric
- Breast



ORIGIN	SURFACE EPITHELIAL CELLS (Surface epithelial–stromal cell tumors)	GERM CELL	SEX CORD–STROMA	METASTASIS TO OVARIES
Overall frequency	65–70%	15–20%	5–10%	5%
Proportion of malignant ovarian tumors	90%	3–5%	2–3%	5%
Age group affected	20+ years	0–25+ years	All ages	Variable
Types	• Serous tumor • Mucinous tumor • Endometrioid tumor • Clear cell tumor • Brenner tumor • Cystadenofibroma	• Teratoma • Dysgerminoma • Endodermal sinus tumor • Choriocarcinoma	• Fibroma • Granulosa–theca cell tumor • Sertoli–Leydig cell tumor	

FIGURE 22-35 Derivation of various ovarian neoplasms and some data on their frequency and age distribution.

Although some of the specific tumors have distinctive features and are hormonally active, most are nonfunctional and tend to produce relatively mild symptoms until they reach a large size. Malignant tumors have usually spread outside the ovary by the time a definitive diagnosis is made. Some of these tumors, principally epithelial tumors, tend to be bilateral. Table 22-6 lists the tumors and their subtypes. Abdominal pain and distention, urinary and gastrointestinal tract symptoms due to compression by the tumor or cancer invasion, and vaginal bleeding are the most common symptoms. The benign forms may be entirely asymptomatic and occasionally are found unexpectedly on abdominal or pelvic examination or during surgery.

TABLE 22-6 -- Frequency of Major Ovarian Tumors

Type	Percentage of Malignant Ovarian Tumors	Percentage That Are Bilateral
Serous		
Benign (60%)		25
Borderline (15%)		30
Malignant (25%)	45	65
Mucinous		
Benign (80%)		5
Borderline (10%)		10

Type	Percentage of Malignant Ovarian Tumors	Percentage That Are Bilateral
Malignant (10%)	5	<5
Endometrioid carcinoma	20	40
Undifferentiated carcinoma	10	—
Clear cell carcinoma	6	40
Granulosa cell tumor	5	5
Teratoma		15
Benign (96%)		
Malignant (4%)	1	Rare
Metastatic	5	>50
Others	3	—

TUMORS OF SURFACE (MÜLLERIAN) EPITHELIUM

Most primary neoplasms in the ovary fall within this category. The classification of epithelial tumors of the ovary is based on both differentiation and extent of proliferation of the epithelium. There are *three major histologic types based on the differentiation of the neoplastic epithelium: serous, mucinous, and endometrioid tumors*.[75] The extent of epithelial proliferation is associated with the biologic behavior of the tumor and is classified as benign (minimal epithelial proliferation), borderline (moderate epithelial proliferation), and malignant (marked epithelial proliferation with stromal invasion). The benign tumors are often further classified based on the components of the tumors, which may include cystic areas (cystadenomas), cystic and fibrous areas (cystadenofibromas), and predominantly fibrous areas (adenofibromas). The borderline tumors and the malignant tumors can also have a cystic component, and when malignant they are sometimes referred to as cystadenocarcinomas. The tumors can be relatively small, or they can grow to fill the entire pelvis before they are detected.

The origin of ovarian epithelial tumors is, at present, unresolved. This is in large part because most tumors are detected relatively late, interfering with the identification of a precursor lesion. The most widely accepted theory for the derivation of müllerian epithelial tumors is the transformation of coelomic epithelium. This view is based on the embryologic pathway by which the müllerian *ducts are formed from the coelomic epithelium and evolve into serous (tubal), endometrioid (endometrial), and mucinous (cervical)* epithelia present in the normal female genital tract. Such tumors are thought to occur predominantly in the ovary, because coelomic epithelium is incorporated into the ovarian cortex to form epithelial inclusion cysts (also known as mesothelial, cortical, or germinal inclusion cysts) (Fig. 22-36). The exact mechanism by which the cysts develop is not known, but they are thought to result from invaginations of the surface epithelium that subsequently loses its connection to the surface.[76] The cysts are most often lined by either mesothelial or tubal-type epithelium. The close association of ovarian carcinomas with either the ovarian surface epithelium or inclusion cysts may explain the development of extra-ovarian carcinomas of similar histology from coelomic epithelial rests (so-called endosalpingiosis) in the mesentery.[75] However, this is clearly an oversimplification of the pathogenesis of ovarian cancer.

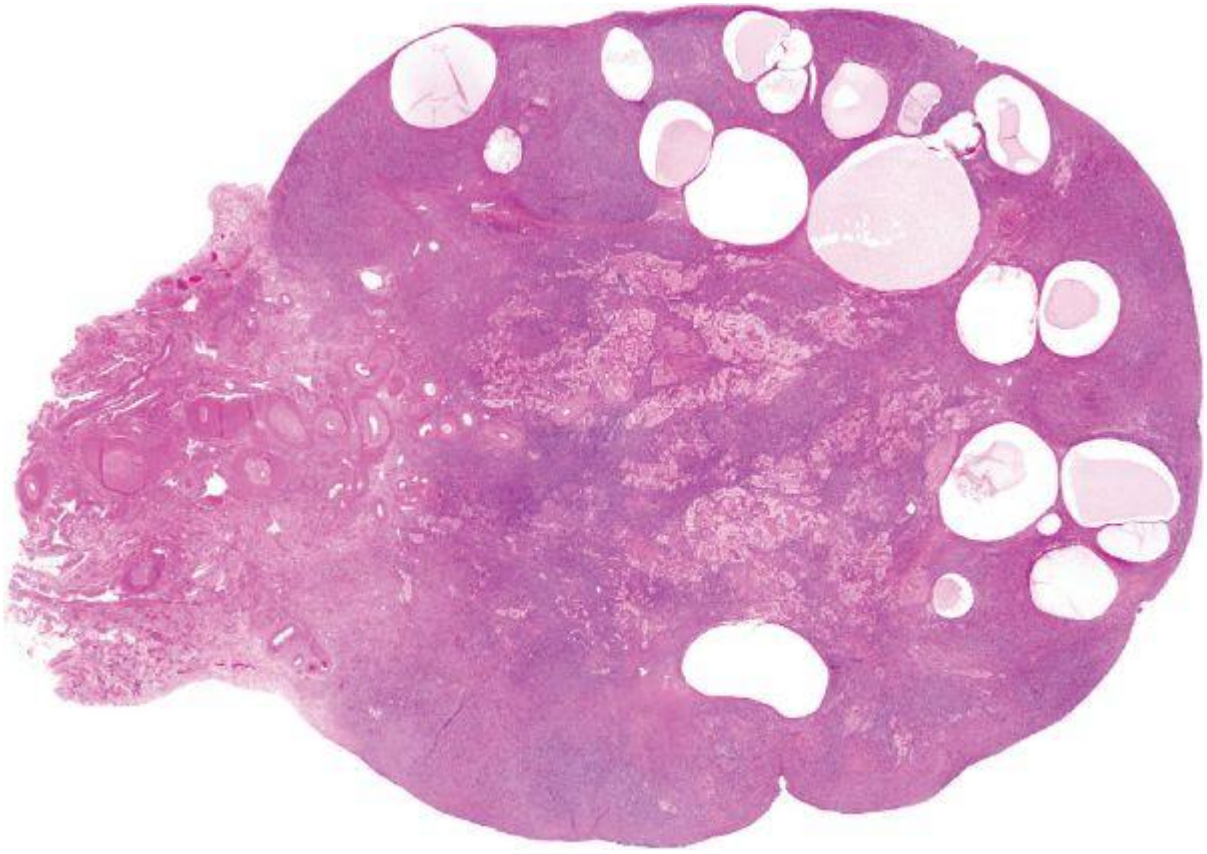


FIGURE 22-36 Cortical inclusion cysts of the ovary. These cysts appear to arise from the overlying mesothelium and are presumed to be the site of origin for many ovarian epithelial neoplasms.

Regardless of their specific origin(s), ovarian epithelial tumors composed of serous, mucinous, and endometrioid cell types are emblematic of the plasticity of müllerian epithelium and range from clearly benign to malignant tumors.[75] Several recent studies have suggested that ovarian carcinomas may be broadly categorized into two different types based on pathogenesis: (1) those that arise in association with borderline tumors, and (2) those that arise as "de novo" carcinomas. Clinicopathologic studies have shown that well-differentiated serous, endometrioid, and mucinous carcinomas often contain areas of borderline tumors of the same epithelial cell type, whereas this association is rarely seen for moderately to poorly differentiated serous carcinoma or MMMTs. Recent molecular studies have provided support for this classification scheme, as will be discussed below in the relevant sections.

Serous Tumors

These common *cystic neoplasms are lined by tall, columnar, ciliated and nonciliated epithelial cells* and are filled with clear serous fluid. Although the term *serous* appropriately describes the cyst fluid, it has become synonymous with the tubal-like epithelium in these tumors. Together the benign, borderline, and malignant types account for about 30% of all ovarian tumors and just over 50% of ovarian epithelial tumors. About 70% are benign or borderline, and 30% are malignant. *Serous carcinomas account for approximately 40% of all cancers of the ovary and are the most common malignant ovarian tumors*. Benign and borderline tumors are most common between the ages of 20 and 45 years. Serous carcinomas occur later in life on average, though somewhat earlier in familial cases.

Molecular Pathogenesis.

Little is known about the risk factors for the development of the benign and borderline tumors. Risk factors for malignant serous tumors (serous carcinomas) are also much less clear than for other genital tumors, but nulliparity, family history, and heritable mutations play a role in tumor development.[71,][77] There is a higher frequency of carcinoma in women with low parity. Gonadal dysgenesis in children is associated with a higher risk of ovarian cancer. Women 40 to 59 years of age who have taken oral contraceptives or undergone tubal ligation have a reduced risk of developing ovarian cancer.[78,][79] The most intriguing risk factors are genetic. As discussed in Chapters 7 and 23 , mutations in both *BRCA1* and *BRCA2* increase susceptibility to ovarian cancer.[71,][77] *BRCA1* mutations occur in about 5% of patients younger than 70 years of age with ovarian cancer. The estimated risk of ovarian cancer in women bearing *BRCA1* or *BRCA2* mutations is 20% to 60% by the age of 70 years.[77]

Based on both clinicopathologic and molecular studies it has recently been proposed that serous ovarian carcinoma be divided into two major groups: (1) low-grade (welldifferentiated) carcinoma and (2) high-grade (moderately to poorly differentiated) carcinoma. This distinction can be made on the basis of nuclear atypia and correlates with patient survival.[80] Some low-grade carcinomas arise in association with serous borderline tumors, while most high-grade carcinomas appear to arise “de novo” without a recognizable precursor lesion.[81]

Molecular studies of low- and high-grade serous carcinoma have revealed distinct molecular genetic changes in the two types of carcinoma.[82] The low-grade tumors arising in serous borderline tumors have mutations in the *KRAS* or *BRAF* oncogenes, with only rare mutations in *p53*. In contrast, the high-grade tumors have a high frequency of mutations in the *p53* gene but lack mutations in either *KRAS* or *BRAF*. Almost all reported cases of ovarian carcinomas arising in women with *BRCA1* or *BRCA2* mutations are high-grade serous carcinoma and commonly have *p53* mutations. Close examination of these tumors has suggested that *a significant percentage of BRCA1- and BRCA2-related tumors arise from the epithelium lining the fimbriated end of the fallopian tube*. This finding has led investigators to speculate that at least some sporadic high-grade ovarian and so-called *primary peritoneal* serous carcinomas may also originate from the distal fallopian tube, an area of current investigation.

Morphology. The characteristic serous tumor may present on gross examination as either a cystic lesion in which the papillary epithelium is contained within a few fibrous walled cysts (intracystic) (Fig. 22-37A), or projecting from the ovarian surface. Benign tumors typically present with a smooth glistening cyst wall with no epithelial thickening or with small papillary projections. Borderline tumors contain an increased number of papillary projections (Fig. 22-37A and C). Bilaterality is common, occurring in 20% of benign serous cystadenomas, 30% of serous borderline tumors, and approximately 66% of serous carcinomas. A significant proportion of both serous borderline tumors and malignant serous tumors involve (or originate from) the surface of the ovary (Fig. 22-37C). On histologic examination, the cysts are lined by columnar epithelium, which has abundant cilia in benign tumors (Fig. 22-38A). Microscopic papillae may be found. Serous borderline tumors exhibit increased complexity of the stromal papillae, stratification of the epithelium and mild nuclear atypia, but destructive infiltrative growth into the stroma is not seen (Fig. 22-38B).[75] This epithelial proliferation often grows in a delicate, papillary pattern referred to as “micropapillary carcinoma” and is thought to be the precursor to low-grade serous carcinoma (Fig. 22-38C). Larger amounts of solid or papillary tumor mass, irregularity in the tumor mass, and fixation or nodularity of the capsule are important indicators of probable malignancy (see Fig. 22-37B). These features are characteristic of high-grade serous carcinoma, which microscopically exhibits even more complex growth patterns and infiltration or frank effacement of the underlying stroma (Fig. 22-38D). The individual tumor cells in the high-grade carcinomas display marked

nuclear atypia, including pleomorphism, atypical mitotic figures, and multinucleation. The cells may even become so undifferentiated that serous features are no longer recognizable. Concentric calcifications (psammoma bodies) characterize serous tumors, but are not specific for neoplasia. Ovarian serous tumors, both low- and high-grade, have a propensity to spread to the peritoneal surfaces and omentum and are commonly associated with the presence of ascites. As with other tumors, the extent of the spread outside the ovary determines the stage of the disease.

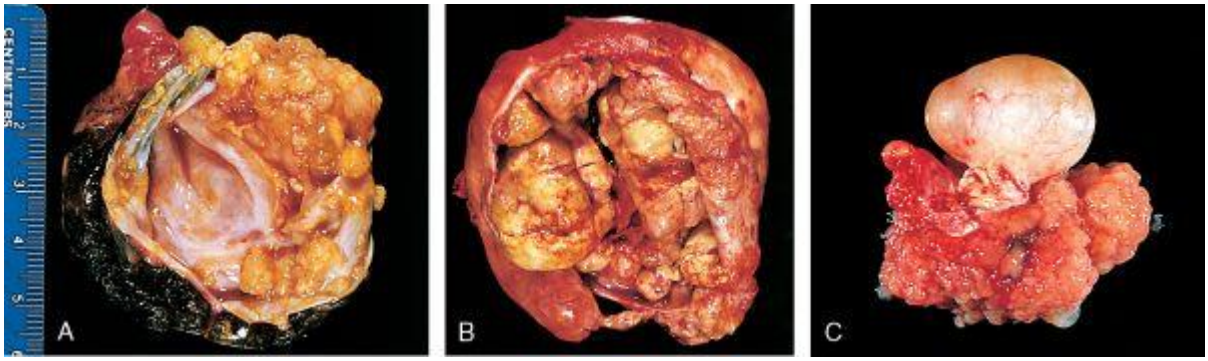

FIGURE 22-37 **A**, Serous borderline tumor opened to display a cyst cavity lined by delicate papillary tumor growths. **B**, Cystadenocarcinoma. The cyst is opened to reveal a large, bulky tumor mass. **C**, Another borderline tumor growing on the ovarian surface *(lower)*.

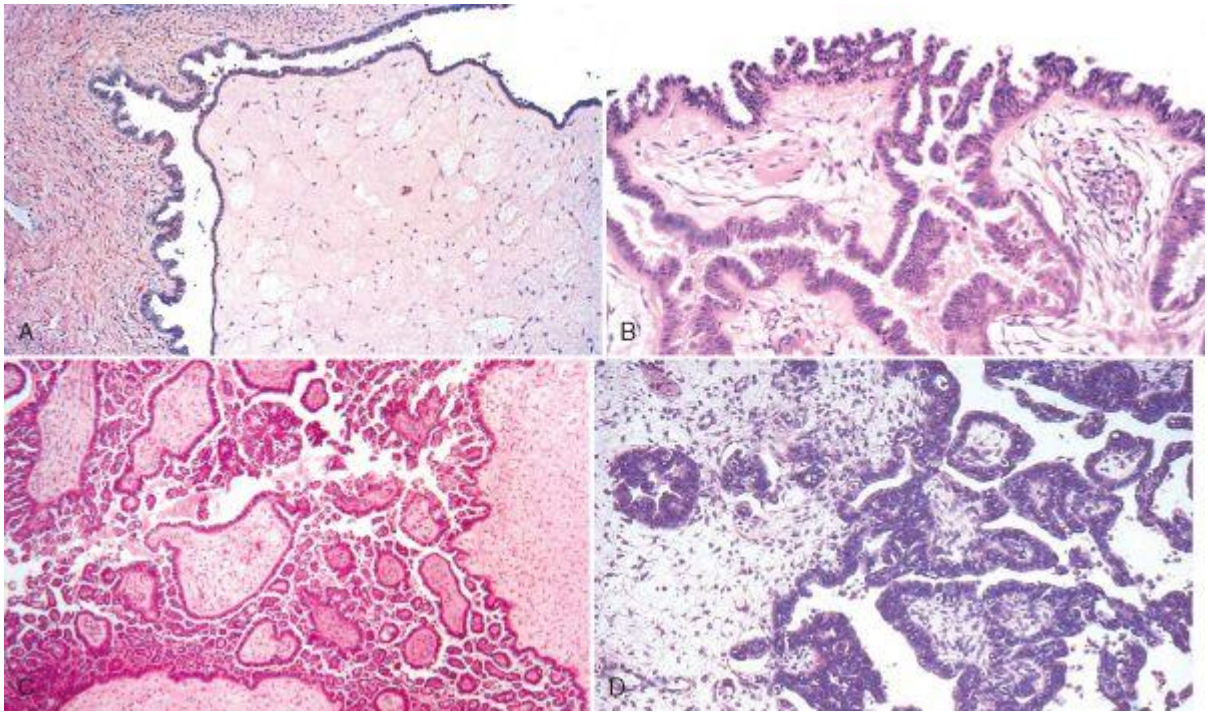

FIGURE 22-38 Serous cystadenomas. **A**, Papillary serous cystadenoma revealing stromal papillae with a columnar epithelium. **B**, Borderline serous tumor showing increased architectural complexity and epithelial cell stratification. **C**, Complex micropapillary growth defines a low-grade "micropapillary" serous carcinoma. **D**, Papillary serous cystadenocarcinoma of the ovary with invasion of underlying stroma.

The biologic behavior of serous tumors depends on degree of differentiation, distribution, and characteristics of the disease in the peritoneum, if present. Importantly, serous tumors may occur on the surface of the ovaries and, rarely, as primary tumors of the peritoneal surface, which are referred to as primary peritoneal serous carcinoma. Predictably, unencapsulated serous tumors of the ovarian surface are more likely to extend to the peritoneal surfaces, and prognosis is closely related to the histologic appearance of the tumor and its growth pattern on the peritoneum. Borderline serous tumors may arise from or extend to the peritoneal surfaces as noninvasive implants, remaining localized and causing no symptoms, or slowly spread, producing intestinal obstruction or other complications after many years. As discussed above, low-grade serous carcinomas can arise in borderline serous tumors and may be associated with what are often referred to as "invasive implants" because they demonstrate destructive, infiltrative growth, similar to metastatic carcinoma. However, the low-grade carcinomas even when spread outside the ovary often progress slowly, and patients may survive for relatively long periods before dying of disease. In contrast, high-grade tumors are often widely metastatic throughout the abdomen at the time of presentation. These findings are associated with rapid clinical deterioration.[75] Consequently, careful pathologic classification of the tumor, even if it has extended to the peritoneum, is relevant to both prognosis and selection of therapy.[75,][83] The 5-year survival rate for borderline and malignant tumors confined within the ovarian mass is, respectively, 100% and 70%, whereas the 5-year survival rate for the same tumors involving the peritoneum is about 90% and 25%, respectively. Because of their protracted course, borderline tumors may recur after many years, and 5-year survival is not synonymous with cure.[75]

Mucinous Tumors

Mucinous tumors are less common than serous tumors, *accounting for about 30% of all ovarian neoplasms*. They occur principally in middle adult life and are rare before puberty and after menopause. *Eighty percent are benign or borderline, and about 15% are malignant*. Primary ovarian mucinous carcinomas are relatively uncommon and account for fewer than 5% of all ovarian cancers.

Molecular Pathogenesis.

Like serous tumors, little is known about the pathogenesis of mucinous ovarian tumors. Most of the studies analyzing risk factors have not segregated the different histologic types of ovarian cancer, so it is not clear how they relate to the individual types. However, recent studies have suggested that mucinous tumors may have different risk factors, including smoking, which is not a risk factor for serous ovarian tumors. Although several molecular studies have been done over the years, very few molecular genetic alterations have been identified in mucinous tumors. The one consistent alteration that has been identified is mutation of the *KRAS* proto-oncogene. Mutations in *KRAS* are common in benign mucinous cystadenomas (58%), mucinous borderline tumors (75% to 86%), and in primary ovarian mucinous carcinomas (85%).[84,][85] Interestingly, one study showed that several tumors with distinct areas of epithelium showing benign, borderline, and carcinoma had identical *KRAS* mutations from each area.[85] Thus, *KRAS* mutations may occur early in the development of these neoplasms.

Morphology. In gross appearance, the mucinous tumors differ from the serous variety in several ways. They are characterized by rarity of surface involvement and are less frequently bilateral. Only 5% of primary mucinous cystadenomas and mucinous cystadenocarcinomas are bilateral. Mucinous tumors tend to produce larger cystic masses; some have been recorded with weights of more than 25 kg. They appear grossly as multiloculated tumors filled with sticky, gelatinous fluid rich in glycoproteins (Fig. 22-39A). On histologic examination, benign mucinous tumors are characterized

by a lining of tall, columnar epithelial cells with apical mucin and the absence of cilia, akin to benign cervical or intestinal epithelia (Fig. 22-39B). One group of typically benign or borderline mucinous tumors arises in endometriosis and is termed *müllerian mucinous cystadenoma*, resembling endometrial or cervical epithelium.[75] The second, more common group includes tumors showing abundant glandlike or papillary growth with nuclear atypia and stratification, an appearance strikingly similar to tubular adenomas or villous adenomas of the intestine. These tumors are presumed precursors to most cystadenocarcinomas. Cystadenocarcinomas contain areas of solid growth and conspicuous epithelial cell atypia and stratification, loss of gland architecture, and necrosis; these tumors are similar to colonic cancer in appearance. Because both borderline and malignant mucinous cystadenomas form complex glands in the stroma, the documentation of clear-cut stromal invasion, which is easily ascertained in serous tumors, is more difficult. Some authors describe a category of "noninvasive" mucinous carcinomas (intraepithelial carcinomas) for those tumors with marked epithelial atypia without obvious stromal alterations.[86] Approximate 10-year survival rates for stage I, noninvasive "intraepithelial carcinomas," and frankly invasive malignant tumors are greater than 95% and 90%, respectively.[87] Mucinous carcinomas that have spread beyond the ovary are usually fatal, but as previously stated, these tumors are uncommon.

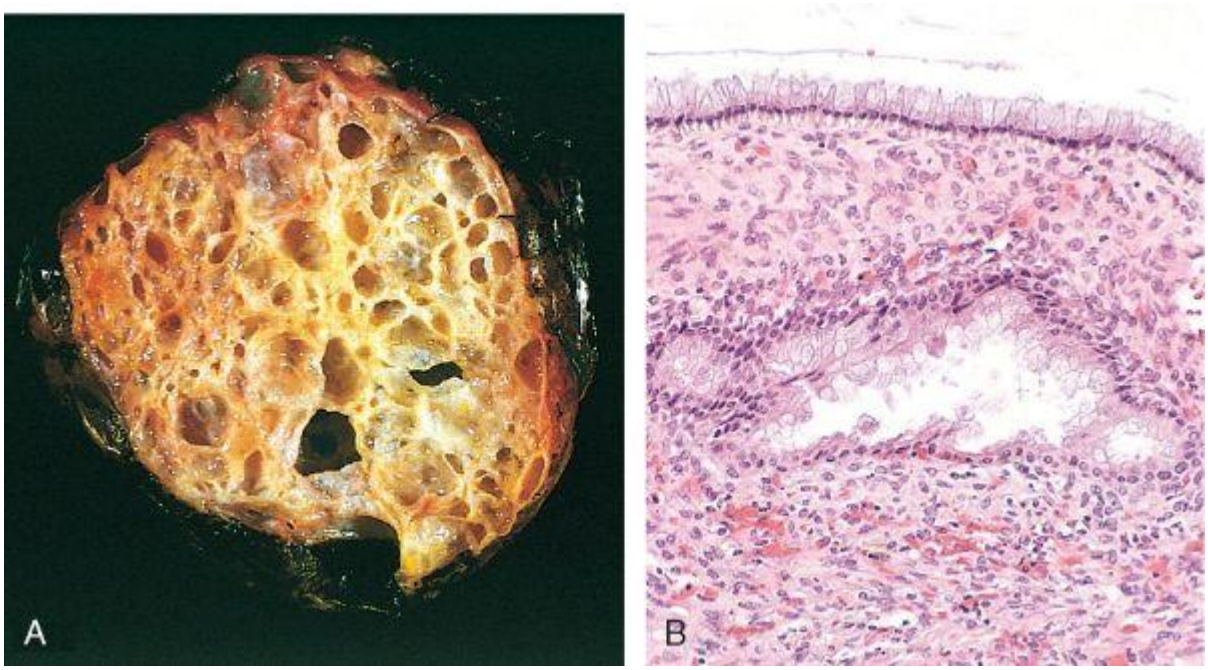

FIGURE 22-39 **A**, A mucinous cystadenoma with its multicystic appearance and delicate septa. Note the presence of glistening mucin within the cysts. **B**, Columnar cell lining of mucinous cystadenoma.

A clinical condition referred to as *pseudomyxoma peritonei* is defined by extensive mucinous ascites, cystic epithelial implants on the peritoneal surfaces, adhesions, and frequently mucinous tumor involving the ovaries (Fig. 22-40). Pseudomyxoma peritonei, if extensive, may result in intestinal obstruction and death. Historically, it was thought that many cases of pseudomyxoma peritonei in women were due to primary ovarian mucinous neoplasms. However, recent evidence points to the presence, in most cases, of extraovarian (usually appendiceal) primary mucinous tumor with secondary ovarian and peritoneal spread (Chapter 17).[88] Because the majority of primary mucinous ovarian

tumors are unilateral, bilateral presentation of mucinous tumors always requires exclusion of a non-ovarian origin.

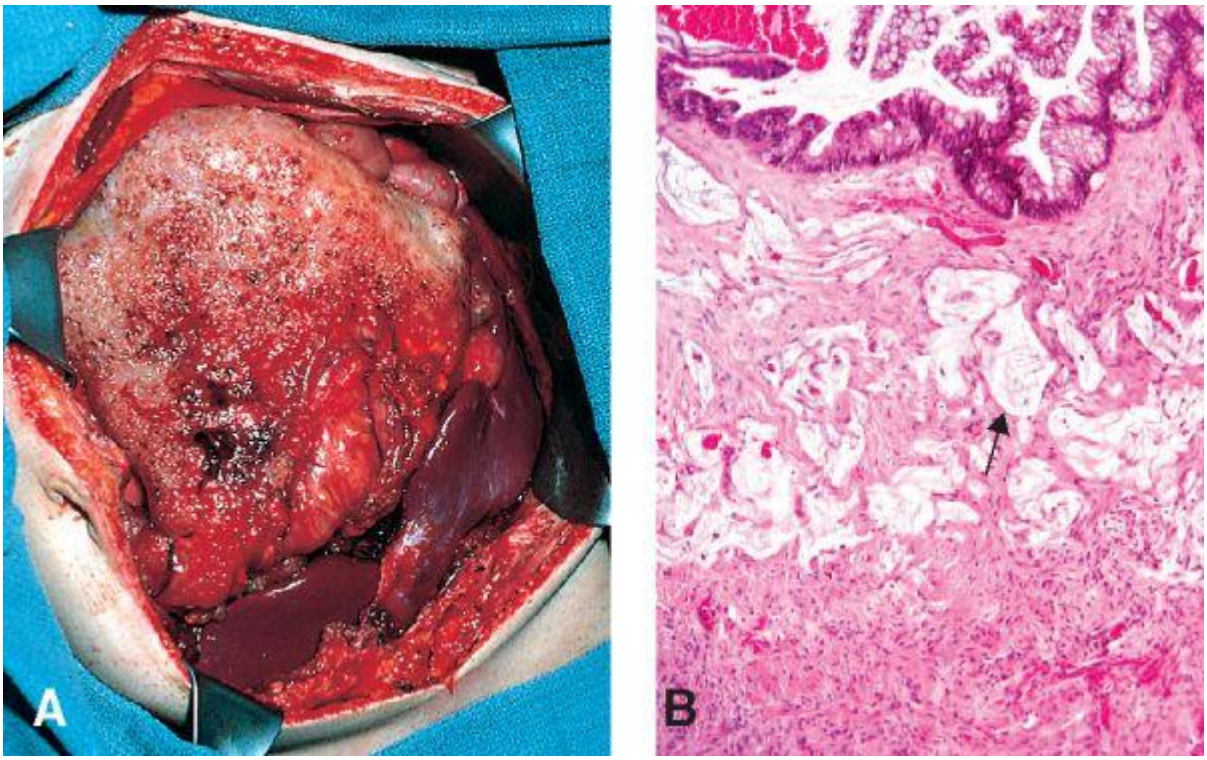

FIGURE 22-40 **A**, Pseudomyxoma peritonei viewed at laparotomy revealing massive overgrowth of a gelatinous metastatic tumor originating from the appendix. **B**, Histology of peritoneal implants from an appendiceal tumor, showing mucin-producing epithelium and free mucin *(arrow). (**A**, Courtesy of Dr. Paul H. Sugarbaker, Washington Hospital Cancer Center, Washington, DC.)*

Endometrioid Tumors

Benign endometrioid tumors, called *endometrioid adenofibromas*, and borderline endometrioid tumors are uncommon. However, *endometrioid carcinomas account for approximately 20% of all ovarian cancers*. Endometrioid tumors are distinguished from serous and mucinous tumors by the presence of tubular glands bearing a close resemblance to benign or malignant endometrium. Endometrioid carcinomas may arise in the setting of endometriosis and are occasionally associated with areas of borderline tumor. Although these tumors are less common than either serous or mucinous tumors, more is known about the molecular genetic alterations associated with their development. This is due to the recent development of mouse models that closely mimic the human disease and molecular genetic overlap with endometrioid carcinomas of the endometrium. In fact, 15% to 30% of ovarian endometrioid carcinomas are accompanied by carcinoma of the endometrium, and the relatively good prognosis in such cases suggests that the two may arise independently rather than by metastatic spread from one another.[89]

Pathogenesis.

About 15% to 20% of cases with endometrioid carcinoma coexist with endometriosis, although an origin directly from ovarian surface epithelium is also possible. The women with associated endometriosis are usually about a decade younger than women with endometrioid carcinoma that is not associated with

endometriosis. Molecular studies have found relatively frequent mutations in the *PTEN tumor suppressor gene and in the KRAS and β-catenin oncogenes, as well as microsatellite instability*.[90] Similar to endometrioid carcinomas of the endometrium, *p53* mutations are common in the poorly differentiated tumors. Interestingly, in endometrioid carcinomas associated with endometriosis, identical *PTEN* mutations have been detected in both the carcinoma and the endometriosis, suggesting that *PTEN* mutations may precede the development of malignancy.[91]

Morphology. In gross appearance, endometrioid carcinomas present as a combination of solid and cystic areas, similar to other cystadenocarcinomas. Forty percent involve both ovaries, and such bilaterality usually, though not always, implies extension of the neoplasm beyond the genital tract. These are low-grade tumors that reveal glandular patterns bearing a strong resemblance to those of endometrial origin. The 5-year survival rate for patients with stage I tumors is approximately 75%.

Clear Cell Adenocarcinoma

Benign and borderline clear cell tumors are exceedingly rare, and clear cell carcinomas are uncommon. They are characterized by large epithelial cells with abundant clear cytoplasm similar to hypersecretory gestational endometrium. Because these tumors sometimes occur in association with endometriosis or endometrioid carcinoma of the ovary and resemble clear cell carcinoma of the endometrium, they are now thought to be of müllerian origin and variants of endometrioid adenocarcinoma.[75] Little is currently known about the molecular alterations that underlie the pathogenesis of these tumors. The clear cell tumors of the ovary can be predominantly solid or cystic. In the solid neoplasm, the clear cells are arranged in sheets or tubules. In the cystic variety, the neoplastic cells line the spaces. The 5-year survival rate is approximately 65% when the tumors are confined to the ovaries; however, these tumors tend to be aggressive, and with spread beyond the ovary, a survival of 5 years is exceptional.

Cystadenofibroma

Cystadenofibromas are variants in which there is more pronounced proliferation of the fibrous stroma that underlies the columnar lining epithelium. These benign tumors are usually small and multilocular and have simple papillary processes that do not become as complicated and branching as those found in the ordinary cystadenoma. They may be composed of mucinous, serous, endometrioid, and transitional (Brenner tumors) epithelium. Borderline lesions with cellular atypia and, rarely, tumors with focal carcinoma occur, but metastatic spread of either is extremely uncommon.

Brenner Tumor

Brenner tumors are classified as *adenofibromas in which the epithelial component consists of nests of transitional-type epithelial cells resembling those lining the urinary bladder*. Less frequently, the nests contain microcysts or glandular spaces lined by columnar, mucin-secreting cells.

Morphology. These neoplasms may be solid or cystic, are usually unilateral (approximately 90%), and vary in size from small lesions less than 1 cm in diameter to massive tumors up to 20 and 30 cm (Fig. 22-41A). The fibrous stroma, resembling that of the normal ovary, is marked by sharply demarcated nests of epithelial cells resembling the epithelium of the urinary tract, often with mucinous glands in their center (Fig. 22-41B). Infrequently, the stroma is composed of somewhat plump fibroblasts resembling theca cells; such neoplasms may have hormonal activity. Most Brenner tumors are benign, but borderline (proliferative Brenner tumor) and malignant counterparts have been

reported.

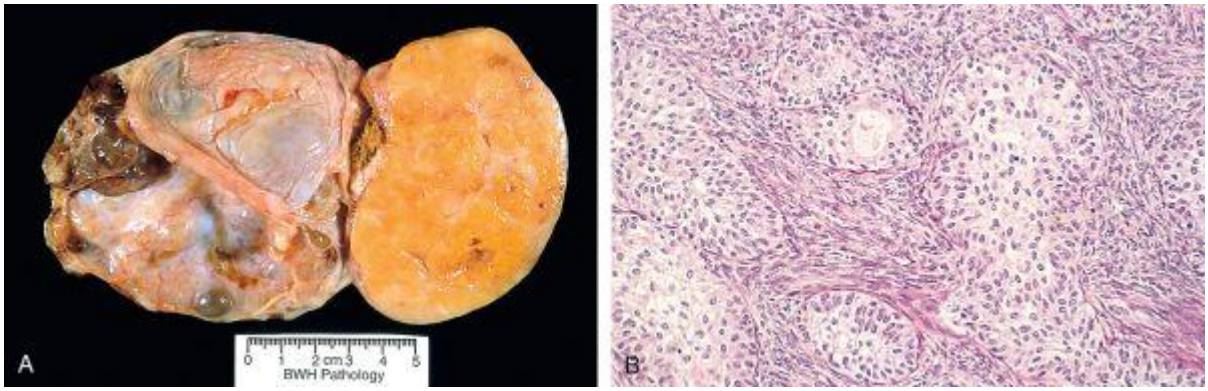

FIGURE 22-41 **A**, Brenner tumor *(right)* associated with a benign cystic teratoma *(left)*. **B**, Histologic detail of characteristic epithelial nests within the ovarian stroma. *(Courtesy of Dr. M. Nucci, Brigham and Women's Hospital, Boston, MA.)*

Several reports have emphasized the occurrence of ovarian tumors that are composed in part or entirely of neoplastic epithelium similar to transitional carcinoma of the bladder but without a coexisting Brenner component. Though often referred to as *transitional cell carcinoma*, these tumors are frequently seen in association with conventional serous or endometrioid carcinomas and probably represent altered differentiation patterns of the tumor cells.

Clinical Course, Detection, and Prevention of Surface Epithelial Tumors

All ovarian epithelial carcinomas produce similar clinical manifestations, most commonly lower abdominal pain and abdominal enlargement. Gastrointestinal complaints, urinary frequency, dysuria, pelvic pressure, and many other symptoms may appear. Benign lesions are easily resected and cured. The malignant forms tend to cause progressive weakness, weight loss, and cachexia characteristic of all malignant neoplasms. If the carcinomas extend through the capsule of the tumor to seed the peritoneal cavity, massive ascites is common. Characteristically, the ascitic fluid is filled with diagnostic exfoliated tumor cells. The peritoneal pattern of spread is distinctive: all serosal surfaces are diffusely seeded with 0.1- to 0.5-cm nodules of tumor. These surface implants rarely invade deeply into the underlying parenchyma. The regional nodes are often involved, and metastases may be found in the liver, lungs, gastrointestinal tract, and elsewhere. Metastasis across the midline to the opposite ovary is discovered in about half the cases by the time of laparotomy and heralds a progressive downhill course to death within a few months or years.

Because ovarian carcinomas often remain undiagnosed until they are large, or originate on the ovarian surface from where they readily spread to the pelvis, many patients are first seen with lesions that are no longer confined to the ovary. This is perhaps the primary reason for the relatively *poor 5- and 10-year survival rates* for these patients, compared with rates in cervical and endometrial carcinoma. For these reasons, both early diagnosis and prevention are top priorities. Specific biochemical markers for tumor antigens or tumor products in the plasma of these patients are being sought vigorously. One such marker, known as CA-125, is a high-molecular-weight glycoprotein present in the serum of more than 80% of patients with serous and endometrioid carcinomas. Although this marker is often used to monitor disease progression after diagnosis, it has not proven to be a reliable marker because elevations in CA-

125 can occur with nonspecific irritation of the peritoneum (e.g., endometriosis, inflammation).[92] Newly identified biomarkers such as osteopontin, which is expressed at significantly higher levels in ovarian cancer patients, may improve early detection.[93] Other attempts to distinguish cancer patients from nonaffected individuals are based on patterns of circulating proteins generated by mass spectroscopic analysis of patient sera.[94] These and other approaches may in the future create a more cost-effective, noninvasive approach to ovarian cancer screening.

Prevention of ovarian cancer remains an elusive goal, but both fallopian tubal ligation and oral contraceptive therapy are associated with significant reductions in relative risk. Long-term contraceptive use has reduced risk by half in women with a family history of ovarian cancer.[78] Tubal ligation reduces risk by more than half and may be effective in subsets of women with *BRCA* mutations and family history of ovarian cancer.[77,][79,][95] Screening strategies based on identifying women at risk (positive for *BRCA* mutations) and using prophylactic salpingo-oophorectomy are currently standard, but the long-term impact of these approaches on ovarian cancer death rates remains to be determined.

GERM CELL TUMORS

Germ cell tumors constitute 15% to 20% of all ovarian tumors.[75] *Most are benign cystic teratomas*, but the remainder, which are found principally in children and young adults, have a higher incidence of malignant behavior and pose problems in histologic diagnosis and in therapy. They bear a remarkable similarity to germ cell tumors in the male testis (Chapter 21) and arise in a similar manner (Fig. 22-42).

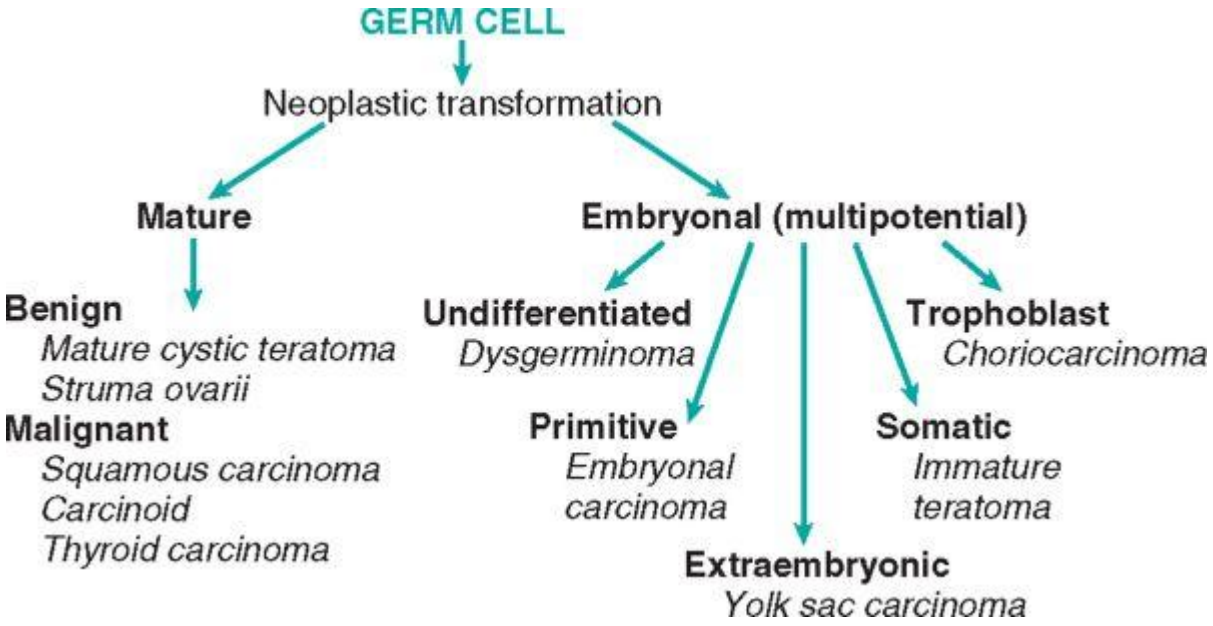

FIGURE 22-42 Histogenesis and interrelationships of tumors of germ cell origin.

Teratomas

Teratomas are divided into three categories: (1) mature (benign), (2) immature (malignant), and (3) monodermal or highly specialized.

Mature (Benign) Teratomas.

Most benign teratomas are cystic and are better known in clinical parlance as *dermoid cysts*. Cystic teratomas are usually found in young women during the active reproductive years.[75] They may be discovered incidentally, but are occasionally associated with clinically important paraneoplastic syndromes, such as inflammatory limbic encephalitits, which may remit upon removal of the tumor.

Morphology. Benign teratomas are bilateral in 10% to 15% of cases. Characteristically they are unilocular cysts containing hair and cheesy sebaceous material (Fig. 22-43). On section, they reveal a thin wall lined by an opaque, gray-white, wrinkled epidermis. From this epidermis, hair shafts frequently protrude. Within the wall, it is common to find tooth structures and areas of calcification.

On histologic examination the cyst wall is composed of stratified squamous epithelium with underlying sebaceous glands, hair shafts, and other skin adnexal structures (Fig. 22-44). In most cases structures from other germ layers can be identified, such as cartilage, bone, thyroid tissue, and neural tissues. Dermoid cysts are sometimes incorporated within the wall of a mucinous cystadenoma. **About 1% of the dermoids undergo malignant transformation (e.g., thyroid carcinoma, melanoma, but most commonly, squamous cell carcinoma)**.

In rare instances a benign teratoma is solid and composed entirely of benign-looking heterogeneous collections of tissues and organized structures derived from all three germ layers. These tumors presumably have the same histogenetic origin as dermoid cysts but lack preponderant differentiation into ectodermal derivatives. These neoplasms may be difficult to differentiate, on gross inspection, from the malignant, immature teratomas.

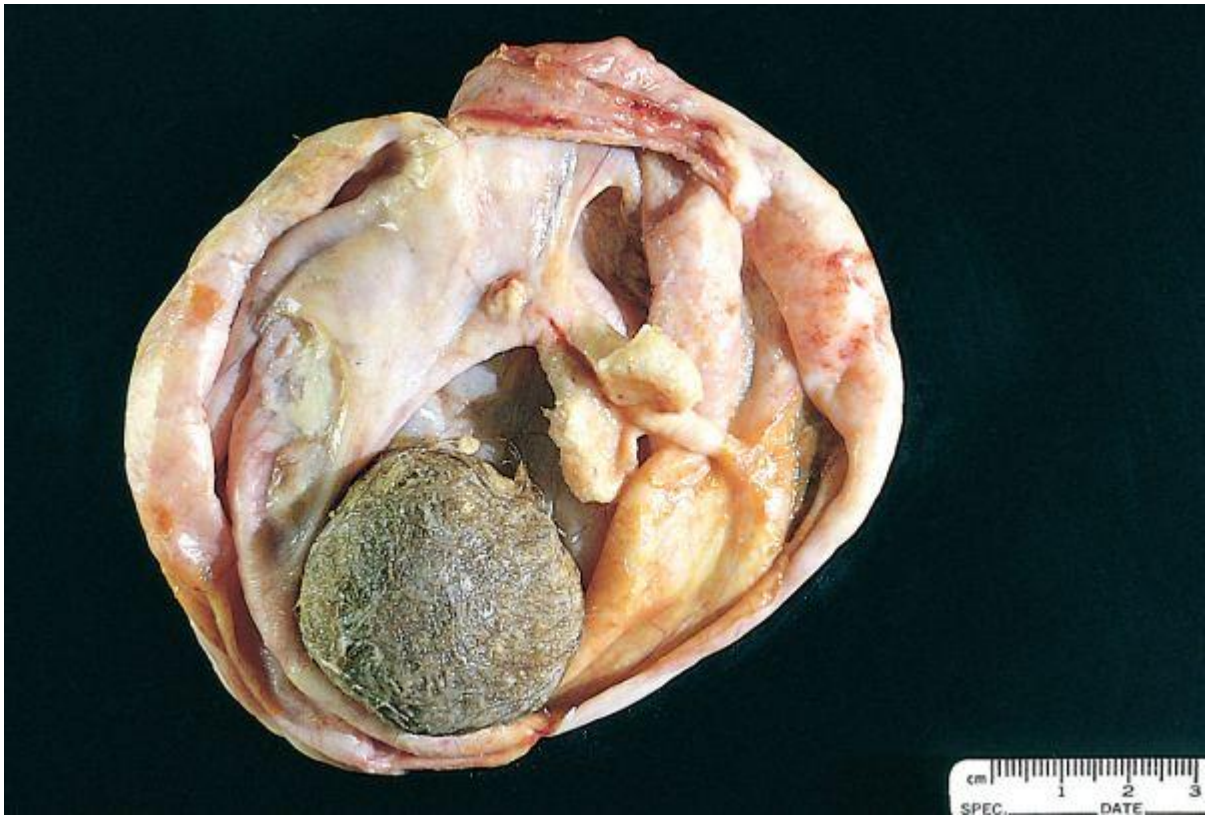

FIGURE 22-43 Opened mature cystic teratoma (dermoid cyst) of the ovary. Hair *(bottom)* and a mixture of tissues are evident.

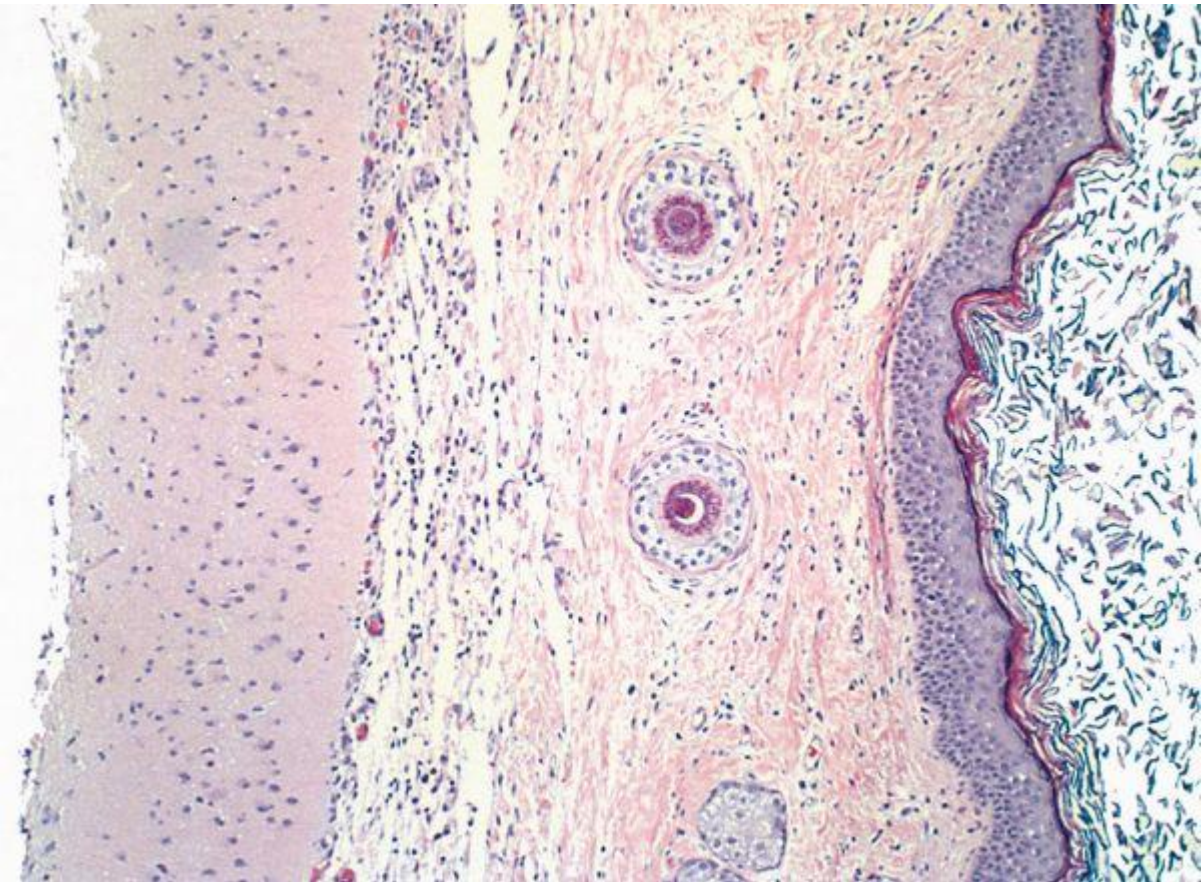

FIGURE 22-44 Benign cystic teratoma. Low-power view of skin *(right edge)*, beneath which there is brain tissue *(left edge)*.

The origin of teratomas has been a matter of fascination for centuries. Some common beliefs blamed witches, nightmares, or adultery with the devil. The karyotype of almost all benign ovarian teratomas is 46,XX. From the results of chromosome banding techniques and the distribution of electrophoretic variants of enzymes in normal and teratoma cells, it has been suggested that the tumors arise from an ovum after the first meiotic division.[96] Other derivations have also been proposed.[97]

Monodermal or Specialized Teratomas.

The specialized teratomas are a remarkable, rare group of tumors, *the most common of which are struma ovarii and carcinoid*. They are always unilateral, although a contralateral teratoma may be present. Struma ovarii is composed entirely of mature thyroid tissue. Interestingly, these thyroidal neoplasms may hyperfunction, causing hyperthyroidism. The ovarian carcinoid, which presumably arises from intestinal epithelium in a teratoma, may also be functional, particularly large (>7 cm) tumors, producing 5-hydroxytryptamine and the carcinoid syndrome. Primary ovarian carcinoid can be distinguished from metastatic intestinal carcinoid, which is virtually always bilateral. Even rarer is the strumal carcinoid, a combination of struma ovarii and carcinoid in the same ovary. Only about 2% of carcinoids metastasize.

Immature Malignant Teratomas.

These are rare tumors that differ from benign teratomas in that the component tissues resemble embryonal and immature fetal tissue. The tumor is found chiefly in prepubertal adolescents and young women, the mean age being 18 years.[98]

Morphology. The tumors are bulky and have a smooth external surface. On section they have a solid (or predominantly solid) structure. There are areas of necrosis and hemorrhage. Hair, sebaceous material, cartilage, bone, and calcification may be present. On microscopic examination there are varying amounts of immature neuroepithelium, cartilage, bone, muscle, and others. An important risk for subsequent extra-ovarian spread is the histologic grade of tumor (I through III), which is based on the proportion of tissue containing immature neuroepithelium (Fig. 22-45).

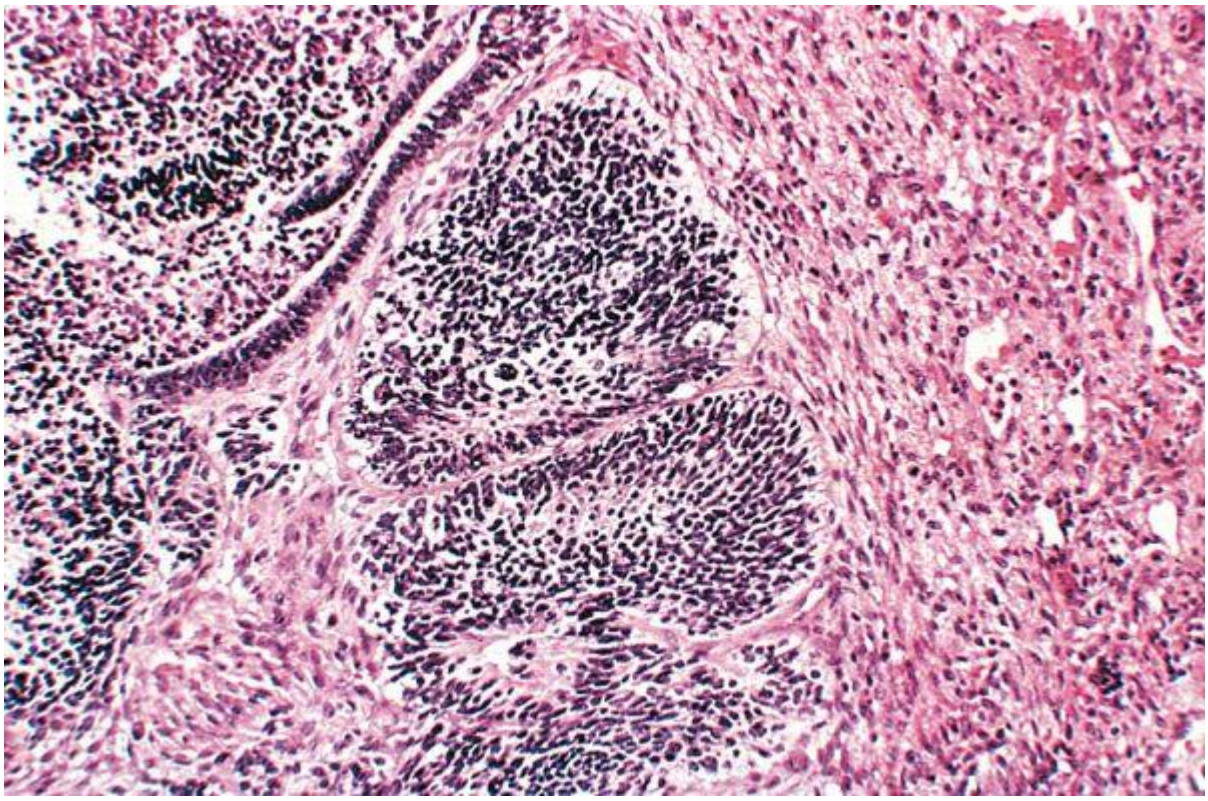

FIGURE 22-45 Immature teratoma of the ovary illustrating primitive neuroepithelium.

Immature teratomas grow rapidly, frequently penetrate the capsule, and spread either locally or distantly. Stage I tumors, however, particularly those with low-grade (grade 1) histology, have an excellent prognosis. Higher grade tumors confined to the ovary are generally treated with prophylactic chemotherapy. Most recurrences develop in the first 2 years, and absence of disease beyond this period carries an excellent chance of cure.

Dysgerminoma

The dysgerminoma is best considered as the *ovarian counterpart of the seminoma of the testis*. Similar to the seminoma, it is composed of large vesicular cells having a clear cytoplasm, well-defined cell boundaries, and centrally placed regular nuclei. Dysgerminomas account for about 2% of all ovarian

cancers yet form about half of malignant germ cell tumors. They may occur in childhood, but 75% occur in the second and third decades. Some occur in patients with gonadal dysgenesis, including pseudohermaphroditism. Most of these tumors have no endocrine function. A few produce elevated levels of chorionic gonadotropin and may have syncytiotrophoblastic giant cells on histologic examination. Like seminomas, dysgerminomas express Oct3, Oct4, and Nanog.[99] These transcription factors are implicated in maintenance of pluripotency. They also express the receptor tyrosine kinase *c-KIT*. These proteins are useful diagnostic markers and, in the case of c-KIT, may also serve as a therapeutic target.[100]

Morphology. Usually unilateral (80% to 90%), most are solid tumors ranging in size from barely visible nodules to masses that virtually fill the entire abdomen. On cut surface they have a yellow-white to gray-pink appearance and are often soft and fleshy. On histologic examination the dysgerminoma cells are dispersed in sheets or cords separated by scant fibrous stroma (Fig. 22-46). As in the seminoma, the fibrous stroma is infiltrated with mature lymphocytes and occasional granulomas. On occasion, small nodules of dysgerminoma are encountered in the wall of an otherwise benign cystic teratoma; conversely, a predominantly dysgerminomatous tumor may contain a small cystic teratoma.

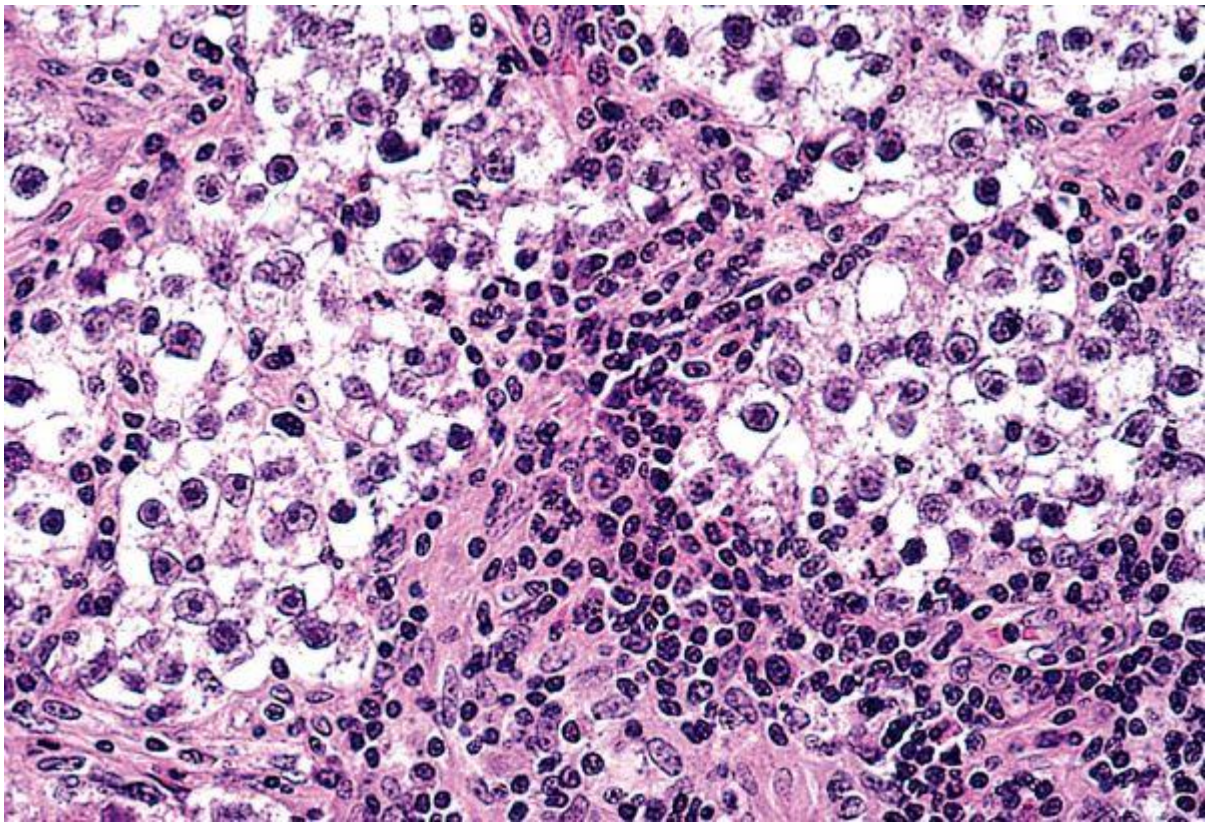

FIGURE 22-46 Dysgerminoma showing polyhedral tumor cells with round nuclei and adjacent inflammation.

All dysgerminomas are malignant, but the degree of histologic atypia is variable, and only about one third are aggressive. Thus, a unilateral tumor that has not broken through the capsule and has not spread has an excellent prognosis (up to 96% cure rate) after simple salpingo-oophorectomy. *These neoplasms*

are responsive to chemotherapy, and even those that have extended beyond the ovary can often be cured.[101] Overall survival exceeds 80%.

Endodermal Sinus (Yolk Sac) Tumor

This tumor is rare but is the second most common malignant tumor of germ cell origin. It is thought to be derived from differentiation of malignant germ cells along the extra-embryonic yolk sac lineage (see Fig. 22-42). Similar to the normal yolk sac, the tumor is *rich in* α-*fetoprotein* and α_1-antitrypsin. Its characteristic histologic feature is a glomerulus-like structure composed of a central blood vessel enveloped by germ cells within a space lined by germ cells (Schiller-Duval body) (Fig. 22-47). Conspicuous intracellular and extracellular hyaline droplets are present in all tumors, and some of these stain for α-fetoprotein by immunoperoxidase techniques.

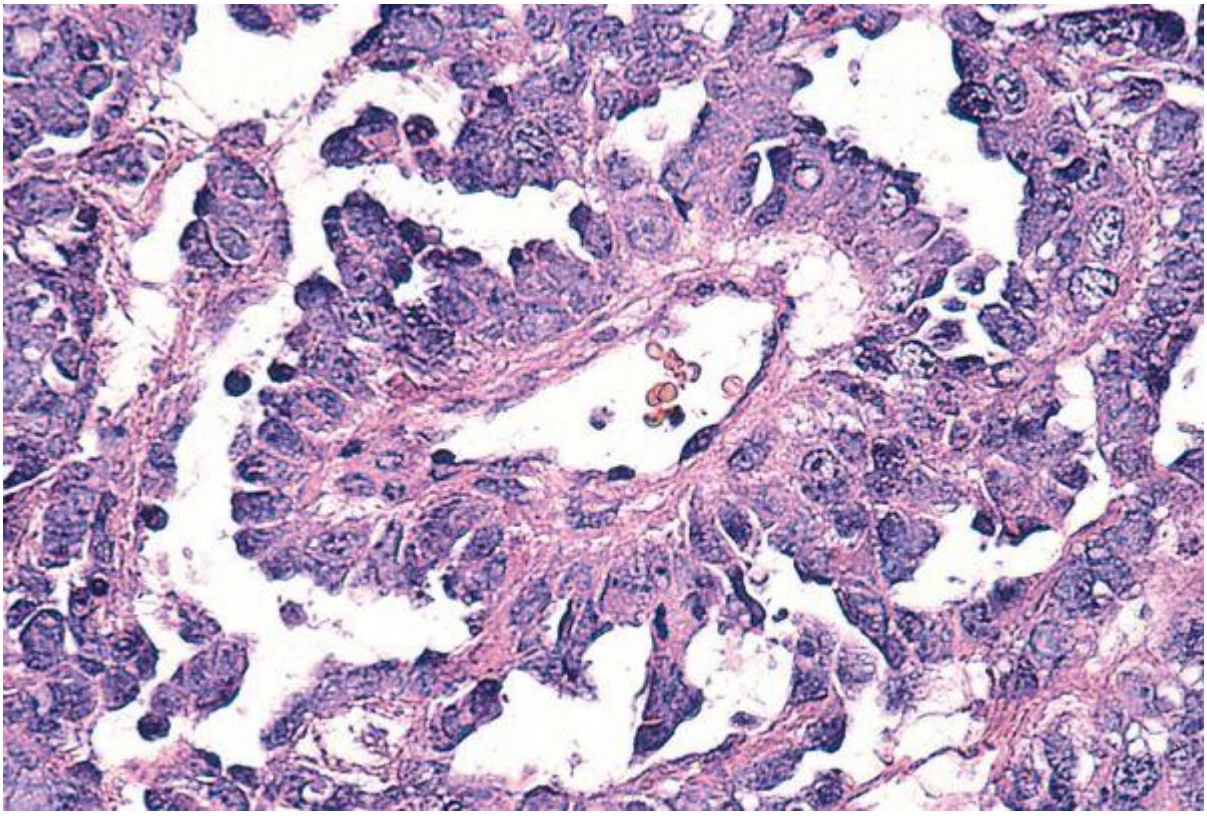

FIGURE 22-47 A Schiller-Duval body in yolk sac carcinoma.

Most patients are children or young women presenting with abdominal pain and a rapidly developing pelvic mass. The tumors usually appear to involve a single ovary but grow rapidly and aggressively. These tumors were once almost uniformly fatal within 2 years of diagnosis, but combination chemotherapy has measurably improved the outcome.

Choriocarcinoma

More commonly of placental origin, the choriocarcinoma, like the endodermal sinus tumor, is an example of extra-embryonic differentiation of malignant germ cells. It is generally held that a germ cell

origin can be confirmed only in the prepubertal girl, because after this age an origin from an ovarian ectopic pregnancy cannot be excluded.

Most ovarian choriocarcinomas exist in combination with other germ cell tumors, and pure choriocarcinomas are extremely rare. They are histologically identical to the more common placental lesions, described later. The ovarian primaries are *aggressive tumors* that generally have metastasized widely through the bloodstream to the lungs, liver, bone, and other viscera by the time of diagnosis. Like all choriocarcinomas they elaborate *high levels of chorionic gonadotropins*, which is sometimes helpful in establishing the diagnosis or detecting recurrences. In contrast to choriocarcinomas arising in placental tissue, those arising in the ovary are generally unresponsive to chemotherapy and are often fatal.

Other Germ Cell Tumors

These include (1) embryonal carcinoma, another highly malignant tumor of primitive embryonal elements, histologically similar to tumors arising in the testes (Chapter 21)[75]; (2) polyembryoma, a malignant tumor containing so-called embryoid bodies; and (3) mixed germ cell tumors containing various combinations of dysgerminoma, teratoma, endodermal sinus tumor, and choriocarcinoma.

SEX CORD–STROMAL TUMORS

These ovarian neoplasms are derived from the ovarian stroma, which in turn is derived from the sex cords of the embryonic gonad. Because the undifferentiated gonadal mesenchyme eventually produces structures of specific cell type in both male (Sertoli and Leydig) and female (granulosa and theca) gonads, tumors resembling all of these cell types can be identified in the ovary.[102] Moreover, because some of these cells normally secrete estrogens (granulosa and theca cells) or androgens (Leydig cells), their corresponding tumors may be either feminizing (granulosa–theca cell tumors) or masculinizing (Leydig cell tumors).

Granulosa–Theca Cell Tumors

This designation embraces ovarian neoplasms composed of varying proportions of granulosa and theca cell differentiation. They may be composed almost entirely of granulosa cells or a mixture of granulosa and theca cells. Collectively, these neoplasms account for about 5% of all ovarian tumors. Although they may be discovered at any age, approximately two thirds occur in postmenopausal women.

Morphology. Granulosa cell tumors are usually unilateral and vary from microscopic foci to large, solid, and cystic encapsulated masses. Tumors that are hormonally active have a yellow coloration to their cut surfaces, due to intracellular lipids. The pure thecomas are solid, firm tumors.

The granulosa cell component of these tumors takes one of many histologic patterns. The small, cuboidal to polygonal cells may grow in anastomosing cords, sheets, or strands (Fig. 22-48A). In occasional cases small, distinctive, gland-like structures filled with an acidophilic material recall immature follicles (Call-Exner bodies). When these structures are evident the diagnosis is straightforward. The thecoma component consists of clusters or sheets of cuboidal to polygonal cells. In some tumors, the granulosa or theca cells may appear plumper and have ample cytoplasm characteristic of luteinization (i.e., luteinized granulosa–theca cell tumors).

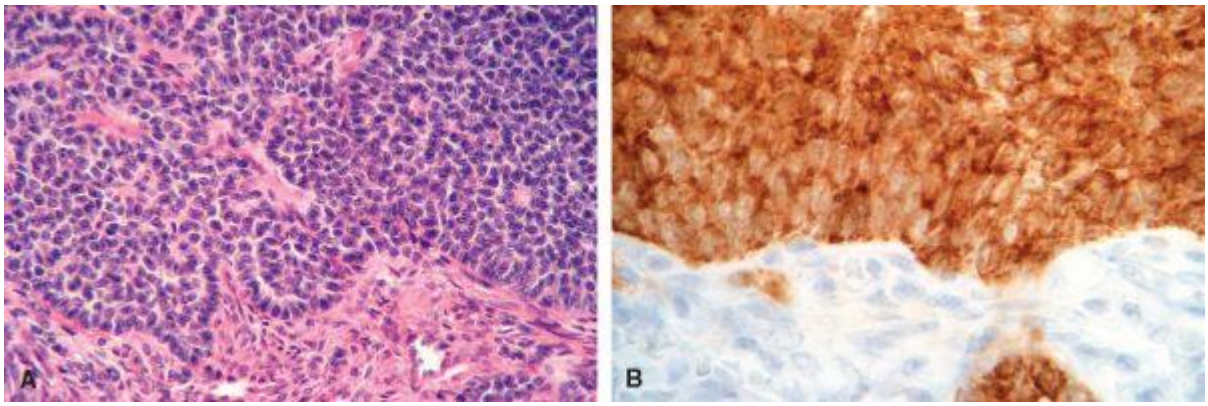

FIGURE 22-48 Granulosa cell tumor. **A**, The tumor cells are arranged in sheets punctuated by small follicle-like structures (Call-Exner bodies). **B**, Strong immunohistochemical positivity with an antibody to inhibin characterizes these tumors.

Granulosa cell tumors have clinical importance for two reasons: (1) *their potential to elaborate large amounts of estrogen* and (2) *the small but distinct hazard of malignancy* in the granulosa cell forms. Functionally active tumors in young girls (juvenile granulosa cell tumors) may produce precocious sexual development in prepubertal girls. In adult women they may be associated with endometrial hyperplasia, cystic disease of the breast, and endometrial carcinoma. About 10% to 15% of women with steroid-producing tumors eventually develop an endometrial carcinoma. Occasionally, granulosa cell tumors produce androgens, masculinizing the patient.

All granulosa cell tumors are potentially malignant. It is difficult to predict their biologic behavior from histology.[102] The estimates of malignancy (recurrence, extension) range from 5% to 25%. In general, malignant tumors pursue an indolent course in which local recurrences may be amenable to surgical therapy. Recurrences within the pelvis and abdomen may appear 10 to 20 years after removal of the original tumor. The 10-year survival rate is approximately 85%. Tumors composed predominantly of theca cells are almost never malignant.

Elevated tissue and serum levels of *inhibin*, a product of granulosa cells, are associated with granulosa cell tumors. This biomarker may be useful for identifying granulosa and other sex cord–stromal tumors, and for monitoring patients being treated for these neoplasms (Fig. 22-48B).[103]

Fibromas, Thecomas, and Fibrothecomas

Tumors arising in the ovarian stroma that are composed of either fibroblasts (fibromas) or plump spindle cells with lipid droplets (thecomas) are relatively common and account for about 4% of all ovarian tumors (Fig. 22-49A). Many tumors contain a mixture of these cells and are termed *fibromathecomas*. Pure thecomas are rare, but tumors in which these cells predominate may be hormonally active.

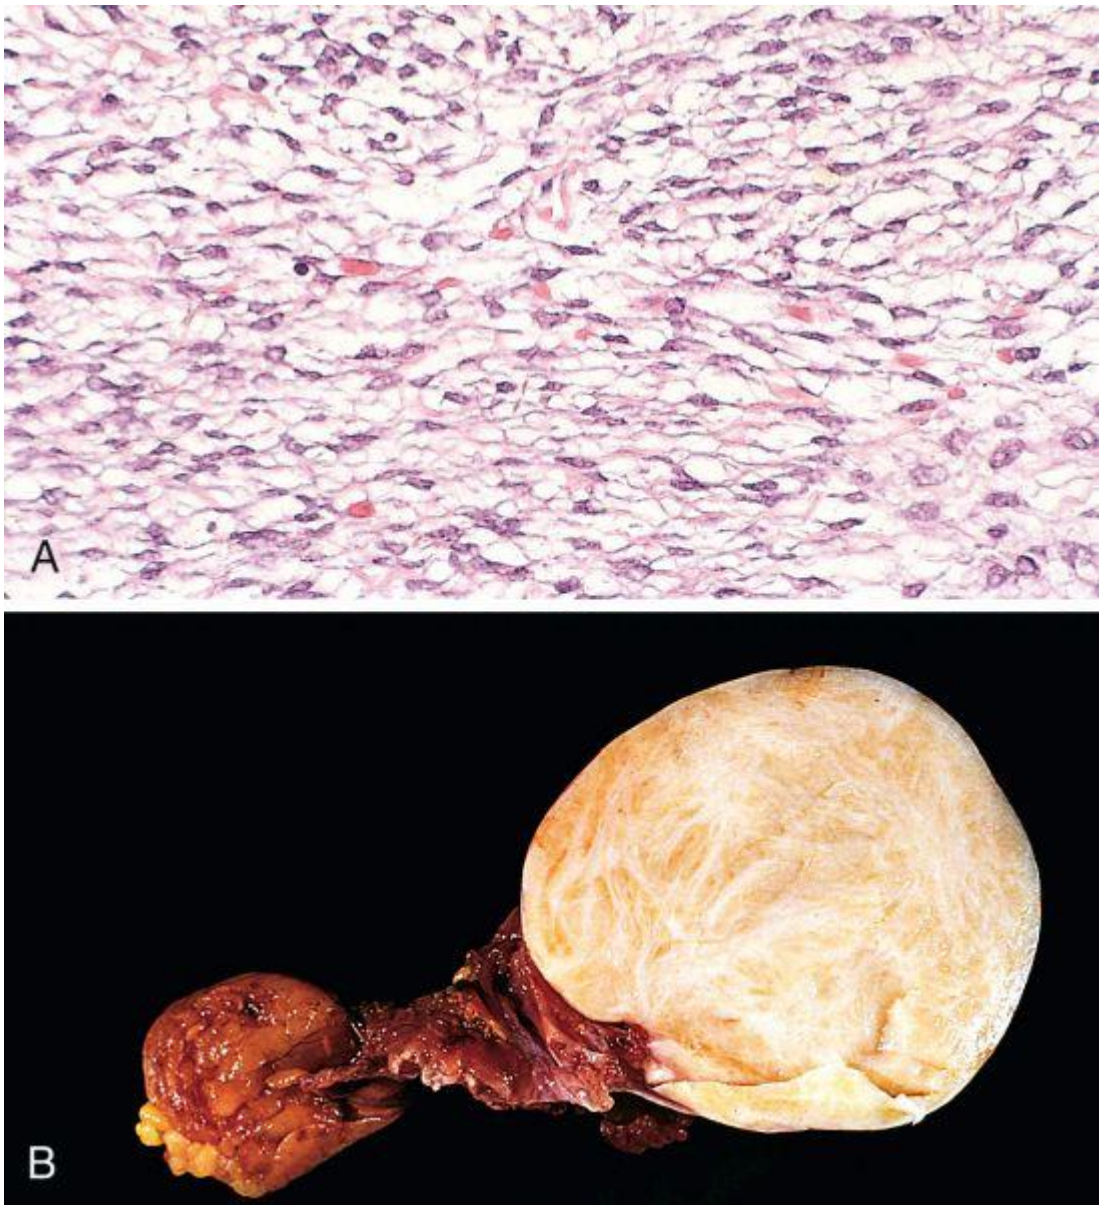

FIGURE 22-49 **A**, Thecoma-fibroma composed of plump, differentiated stromal cells with thecal appearance. **B**, Large bisected fibroma of the ovary apparent as a white, firm mass *(right)*. The fallopian tube is attached.

Fibromas of the ovary are unilateral in about 90% of cases and are usually solid, spherical or slightly lobulated, encapsulated, hard, gray-white masses covered by glistening, intact ovarian serosa (Fig. 22-49B). On histologic examination, they are composed of well-differentiated fibroblasts and a scant interspersed collagenous connective tissue. Focal areas of thecal differentiation may be identified.

Most of these tumors are pure fibromas and are hormonally inactive. These tumors usually come to attention as a pelvic mass, sometimes accompanied by pain and through two other curious associations. The first is ascites, which is found in about 40% of cases in which the tumors measure more than 6 cm in diameter. Uncommonly there is also a hydrothorax, usually only of the right side. *This combination of findings (i.e., ovarian tumor, hydrothorax, and ascites) is designated Meigs syndrome*. Its genesis is unknown. The second association is with the basal cell nevus syndrome, described in Chapter 25 . The

vast majority of fibromas, fibrothecomas, and thecomas are benign. Rarely, cellular fibromas with mitotic activity and increased nuclear-to-cytoplasmic ratio are identified; because they may pursue a malignant course, they are termed *fibrosarcomas*.[104]

Sertoli–Leydig Cell Tumors (Androblastomas)

These tumors recapitulate, to a certain extent, the cells of the testis at various stages of development.[105] They commonly produce *masculinization or at least defeminization, but a few have estrogenic effects*. They occur in women of all ages, although the peak incidence is in the second and third decades. The embryogenesis of such male-directed stromal cells remains a puzzle. These tumors are *unilateral* and may resemble granulosa–theca cell neoplasms.

Morphology. The cut surface is usually solid and varies from gray to golden brown in appearance (Fig. 22-50A). On histologic examination the well-differentiated tumors show tubules composed of Sertoli cells or Leydig cells interspersed with stroma (Fig. 22-50B). The intermediate forms show only outlines of immature tubules and large eosinophilic Leydig cells. The poorly differentiated tumors have a sarcomatous pattern with a disorderly disposition of epithelial cell cords. Leydig cells may be absent. Heterologous elements, such as mucinous glands, bone, and cartilage, may be present in some tumors.

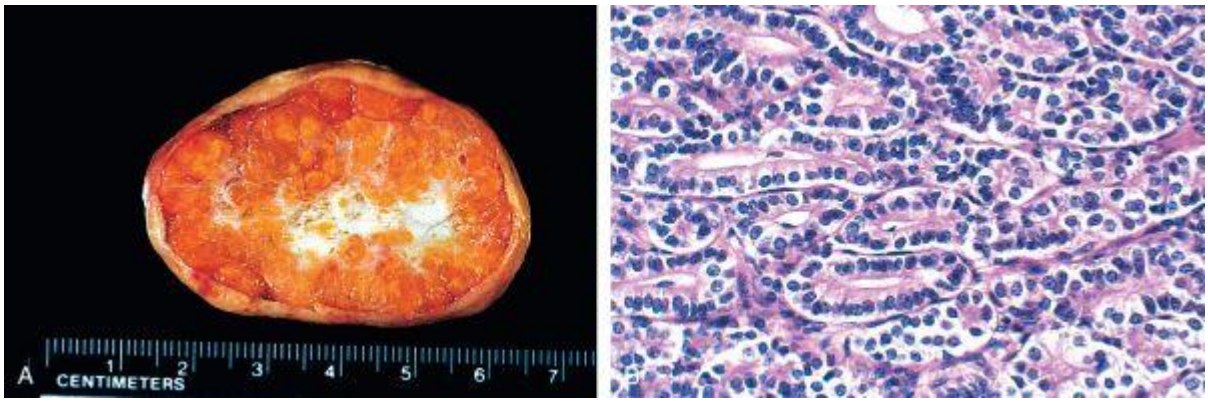

FIGURE 22-50 Sertoli cell tumor. **A**, Gross photograph illustrating characteristic golden-yellow appearance of the tumor. **B**, Photomicrograph showing well-differentiated Sertoli cell tubules. *(Courtesy of Dr. William Welch, Brigham and Women's Hospital, Boston, MA.)*

The incidence of recurrence or metastasis by Sertoli–Leydig cell tumors is less than 5%. These neoplasms may block normal female sexual development in children and may cause defeminization of women, manifested by atrophy of the breasts, amenorrhea, sterility, and loss of hair. The syndrome may progress to striking virilization (hirsutism) associated with male distribution of hair, hypertrophy of the clitoris, and voice changes.

Other Sex Cord–Stromal Tumors

The ovarian hilum normally contains clusters of polygonal cells arranged around vessels (hilar cells). *Hilus cell tumors (pure Leydig cell tumors)* are derived from these cells and are rare, unilateral, and characterized histologically by large lipid-laden cells with distinct borders. A typical cytoplasmic

structure characteristic of Leydig cells (Reinke crystalloids) is usually present. Women with hilus cell tumors usually present with evidence of masculinization, hirsutism, voice changes, and clitoral enlargement. The tumors are unilateral. The most consistent laboratory finding is an elevated 17-ketosteroid excretion level unresponsive to cortisone suppression. Treatment is surgical excision. True hilus cell tumors are almost always benign. On occasion, histologically identical tumors occur in the cortical stroma *(nonhilar Leydig cell tumors)*.

In addition to Leydig cell tumors, the stroma may rarely give rise to tumors composed of pure luteinized cells, producing small benign tumors generally less than 3 cm in diameter. The tumor may produce the clinical effects of androgen, estrogen, or progesterone stimulation.

As mentioned before, the ovary in pregnancy may show microscopic nodular proliferation of theca cells in response to gonadotropins. Rarely, a frank tumor may develop (termed *pregnancy luteoma*) that closely resembles a corpus luteum of pregnancy. These tumors have been associated with virilization in pregnant patients and in their respective female infants.

Gonadoblastoma is an uncommon tumor thought to be composed of germ cells and sex cord–stroma derivatives. It occurs in individuals with abnormal sexual development and in gonads of indeterminate nature. Eighty percent of patients are phenotypic females, and 20% are phenotypic males with undescended testicles and female internal secondary organs. On microscopic examination the tumor consists of a mixture of germ cells and sex cord derivatives resembling immature Sertoli and granulosa cells arranged in nests. A coexistent dysgerminoma occurs in 50% of the cases. The prognosis is excellent if the tumor is completely excised.[106]

Metastatic Tumors

The most common metastatic tumors of the ovary are derived from tumors of müllerian origin: the uterus, fallopian tube, contralateral ovary, or pelvic peritoneum. The most common extra-müllerian tumors metastatic to the ovary are carcinomas of the breast and gastrointestinal tract, including colon, stomach, biliary tract, and pancreas. Also included in this group are the rare cases of pseudomyxoma peritonei, derived from appendiceal tumors. A classic example of metastatic gastrointestinal neoplasia to the ovaries is termed *Krukenberg tumor*, characterized by bilateral metastases composed of mucin-producing, signet-ring cancer cells, most often of gastric origin.[7]

3.12.10 Gestational & Placental Disorders

Diseases of pregnancy and pathologic conditions of the placenta are important causes of intrauterine or perinatal death, congenital malformations, intrauterine growth retardation, maternal death, and a great deal of morbidity for both mother and child.[8] Here we discuss only a limited number of the disorders in which knowledge of the morphologic lesions contributes to an understanding of the clinical problem. This discussion is divided into selected disorders of early pregnancy, late pregnancy, and trophoblastic neoplasia. But first we will review the unique structure of the placenta to facilitate an understanding of placental changes that underlie various conditions.

The placenta is composed of chorionic villi (Fig. 22-51) that sprout from the chorion to provide a large contact area between the fetal and maternal circulations. In the mature placenta, the maternal blood enters the intervillous space through endometrial arteries (spiral arteries) and circulates around the villi allowing for gaseous and nutrient exchange (Fig. 22-52). The deoxygenated blood flows back from the intervillous space to the decidua and enters the endometrial veins. Deoxygenated fetal blood enters the placenta through two umbilical arteries that branch radially to form chorionic arteries. Chorionic arteries additionally branch as they enter the villi. In the chorionic villi they form an extensive capillary system, bringing fetal blood in close proximity to maternal blood. The gas and nutrient diffusion occurs through

the villous capillary endothelial cells and thinned-out syncytiotrophoblast and cytotrophoblast. Under normal circumstances there is no mixing between the fetal and maternal blood. Blood oxygenated in the placenta returns to the fetus through the single umbilical vein.

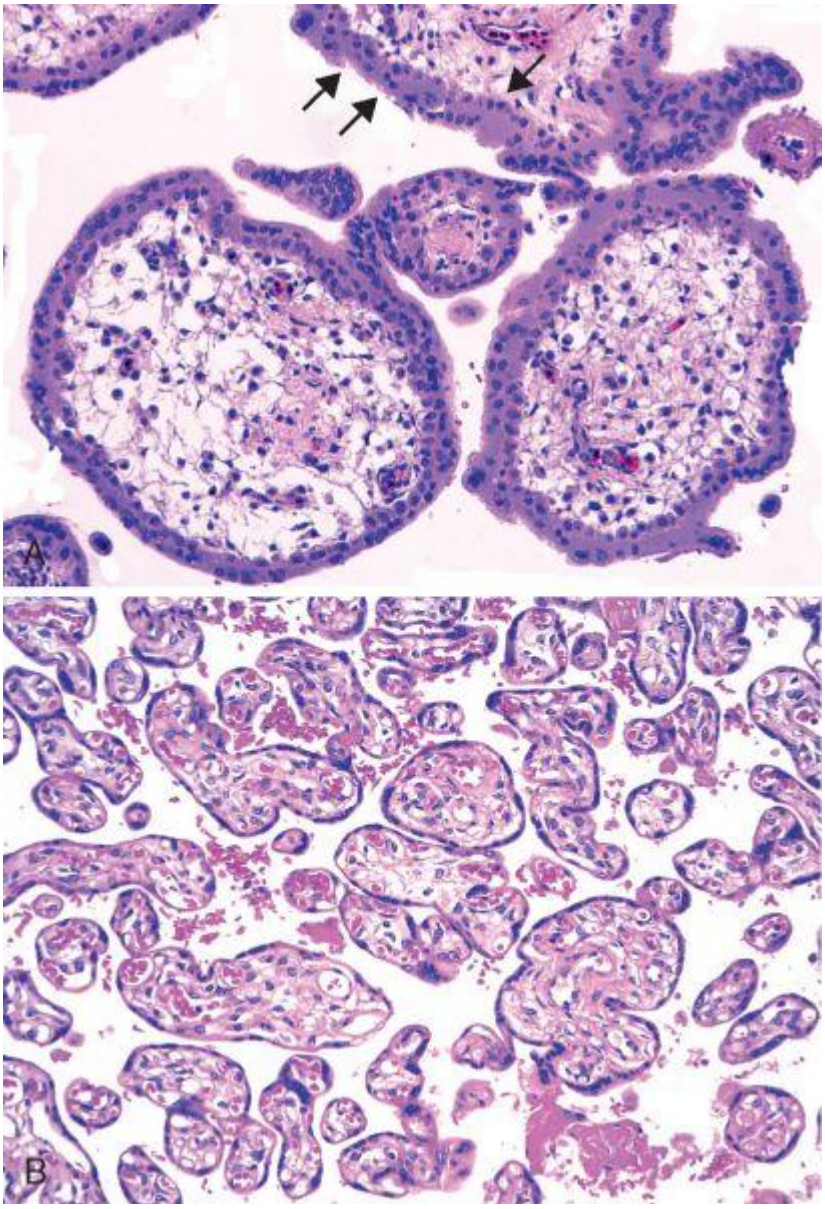

FIGURE 22-51 A, First-trimester chorionic villi composed of delicate mesh of central stroma surrounded by two discrete layers of epithelium—the outer layer consisting of syncytiotrophoblast *(two arrows)* and the inner layer consisting of cytotrophoblast *(arrow)*. **B**, Third-trimester chorionic villi composed of stroma with dense network of dilated capillaries surrounded by markedly thinned-out syncytiotrophoblast and cytotrophoblast (same magnification as **A**.)

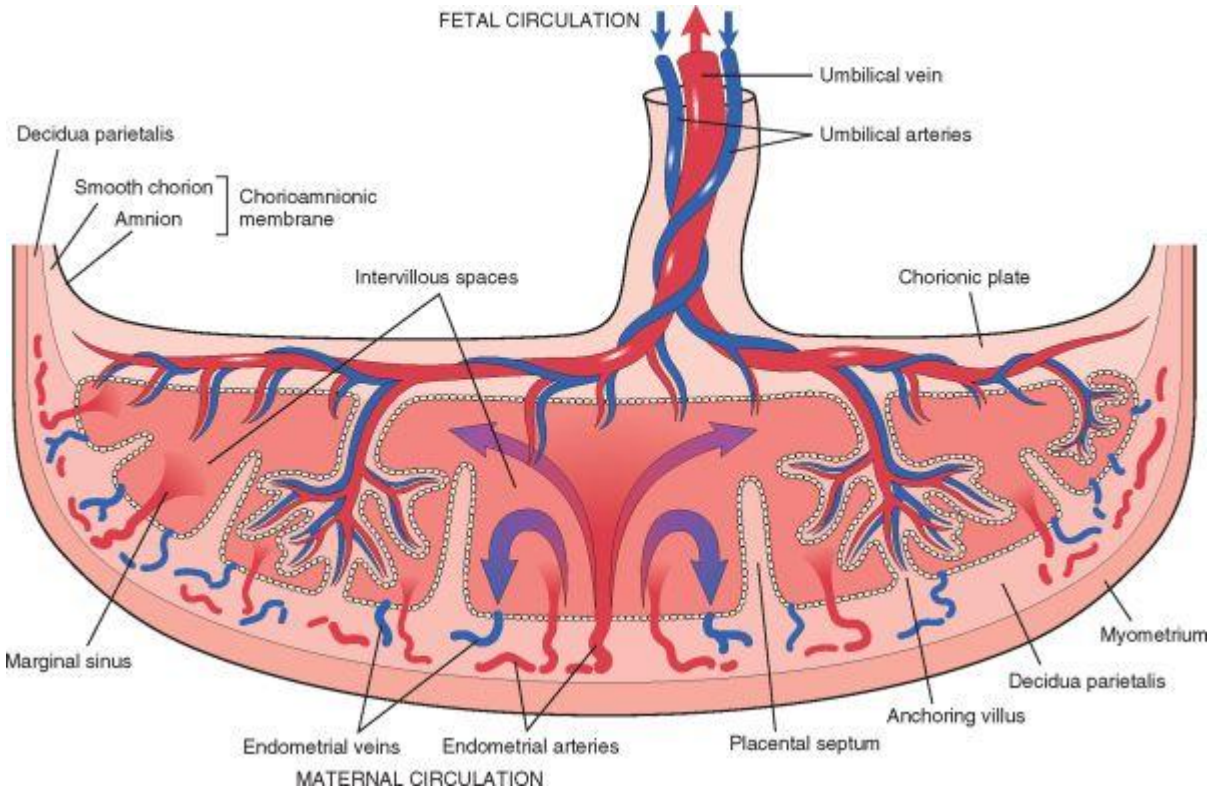

FIGURE 22-52 Diagram of placental anatomy. Within the outer boundary of myometrium is a layer of decidua, from which the maternal vessels originate and deliver blood to and from the intervillous spaces. Umbilical vessels branch and terminate in placental villi, where nutrient exchange takes place.

3.12.10.1 Disorders of Early Pregnancy

SPONTANEOUS ABORTION

Spontaneous abortion, or "miscarriage," is defined as pregnancy loss before 20 weeks of gestation. Most of these occur before 12 weeks. Ten to fifteen percent of clinically recognized pregnancies terminate in spontaneous abortion. However, using sensitive chorionic gonadotropin assays, it has been identified that an additional 22% of early pregnancies in otherwise healthy women terminate spontaneously.[107] The causes of spontaneous abortion are both fetal and maternal. Chromosomal anomalies such as aneuploidy, polyploidy, and translocations are present in approximately 50% of early abortuses. More subtle genetic defects, for which routine genetic testing is not readily available, account for an additional fraction of abortions. Maternal factors include luteal-phase defect, poorly controlled diabetes, and other uncorrected endocrine disorders. Physical defects of the uterus, such as submucosal leiomyomas, uterine polyps, or uterine malformations may prevent implantation adequate to support fetal development. Systemic disorders affecting maternal vasculature, such as antiphospholipid antibody syndrome, coagulopathies, and hypertension, may predispose to miscarriage. Finally, infections with bacteria such as *Toxoplasma*, *Mycoplasma*, and *Listeria*, as well as viral infections, have also been implicated as causes of abortion. Ascending infection is particularly common in second-trimester losses.[8] In many cases, however, the mechanisms leading to early loss of pregnancy are still unknown.

ECTOPIC PREGNANCY

Ectopic pregnancy is the term applied to implantation of the fetus in any site other than a normal intrauterine location. *The most common site is within the fallopian tubes (~90%).* Other sites include the ovary, the abdominal cavity, and the intrauterine portion of the fallopian tube (cornual pregnancy).

Ectopic pregnancies occur about once in every 150 pregnancies. The most important predisposing condition, present in 35% to 50% of patients, is prior pelvic inflammatory disease resulting in fallopian tube scarring (chronic follicular salpingitis). Other factors leading to peritubal scarring and adhesions are appendicitis, endometriosis, and previous surgery. In some cases, however, the fallopian tubes are apparently normal. Intrauterine contraceptive devices also increase the risk of ectopic pregnancy by about 2.5 fold.[108]

Ovarian pregnancy is presumed to result from the rare fertilization and trapping of the ovum within the follicle just at the time of its rupture. Abdominal pregnancies may develop when the fertilized ovum fails to enter or drops out of the fimbriated end of the tube. In all these abnormal locations, the fertilized ovum undergoes its usual development with the formation of placental tissue, amniotic sac, and fetus, and the host implantation site may develop decidual changes.

Morphology. Tubal pregnancy is the most common cause of **hematosalpinx** (blood-filled fallopian tube) and should always be suspected when a tubal hematoma is present. Initially the embryonal sac, surrounded by placental tissue composed of immature chorionic villi, implants in the lumen of the fallopian tube. With time trophoblastic cells and chorionic villi start to invade the fallopian tube wall as they do in the uterus during normal pregnancy. However, proper decidualization is lacking in the fallopian tube, and growth of the gestational sac distends the fallopian tube causing thinning and rupture. Fallopian tube rupture frequently results in massive intraperitoneal hemorrhage. Less commonly the tubal pregnancy may undergo spontaneous regression and resorption of the entire conceptus. Still less commonly, the tubal pregnancy is extruded through the fimbriated end into the abdominal cavity (tubal abortion).

Clinical Features.

The clinical course of ectopic pregnancy is punctuated by the onset of *severe abdominal pain*, most commonly about 6 weeks after a previous normal menstrual period, when rupture of the tube leads to pelvic hemorrhage. *Rupture* of a tubal pregnancy constitutes a medical emergency. In such cases the patient may rapidly develop *hemorrhagic shock* with signs of an acute abdomen, and early diagnosis is critical. Chorionic gonadotropin assays, ultrasound studies, and laparoscopy may be helpful. Endometrial biopsy specimens may or may not disclose decidual changes, but—excluding the extremely rare dual pregnancy—do not exhibit chorionic villi or evidence of an implantation site.

3.12.10.2 Disorders of Late Pregnancy

The multitude of disorders that can occur in the third trimester are related to the complex anatomy of the maturing placenta. Complete interruption of blood flow through the umbilical cord from any cause (such as constricting knots or compression) can be lethal to the fetus. Ascending infections involving the chorioamnionic membranes may lead to premature rupture and delivery. Retroplacental hemorrhage at the interface of placenta and myometrium (abruptio placentae) threatens both mother and fetus. Disruption of the fetal vessels in terminal villi may produce a significant loss of fetal blood with resultant fetal injury or death. Uteroplacental malperfusion can be precipitated by abnormal placental implantation or development, or maternal vascular disease; the effects may range from mild intrauterine growth retardation to severe uteroplacental ischemia, and maternal preeclampsia.

TWIN PLACENTAS

Twin pregnancies arise from fertilization of two ova (dizygotic) or from division of one fertilized ovum (monozygotic). There are three basic types of twin placentas (Fig. 22-53): diamnionic dichorionic (which may be fused), diamnionic monochorionic, and monoamnionic monochorionic. Monochorionic

placentas imply monozygotic (identical) twins, and the time at which splitting occurs determines whether one or two amnions are present. Dichorionic placentation may occur with either monozygotic or dizygotic twins and is not specific.

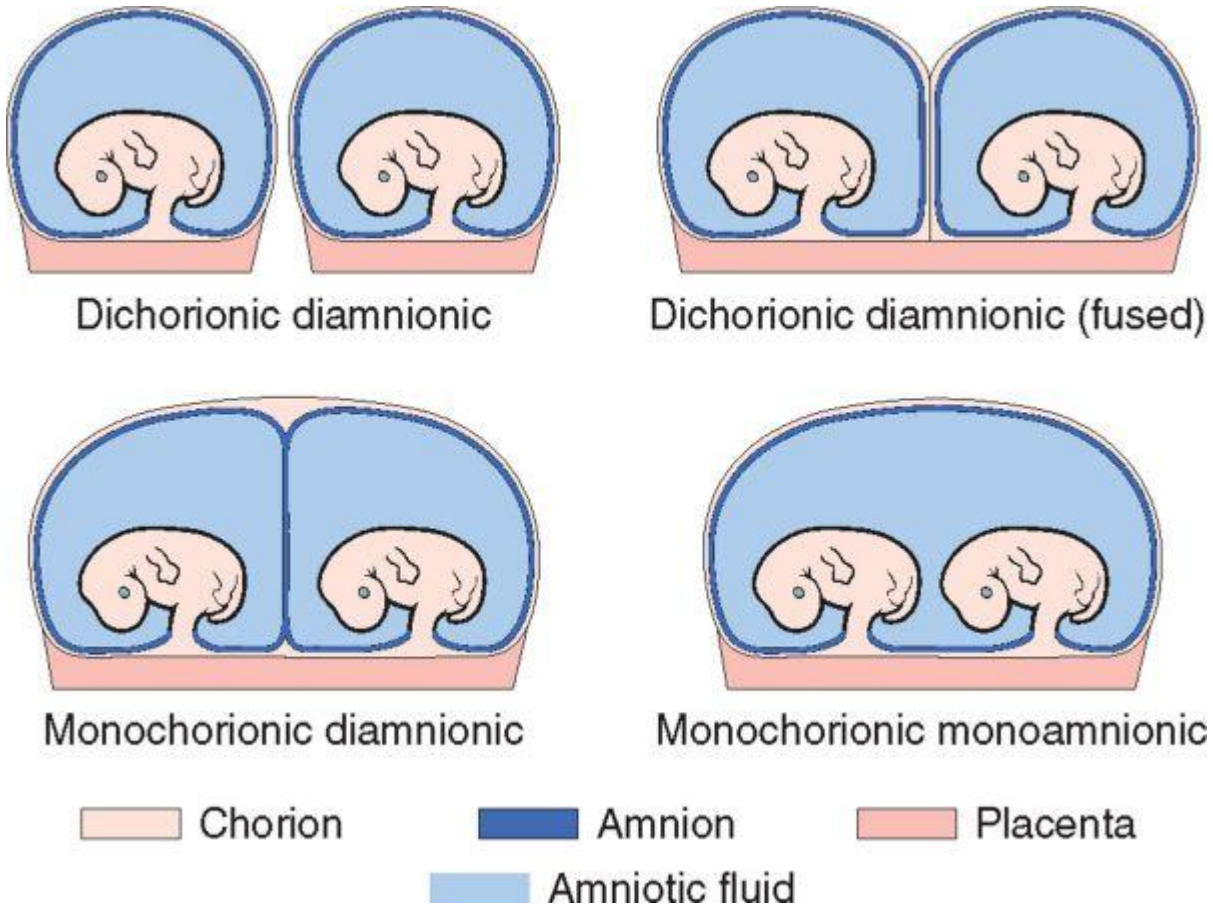

FIGURE 22-53 Diagrammatic representation of the various types of twin placentation and their membrane relationships. *(Adapted from Gersell D et al.: Diseases of the placenta. In Kurman R (ed): Blaustein's Pathology of the Female Genital Tract. New York, Springer-Verlag, 1994.)*

One complication of monochorionic twin pregnancy is twin-twin transfusion syndrome. In all monochorionic twin placentas there are vascular anastomoses, which connect the circulations of the twins. In some cases there is an abnormal sharing of fetal circulations through an arteriovenous shunt. If an imbalance in blood flow occurs, a marked disparity in fetal blood volumes may result in twin-twin transfusion syndrome and the death of one or both fetuses.

ABNORMALITIES OF PLACENTAL IMPLANTATION

Abnormal placental implantations may have significant consequences for the pregnancy outcome. *Placenta previa* is a condition in which the placenta implants in the lower uterine segment or cervix, often with serious third-trimester bleeding. A complete placenta previa covers the internal cervical os and thus requires delivery via cesarean section to avert placental rupture and fatal maternal hemorrhage during vaginal delivery. *Placenta accreta* is caused by partial or complete absence of the decidua with adherence of the placental villous tissue directly to the myometrium and failure of placental separation.

It is an important cause of postpartum bleeding, which often may be life-threatening to the mother. Common predisposing factors are placenta previa (in up to 60% of cases) and history of previous cesarean section.

PLACENTAL INFECTIONS

Infections in the placenta develop by two pathways: (1) ascending infection through the birth canal and (2) hematogenous (transplacental) infection. Ascending infections are by far the most common and are virtually always bacterial; in many such instances, localized infection of the membranes by an organism produces premature rupture of membranes and preterm delivery. The amniotic fluid may be cloudy with purulent exudate, and histologically the chorion-amnion contains a polymorphonuclear leukocytic infiltrate accompanied by edema and congestion of the vessels (Fig. 22-54A and B). The infection frequently elicits a fetal response with "vasculitis" of umbilical and fetal chorionic plate vessels. Uncommonly, bacterial infections may arise by the hematogenous spread of bacteria directly to the placenta. The villi will then show acute inflammatory cells (acute villitis) (Fig. 22-54C).

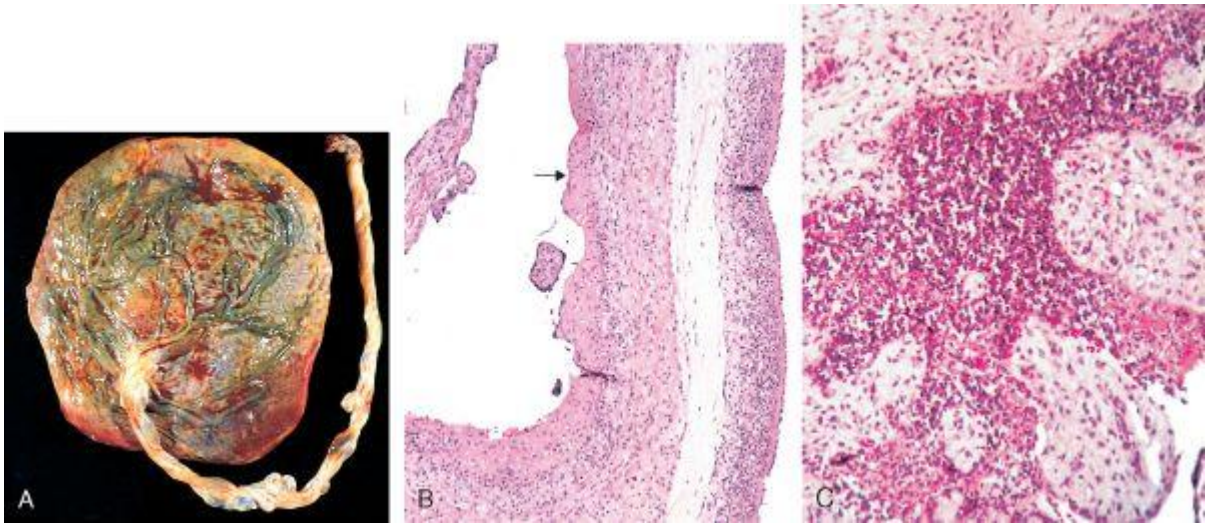

FIGURE 22-54 Placental infections derived from ascending and blood-borne routes. Acute chorioamnionitis. **A**, On gross examination the placenta contains greenish opaque membranes. **B**, A photomicrograph illustrates a dense bandlike inflammatory exudate on the amniotic surface *(arrow)*. **C**, Acute necrotizing intervillositis, from a fetal-maternal infection by *Listeria*.

Several hematogenous infections, classically TORCH (toxoplasmosis and others [syphilis, tuberculosis, listeriosis], rubella, cytomegalovirus, herpes simplex), can affect the placenta. They give rise to inflammatory infiltrates in the chorionic villi, usually of chronic inflammatory cells (chronic villitis). Often, the cause of chronic villitis is obscure and may involve immunological phenomena[8] (see also Chapter 10).

PREECLAMPSIA AND ECLAMPSIA

Preeclampsia refers to a *systemic syndrome characterized by widespread maternal endothelial dysfunction presenting clinically with hypertension, edema, and proteinuria during pregnancy*. It occurs in about 3% to 5% of pregnant women, usually in the last trimester and more commonly in primiparas (women pregnant for the first time). Some of these women become more seriously ill, developing convulsions; this more severe form is termed *eclampsia*. Other complications stemming from systemic endothelial dysfunction include hypercoaguability, acute renal failure and pulmonary edema.

Approximately 10% of women with severe preeclampsia develop hemolysis, elevated liver enzymes, and low platelets, referred to as the HELLP syndrome (Chapter 18). Preeclampsia should be distinguished from gestational hypertension that can develop in pregnancy without proteinuria.

Pathogenesis.

The exact mechanisms leading to development of preeclampsia are still being investigated; however, *it is clear that the placenta plays a central role in the pathogenesis of the syndrome*, since the symptoms disappear rapidly after delivery of the placenta. *The critical abnormalities in preeclampsia are diffuse endothelial dysfunction, vasoconstriction (leading to hypertension), and increased vascular permeability (resulting in proteinuria and edema)*. Recent work has demonstrated that these effects are most likely mediated by placenta derived factor(s) released into the maternal circulation. Although the release of these factors and the clinical syndrome develop late in gestation, the pathogenesis of the disease appears to be closely tied to the earliest events of pregnancy and placentation. The principal pathophysiologic aberrations appear to be the following.

- *Abnormal placental vasculature*. The initial event in the pathogenesis of preeclampsia is abnormal trophoblastic implantation and lack of development of physiologic alterations in the maternal vessels required for adequate perfusion of the placental bed.[109] In normal pregnancy, fetal extravillous trophoblastic cells (trophoblastic cells not associated with chorionic villi) at the implantation site invade the maternal decidua and decidual vessels, destroy the vascular smooth muscle and replace the maternal endothelial cells with fetal trophoblastic cells (forming hybrid feto-maternal blood vessels). *This process converts the decidual spiral arteries from small-caliber resistance vessels to large capacity uteroplacental vessels lacking a smooth muscle coat* (Fig. 22-55). In preeclampsia this remodeling fails to occur, leaving the placenta ill equipped to meet the increased circulatory demands of late gestation and setting the stage for the development of placental ischemia.
- *Endothelial dysfunction and imbalance of angiogenic and anti-angiogenic factors*. Although not formally proven, it is postulated that in response to hypoxia, the ischemic placenta releases factors into the maternal circulation that cause an imbalance in circulating angiogenic and anti-angiogenic factors; this in turn leads to systemic maternal endothelial dysfunction and the clinical symptoms of the disease.[110,][111] In support of this, the blood levels of two placenta-derived *anti-angiogenic factors*, soluble fms-like tyrosine kinase (sFltl) and endoglin, are several orders of magnitude higher in women with preeclampsia than in healthy controls. Placental hypoxia causes overproduction of sFlt1 from the villous trophoblast; sFltl is a truncated soluble form of VEGF receptor that acts as a decoy receptor, binding VEGF and placental growth factor in circulation and thereby neutralizing their pro-angiogenic activity. Similarly circulating endoglin, a soluble form of a TGF-β receptor, can bind TGF-β and inhibit signaling via cellular TGF-β receptors. Normally, in late gestation, levels of sFltl and soluble endoglin in the blood increase while placental growth factor and vascular endothelial growth factor decrease, leading to a reduction in angiogenic activity. *In preeclampsia, high levels of sFlt1 and soluble endoglin bring about a decrease in angiogenesis much earlier than in normal pregnancy. The result is defective vascular development in the placenta*.
  Studies in animal models also implicate sFltl and soluble endoglin in the pathogenesis of endothelial dysfunction. When sFlt and endoglin are overexpressed together, rats develop nephrotic-range proteinuria, severe hypertension, and fetal growth restriction, the hallmarks of severe preeclampsia, as well as features of the HELLP syndrome, including elevated liver enzymes, decreased platelet counts, and hemolysis. Thus, it seems that *sFlt1 and soluble endoglin are key mediators that link the placenta to the characteristic maternal endothelial dysfunction of preeclampsia*.[112] These effects of sFltl and endoglin appear to be related to their inhibition of VEGF and TGF-β-mediated production of endothelial-dependent nitric oxide (NO) and prostacyclin (PGI_2). The capillary endothelium of the kidney is extremely sensitive to locally produced VEGF, which may explain why proteinuria and renal dysfunction are early markers of preeclampsia.
- *Coagulation abnormalities*. Preeclampsia is associated with a hypercoaguable state; thrombosis of arterioles and capillaries may occur throughout the body, particularly in the liver, kidneys, brain, and pituitary. This hypercoaguability is likely related to the reduced endothelial production of PGI_2, a potent antithrombotic factor, and increased release of procoagulant factors. Production of PGI_2 is stimulated by both VEGF and TGF-β, and women with preeclampsia have been shown to have decreased endothelial production of PGI_2.

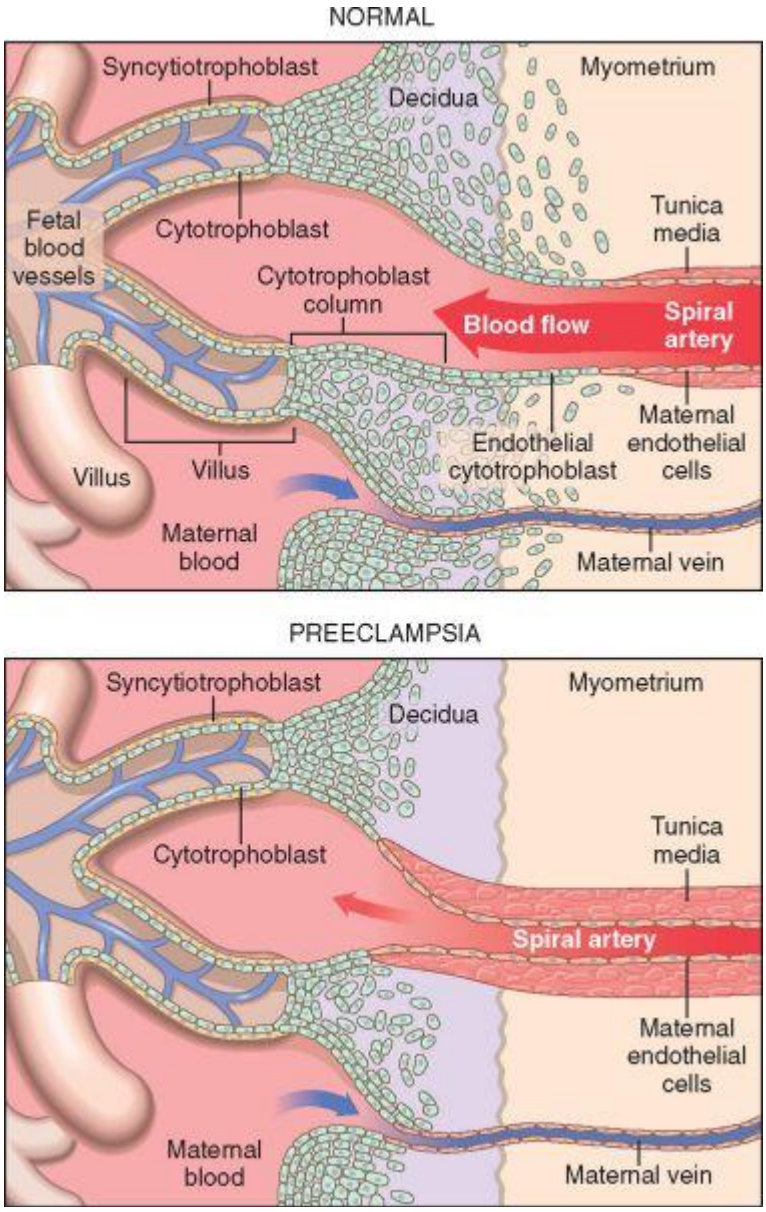

FIGURE 22-55 The physiologic alterations in the uterine spiral arteries and the failure of their remodeling in preeclampsia *(Modifi ed from Maynard S, Epstein FH, Karumanchi, SA: Preeclampsia and angiogenic imbalance. Ann Rev Med. 59: 61, 2008.)*

Morphology. The **placenta** reveals various microscopic changes, most of which reflect malperfusion, ischemia, and vascular injury. These include: (1) Placental infarcts—small, peripheral ones that may occur in normal full-term placentas—are larger and more numerous in preeclampsia. There is also an exaggeration of ischemic changes in the chorionic villi and trophoblast. This includes increased syncytial knots and the appearance of accelerated villous maturity. (2) There is increased frequency of retroplacental hematomas due to bleeding and instability of uteroplacental vessels. (3) The most characteristic finding is in the decidual vessels, reflecting abnormal implantation. This can be in the form of thrombosis, lack of normal physiologic conversion (described earlier), fibrinoid necrosis, or intraintimal lipid deposition (acute atherosis) (Fig. 22-56).

The **liver** lesions, when present, take the form of irregular, focal, subcapsular, and intraparenchymal hemorrhages. On histologic examination there are fibrin thrombi in the portal capillaries and foci of hemorrhagic necrosis.

The **kidney** lesions are variable. Glomerular lesions are diffuse, when assessed by electron microscopy. They consist of marked swelling of endothelial cells, the deposition of fibrinogen-derived amorphous dense deposits on the endothelial side of the basement membrane, and mesangial cell hyperplasia. Immunofluorescent studies show an abundance of fibrin in glomeruli. In the better defined cases, fibrin thrombi are present in the glomeruli and capillaries of the cortex. When the lesion is far advanced, it may produce complete destruction of the cortex in the pattern referred to as bilateral renal cortical necrosis (Chapter 20). The **brain** may have gross or microscopic foci of hemorrhage along with small-vessel thromboses. Similar changes are often found in the **heart** and the **anterior pituitary**.

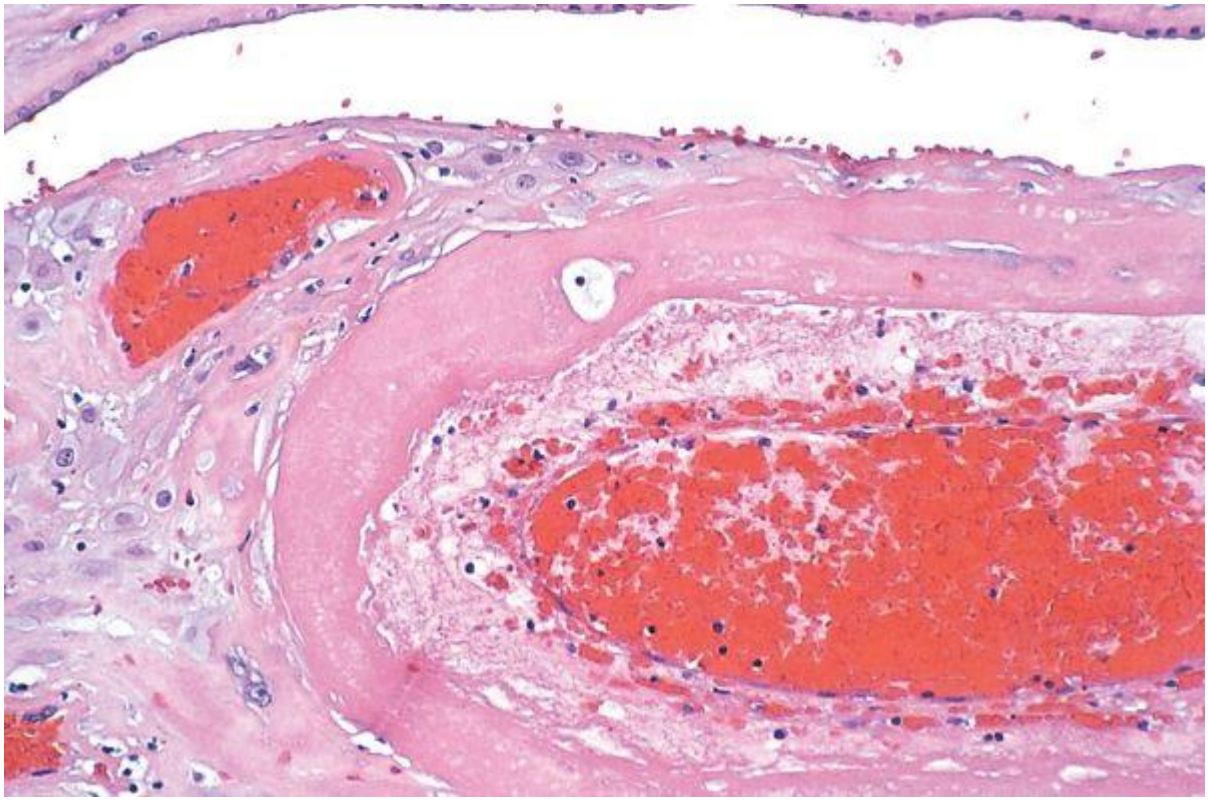

FIGURE 22-56 Acute atherosis of uterine vessels in eclampsia. Note fibrinoid necrosis of the vessel walls, subendothelial macrophages, and perivascular lymphocytic infiltrate. *(Courtesy of Dr. Drucilla J. Roberts, Massachusetts General Hospital, Boston, MA.)*

Clinical Feature.

Preeclampsia most commonly starts after 34 weeks of gestation but begins earlier in women with hydatidiform mole (discussed below) or preexisting kidney disease, hypertension, or coagulopathies. The onset is typically insidious, characterized by hypertension and edema, with protein uria following within several days. Headaches and visual disturbances are serious events and are indicative of severe preeclampsia, often requiring delivery. *Eclampsia* is heralded by central nervous system involvement, including convulsions and eventual coma. Management of preeclampsia differs depending upon the

gestational age and severity of disease. For term pregnancies, delivery is the treatment of choice regardless of disease severity. In preterm pregnancies, where delivery may not be in the best interest of the fetus, patients with mild disease can be managed expectantly with close monitoring of the mother and fetus. However, eclampsia, severe preeclampsia with maternal end-organ dysfunction, fetal compromise, or the HELLP syndrome are indications for delivery regardless of gestational age. Antihypertensive therapy does not affect the disease course or improve outcomes. Proteinuria and hypertension usually disappear within 1 to 2 weeks after delivery except when they predate the pregnancy. Although it is typically believed that preeclampsia has no lasting sequelae, recent studies indicate that about 20% of women develop hypertension and microalbuminuria within 7 years of a pregnancy complicated by preeclampsia. There is also a two-fold increase in the long-term risk of vascular diseases of the heart and the brain.

3.12.10.3 Gestational Trophoblastic Disease

Gestational trophoblastic disease constitutes a spectrum of tumors and tumor-like conditions characterized by proliferation of placental tissue, either villous or trophoblastic. The lesions include hydatidiform mole (complete and partial), invasive mole, and the frankly malignant choriocarcinoma and placental-site trophoblastic tumor.

HYDATIDIFORM MOLE

Hydatidiform mole is characterized histologically by cystic swelling of the chorionic villi, accompanied by variable trophoblastic proliferation. The most important reason for the correct recognition of moles is that they are associated with an increased risk of persistent trophoblastic disease (invasive mole) or choriocarcinoma. In the past, most patients presented in the fourth or fifth month of pregnancy with vaginal bleeding. Currently, hydatidiform moles are being diagnosed at earlier gestational ages (8.5 versus 17.0 weeks) due to routine ultrasound and close monitoring of early pregnancy. Molar pregnancy can develop at any age, but the risk is higher at the far ends of reproductive life: in teens and between the ages of 40 and 50 years. For poorly explained reasons, the incidence varies considerably in different regions of the world. Hydatidiform mole is a rather infrequent complication of gestation in the United States, occurring about once in every 1000 to 2000 pregnancies, but is quite common in the Far East; the incidence is 1 in 100 in Indonesia.[114] Two types of benign, noninvasive moles—complete and partial—can be identified by cytogenetic (Fig. 22-57) and histologic studies.

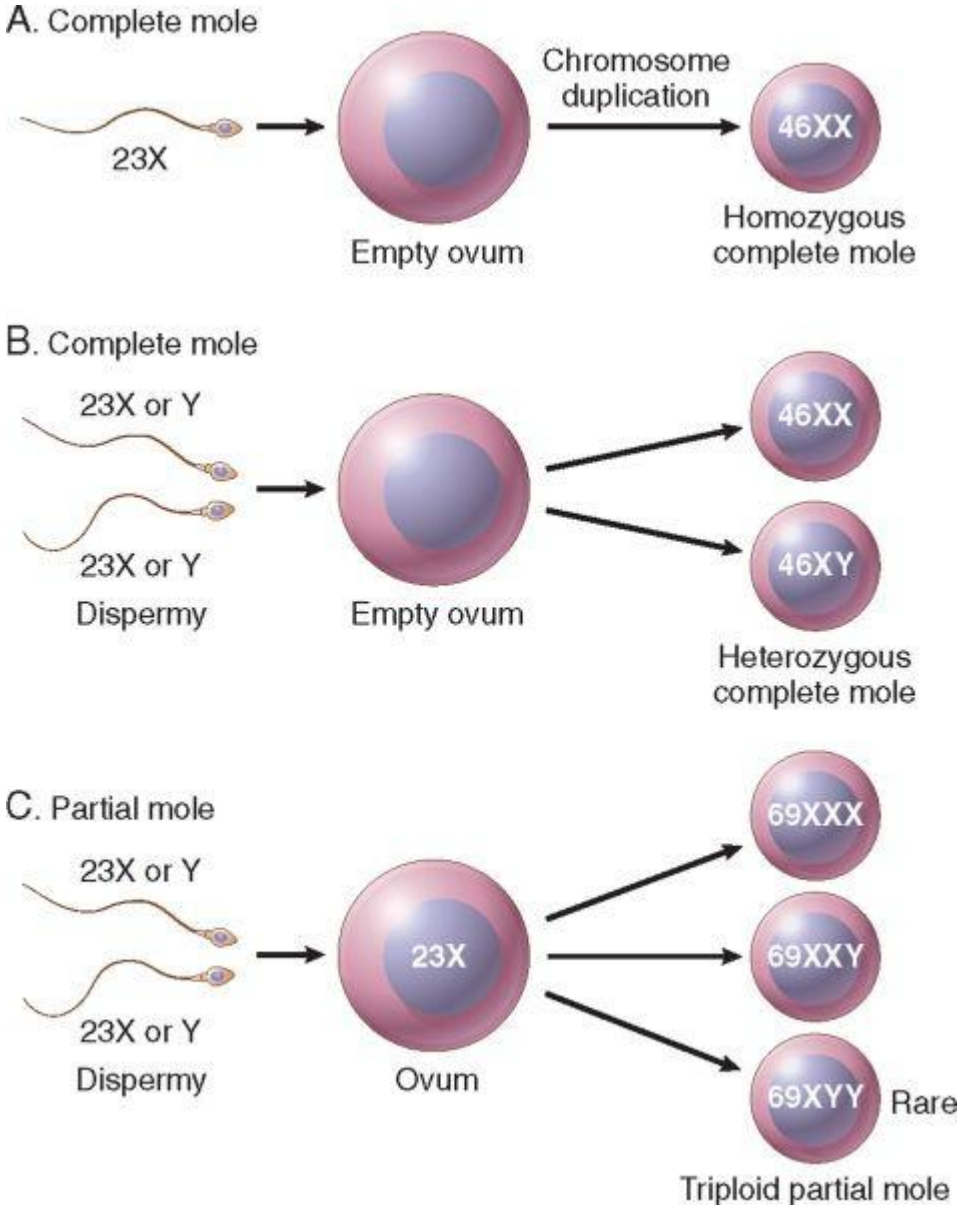

FIGURE 22-57 Origin of complete and partial hydatidiform moles. **A**, Complete moles most commonly arise from fertilization of an empty ovum by a single sperm that undergoes duplication of its chromosomes. **B**, Less commonly, complete moles arise from dispermy in which two sperm fertilize an empty ovum. **C**, Partial moles arise from two sperm fertilizing a single ovum.

Complete Mole

Complete mole results from fertilization of an egg that has lost its chromosomes, and the genetic material is completely paternally derived (Fig. 22-57A and B). Ninety percent have a 46,XX diploid pattern, all derived from duplication of the genetic material of one sperm (a phenomenon called androgenesis). The remaining 10% are from the fertilization of an empty egg by two sperm (46,XX and 46,XY). Histologically, in complete mole all or most of the villi are enlarged and edematous, and there is diffuse trophoblast hyperplasia. Although fetal vessels and fetal parts are extremely rare in complete moles since the embryo dies very early in development, they do occur. Patients have 2.5% risk of subsequent choriocarcinoma.

Partial Mole

Partial moles result from fertilization of an egg with two sperm (Fig. 22-57C). In these moles the karyotype is triploid (e.g., 69,XXY) or even occasionally tetraploid (92,XXXY). Fetal parts are more commonly present than in complete moles. In partial moles some of the villi are edematous, and other villi show only minor changes; the trophoblastic proliferation is focal and less marked. Although partial moles have an increased risk of persistent molar disease, they are not considered to have an increased risk for choriocarcinoma.

Morphology. The classic gross appearance is of a delicate, friable mass of thin-walled, translucent, cystic, grapelike structures consisting of swollen edematous (hydropic) villi (Figs. 22-58 and 22-59). Fetal parts are frequently seen in partial moles. On histologic examination **complete moles** show abnormalities that involve all or most of the villous tissue. The chorionic villi are enlarged, scalloped in shape with central cavitation (cisterns), and lack adequately developed vessels. The most impressive abnormality is, however, an extensive trophoblast proliferation that involves the entire circumference of the villi, in addition to "extravillous" islands of trophoblast proliferation. The implantation site often displays atypia and an exuberant proliferation of implantation trophoblast. In contrast, **partial moles** demonstrate villous enlargement and architectural disturbances in only a proportion of villi. The trophoblastic proliferation is moderate but still may be circumferential.

Histologic distinction of complete mole from partial molar gestations is important. In equivocal cases immunostaining for p57, a cell cycle inhibitor, may aid the diagnosis. The *p57KIP2* gene is maternally transcribed but **paternally imprinted**, and shows expression in maternal decidual tissue as well as cytotrophoblast and stromal cells of the villi, when maternal genetic material is present in the conceptus (Fig. 22-60A). In contrast, since both the X chromosomes in complete moles are derived from the father, there is no expression of p57 protein in the cytotrophoblast or stromal cells of the villi in complete moles (Fig. 22-60B).

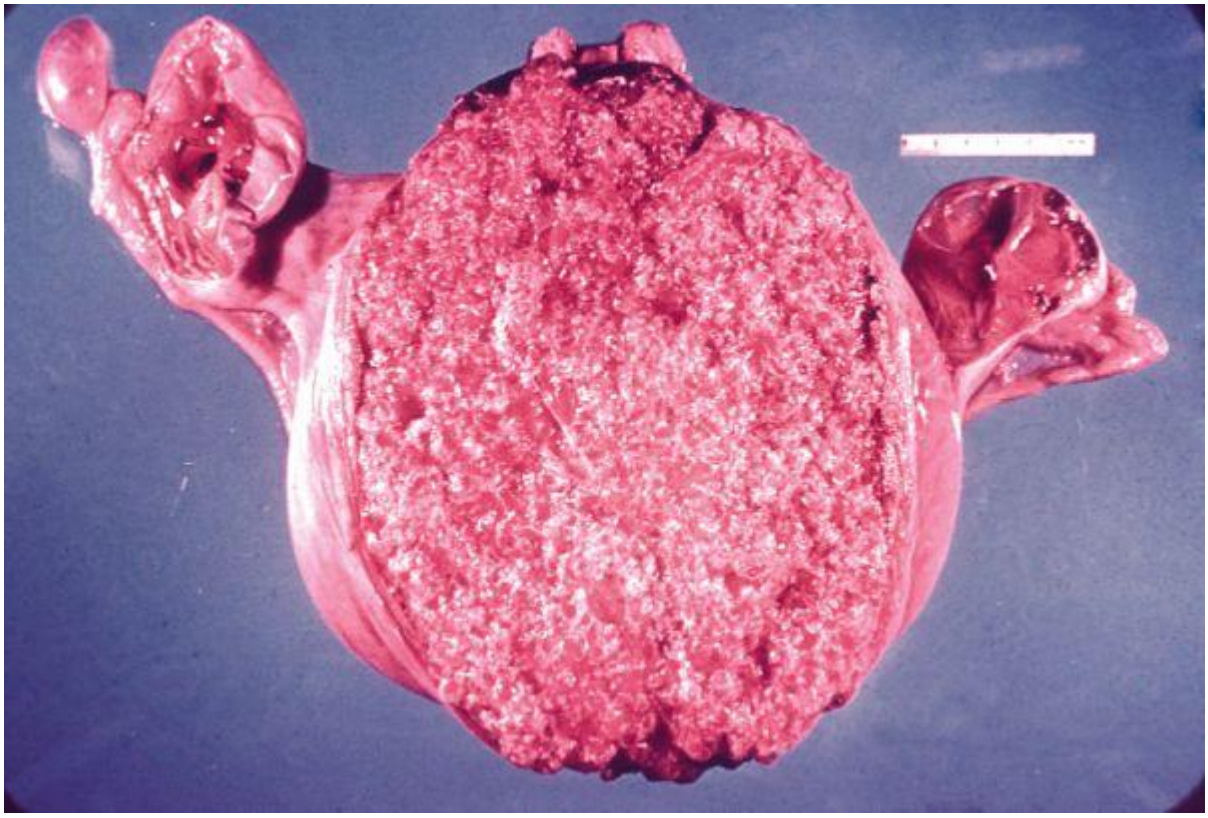

FIGURE 22-58 Complete hydatidiform mole. Note marked distention of the uterus by vesicular chorionic villi. Adnexa (ovaries and fallopian tubes) are visible on the *left* and *right side* of the uterus.

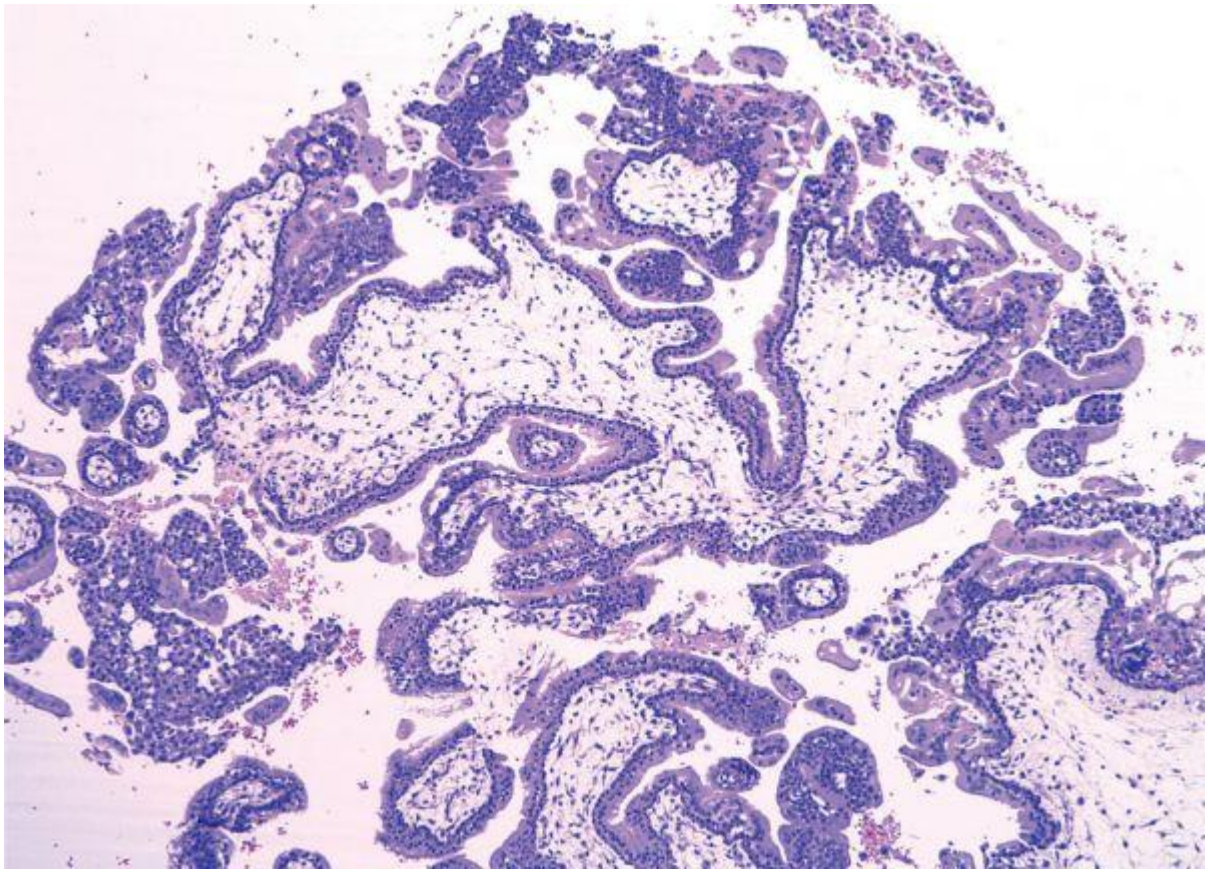

FIGURE 22-59 Complete hydatidiform mole demonstrating marked villous enlargement, edema, and circumferential trophoblast proliferation.

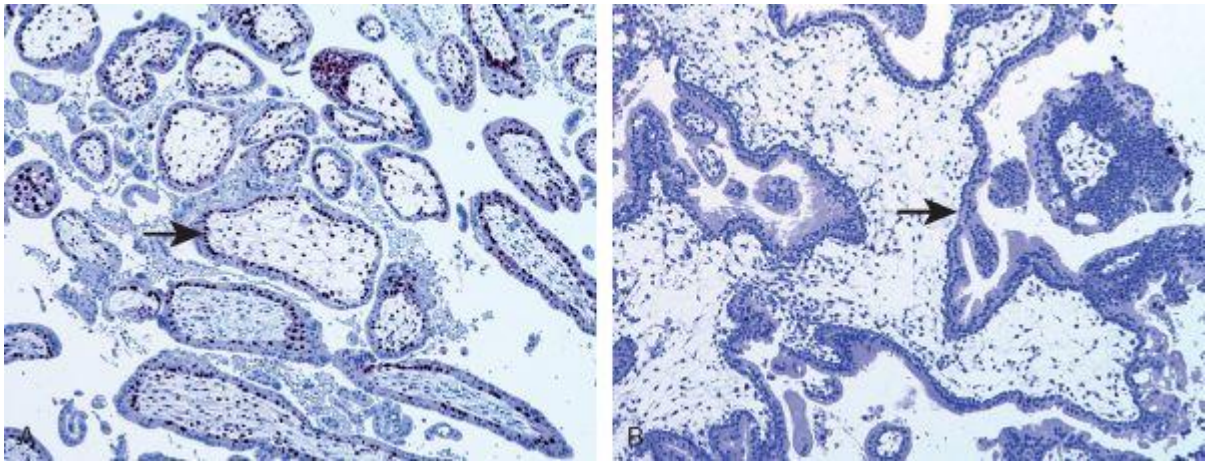

FIGURE 22-60 **A**, Normal chorionic villi immunostained for p57 exhibit staining in both stromal and cytotrophoblast *(arrow)* nuclei. **B**, Complete moles lack expression of p57 in the cytotrophoblast *(arrow)* and villous stroma.

Clinical Features.

Most women with partial and early complete moles present with spontaneous pregnancy loss or undergo curettage because of abnormalities in ultrasound showing diffuse villous enlargement. In complete moles quantitative analysis of human chorionic gonadotropin (HCG) shows levels of hormone greatly exceeding those produced during a normal pregnancy of similar gestational age. Serial hormone determination indicates a rapidly mounting level that climbs faster than for the usual normal single or even multiple pregnancy. The vast majority of moles are removed by thorough curettage. Monitoring serum concentrations of HCG is necessary to determine the early development of persistent trophoblastic disease, since up to 10% of moles develop into persistent or invasive moles.[115] In addition, 2.5% of complete moles evolve into gestational choriocarcinoma. Therefore, serum HCG levels are usually followed until they fall to and remain at zero for 6 months to a year.

INVASIVE MOLE

This is defined as a mole that penetrates or even perforates the uterine wall (Fig. 22-61). There is invasion of the myometrium by hydropic chorionic villi, accompanied by proliferation of both cytotrophoblast and syncytiotrophoblast. The tumor is locally destructive and may invade parametrial tissue and blood vessels. Hydropic villi may embolize to distant sites, such as lungs and brain, but do not grow in these organs as true metastases, and even without chemotherapy they eventually regress. The tumor is manifested clinically by vaginal bleeding and irregular uterine enlargement. It is always associated with a persistently elevated serum HCG and varying degrees of luteinization of the ovaries. The tumor responds well to chemotherapy but may result in uterine rupture and necessitate hysterectomy.

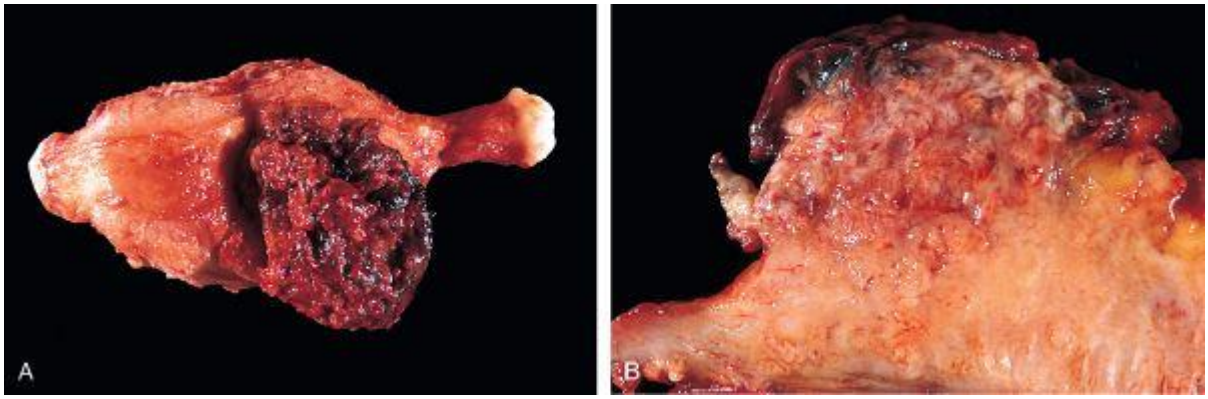

FIGURE 22-61 **A**, Invasive mole presenting as a hemorrhagic mass adherent to the uterine wall. **B**, On cross-section, the tumor invades into the myometrium. *(Courtesy of Dr. David R. Genest, Brigham and Women's Hospital, Boston, MA.)*

CHORIOCARCINOMA

Gestational choriocarcinoma is a malignant neoplasm of trophoblastic cells derived from a previously normal or abnormal pregnancy, which can even include extrauterine ectopic pregnancy. Choriocarcinoma is rapidly invasive and metastasizes widely, but once identified responds well to chemotherapy.

Incidence.

This is an uncommon condition that arises in 1 in 20,000 to 30,000 pregnancies in the United States. It is much more common in some African countries; for example, it occurs in 1 in 2500 pregnancies in Ibadan, Nigeria. It is preceded by several conditions; 50% arise in hydatidiform moles, 25% in previous abortions, approximately 22% in normal pregnancies (intraplacental choriocarcinoma), with the remainder occuring in ectopic pregnancies. Very rarely, a nongestational choriocarcinoma may develop from germ cells in the ovaries or the mediastinum. About 1 in 40 complete hydatidiform moles may be expected to give rise to a choriocarcinoma, in contrast to 1 in approximately 150,000 normal pregnancies.

Morphology. Choriocarcinoma is classically a soft, fleshy, yellow-white tumor with a marked tendency to form large pale areas of ischemic necrosis, foci of cystic softening, and extensive hemorrhage (Fig. 22-62A). Histologically, it does not produce chorionic villi and consists entirely of a mixed proliferation of syncytiotrophoblasts and cytotrophoblasts (Fig. 22-62B). Mitoses are abundant and sometimes abnormal. The tumor invades the underlying myometrium, frequently penetrates blood vessels and lymphatics, and in some cases extends out onto the uterine serosa and into adjacent structures. Due to rapid growth it is subject to hemorrhage, ischemic necrosis, and secondary inflammation. In fatal cases metastases are found in the lungs, brain, bone marrow, liver, and other organs. On occasion, metastatic choriocarcinoma is discovered without a detectable primary in the uterus (or ovary), presumably because the primary has undergone complete necrosis.

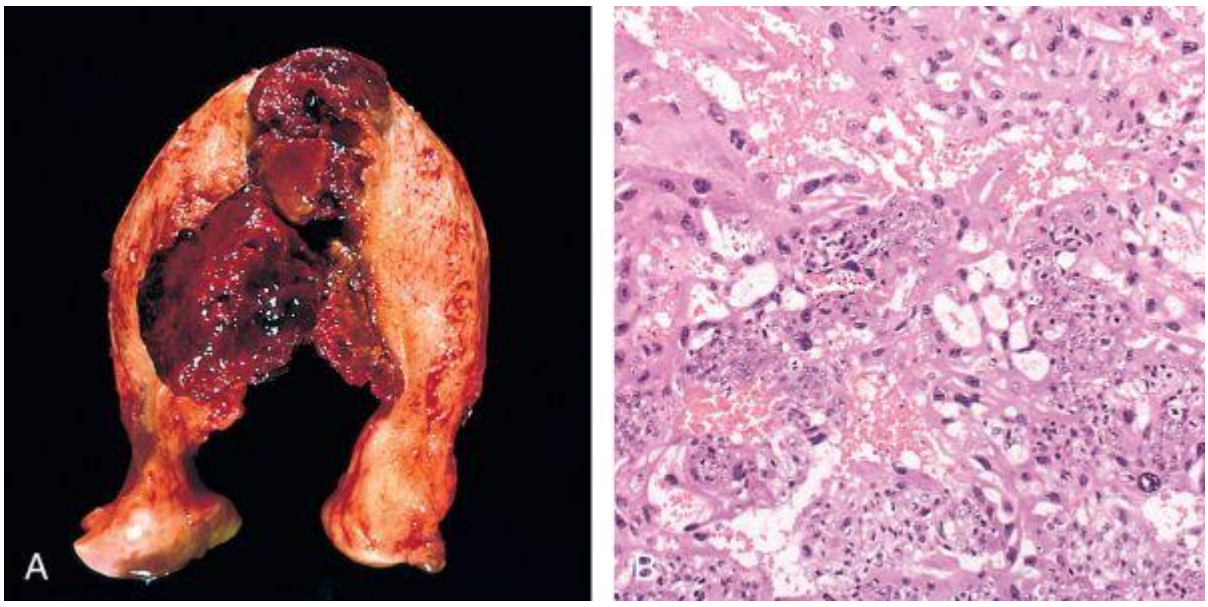

FIGURE 22-62 **A**, Choriocarcinoma presenting as a bulky hemorrhagic mass invading the uterine wall. **B**, Photomicrograph of choriocarcinoma illustrating both neoplastic cytotrophoblast and syncytiotrophoblast. *(Courtesy of Dr. David R. Genest, Brigham and Women's Hospital, Boston, MA.)*

Clinical Features.

Uterine choriocarcinoma usually does not produce a large, bulky mass, but it manifests as irregular vaginal spotting of a bloody, brown fluid. This discharge may appear in the course of an apparently normal pregnancy, after a miscarriage, or after curettage. Sometimes the tumor does not appear until months after these events. Usually, by the time the tumor is discovered, radiographs of the chest and bones already disclose the presence of metastatic lesions. The titers of HCG are elevated to levels above those encountered in hydatidiform moles. Occasionally, tumors produce little hormone, and some tumors become so necrotic as to become functionally inactive. Widespread metastases are characteristic. Frequent sites of involvement are the lungs (50%) and vagina (30% to 40%), followed in descending order of frequency by the brain, liver, and kidney.

The treatment of gestational choriocarcinoma (and other trophoblastic neoplasms) depends on the type and stage of the tumor and includes evacuation of the contents of the uterus, surgery, and chemotherapy. The results of chemotherapy for gestational choriocarcinoma are spectacular and result in nearly 100% remission and a high rate of cures. Many of the cured patients have had normal subsequent pregnancies and deliveries. By contrast, nongestational choriocarcinomas are much more resistant to therapy. The difference is believed to be due to the expression of paternal antigens in gestational choriocarcinomas that can evoke an immune response from the mother.

PLACENTAL-SITE TROPHOBLASTIC TUMOR (PSTT)

PSTTs compose less than 2% of gestational trophoblastic neoplasms and represent neoplastic proliferation of extravillous trophoblast, also called intermediate trophoblast. In normal pregnancy, extravillous (intermediate) trophoblast is found in nonvillous sites such as the implantation site, in islands of cells within the placental parenchyma, in the chorionic plate, and in the placental membranes. In contrast, syncytiotrophoblast and cytotrophoblast are present on the chorionic villi. Normal extravillous trophoblasts are polygonal mononuclear cells that have abundant cytoplasm and produce human placental lactogen. Malignant transformation of extravillous trophoblast gives rise to PSTT, which presents as a uterine mass (Fig. 22-63A), accompanied by either abnormal uterine bleeding or amenorrhea and moderate elevation of β-HCG. Histologically, PSTT is composed of malignant trophoblastic cells diffusely infiltrating the endomyometrium (Fig. 22-63B). PSTTs may be preceded by a normal pregnancy (one half), spontaneous abortion (one sixth), or hydatidiform mole (one fifth).[116,][117] Patients with localized disease or a less than 2-year interval from the prior pregnancy to diagnosis have an excellent prognosis. Tumors diagnosed at advanced stage, or diagnosed 2 or more years following pregnancy, have a poor prognosis; overall, about 10% to 15% of women with PSTT die of disseminated disease.[118]

3.13 23. The Breast

3.13.1 The Female Breast

THE FEMALE BREAST

The class Mammalia is distinguished from other animals by highly evolved modified skin appendages, known as mammary glands or breasts, that provide a complete source of nourishment and an important degree of immunological protection for offspring. In humans, paired mammary glands rest on the pectoralis muscle on the upper chest wall. The breasts are composed of specialized epithelium and stroma that may give rise to both benign and malignant lesions (Fig. 23-1).

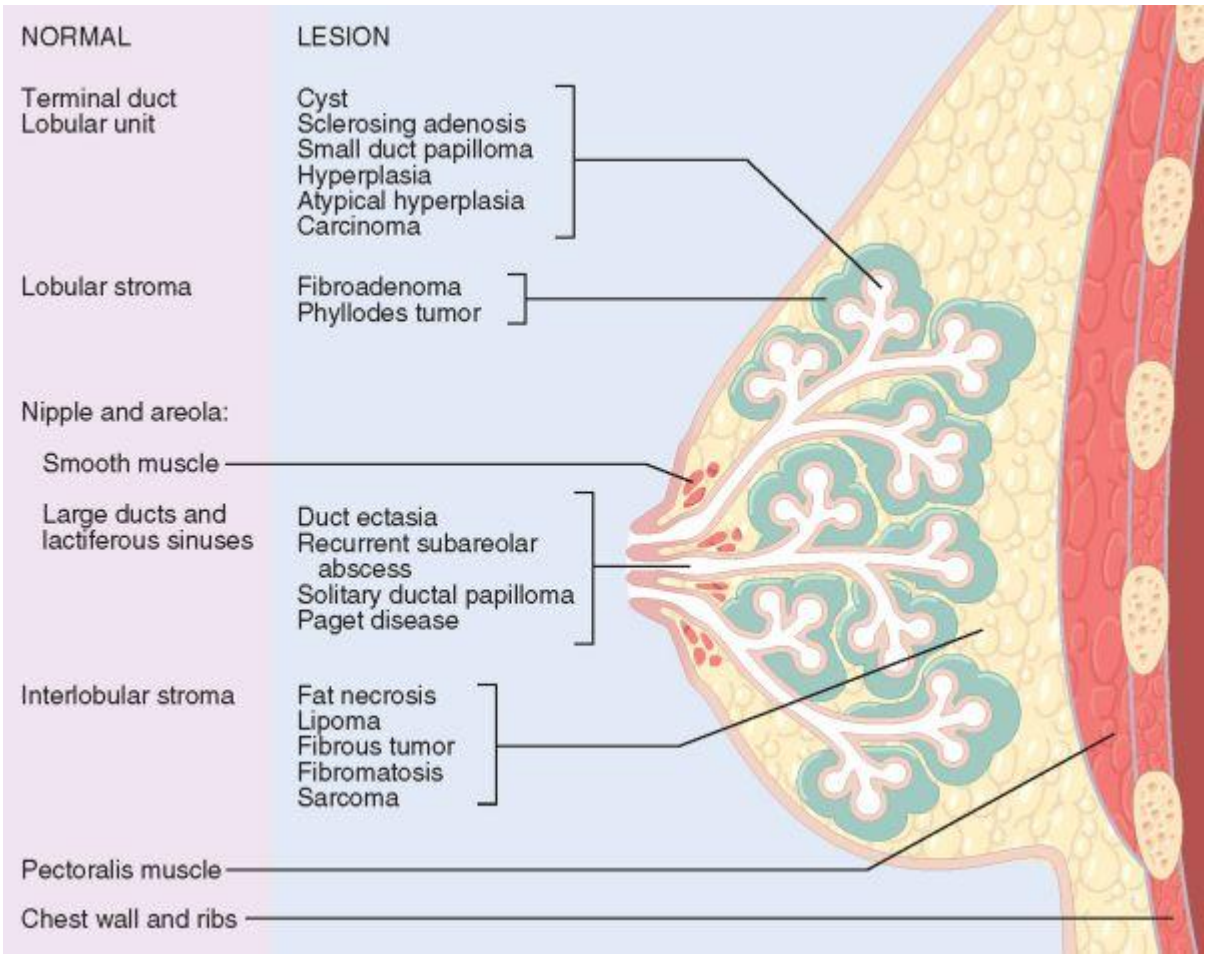

FIGURE 23-1 Anatomic origins of common breast lesions.

Diseases of the breast are best understood in the context of its normal anatomy. The human breast contains six to ten major ductal systems. The keratinizing squamous epithelium of the overlying skin dips into the orifices at the nipple and then abruptly changes to a double-layered cuboidal epithelium lining the ducts. Successive branching of the large ducts eventually leads to the terminal duct lobular unit. In adult women the terminal duct branches into a grapelike cluster of small acini to form a lobule (Figs. 23-1 and 23-2B). Each ductal system typically occupies more than one quadrant of the breast, and the systems extensively overlap one another. In some women, ducts extend into the subcutaneous tissue of the chest wall and into the axilla.

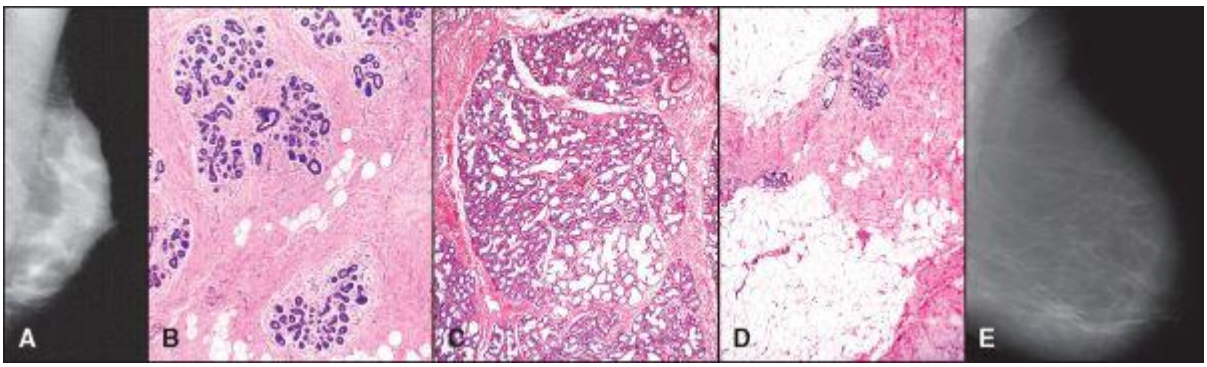

FIGURE 23-2 Life cycle changes. **A**, Mammograms in young women are typically radiodense or white in appearance, making mass-forming lesions or calcifications (which are also radiodense) difficult to detect. **B**, The density of a young woman's breast stems from the predominance of fibrous interlobular stroma and the paucity of adipose tissue. Before pregnancy the lobules are small and are invested by loose cellular intralobular stroma. Larger ducts connect lobules. **C**, During pregnancy, branching of terminal ducts produces more numerous, larger lobules. Luminal cells within lobules undergo lactational change, a precursor to milk formation. **D**, With increasing age the lobules decrease in size and number, and the interlobular stroma is replaced by adipose tissue. **E**, Mammograms become more radiolucent with age as a result of the increase in adipose tissue, which facilitates the detection of radiodense mass-forming lesions and calcifications. *(**A, E**, Courtesy of Dr. Darrell Smith, Brigham and Women's Hospital, Boston, MA.)*

Two cell types line the ducts and lobules. Contractile myoepithelial cells containing myofilaments lie in a meshlike pattern on the basement membrane. These cells assist in milk ejection during lactation and provide structural support to the lobules. Luminal epithelial cells overlay the myoepithelial cells. Only the lobular luminal cells are capable of producing milk. A committed stem cell in the terminal duct is postulated to give rise to both luminal and myoepithelial cells.[1]

There are also two types of breast stroma. The interlobular stroma consists of dense fibrous connective tissue admixed with adipose tissue. The intralobular stroma envelopes the acini of the lobules and consists of breast-specific hormonally responsive fibroblast-like cells admixed with scattered lymphocytes. There is important cross-talk between breast epithelium and stroma that promotes the normal structure and function of the breast.[2]

In the prepubertal breast in males and females, the large duct system ends in terminal ducts with minimal lobule formation. Changes in the breast are most dynamic and profound during the reproductive years (Fig. 23-2). Just as the endometrium grows and ebbs with each menstrual cycle, so does the breast.[3] In the first half of the menstrual cycle the lobules are relatively quiescent. After ovulation, under the influence of estrogen and rising progesterone levels, cell proliferation increases, as does the number of acini per lobule. The intralobular stroma also becomes markedly edematous. Upon menstruation, the fall in estrogen and progesterone levels induces the regression of the lobules and the disappearance of the stromal edema.

Only with the onset of pregnancy does the breast become completely mature and functional. Lobules increase progressively in number and size. As a consequence, by the end of the pregnancy the breast is composed almost entirely of lobules separated by relatively scant stroma (Fig. 23-2C).

Immediately after delivery of the baby the luminal cells of the lobules produce colostrum (high in protein), which changes to milk (higher in fat and calories) over the next 10 days as progesterone levels drop. Not surprisingly, given these profound morphologic changes, the terminally differentiated breast has a specific pattern of gene expression.[4]

Breast milk not only provides complete nourishment from birth until several years of age, but it also provides protection against infection, allergies, and some autoimmune diseases. Maternal antibodies (chiefly secretory IgA), vitamins, enzymes, and numerous other mediators (e.g., cytokines, antioxidants, fibronectin, and lysozyme) augment the infant's own developing immune defenses. However, certain drugs, radioactive compounds given during diagnostic procedures, and viruses can also be passed to the infant through breast milk.

Upon the cessation of lactation, the breast epithelium and stroma undergo extensive remodeling.[5] Epithelial cells undergo apoptosis, lobules regress and atrophy, and the total breast size is diminished. However, full regression does not occur, and as a result pregnancy causes a permanent increase in the size and number of lobules.

After the third decade, long before menopause, lobules and their specialized stroma start to involute. Lobular atrophy may be almost complete in elderly females (Fig. 23-2D). The interlobular stroma also changes, since the radiodense fibrous stroma of the young female (see Fig. 23-2A) is progressively replaced by radiolucent adipose tissue (Fig. 23-2E).

3.13.1.1 Disorders of Development

Milkline Remnants.

Supernumerary nipples or breasts result from the persistence of epidermal thickenings along the milk line, which extends from the axilla to the perineum. The disorders that affect the normally situated breast rarely arise in these heterotopic, hormone-responsive foci, which most commonly come to attention as a result of painful premenstrual enlargements.

Accessory Axillary Breast Tissue.

In some women the normal ductal system extends into the subcutaneous tissue of the chest wall or the axillary fossa (the "axillary tail of Spence"). This epithelium can undergo lactational changes (resulting in a palpable mass) or give rise to carcinomas outside the breast proper. Therefore, prophylactic mastectomies markedly reduce, but do not completely eliminate, the risk of breast cancer.

Congenital Nipple Inversion.

The failure of the nipple to evert during development is common and may be unilateral. Congenitally inverted nipples usually correct spontaneously during pregnancy, or can sometimes be everted by simple traction. Acquired nipple retraction is of more concern, since it may indicate the presence of an invasive cancer or an inflammatory disorder (e.g., recurrent subareolar abscess or duct ectasia).

3.13.1.2 Clinical Presentations of Breast Disease

The most common symptoms reported by women are pain, a palpable mass, "lumpiness" (without a discrete mass), or nipple discharge (Fig. 23-3). Asymptomatic women with abnormal findings on mammographic screening also require further evaluation.

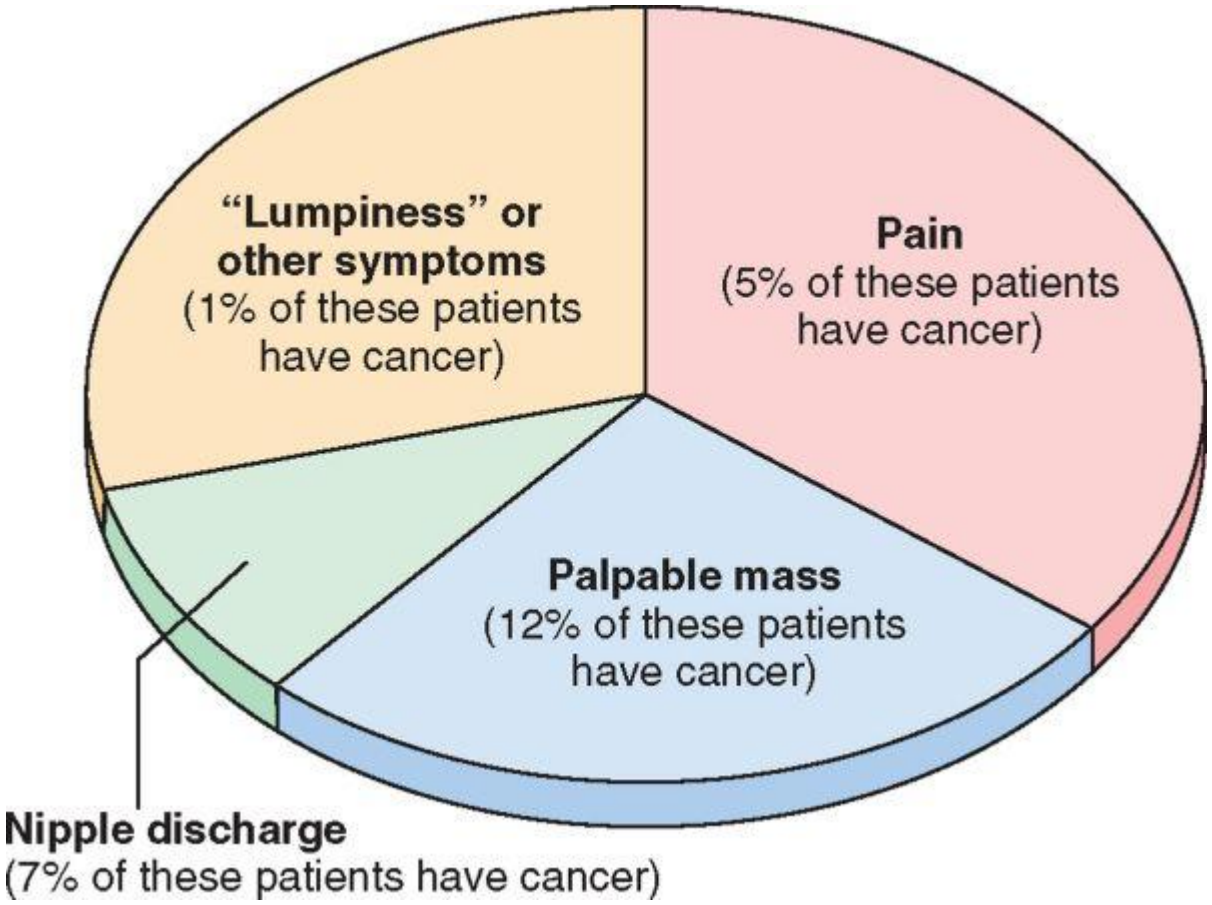

FIGURE 23-3 Common clinical symptoms of breast disease.

Pain (mastalgia or mastodynia) is a common symptom that may be cyclic with menses or noncyclic. Diffuse cyclic pain has no pathologic correlate, and most effective treatments target hormone levels. Noncyclic pain is usually localized to one area of the breast. Causes include ruptured cysts, physical injury, and infections, but most often no specific lesion is identified. Although roughly 95% of painful masses are benign, it must be remembered that about 10% of breast cancers are painful.

Discrete *palpable masses* are also common and must be distinguished from the normal nodularity (or "lumpiness") of the breast. The most common palpable lesions are invasive carcinomas, fibroadenomas, and cysts. A breast mass generally becomes palpable when it is at least 2 cm in size. Palpable masses are most common in premenopausal women (Fig. 23-4), but the likelihood of a palpable mass being malignant increases with age. For example, only 10% of breast masses in women under age 40 are malignant as compared with 60% of masses in women over age 50. Approximately 50% of carcinomas arise in the upper outer quadrant, 10% in each of the remaining quadrants, and about 20% in the central or subareolar region.

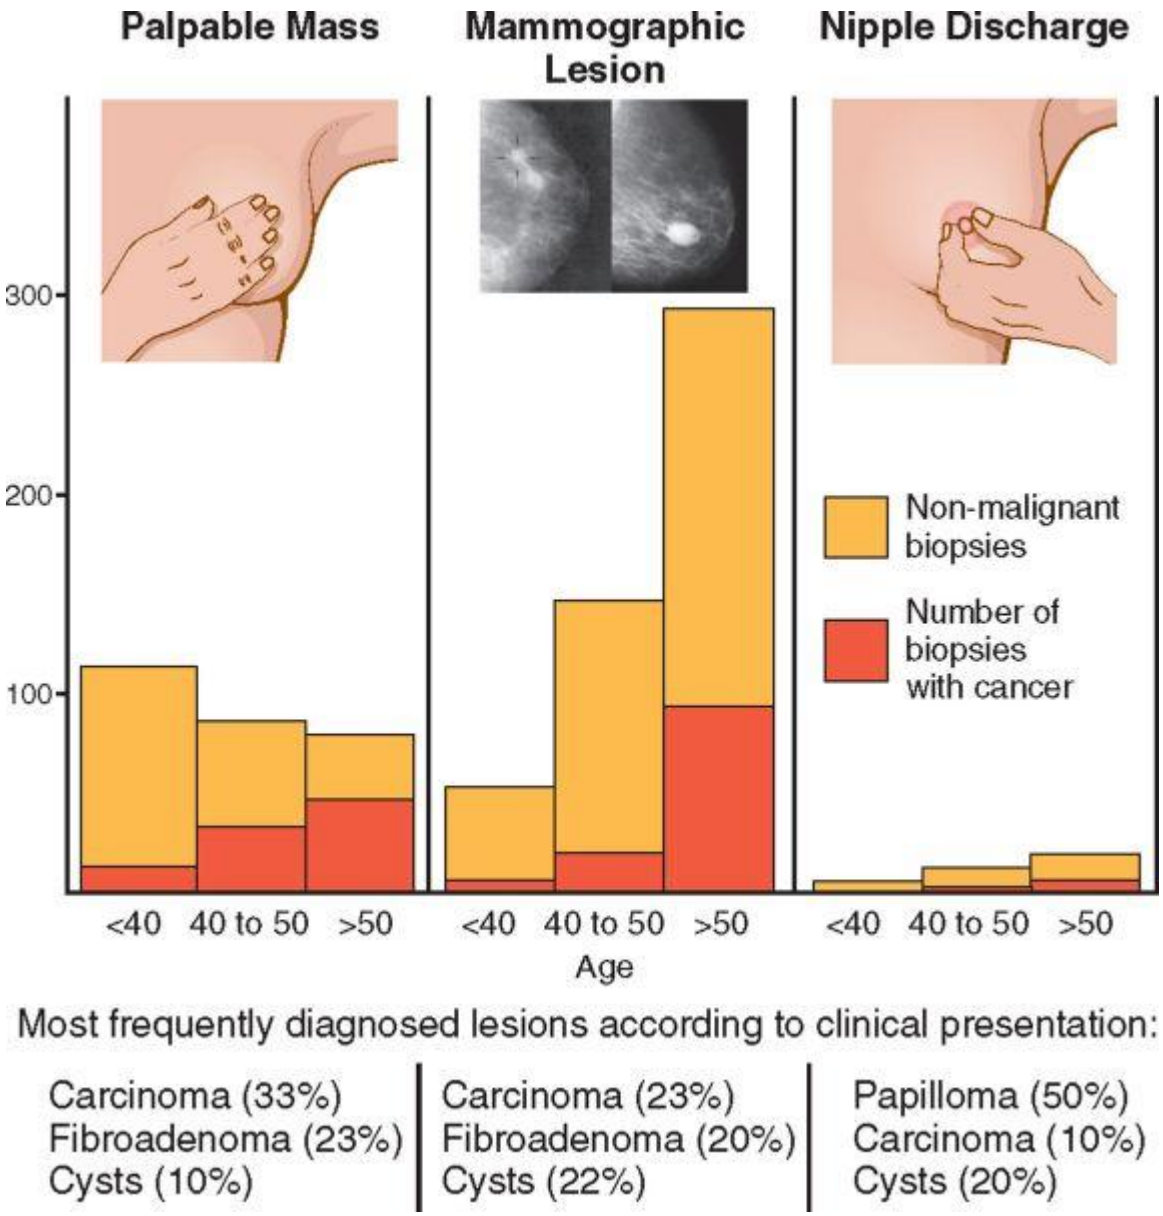

FIGURE 23-4 Frequency of pathologically diagnosed benign and malignant breast lesions by clinical presentation and age. Based on 914 women undergoing diagnostic breast surgery at Brigham and Women's Hospital (Boston, MA) from January to June 2001.

Nipple discharge is a less common finding that is most worrisome when it is spontaneous and unilateral, since it might be from an underlying carcinoma. A small discharge is often produced by the manipulation of normal breasts. Milky discharges (galactorrhea) are associated with elevated prolactin levels (e.g., by a pituitary adenoma), hypothyroidism, or endocrine anovulatory syndromes, and can also occur in patients taking oral contraceptives, tricyclic antidepressants, methyldopa, or phenothiazines. Repeated nipple stimulation can also induce lactation (a method sometimes used by women who wish to breastfeed adopted infants). Galactorrhea is not associated with malignancy.

Bloody or serous discharges are also most commonly associated with benign conditions, but in a significant minority of cases can be a sign of malignancy. The most common etiologies are solitary large duct papillomas and cysts. Benign bloody discharges may also occur during pregnancy, possibly as a result of the rapid growth and remodeling of the breast. The risk of malignancy with discharge

increases with age, since it is associated with carcinoma in 7% of women younger than 60 years and in 30% of women older than 60 years (see Fig. 23-4). There is considerable interest in using induced nipple discharges as a source of cells and DNA for noninvasive cytologic and molecular breast cancer screening tests.[6]

Mammographic screening was introduced in the 1980s as a means to detect small, nonpalpable, asymptomatic breast carcinomas (discussed later). The sensitivity and specificity of mammography increase with age, as a result of replacement of the fibrous, radiodense tissue of youth with the fatty, radiolucent tissue of the elderly (see Fig. 23-2). At age 40, the probability that a mammographic lesion is cancer is only 10%, but this rises to greater than 25% in women over 50 (see Fig. 23-4). *The principal mammographic signs of breast carcinoma are densities and calcifications:*

- *Densities*. Mammographic densities are produced most commonly by invasive carcinomas, fibroadenomas, or cysts (see Fig. 23-4). Most neoplasms are radiologically denser than the intermingled normal breast tissue. The value of mammography lies in its ability to identify small, nonpalpable cancers. For example, the average size of an invasive carcinoma detected by mammography (1.1 cm) is less than half that of carcinomas detected by palpation (2.4 cm).
- *Calcifications*. Calcifications form on secretions, necrotic debris, or hyalinized stroma. Benign calcifications are often associated with clusters of apocrine cysts, hyalinized fibroadenomas, and sclerosing adenosis. Calcifications associated with malignancy are usually small, irregular, numerous, and clustered. Ductal carcinoma in situ (DCIS) is most commonly detected as mammographic calcifications, which are often deposited in a linear, branching pattern as the carcinoma fills the ductal system. Mammographic screening has increased the number of breast cancers diagnosed as DCIS (see Fig. 23-13). Invasive carcinomas presenting as calcifications without an accompanying radiodensity are uncommon, generally small in size, and rarely associated with lymph node metastases.

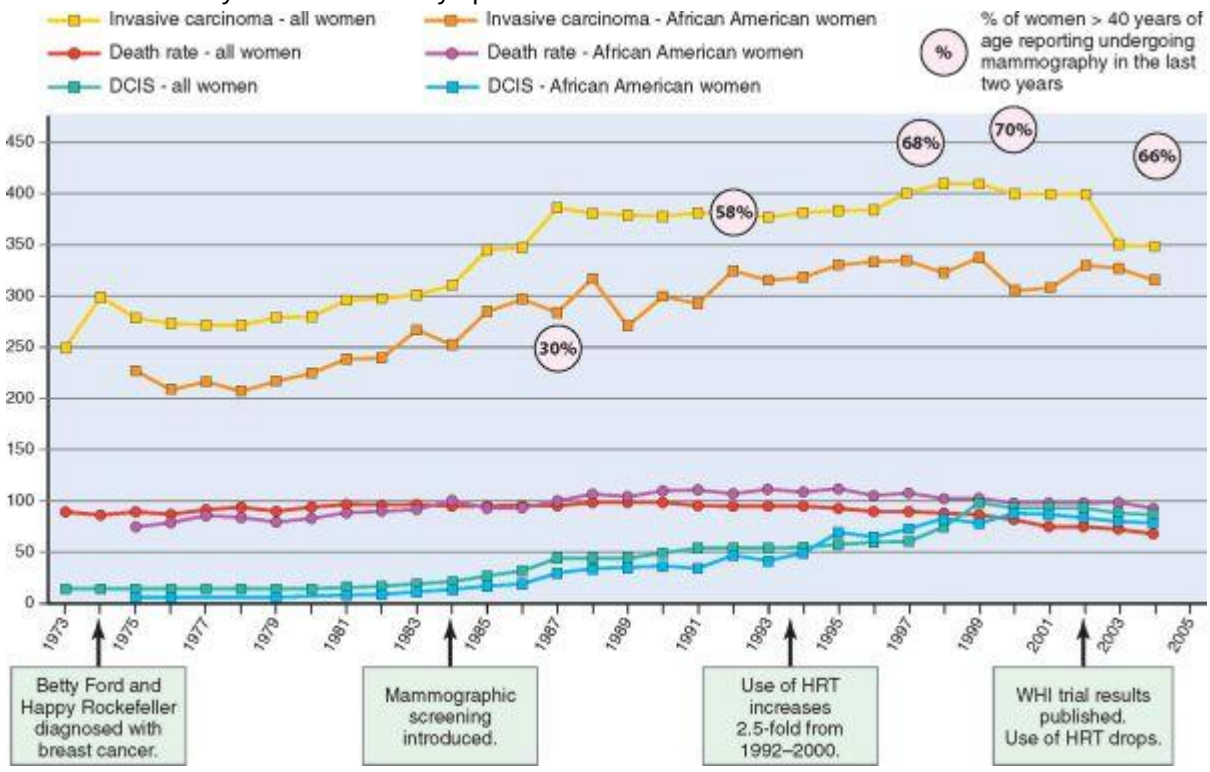

FIGURE 23-13 Breast cancer incidence and mortality rates for women over 50 years of age. Rates are per 100,000 women and are age-adjusted to the 2000 US standard million population. (SEER Cancer Statistics Review; http://seer.cancer.gov/)

In about 10% of cases, carcinomas are missed by mammography. The principal causes of these failures are the presence of surrounding radiodense tissue (especially in younger women) that obscures the tumor, the absence of calcifications, small size, a diffuse infiltrative pattern with little or no desmoplastic response, or a location close to the chest wall or in the periphery of the breast. The inability to image a palpable mass does not indicate that it is benign, and all palpable masses require further investigation.

Other imaging modalities are useful adjuncts. Ultrasonography distinguishes between solid and cystic lesions and can define more precisely the borders of solid lesions. Most palpable masses that are not imaged by mammography are detectable by ultrasound. Magnetic resonance imaging (MRI) detects cancers by the rapid uptake of contrast agents due to increased tumor vascularity and blood flow. It is useful in screening for cancer in women with dense breasts or at very high risk for cancer, in determining the extent of chest wall invasion by locally advanced cancers, and in the evaluation of breast implant rupture. A high rate of false-positive results limits its usefulness in screening women outside of these groups.

3.13.1.3 Inflammatory Disorders

Inflammatory diseases of the breast are uncommon, accounting for less than 1% of women with breast symptoms. Women usually present with an erythematous swollen painful breast. “Inflammatory breast cancer” mimics inflammation by obstructing dermal vasculature with tumor emboli, resulting in an enlarged erythematous breast, and should always be suspected in a nonlactating woman with the clinical appearance of mastitis.

ACUTE MASTITIS

Almost all cases of acute mastitis occur during the first month of breastfeeding. During this time the breast is vulnerable to bacterial infection because of the development of cracks and fissures in the nipples. From this portal of entry, *Staphylococcus aureus* or, less commonly, streptococci invade the breast tissue. The breast is erythematous and painful, and fever is often present. At the outset only one duct system or sector of the breast is involved. If not treated the infection may spread to the entire breast.

Morphology. Staphylococcal infections usually produce a localized area of acute inflammation that may progress to the formation of single or multiple abscesses. Streptococcal infections tend to cause (as elsewhere) a diffuse spreading infection that eventually involves the entire breast. The involved breast tissue is infiltrated by neutrophils and may be necrotic.

Most cases of lactational mastitis are easily treated with appropriate antibiotics and continued expression of milk from the breast. Rarely, surgical drainage is required.

PERIDUCTAL MASTITIS

This condition is known by a variety of names, including recurrent subareolar abscess, squamous metaplasia of lactiferous ducts, and Zuska disease. Women, and sometimes men, present with a painful erythematous subareolar mass that clinically appears to be an infectious process. More than 90% of the afflicted are smokers. This condition is not associated with lactation, a specific reproductive history, or age. In recurrent cases, a fistula tract often tunnels under the smooth muscle of the nipple and opens onto the skin at the edge of the areola. Many women with this condition have an inverted nipple, most likely as a secondary effect of the underlying inflammation. The strong association with cigarette

smoking is intriguing. It has been suggested that the vitamin A deficiency associated with smoking or toxic substances in tobacco smoke alter the differentiation of the ductal epithelium.[7]

Morphology. The key histologic feature is keratinizing squamous metaplasia of the nipple ducts (Fig. 23-5). Keratin shed from these cells plugs the ductal system, causing dilation and eventually rupture of the duct. An intense chronic and granulomatous inflammatory response develops once keratin spills into the surrounding periductal tissue. Sometimes a secondary bacterial infection supervenes and causes acute inflammation.

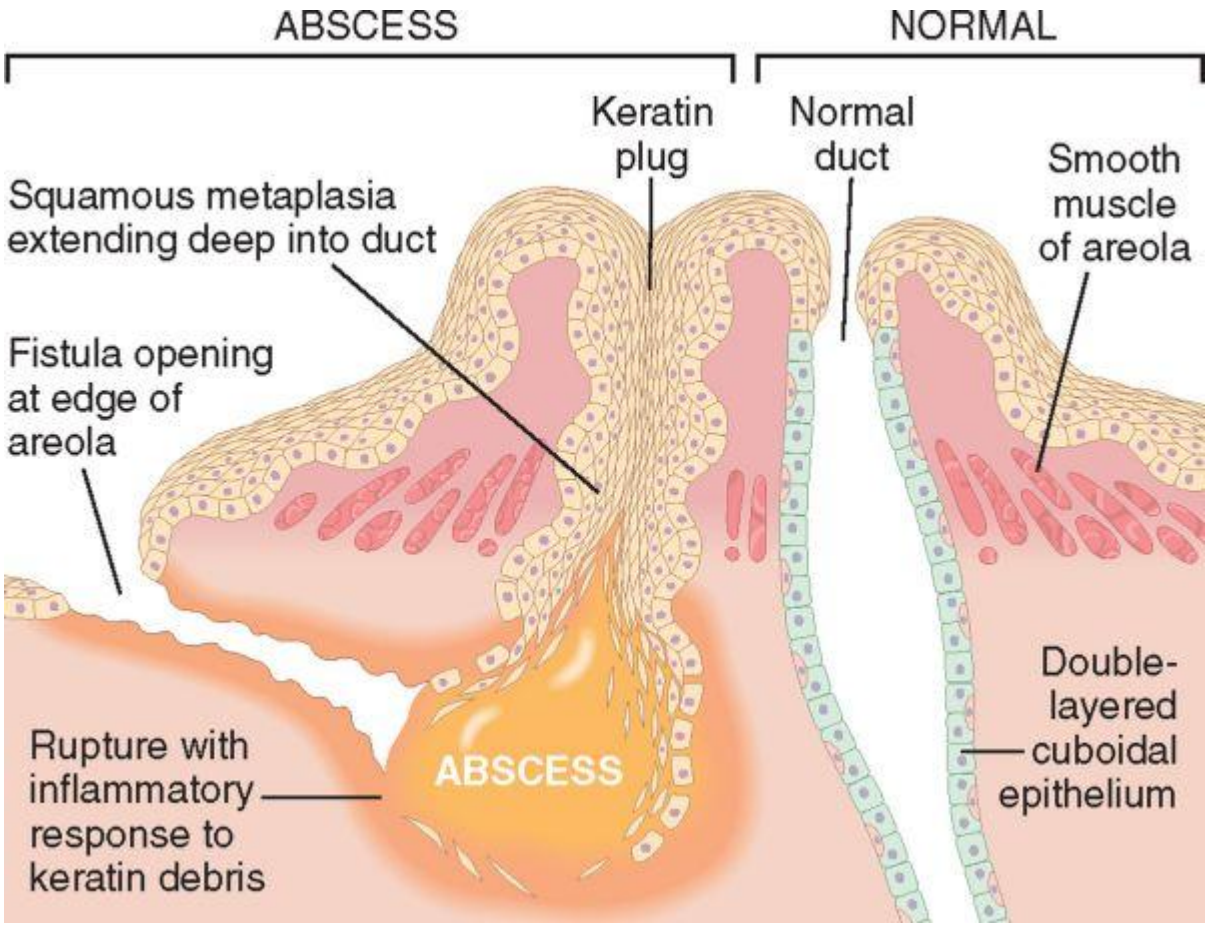

FIGURE 23-5 Recurrent subareolar abscess. When squamous metaplasia extends deep into a nipple duct, keratin becomes trapped and accumulates. If the duct ruptures, the ensuing intense inflammatory response to keratin results in an erythematous painful mass. A fistula tract may burrow beneath the smooth muscle of the nipple to open at the edge of the areola.

In most cases en bloc surgical removal of the involved duct and contiguous fistula tract is curative.[7] Simple incision drains the abscess cavity, but the offending keratinizing epithelium remains and recurrences are common. When bacterial infection is present, antibiotics also have a therapeutic role.

MAMMARY DUCT ECTASIA

This disorder tends to occur in the fifth or sixth decade of life, usually in multiparous women. Unlike periductal mastitis, it is not associated with cigarette smoking. Patients present with a poorly defined

palpable periareolar mass that is often associated with thick, white nipple secretions and sometimes with skin retraction. Pain and erythema are uncommon.

Morphology. This lesion is characterized chiefly by dilation of ducts, inspissation of breast secretions, and a marked periductal and interstitial chronic granulomatous inflammatory reaction (Fig. 23-6). The dilated ducts are filled by granular debris that contains numerous lipid-laden macrophages. The periductal and interductal tissue contains dense infiltrates of lymphocytes and macrophages, and variable numbers of plasma cells. On occasion, granulomatous inflammation forms around cholesterol deposits. Fibrosis may eventually produce skin and nipple retraction. Squamous metaplasia of nipple ducts is absent.

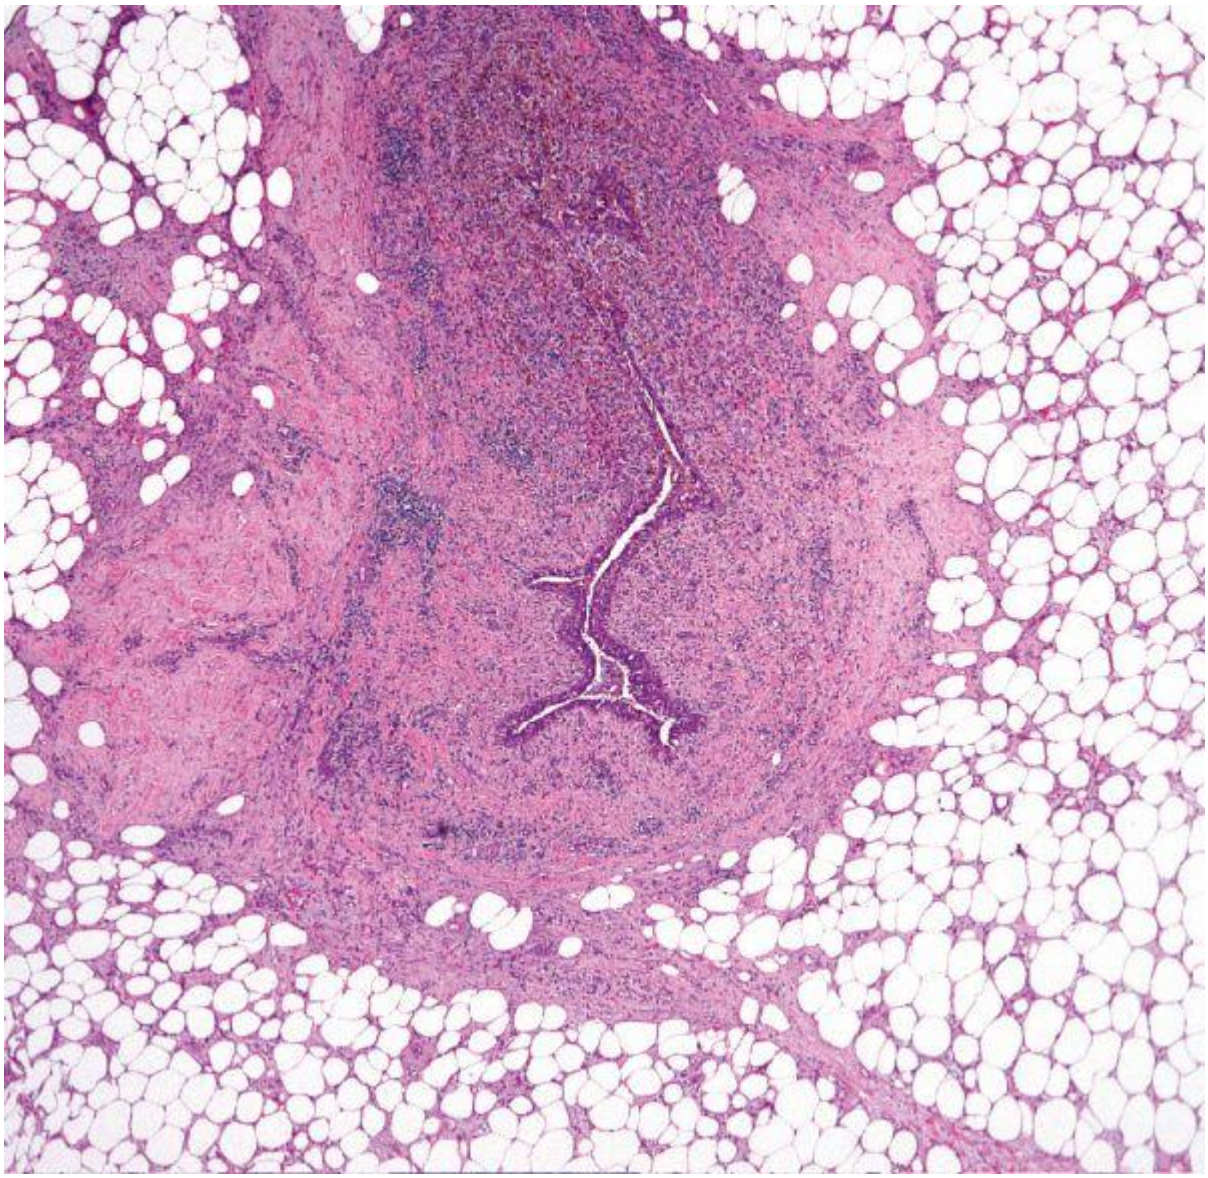

FIGURE 23-6 Mammary duct ectasia. Chronic inflammation and fibrosis surround an ectatic duct filled with inspissated debris. The fibrotic response can produce a firm irregular mass that mimics invasive carcinoma on palpation or mammogram.

The principal significance of this disorder is that it produces an irregular palpable mass that mimics the mammographic appearance of carcinoma.

FAT NECROSIS

Fat necrosis can present as a painless palpable mass, skin thickening or retraction, a mammographic density, or mammographic calcifications. The majority of affected women have a history of breast trauma or prior surgery.

Morphology. Acute lesions may be hemorrhagic and contain central areas of liquefactive fat necrosis. In subacute lesions the areas of fat necrosis take on the appearance of ill-defined, firm, gray-white nodules containing small chalky-white foci or dark hemorrhagic debris. The central region of necrotic fat cells is initially associated with an intense neutrophilic infiltrate mixed with macrophages. Over the next few days proliferating fibroblasts associated with new vessels and chronic inflammatory cells surround the injured area. Subsequently, giant cells, calcifications, and hemosiderin make their appearance, and eventually the focus is replaced by scar tissue or is encircled and walled off by fibrous tissue.

As with other inflammatory breast disorders, the major clinical significance of the condition is its possible confusion with breast cancer.

LYMPHOCYTIC MASTOPATHY (SCLEROSING LYMPHOCYTIC LOBULITIS)

This condition presents with single or multiple hard palpable masses. The masses may be bilateral and may be detected as mammographic densities. The lesions are so hard that it can be difficult to obtain tissue with a needle biopsy. Microscopically, they show collagenized stroma surrounding atrophic ducts and lobules. The epithelial basement membrane is often thickened. A prominent lymphocytic infiltrate surrounds the epithelium and small blood vessels. This condition is most common in women with type 1 (insulin-dependent) diabetes or autoimmune thyroid disease. Based on this association, it is hypothesized to have an autoimmune basis. Its only clinical significance is that it must be distinguished from breast cancer.

GRANULOMATOUS MASTITIS

Granulomatous inflammation is present in less than 1% of all breast biopsy specimens. The causes include systemic granulomatous diseases (e.g., Wegener granulomatosis or sarcoidosis) that occasionally involve the breast, and granulomatous infections caused by mycobacteria or fungi. Infections of this type are most common in immunocompromised patients or adjacent to foreign objects such as breast prostheses or nipple piercings. *Granulomatous lobular mastitis* is an uncommon breast-limited disease that only occurs in parous women. The granulomatous inflammation is confined to the lobules, suggesting that it is caused by a hypersensitivity reaction to antigens expressed by lobular epithelium during lactation.

3.13.1.4 Benign Epithelial Lesions

A wide variety of benign alterations in ducts and lobules are observed in the breast. Most come to clinical attention when detected by mammography or as incidental findings in surgical specimens. These lesions have been divided into three groups, according to the subsequent risk of developing breast cancer: (1) nonproliferative breast changes, (2) proliferative breast disease, and (3) atypical hyperplasia.

NONPROLIFERATIVE BREAST CHANGES (FIBROCYSTIC CHANGES)

This group includes a number of very common morphologic alterations that are often grouped under the term *fibrocystic changes*. To the clinician the term might mean "lumpy bumpy" breasts on palpation; to the radiologist, a dense breast with cysts; and to the pathologist, benign histologic findings. These lesions are termed *nonproliferative* to distinguish them from "proliferative" changes, which are associated with an increased risk of breast cancer.

Morphology. There are three principal morphologic changes: (1) cystic change, often with apocrine metaplasia; (2) fibrosis; and (3) adenosis.

- ***Cysts*.** Small cysts form by the dilation and unfolding of lobules, and in turn may coalesce to form larger cysts. Unopened cysts contain turbid, semi-translucent fluid that produces a brown or blue color (blue-dome cysts) (Fig. 23-7B). Cysts are lined either by a flattened atrophic epithelium or by metaplastic apocrine cells. The latter cells, which have an abundant granular, eosinophilic cytoplasm and round nuclei, closely resemble the normal apocrine epithelium of sweat glands (Fig. 23-7C). Calcifications are common and may be detected by mammography (see Fig. 23-7A). "Milk of calcium" is a term mammographers use to describe calcifications that line the bottom of a rounded cyst. Cysts are alarming when they are solitary and firm to palpation. The diagnosis is confirmed by the disappearance of the cyst after fine-needle aspiration of its contents.
- ***Fibrosis*.** Cysts frequently rupture, releasing secretory material into the adjacent stroma. The resulting chronic inflammation and fibrosis contribute to the palpable firmness of the breast.
- ***Adenosis*.** Adenosis is defined as an increase in the number of acini per lobule. A normal physiologic adenosis occurs during pregnancy. In nonpregnant women, adenosis can occur as a focal change. The acini are often enlarged (blunt-duct adenosis), but are not distorted as is seen in sclerosing adenosis, described later. Calcifications are occasionally present within the lumens. The acini are lined by columnar cells, which may appear benign or show atypical features ("flat epithelial atypia"). These lesions may be the earliest recognizable precursor of epithelial neoplasia. [8] [9] [10]

Lactational adenomas present as palpable masses in pregnant or lactating women. They are formed by normal-appearing breast tissue with physiologic adenosis and lactational changes. These lesions are probably not true neoplasms but an exaggerated focal response to hormonal influences.

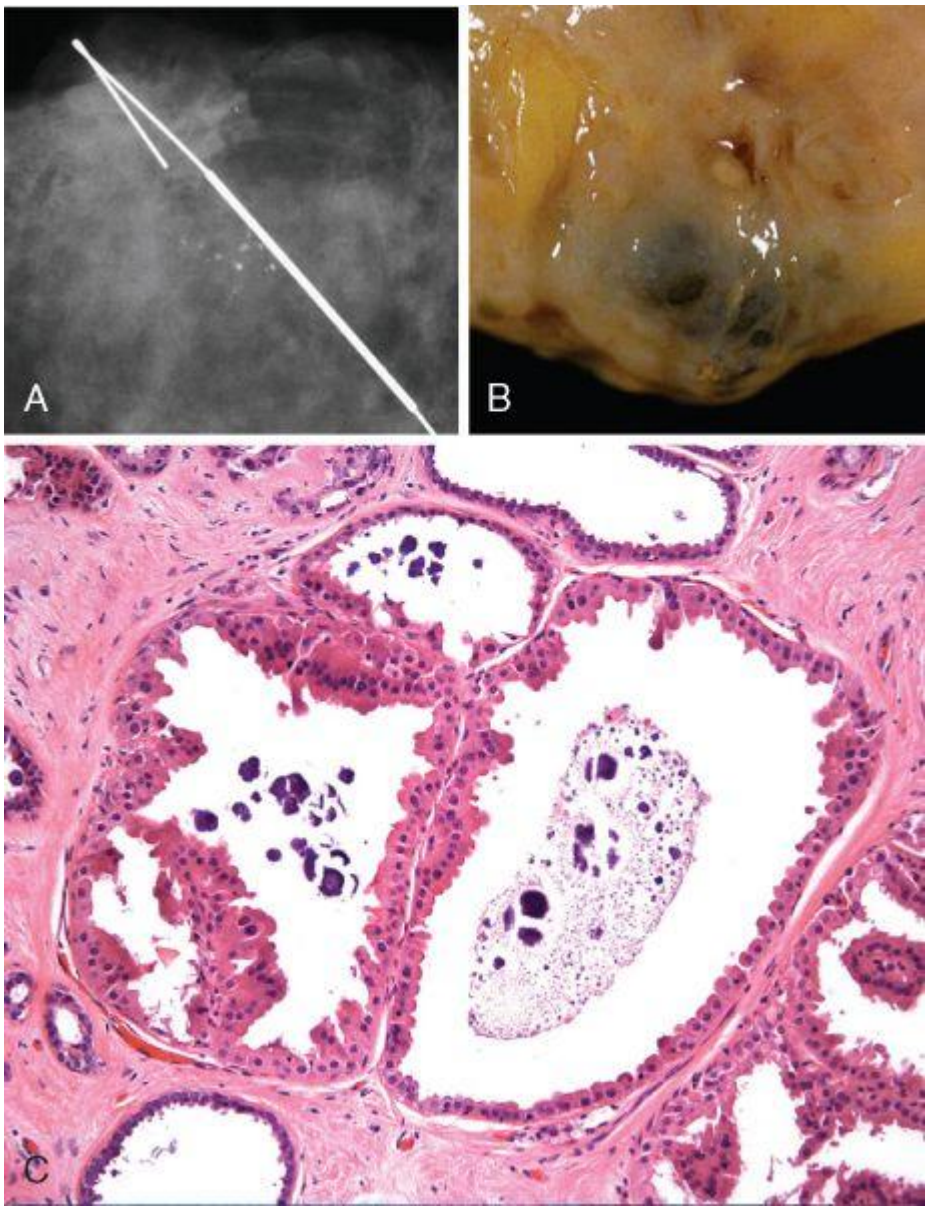

FIGURE 23-7 Apocrine cysts. **A**, Clustered, rounded calcifications are seen in a radiograph. **B**, Gross appearance of typical cysts filled with dark, turbid fluid contents. **C**, Cysts are lined by apocrine cells with round nuclei and abundant granular cytoplasm. Note the luminal calcifications, which form on secretory debris.

PROLIFERATIVE BREAST DISEASE WITHOUT ATYPIA

These changes are commonly detected as mammographic densities, calcifications, or as incidental findings in specimens from biopsies performed for other reasons. Although each can be found in isolation, typically more than one lesion is present, frequently in association with nonproliferative breast changes.

These lesions are characterized by proliferation of ductal epithelium and/or stroma without cytologic or architectural features suggestive of carcinoma in situ.

Morphology

***Epithelial Hyperplasia*.** Normal breast ducts and lobules are lined by a double layer of myoepithelial cells and luminal cells (Fig. 23-8A). Epithelial hyperplasia is defined by the presence of more than two cell layers. The additional cells consist of both luminal and myoepithelial cell types that fill and distend ducts and lobules. Irregular lumens can often be discerned at the periphery of the cellular masses (Fig. 23-8B). Epithelial hyperplasia is usually an incidental finding.

***Sclerosing Adenosis*.** The number of acini per terminal duct is increased to at least double the number found in uninvolved lobules. The normal lobular arrangement is maintained. The acini are compressed and distorted in the central portions of the lesion but characteristically dilated at the periphery. Myoepithelial cells are usually prominent. On occasion, stromal fibrosis may completely compress the lumens to create the appearance of solid cords or double strands of cells lying within dense stroma, a histologic pattern that at times closely mimics the appearance of invasive carcinoma (Fig. 23-9). Sclerosing adenosis can come to attention as a palpable mass, a radiologic density, or calcifications.

***Complex Sclerosing Lesion.*.** Complex sclerosing lesions have components of sclerosing adenosis, papillomas, and epithelial hyperplasia. One member of this group, the radial sclerosing lesion ("radial scar"), is the only commonly occurring benign lesion that forms irregular masses and can closely mimic invasive carcinoma mammographically, grossly, and histologically (Fig. 23-10). There is a central nidus of entrapped glands in a hyalinized stroma with long radiating projections into stroma. The term *radial scar* is a misnomer, as these lesions are not associated with prior trauma or surgery.

***Papillomas*.** Papillomas are composed of multiple branching fibrovascular cores, each having a connective tissue axis lined by luminal and myoepithelial cells (Fig. 23-11). Growth occurs within a dilated duct. Epithelial hyperplasia and apocrine metaplasia are frequently present. Large duct papillomas are usually solitary and situated in the lactiferous sinuses of the nipple. Small duct papillomas are commonly multiple and located deeper within the ductal system.

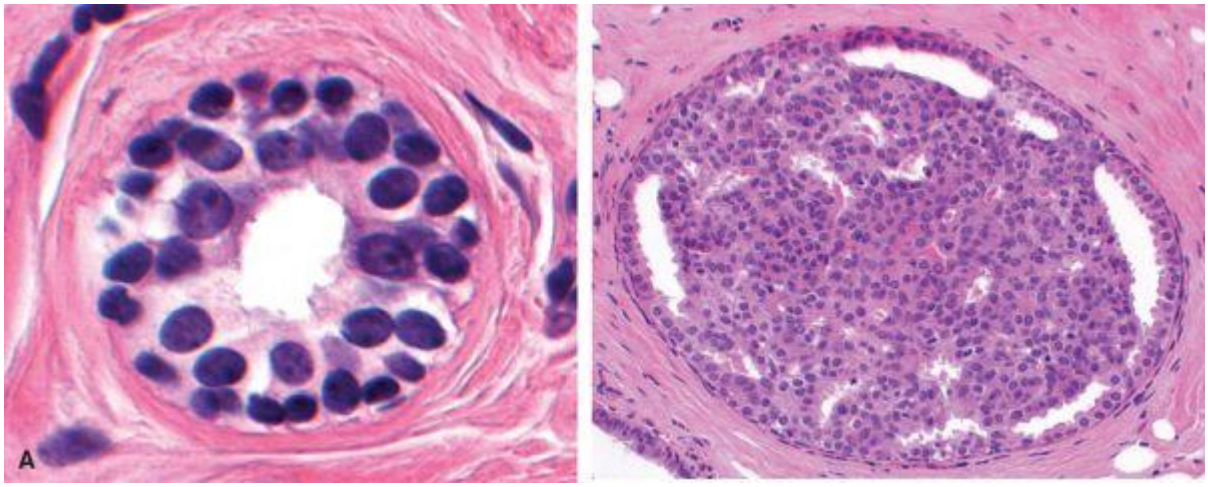

FIGURE 23-8 A, A normal duct or acinus with a single basally located myoepithelial cell layer (cells with dark, compact nuclei and scant cytoplasm) and a single luminal cell layer (cells with larger open nuclei, small nucleoli, and more abundant cytoplasm). **B**, Epithelial hyperplasia. The lumen is filled by a heterogeneous, mixed population of luminal and myoepithelial cell types. Irregular slitlike fenestrations are prominent at the periphery.

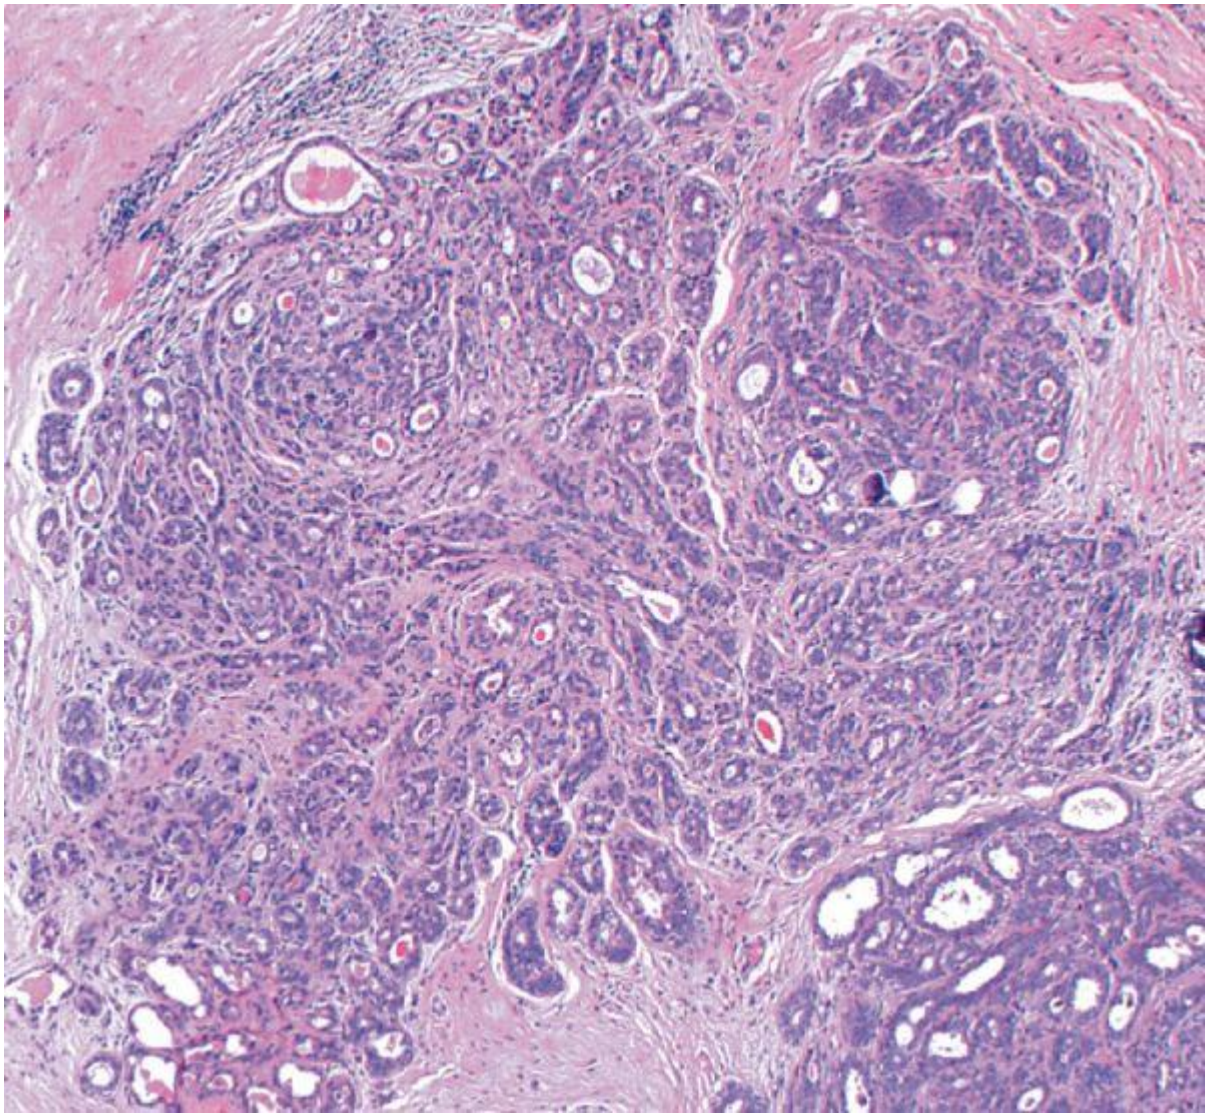

FIGURE 23-9 Sclerosing adenosis. The involved terminal duct lobular unit is enlarged, and the acini are compressed and distorted by dense stroma. Calcifications are present within some of the lumens. Unlike carcinomas, the acini are arranged in a swirling pattern, and the outer border is well circumscribed.

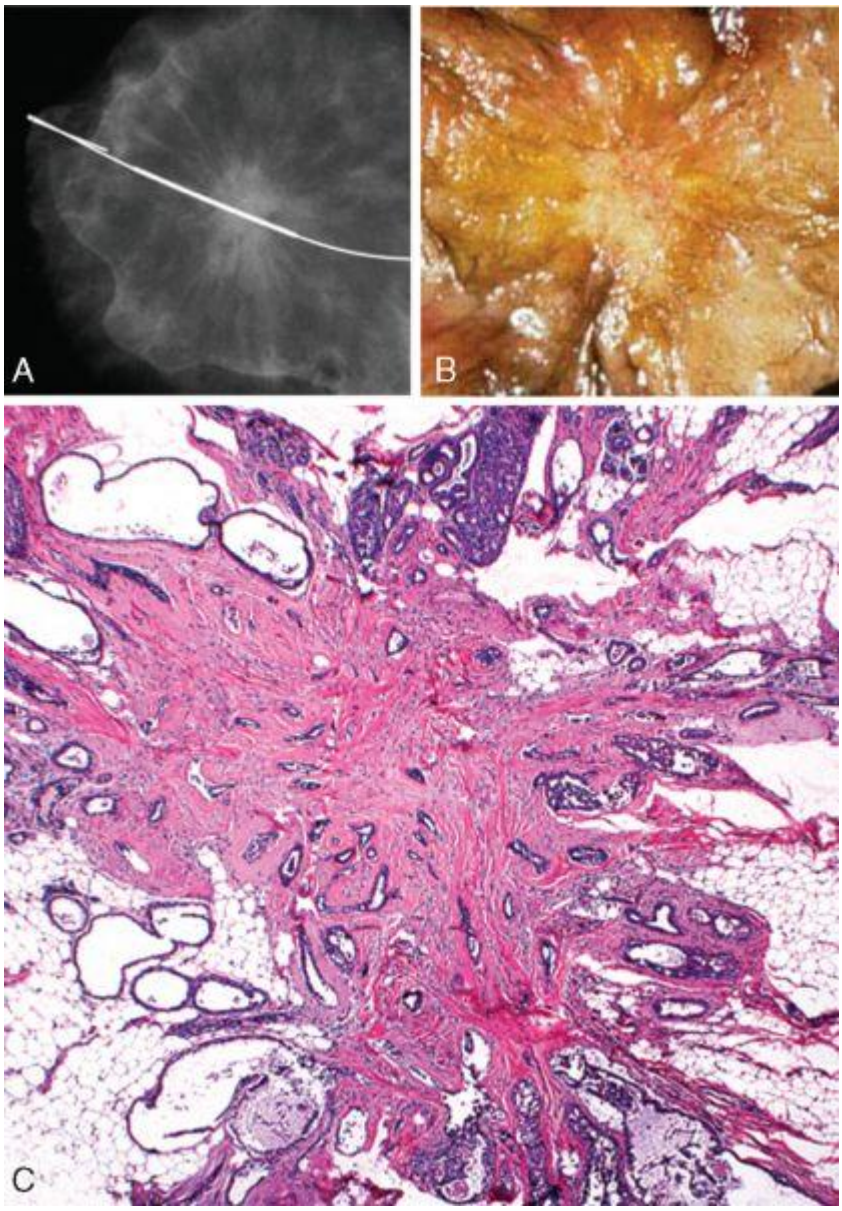

FIGURE 23-10 Radial sclerosing lesion. **A**, The radiograph shows an irregular central mass with long radiodense projections. **B**, Grossly the mass appears solid and has irregular borders, but it is not as firm as an invasive carcinoma. **C**, The mass consists of a central nidus of small tubules entrapped in a densely fibrotic stroma and numerous projections containing epithelium with varying degrees of cyst formation and hyperplasia.

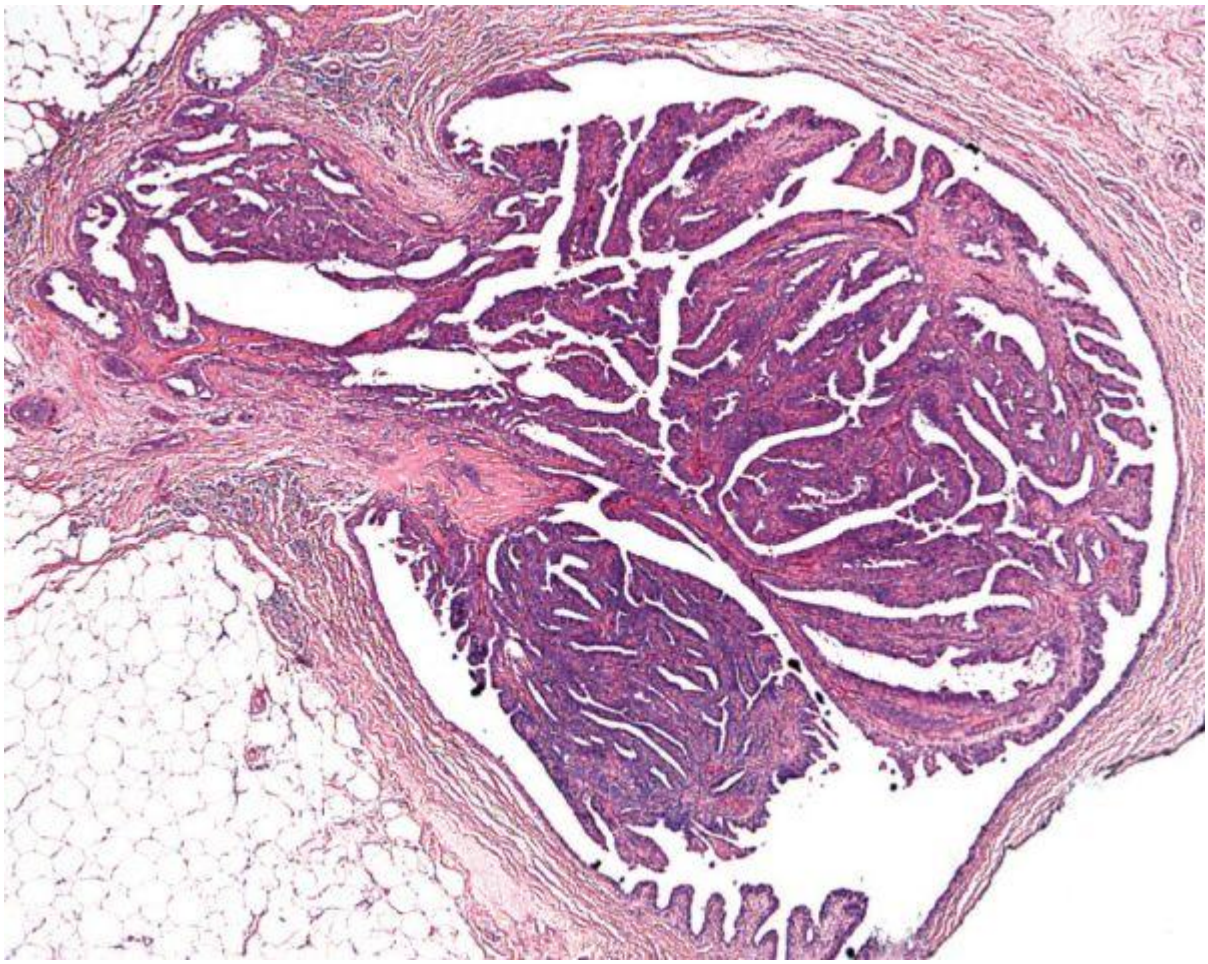

FIGURE 23-11 Intraductal papilloma. A central fibrovascular core extends from the wall of a duct. The papillae arborize within the lumen and are lined by myoepithelial and luminal cells.

More than 80% of large duct papillomas produce a nipple discharge. Large papillomas may undergo infarction, possibly because of torsion on the stalk, resulting in a bloody discharge. Nonbloody discharge probably results from intermittent blockage and release of normal breast secretions or irritation of the duct by the papilloma. The remaining large duct papillomas and most small duct papillomas come to clinical attention as small palpable masses, or as densities or calcifications seen on mammograms.

PROLIFERATIVE BREAST DISEASE WITH ATYPIA

Proliferative disease with atypia includes atypical ductal hyperplasia and atypical lobular hyperplasia. Atypical ductal hyperplasia is present in 5% to 17% of specimens from biopsies performed for calcifications and is found less frequently in specimens from biopsies for mammographic densities or palpable masses. Occasionally, atypical ductal hyperplasia is associated with radiologic calcifications; more commonly it is adjacent to another calcifying lesion. Atypical lobular hyperplasia is an incidental finding and is found in fewer than 5% of specimens from biopsies performed for any reason.

Morphology. Atypical hyperplasia is a cellular proliferation resembling carcinoma in situ but lacking sufficient qualitative or quantitative features for diagnosis as carcinoma. Unlike other benign changes, atypical hyperplasias harbor some of the same acquired genetic losses and gains that are present in carcinoma in situ.

Atypical ductal hyperplasia is recognized by its histologic resemblance to ductal carcinoma in situ (DCIS). It consists of a relatively monomorphic proliferation of regularly spaced cells, sometimes with cribriform spaces. It is distinguished from DCIS by being limited in extent and only partially filling ducts (Fig. 23-12A).

Atypical lobular hyperplasia is defined as a proliferation of cells identical to those of lobular carcinoma in situ (LCIS, described later), but the cells do not fill or distend more than 50% of the acini within a lobule (Fig. 23-12B). Atypical lobular hyperplasia can also involve contiguous ducts through pagetoid spread, in which atypical lobular cells lie between the ductal basement membrane and overlying normal ductal epithelial cells.

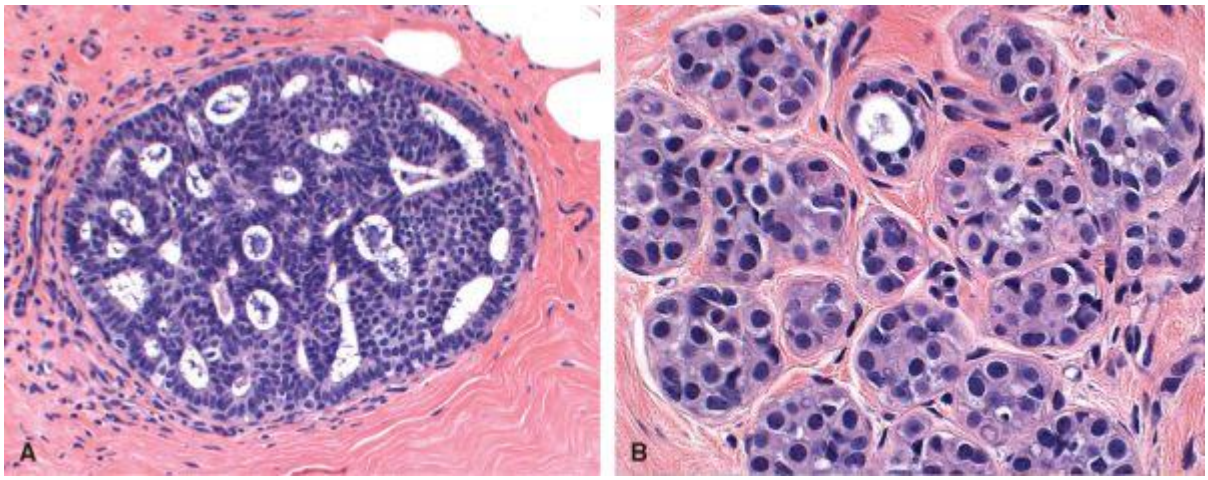

FIGURE 23-12 **A**, Atypical ductal hyperplasia. A duct is filled with a mixed population of cells consisting of oriented columnar cells at the periphery and more rounded cells within the central portion. Although some of the spaces are round and regular, the peripheral spaces are irregular and slitlike. These features are highly atypical, but fall short of a diagnosis of DCIS. **B**, Atypical lobular hyperplasia. A population of monomorphic small, round, loosely cohesive cells partially fill a lobule. Some intracellular lumens can be seen. Although the cells are morphologically identical to the cells of LCIS, the extent of involvement is not sufficient for this diagnosis.

CLINICAL SIGNIFICANCE OF BENIGN EPITHELIAL CHANGES

Multiple epidemiologic studies have classified benign histologic changes in the breast and determined their association with the later development of invasive cancer [11] [12] [13] (Table 23-1). Nonproliferative changes do not increase the risk of cancer. Proliferative disease is associated with a mild increase in risk, while proliferative disease with atypia confers a moderate increase in risk. Both breasts are at increased risk, although a few more subsequent carcinomas occur in the same breast.[14] Risk reduction can be achieved by bilateral prophylactic mastectomy or treatment with estrogen antagonists, such as tamoxifen.[15] However, more than 80% of women with atypical hyperplasia will not develop breast cancer, and many choose careful clinical and radiologic surveillance over intervention.

TABLE 23-1 -- Epithelial Breast Lesions and the Risk of Developing Invasive Carcinoma

Pathologic Lesion	Relative Risk (Absolute Lifetime Risk)[*]
NONPROLIFERATIVE BREAST CHANGES (Fibrocystic changes)	1.0 (3%)
Duct ectasia	
Cysts	
Apocrine change	
Mild hyperplasia	
Adenosis	
Fibroadenoma w/o complex features	
PROLIFERATIVE DISEASE WITHOUT ATYPIA	1.5 to 2.0 (5% to 7%)
Moderate or florid hyperplasia	
Sclerosing adenosis	
Papilloma	
Complex sclerosing lesion (radial scar)	
Fibroadenoma with complex features	
PROLIFERATIVE DISEASE WITH ATYPIA	4.0 to 5.0 (13% to 17%)
Atypical ductal hyperplasia (ADH)	
Atypical lobular hyperplasia (ALH)	
CARCINOMA IN SITU	8.0 to 10.0 (25% to 30%)
Lobular carcinoma in situ (LCIS)	
Ductal carcinoma in situ (DCIS)	

* Relative risk is the risk compared to women without any risk factors. Absolute lifetime risk is the percentage of patients expected to develop invasive carcinoma if untreated.

3.13.1.5 Carcinoma of the Breast

Carcinoma of the breast is the most common non-skin malignancy in women. A woman who lives to age 90 has a one in eight chance of developing breast cancer. In 2007 an estimated 178,480 women were diagnosed with invasive breast cancer, 62,030 with carcinoma in situ, and over 40,000 women died of the disease (Surveillance Epidemiology and End Results [SEER] data at http://seer.cancer.gov/). As the demographic bulge of the "baby boomers" continues to grow older, the number of women with breast cancer is expected to increase by about a third over the next 20 years. It is both ironic and tragic that a neoplasm arising in an exposed organ, readily accessible to self-examination and clinical diagnosis, continues to exact such a heavy toll. Only lung cancer causes more cancer deaths in women living in the United States.

It has long been appreciated that breast cancer is a heterogeneous disease with a wide array of histologic appearances. Recent gene profiling studies have confirmed that there are many types of cancers but also show that most carcinomas cluster into several major groups with important biologic and clinical differences. The majority of carcinomas are estrogen receptor (ER) positive and are characterized by a gene signature dominated by the dozens of genes under the control of estrogen. Among the ER-negative tumors, many fall into a distinctive "basal-like" group that is discussed later.

ER-positive and ER-negative carcinomas show striking differences with regard to patient characteristics, pathologic features, treatment response, and outcome. In the past, most studies grouped all breast

cancers together, but it is now widely recognized that the diagnosis of breast cancer encompasses multiple molecular subclasses of disease, as discussed later.

INCIDENCE AND EPIDEMIOLOGY

After remaining constant for many years (except for a transient rise in 1974 attributed to increased awareness surrounding the recurrence of breast cancer in Betty Ford and Happy Rockefeller), the incidence of breast cancer began to increase in older women (Fig. 23-13). What seemed to be an alarming trend was, in part, due to the introduction of mammographic screening in the early 1980s. Rates of screening gradually increased but have recently reached a plateau of 60% to 80% of eligible women. The main benefit of screening is the detection of small, predominantly ER-positive invasive carcinomas and in situ carcinomas. DCIS is almost exclusively detected by mammography, providing an explanation for the sharp increase in the diagnosis of DCIS since 1980 (see Fig. 23-13). Small node-negative carcinomas (stage I), which are best detected by mammography, increased in frequency as the number of large, advanced-stage breast carcinomas (stages II to IV) diminished modestly (Fig. 23-14). Over the same time period the incidence of breast carcinoma in younger women, for whom screening is not recommended, did not change.

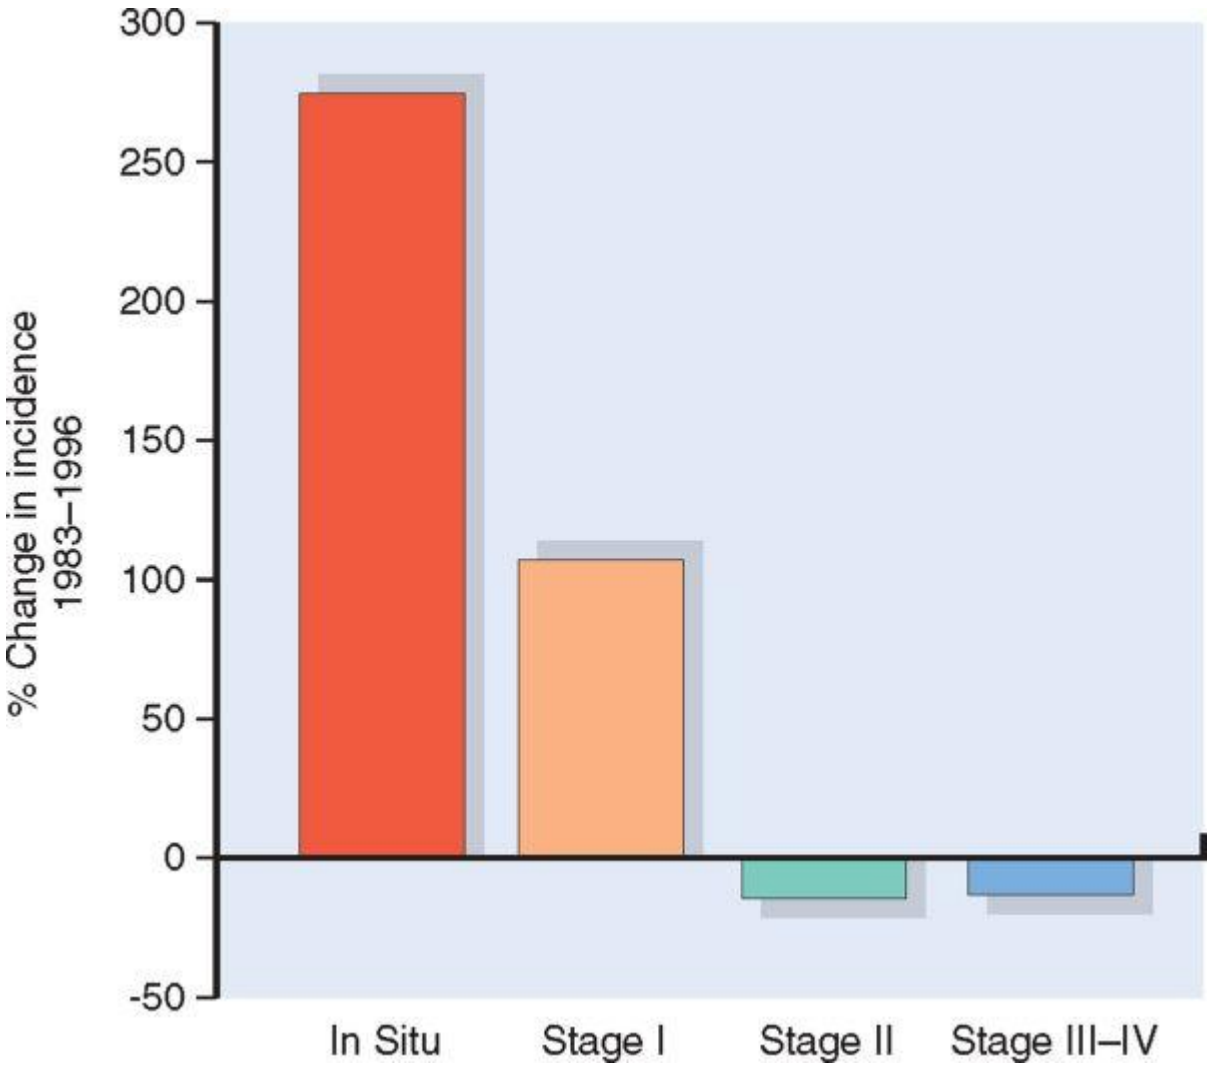

FIGURE 23-14 Change in stage of breast cancer at presentation from 1983 to 1996. (SEER Cancer Statistics Review, http://seer.cancer.gov/

)

From 2001 to 2004, the incidence of ER-positive invasive cancer decreased. The reasons for this trend are probably multifactorial. The plateau in the number of women screened should be associated with a decrease in incidence back to prescreening levels. In addition, in 2002 many women stopped using postmenopausal hormone replacement therapy after the results of the Women's Health Initiative trial showed that this treatment had limited benefits.[16] It is possible that this treatment stimulated the growth or development of ER-positive cancers. During the same time period the incidence of breast cancer for African American women remained stable and the number of ER-negative cancers increased, suggesting that these cancers are not affected by hormonal treatment. Finally, there may have been changes in modifiable risk factors (e.g., the frequency and length of breastfeeding) or the use of chemopreventive agents that can lower risk. Whatever the reason or reasons, the decrease in breast cancers is a promising trend that hopefully will continue.

During the 1980s the number of women dying of breast cancer remained constant, while the incidence of breast cancer was increasing. Since 1994 the breast cancer mortality rate for all women has slowly declined from 30% to 20% (Fig. 23-13). The decrease is attributed to the detection of clinically significant cancers at a curable stage due to screening, as well as better and more effective treatment modalities. The number of women dying from their breast cancer has decreased from 30% to 20%. However, the decline in the death rate has been less impressive for African American women, women in other ethnic groups, and women with ER-negative cancers. The mortality is higher in these groups even though the incidence of cancer is lower than in white women.

Risk Factors.

The most important risk factor is gender; only 1% of breast cancer cases occur in men. Common risk factors for women identified by epidemiologic studies have been combined into the Breast Cancer Risk Assessment Tool (BCRAT), which now includes information from the Contraceptive and Reproductive Experiences study,[17,][18] which provides more accurate information for African American women. The model can be used to calculate the absolute risk of an individual woman developing invasive cancer within the next 5 years or over a lifetime. The BCRAT incorporates the following risk factors.

Age.

The incidence rises throughout a woman's lifetime, peaking at the age of 75–80 years and then declining slightly thereafter. The average age at diagnosis is 61 for white women, 56 for Hispanic women, and 46 for African American women. Only 20% of non-Hispanic white women are diagnosed under the age of 50, compared with 35% of African American women and 31% of Hispanic women. Breast cancer is very rare in all groups before the age of 25.

Although carcinoma is uncommon in young women, almost half of these are either ER negative or human epidermal growth factor receptor 2 (HER2/neu) positive, whereas these cancers make up less than a third of cancers in women over the age of 40.

Age at Menarche.

Women who reach menarche when younger than 11 years of age have a 20% increased risk compared with women who are more than 14 years of age at menarche. Late menopause also increases risk.

Age at First Live Birth.

Women who experience a first full-term pregnancy at ages younger than 20 years have half the risk of nulliparous women or women over the age of 35 at their first birth. It is hypothesized that pregnancy results in terminal differentiation of milk-producing luminal cells, removing them from the potential pool of cancer precursors.[4] This protective effect might be overshadowed in older women by stimulation of proliferation early in pregnancy of cells that have already undergone preneoplastic changes. It is also possible that the changes in stroma that allow the growth and expansion of lobules during pregnancy facilitate the transition from in situ to invasive carcinoma. These pregnancy-related changes may help explain the transient increase in cancer risk that follows a pregnancy, an effect that is most pronounced in older women.[5] Age at first live birth is not a strong risk factor for African American women.

First-Degree Relatives with Breast Cancer.

The risk of breast cancer increases with the number of affected first-degree relatives (mother, sister, or daughter), especially if the cancer occurred at a young age. However, most women do not have a family history. Only 13% of women with breast cancer have one affected first-degree relative, and only 1% have two or more. In turn, over 87% of women with a family history will not develop breast cancer. Most family risk is probably due to the interaction of low-risk susceptibility genes and nongenetic factors. The BCRAT is not designed to calculate the risk for women with a mutation in a high-risk breast cancer gene, such as *BRCA1* or *BRCA2* (see the section “Hereditary Breast Cancer” below).

Atypical Hyperplasia.

A history of prior breast biopsies, especially if revealing atypical hyperplasia, increases the risk of invasive carcinoma. There is a smaller increase in risk associated with proliferative breast changes without atypia (see Table 23-1).

Race/Ethnicity.

Non-Hispanic white women have the highest rates of breast cancer. The risk of developing an invasive carcinoma within the next 20 years at age 50 is 1 in 15 for this group, 1 in 20 for African Americans, 1 in 26 for Asian/Pacific Islanders, and 1 in 27 for Hispanics.[19] However, women of African or Hispanic ancestry present at a more advanced stage and have an increased mortality rate. Social factors such as decreased access to health care and lower use of mammography may well contribute to these disparities, but biologic differences also play an important role.[20] African American and Hispanic women tend to develop cancers at a younger age, prior to menopause, that are more likely to be poorly differentiated and ER negative. Mutations in *p53* are more common in African American women but less common in Hispanic women, as compared with non-Hispanic white women. It is suspected that variation in breast cancer risk genes across ethnic groups is responsible, at least in part, for these differences. One known example is the incidence of *BRCA1* and *BRCA2* mutations, which occur at different frequencies in different ethnic groups.[21]

Additional risk factors (listed below) are recognized, but have not been incorporated into the BCRAT model because of their rarity or uncertainties about quantifying the magnitude of risk.

Estrogen Exposure.

Postmenopausal hormone replacement therapy increases the risk of breast cancer 1.2- to 1.7-fold, and adding progesterone increases the risk further. Most excess cancers are ER-positive carcinomas, including invasive lobular carcinomas, that tend to be of small size when detected. As a result, any effect on the death rate is expected to be small. After publication of the Women's Health Initiative trial in 2002, the number of postmenopausal women receiving hormone replacement therapy dropped from

approximately 17% to 7%, a change that was followed by a substantial drop in ER-positive invasive breast cancers in 2003 and 2004 (see Fig. 23-13).[16]

Oral contraceptives have not been shown convincingly to affect breast cancer risk but do decrease the risk of endometrial and ovarian carcinomas. Reducing endogenous estrogens by oophorectomy decreases the risk of developing breast cancer by up to 75%. Drugs that block estrogenic effects (e.g., tamoxifen) or block the formation of estrogen (e.g., aromatase inhibitors) also decrease the risk of ER-positive breast cancer.

Breast Density.

High breast radiodensity is a strong risk factor for developing cancer. High density is correlated with young age and hormone exposure, and clusters in families. High breast density may be related to less complete involution of lobules at the end of each menstrual cycle, which in turn may increase the number of cells that are potentially susceptible to neoplastic transformation.

Dense breasts also make detection of cancer more difficult by mammography. Other modalities, such as MRI, may be helpful in such women.

Radiation Exposure.

Radiation to the chest, whether due to cancer therapy, atomic bomb exposure, or nuclear accidents, results in a higher rate of breast cancer. The risk is greatest with exposure at young ages and with high radiation doses. For example, women in their teens and early 20s who received radiation to the chest for Hodgkin lymphoma have a 20% to 30% risk of developing breast cancer over 10 to 30 years. Recognition of this iatrogenic complication has led to a much more judicious use of radiation therapy in adolescents and young women undergoing cancer treatment. The risks of radiation exposure are substantially lower in women over the age of 25. Current mammographic screening uses low doses of radiation and is unlikely to have an effect on the risk of breast cancer.

Carcinoma of the Contralateral Breast or Endometrium.

Approximately 1% of women with breast cancer develop a second contralateral breast carcinoma per year. The risk is higher for women with germline mutations in high-risk breast cancer genes such as *BRCA1* and *BRCA2*, who frequently develop multiple cancers. Breast and endometrial carcinomas have several risk factors in common, the most important of which is exposure to prolonged estrogenic stimulation.

Geographic Influence.

Breast cancer incidence rates in the United States and Europe are four to seven times higher than those in other countries. Unfortunately, the rates are rising worldwide, and by 2020 it is estimated that 70% of cases will be in developing countries.

The risk of breast cancer increases in immigrants to the United States with each generation. The factors responsible for this increase are of considerable interest because they are likely to include modifiable risk factors. Reproductive history (number and timing of pregnancies), breastfeeding, diet, obesity, physical activity, and environmental factors all probably play a role.

Diet.

Large studies have failed to find strong correlations between breast cancer risk and dietary intake of any specific type of food. Coffee addicts will be pleased to know that caffeine consumption may decrease

the risk of breast cancer. On the other hand, moderate or heavy alcohol consumption increases risk. Higher estrogen levels and lower folate levels may underlie this association.

Obesity.

There is decreased risk in obese women younger than 40 years as a result of the association with anovulatory cycles and lower progesterone levels late in the cycle. In contrast, the risk is increased for postmenopausal obese women, which is attributed to the synthesis of estrogens in fat depots.

Exercise.

There is a probable small protective effect for women who are physically active. The decrease in risk is greatest for premenopausal women, women who are not obese, and women who have had full-term pregnancies.

Breastfeeding.

The longer women breastfeed, the greater the reduction in risk. Lactation suppresses ovulation and may trigger terminal differentiation of luminal cells.[4] The lower incidence of breast cancer in developing countries largely can be explained by the more frequent and longer nursing of infants.[22]

Environmental Toxins.

There is concern that environmental contaminants, such as organochlorine pesticides, have estrogenic effects on humans. Possible links to breast cancer risk are being investigated intensively, but definitive associations have yet to be made.

Tobacco.

Cigarette smoking has not been clearly associated with breast cancer but is associated with the development of periductal mastitis (subareolar abscess; discussed earlier). Breast cancer was the leading cause of cancer deaths in women until the early 1990s, when lung cancer deaths surged ahead. Currently, twice as many women die from lung cancer—surely a good reason to avoid tobacco use.

ETIOLOGY AND PATHOGENESIS

The major risk factors for the development of breast cancer are hormonal and genetic. Breast carcinomas can therefore be divided into sporadic cases, probably related to hormonal exposure, and hereditary cases, associated with germline mutations. Hereditary carcinoma has received intense scrutiny in the hopes that the specific genetic mutations can be identified and that these alterations will illuminate the causes of nonfamilial breast cancers as well. Recent studies have borne out these hopes. We begin our discussion with hereditary breast cancer and follow with sporadic breast cancer.

Hereditary Breast Cancer

The inheritance of a susceptibility gene or genes is the primary cause of approximately 12% of breast cancers.[23,][24] The probability of a hereditary etiology increases with multiple affected first-degree relatives, when individuals are affected before menopause and/or have multiple cancers, or there are family members with other specific cancers (discussed below).

In some families the increased risk is the result of a single mutation in a highly penetrant breast cancer gene (Table 23-2). Mutations in *BRCA1* and *BRCA2* account for the majority of cancers attributable to single mutations and about 3% of all breast cancers. Penetrance (the percentage of carriers who develop breast cancer) varies from 30% to 90% depending on the specific mutation present. Mutations in

BRCA1 also markedly increase the risk of developing ovarian carcinoma, which occurs in as many as 20% to 40% of carriers. *BRCA2* confers a smaller risk for ovarian carcinoma (10% to 20%) but is associated more frequently with male breast cancer. *BRCA1* and *BRCA2* carriers are also at higher risk for other epithelial cancers, such as prostatic and pancreatic carcinomas.

TABLE 23-2 -- Most Common "Single Gene" Mutations Associated with Hereditary Susceptibility to Breast Cancer

GENE (location) Syndrome (Incidence)[*]	% of "Single Gene" Hereditary Cancers[†]	Breast Cancer Risk by Age 70[‡]	Changes in Sporadic Breast Cancer	Other Associated Cancers	Functions	Comments
BRCA1 (17q21) Familial breast and ovarian cancer (1 in 860)	52% (~2% of all breast cancers)	40% to 90%	Mutations rare; inactivated in 50% of some subtypes (e.g. medullary and metaplastic) by methylation	Ovarian, male breast cancer (but lower than BRCA2), prostate, pancreas, fallopian tube	Tumor suppressor, transcriptional regulation, repair of double-stranded DNA breaks	Breast carcinomas are commonly poorly differentiated and triple negative (basal-like), and have *P53* mutations.
BRCA2 (13q12-13) Familial breast and ovarian cancer (1 in 740)	32% (~1% of all breast cancers)	30% to 90%	Mutations and loss of expression rare	Ovarian, male breast cancer, prostate, pancreas, stomach, melanoma, gallbladder, bile duct, pharynx	Tumor suppressor, transcriptional regulation, repair of double-stranded DNA breaks	Biallelic germline mutations cause a rare form of Fanconi anemia (Chapter 7)
p53 (17p13.1) Li-Fraumeni (1 in 5,000)	3% (<1% of all breast cancers)	>90%	Mutations in 20%, LOH in 30% to 42%; most frequent in triple negative cancers	Sarcoma, leukemia, brain tumors, adrenocortical carcinoma, others	Tumor suppressor with critical roles in cell cycle control, DNA replication, DNA repair, and apoptosis	*p53* is the most commonly mutated gene in sporadic breast cancers
CHEK2 (22q12.1) Li-Fraumeni variant (1 in 100)	5% (~1% of all breast cancers)	10% to 20%	Mutations rare (<5%); loss of protein expression in at least one third by unknown mechanism(s)	Prostate, thyroid, kidney, colon	Cell cycle checkpoint kinase, recognition and repair of DNA damage, activates BRCA1 and p53 by phosphorylation	May increase risk for breast cancer after radiation exposure

[*] Frequency of heterozygotes in the U.S. population; the incidence of gene mutations is higher in some ethnic populations (e.g., *BRCA1* and *BRCA2* mutations occur at high frequencies in Askenazi Jews).

[†] Defined as familial breast cancers showing a pattern of inheritance consistent with a major effect of a single gene.

[‡] Risk varies with specific mutations and is likely modified by other genes.

BRCA1 and *BRCA2* are both large genes over 80 kilobases in size. Hundreds of different mutations distributed throughout the coding regions have been reported for each. The frequency of mutations that

increase breast cancer risk is only 0.1% to 0.2% in the general population, and inconsequential polymorphisms are common. As a result, genetic testing is difficult and generally restricted to individuals with a strong family history or those belonging to certain ethnic groups. For example, 2% to 3% of people of Ashkenazi Jewish descent carry one of three specific mutations, two in *BRCA1* and one in *BRCA2*. Identification of carriers is important, since increased surveillance, prophylactic mastectomy, and oophorectomy can reduce cancer-related morbidity and mortality.

BRCA1-associated breast cancers are commonly poorly differentiated, have "medullary features" (a syncytial growth pattern with pushing margins and a lymphocytic response), and do not express hormone receptors or overexpress HER2/neu (the so-called "triple negative" phenotype). Their gene profiling signature is very similar to basal-like breast cancers, a distinct molecular subtype that is discussed later. *BRCA1* cancers are also frequently associated with loss of the inactive X chromosome and reduplication of the active X, resulting in the absence of the Barr body.[25] *BRCA2*-associated breast carcinomas also tend to be relatively poorly differentiated, but are more often ER positive than *BRCA1* cancers.

Other known susceptibility genes are much less commonly implicated; together, this group accounts for fewer than 10% of hereditary breast carcinomas (see Table 23-2). Li-Fraumeni syndrome (due to germline mutations in *p53*) and Li-Fraumeni variant syndrome (due to germline mutations in *CHEK2*) together account for about 8% of breast cancers caused by single genes. Three other tumor suppressor genes, *PTEN* (Cowden syndrome), *LKBI/STK11* (Peutz-Jeghers syndrome), and *ATM* (ataxia telangiectasia), are mutated in less than 1% of all breast cancers and are described elsewhere.

The known high-risk breast cancer genes account for only about one quarter of familial breast cancers. The search for a high-risk "*BRCA3*" gene has been unsuccessful, and other highly penetrant genes may not exist. As a result, it is likely that the remaining familial cancers are caused by multiple genes with weak effects. As with other multigenic diseases, genome-wide association studies (GWAS) have commenced and have identified a number of candidate genes associated with risk, including the fibroblast growth factor receptor-2 (FGFR2).[24] Such studies will need to take into account genetic variation across different ethnic groups, which (as we have seen) correlates with both overall breast cancer risk and susceptibility to particular molecular subtypes.

The major susceptibility genes for breast cancer are tumor suppressors that have normal roles in DNA repair, cell cycle control, and the regulation of apoptosis in many tissues (Chapter 7). Except for *p53*, mutations in genes implicated in hereditary breast cancer are uncommon in sporadic breast cancers. However, decreased expression of *BRCA1* and *CHEK2* is common in sporadic cancers, particularly those that are "triple-negative" or poorly differentiated, and basal-like cancers, which comprise a large subset of the triple-negative group, have a gene expression profile that bears a striking resemblance to hereditary cancers arising in *BRCA1* carriers. Based on these observations, it is suspected that the pathways that these genes participate in are frequently disrupted in sporadic cancers through currently unknown mechanisms.

Sporadic Breast Cancer

The major risk factors for sporadic breast cancer are related to hormone exposure: gender, age at menarche and menopause, reproductive history, breastfeeding, and exogenous estrogens. The majority of sporadic cancers occur in postmenopausal women and are ER positive.

Hormonal exposure increases the number of potential target cells by stimulating breast growth during puberty, menstrual cycles, and pregnancy. Exposure also drives cycles of proliferation that place cells at risk for DNA damage. Once premalignant or malignant cells are present, hormones can stimulate their

growth, as well as the growth of normal epithelial and stromal cells that may aid and abet tumor development.

Estrogen may also play a more direct role in carcinogenesis. Metabolites of estrogen can cause mutations or generate DNA-damaging free radicals in cell and animal model systems.[26] It also has been proposed that variants of genes involved in estrogen synthesis and metabolism could increase the risk of breast cancer. Such variants would be analogous to cytochrome P-450 alleles that alter the metabolism of tamoxifen in some women.[27]

Overview of Carcinogenesis and Tumor Progression

The diverse histologic appearances of carcinomas and putative precursor lesions are the outward manifestations of the complex genetic and epigenetic changes that drive carcinogenesis. One model of carcinogenesis postulates that a normal cell must acquire several new capabilities to become malignant (see Chapter 7).[28,][29] Each may be achieved by a change in the activity of one of many different genes that regulate common cellular activities.

Populations of cells that harbor some, but not all, of the genetic and epigenetic changes that are required for carcinogenesis give rise to morphologically recognizable breast lesions (discussed earlier) that are associated with an increased risk of progression to cancer. The earliest such alterations are proliferative changes, which may stem from the loss of growth-inhibiting signals, aberrant increases in pro-growth signals, or decreased apoptosis. For example, most early lesions (such as atypical ductal hyperplasia and atypical lobular hyperplasia) show increased expression of hormone receptors and abnormal regulation of proliferation.[10,][30] LOH is rarely detected in typical proliferative change but becomes more frequent in atypical hyperplasias and is almost universally present in carcinoma in situ. Profound DNA instability in the form of aneuploidy, which manifests morphologically by nuclear enlargement, irregularity, and hyperchromasia, is observed only in high-grade DCIS and some invasive carcinomas. At some point during tumor progression the malignant clone also becomes immortalized and acquires the ability to drive neo-angiogenesis. The morphologic and biologic features of carcinomas are usually established at the in situ stage, since in the majority of cases the in situ lesion closely resembles the accompanying invasive carcinoma.

The cell of origin of breast cancers is of interest, since this has important implications for etiology and treatment. The “cancer stem cell hypothesis” proposes that malignant changes occur in a stem cell population that has unique properties distinguishing them from more differentiated cells.[31,][32] Although the majority of tumor cells would consist of non–stem cell progeny, only the malignant stem cells would contribute to tumor progression or recurrence. Effective treatment would need to target only this population, which to date has been difficult to define.

The most likely cell type of origin for the majority of carcinomas is the ER-expressing luminal cell, since the majority of cancers are ER-positive and precursor lesions, such as atypical hyperplasias, are most similar to this type of cell (Fig. 23-15). ER-negative carcinomas may arise from ER-negative myoepithelial cells.[33,][34] This would explain why many proteins found in myoepithelial cells are shared by the “triple-negative” or basal-like cancers. An alternative possibility is an origin from an ER-positive precursor that loses ER expression.[10,][35] The precursor lesion for ER-negative tumors is unknown (see Fig. 23-15).

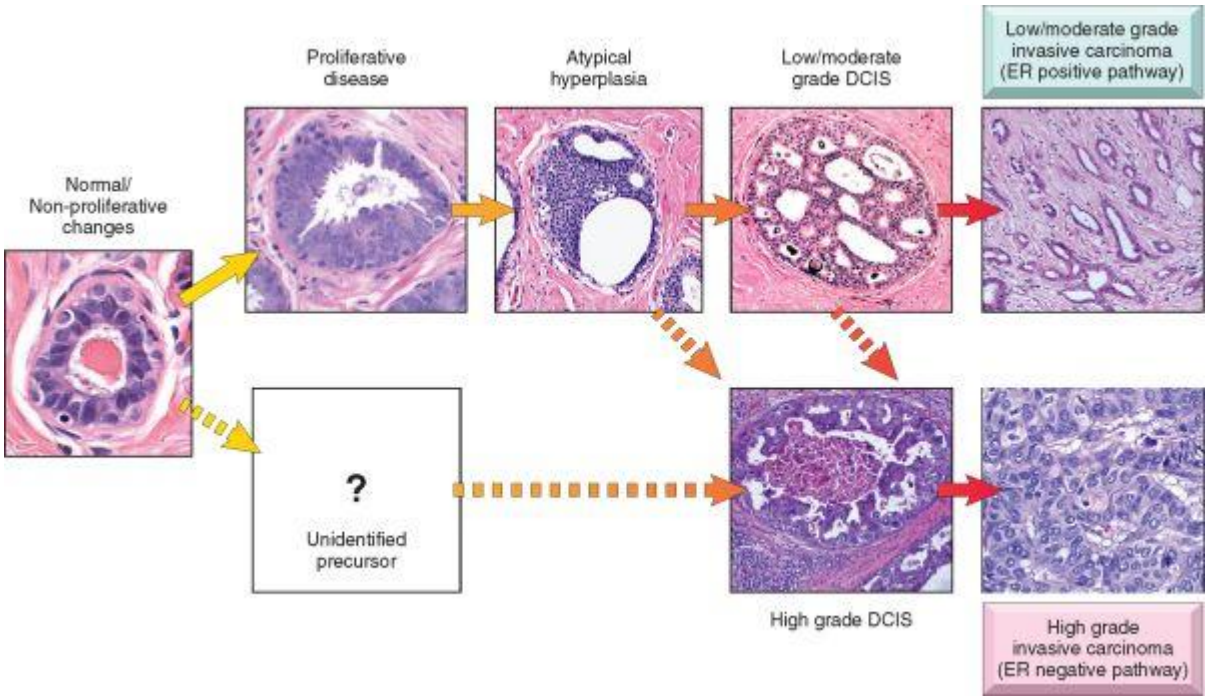

FIGURE 23-15 Proposed precursor-carcinoma sequences in breast cancer. Morphologic changes are displayed from left to right according to the risk for subsequent invasive carcinoma.

The final step of carcinogenesis, the transition of carcinoma in situ to invasive carcinoma, is the most important and unfortunately the least understood. Genetic markers specific for invasive carcinomas have been difficult to identify. It is important to remember that the structure and function of the normal breast depend on a complex interplay between luminal cells, myoepithelial cells, and stromal cells. The same molecular events that allow for the normal formation of new ductal branch points and lobules during puberty and pregnancy—abrogation of the basement membrane, increased proliferation, escape from growth inhibition, angiogenesis, and invasion of stroma—may be recapitulated during carcinogenesis.[2] Remodeling of the breast, which involves inflammatory and "wound healing–like" tissue reactions, could explain the transient increase in breast cancers during and shortly after pregnancy, since such changes could facilitate the transition of carcinoma in situ to invasive cancer.[5,][36,][37]

As can be surmised from this discussion, there are many paths that can lead to the development of breast cancer. Breast cancer is not one disease, but many, each with its own clinical characteristics and optimal prevention and treatment strategies. This recognition has led to the introduction of molecular classification systems, which are discussed below.

CLASSIFICATION OF BREAST CARCINOMA

Greater than 95% of breast malignancies are adenocarcinomas, which are divided into in situ carcinomas and invasive carcinomas. Carcinoma in situ refers to a neoplastic proliferation that is limited to ducts and lobules by the basement membrane. Invasive carcinoma (synonymous with "infiltrating" carcinoma) has penetrated through the basement membrane into stroma. Here, the cells have the potential to invade into the vasculature and thereby reach regional lymph nodes and distant sites.

Despite evidence that all breast carcinomas arise from cells in the terminal duct lobular unit[38], the use of the terms *lobular* and *ductal* to describe both in situ and invasive carcinomas persists. Carcinoma in situ was originally classified as ductal or lobular based on the resemblance of the involved spaces to normal ducts or lobules. However, it is now recognized that varied patterns of growth in situ are not related to the site or cell of origin, but rather reflect differences in tumor cell biology, such as whether the tumor cells express the cell adhesion protein E-cadherin or not. By current convention, "lobular" refers to carcinomas of a specific type, and "ductal" is used more generally for adenocarcinomas that have no other designation.

Carcinoma in Situ

Ductal Carcinoma in Situ (DCIS; Intraductal Carcinoma)

With the advent of mammographic screening, the diagnosis of DCIS rapidly increased from fewer than 5% of all carcinomas to 15% to 30% of carcinomas in well-screened populations (see Fig. 23-13).[39] Among cancers detected mammographically, almost half are DCIS. Most are detected as a result of calcifications; less commonly, periductal fibrosis surrounding DCIS forms a mammographic density or a vaguely palpable mass. Rarely, DCIS (often of micropapillary type) produces a nipple discharge or is detected as an incidental finding upon biopsy for another lesion.

DCIS consists of a malignant clonal population of cells limited to ducts and lobules by the basement membrane. The myoepithelial cells are preserved, although they may be diminished in number. DCIS can spread throughout ducts and lobules and produce extensive lesions involving an entire sector of a breast. When DCIS involves lobules, the acini are usually distorted and unfolded and take on the appearance of small ducts.

Morphology. Historically, DCIS has been divided into five architectural subtypes: comedocarcinoma, solid, cribriform, papillary, and micropapillary. Some cases of DCIS have a single growth pattern, but the majority show a mixture of patterns.

Comedocarcinoma is characterized by the presence of solid sheets of pleomorphic cells with "high-grade" hyperchromatic nuclei and areas of central necrosis (see Fig. 23-16C). The necrotic cell membranes commonly calcify and are detected on mammography as clusters or linear and branching microcalcifications (Fig. 23-16A). Periductal concentric fibrosis and chronic inflammation are common, and extensive lesions are sometimes palpable as an area of vague nodularity (Fig. 23-16B).

Noncomedo DCIS consists of a monomorphic population of cells with nuclear grades ranging from low to high. Several morphologic variants can be seen. In cribriform DCIS, intraepithelial spaces are evenly distributed and regular in shape (cookie cutter–like) (Fig. 23-17A). Solid DCIS completely fills the involved spaces (Fig. 23-17B). Papillary DCIS grows into spaces along fibrovascular cores that typically lack the normal myoepithelial cell layer (Fig. 23-18A). Micropapillary DCIS is recognized by bulbous protrusions without a fibrovascular core, often arranged in complex intraductal patterns (Fig. 23-18B). Calcifications may be associated with central necrosis but more commonly form on intraluminal secretions.

Paget disease of the nipple is a rare manifestation of breast cancer (1% to 4% of cases) and presents as a unilateral erythematous eruption with a scale crust. Pruritus is common, and the lesion may be mistaken for eczema. Malignant cells (Paget cells) extend from DCIS within the ductal system, via the lactiferous sinuses, into nipple skin without crossing the basement membrane (Fig. 23-19). The tumor cells disrupt the normal epithelial barrier, allowing extracellular fluid to seep out onto the nipple surface. The Paget cells are readily detected by nipple biopsy or cytologic preparations of the

exudate.

A palpable mass is present in 50% to 60% of women with Paget disease, and almost all of these women have an underlying invasive carcinoma. In contrast, the majority of women without a palpable mass have only DCIS. The carcinomas are usually poorly differentiated, ER negative, and overexpress HER2/neu.

Prognosis of Paget disease depends on the features of the underlying carcinoma and is not affected by the presence or absence of DCIS involving the skin when matched for other prognostic factors.

DCIS with microinvasion is diagnosed when there is an area of invasion through the basement membrane into stroma measuring no more than 0.1 cm. Microinvasion is most commonly seen in association with comedocarcinoma. If only one or a few foci of microinvasion are present, the prognosis is very similar to DCIS.

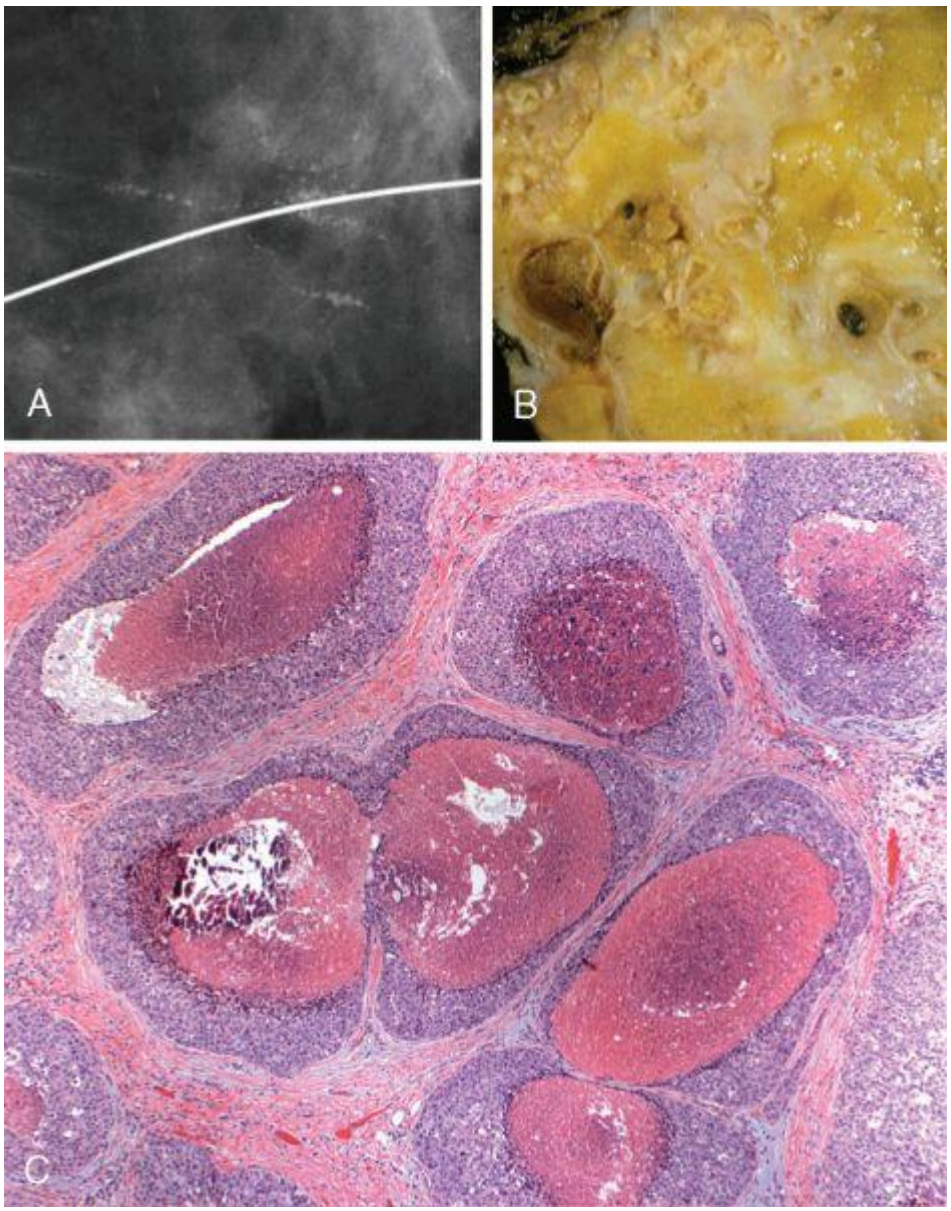

FIGURE 23-16 Ductal carcinoma in situ (DCIS) comedo type. **A**, The specimen radiogram reveals linear and branching calcifications

within the ductal system. **B**, Ducts filled with punctate areas of necrosis ("comedone" like) and surrounded by periductal fibrosis are seen. **C**, DCIS with large central zones of necrosis and calcifications fills several adjacent ducts.

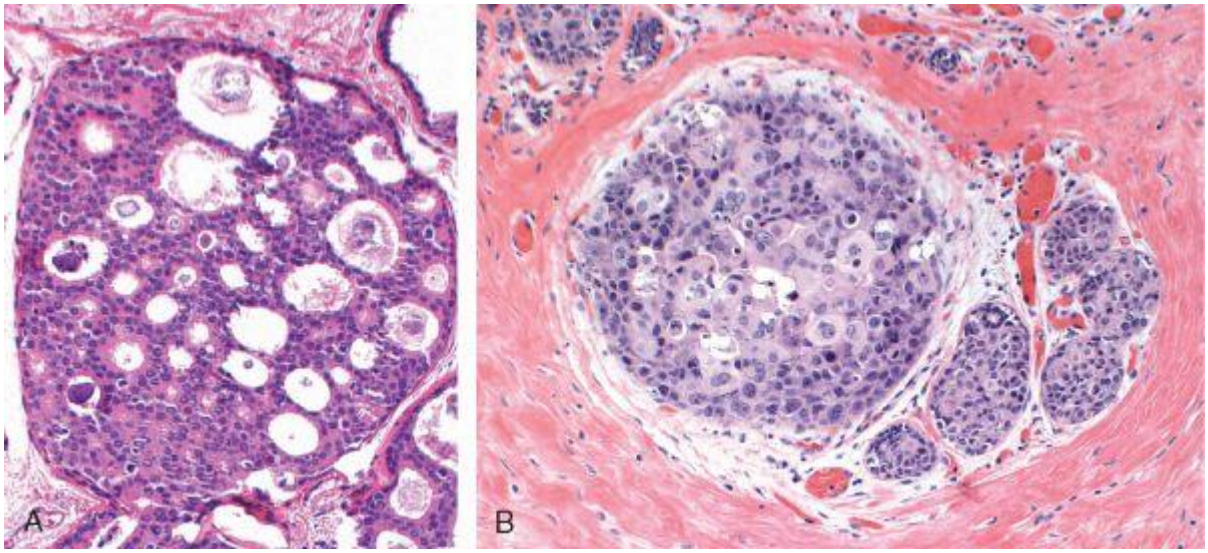

FIGURE 23-17 Noncomedo DCIS. **A**, Cribriform DCIS composed of cells forming round, regular ("cookie cutter") spaces. The lumens are filled with calcifying secretory material. **B**, This solid DCIS has almost completely filled and distorted this lobule with only a few remaining normal luminal cells visible. This type of DCIS is not usually associated with calcifications and may be clinically occult.

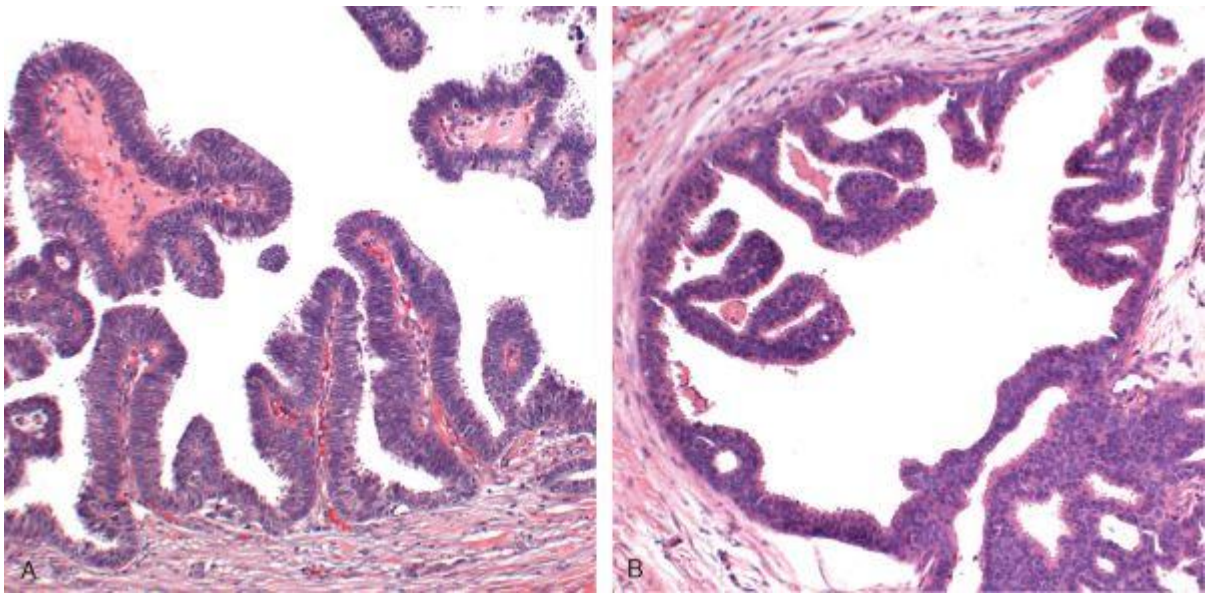

FIGURE 23-18 Noncomedo DCIS. **A**, Papillary DCIS. Delicate fibrovascular cores extend into a duct and are lined by a monomorphic population of tall columnar cells. Myoepithelial cells are absent. **B**, Micropapillary DCIS. The papillae are connected to the duct wall by a narrow base and often have bulbous or complex outgrowths. The papillae are solid and lack fibrovascular cores.

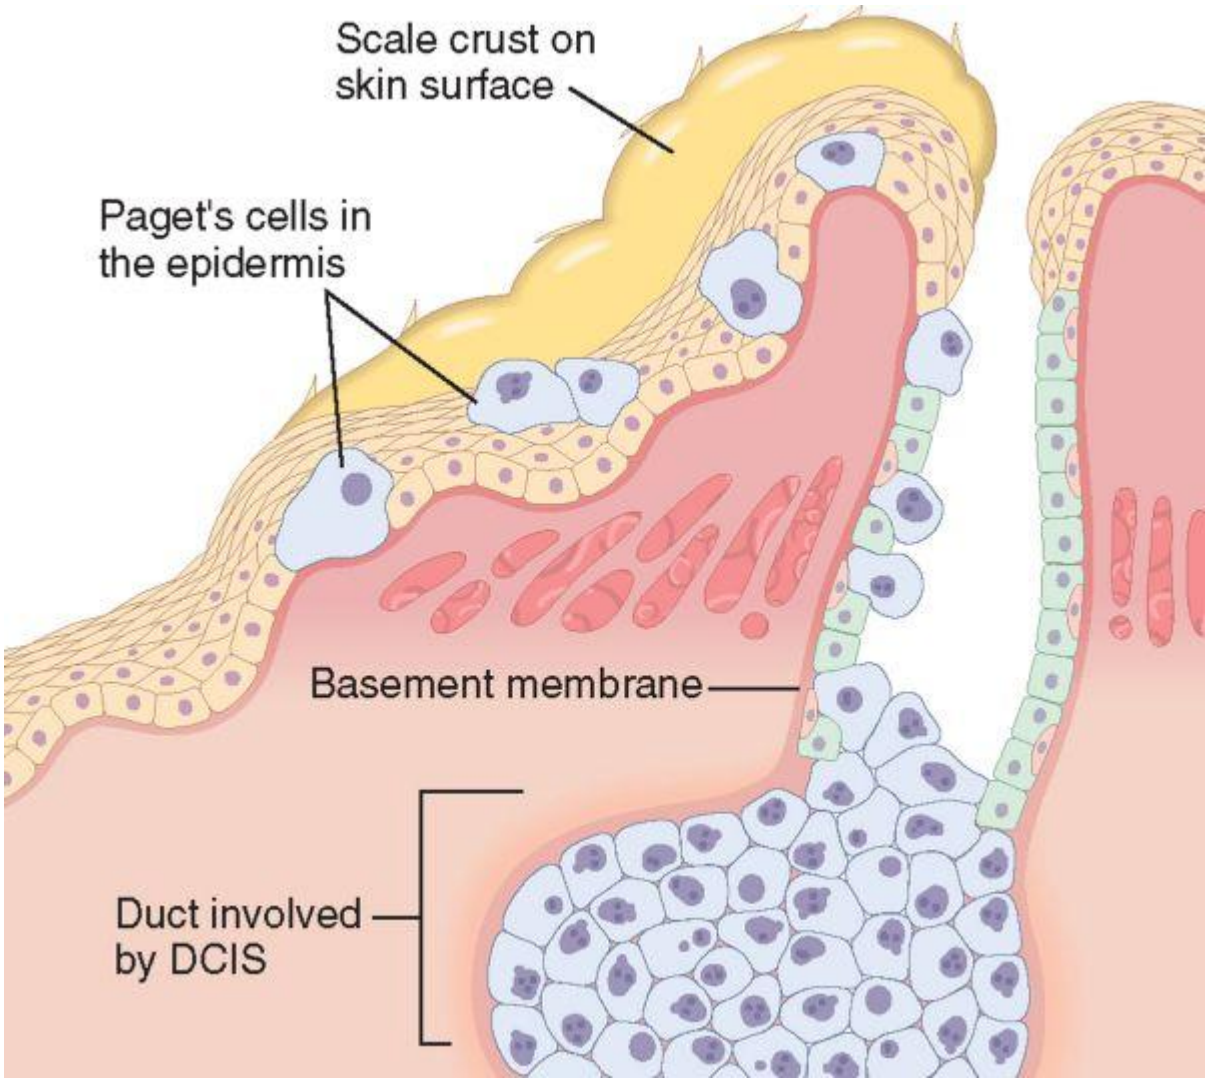

FIGURE 23-19 Paget disease of the nipple. DCIS arising within the ductal system of the breast can extend up the lactiferous ducts and into the skin of the nipple without crossing the basement membrane. The malignant cells disrupt the normally tight squamous epithelial cell barrier, allowing extracellular fluid to seep out and form an oozing scaly crust.

The natural history of DCIS has been difficult to determine because, until recently, all women were treated with mastectomy, and the current practice of surgical excision, usually followed by radiation, is largely curative. If untreated, women with small, low-grade DCIS develop invasive cancer at a rate of about 1% per year.[40] The majority of these cancers are in the same quadrant and have a similar grade and expression pattern of ER and HER2/neu as the DCIS. It is assumed that women with high-grade or extensive DCIS progress to invasive carcinoma at higher rates. Specific biologic features that predict recurrence or progression to invasion are being sought so as to target treatment to these patients.[35]

Mastectomy for DCIS is curative for over 95% of patients. Rare recurrences and/or death are usually due to residual DCIS in ducts in subcutaneous adipose tissue that was not removed during surgery, or occult foci of invasion that were not detected at the time of diagnosis.

Breast conservation is appropriate for most women with DCIS but results in a slightly higher risk of recurrence. The major risk factors for recurrence are (1) grade, (2) size, and (3) margins. However, if wide margins (i.e., at least 1 cm) can be achieved, the rate of recurrence is quite low. Complete excision of DCIS presents a challenge, since its extent can only be reliably predicted by pathologic evaluation. Postoperative radiation therapy and tamoxifen also reduce the risk of recurrence. The benefit of tamoxifen may be restricted to women with ER-positive DCIS.[41] If DCIS is treated adequately, the risk of recurrence in the same breast is only slightly higher than the risk in the contralateral breast for subsequent carcinoma.[42] Whatever the treatment, deaths from breast cancer are very uncommon, occurring in fewer than 2% of women with DCIS.

Lobular Carcinoma in Situ (LCIS)

LCIS is always an incidental biopsy finding, since it is not associated with calcifications or stromal reactions that produce mammographic densities. As a result, its incidence (1% to 6% of all carcinomas) has not been affected by the introduction of mammographic screening. When both breasts are biopsied, LCIS is bilateral in 20% to 40% of cases, compared with 10% to 20% of cases of DCIS. LCIS is more common in young women, with 80% to 90% of cases occurring before menopause.

The cells of LCIS and invasive lobular carcinoma are identical in appearance and share genetic abnormalities, such as those that lead to loss of expression of E-cadherin, a transmembrane cell adhesion protein that contributes to the cohesion of normal breast epithelial cells.

Morphology. Atypical lobular hyperplasia, LCIS, and invasive lobular carcinoma all consist of dyscohesive cells with oval or round nuclei and small nucleoli (Fig. 23-20A). The cells lack the cell adhesion protein E-cadherin, resulting in the cells appearing rounded without attachment to adjacent cells (Fig. 23-20B). Mucin-positive signet-ring cells are commonly present. LCIS rarely distorts the underlying architecture, and the involved acini remain recognizable as lobules. LCIS almost always expresses ER and PR. Overexpression of HER2/neu is not observed.

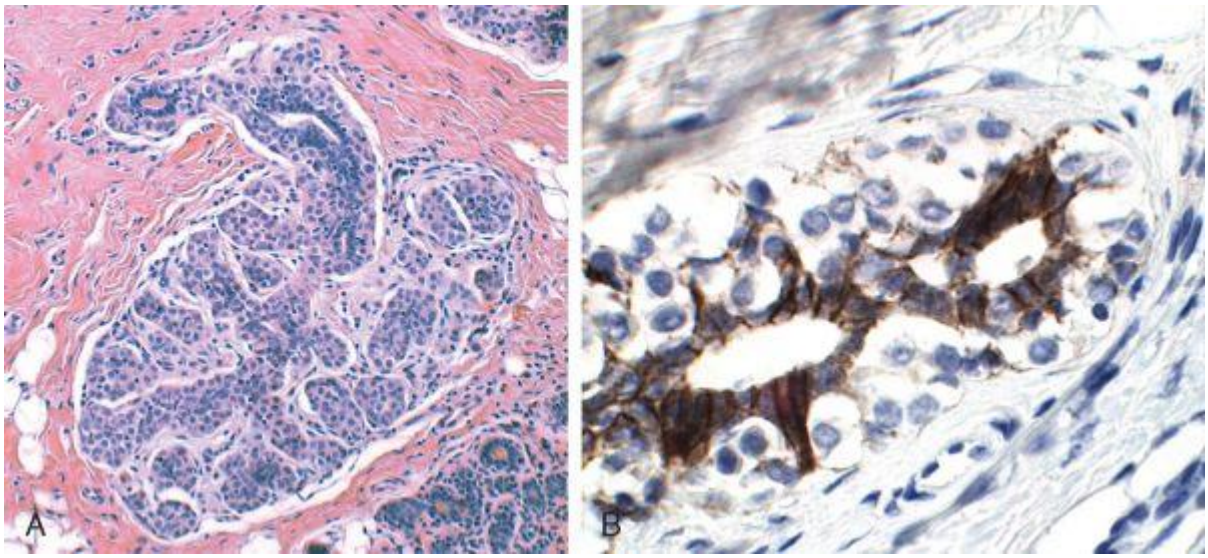

FIGURE 23-20 Lobular carcinoma in situ. **A**, A monomorphic population of small, rounded, loosely cohesive cells fills and expands the acini of a lobule. The underlying lobular architecture can still be recognized. The cells extend into the adjacent lobule by pagetoid spread. **B**, An immunoperoxidase study shows E-cadherin-positive normal luminal cells that have been undermined by E-cadherin-negative LCIS cells spreading along the basement membrane.

Women with LCIS develop invasive carcinomas at a frequency similar to that of women with untreated DCIS. In patients observed for more than 20 years, invasive carcinoma develops in 25% to 35%, or at about 1% per year. Although both breasts are at increased risk, the risk is slightly higher in the ipsilateral breast. [42] [43] [44] Invasive carcinomas developing in women after a diagnosis of LCIS are threefold more likely to be of the lobular type, but the majority do not show specific lobular morphology. Treatment choices include bilateral prophylactic mastectomy, tamoxifen, or, more typically, close clinical follow-up and mammographic screening.

Rare cases of carcinoma in situ that lack E-cadherin have high-grade nuclei and/or central necrosis. The cells may be ER negative, and some overexpress HER2/neu. The natural history of this type of CIS is not known and may well be different from typical LCIS.[44]

Invasive (Infiltrating) Carcinoma

In the absence of mammographic screening, invasive carcinoma almost always presents as a palpable mass. *Palpable tumors are associated with axillary lymph node metastases in over 50% of patients*. Larger carcinomas may be fixed to the chest wall or cause dimpling of the skin. When the tumor involves the central portion of the breast, retraction of the nipple may develop. Lymphatics may become so involved as to block the local area of skin drainage and cause lymphedema and thickening of the skin. In such cases, tethering of the skin to the breast by Cooper ligaments mimics the appearance of an orange peel, an appearance referred to as *peau d'orange*.

In older women undergoing mammography, invasive carcinomas most commonly present as a radiodense mass (Fig. 23-21A). Mammographically detected cancers are, on average, half the size of palpable cancers. Fewer than 20% will have nodal metastases. Invasive carcinomas presenting as mammographic calcifications without an associated density are very small in size, and metastases are unusual.

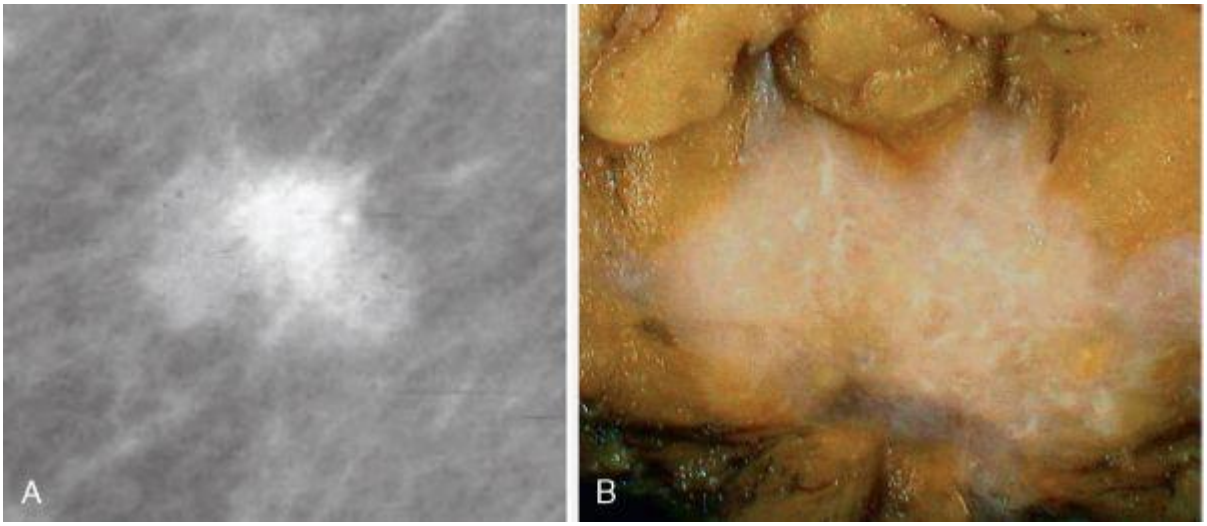

FIGURE 23-21 Invasive ductal carcinoma. **A**, The radiograph shows an invasive cancer with a characteristic irregular border. **B**, Grossly, the irregular firm white mass contains chalky areas of elastotic stroma that extend out into the surrounding yellow adipose tissue. ***(B**, Courtesy of Dr. Anna Laury, Brigham and Women's Hospital, Boston, MA.)*

The term *inflammatory carcinoma* is reserved for tumors that present with a swollen, erythematous breast. This gross appearance is caused by extensive invasion and obstruction of dermal lymphatics by tumor cells. The underlying carcinoma is usually diffusely infiltrative and typically does not form a discrete palpable mass. This can result in confusion with true inflammatory conditions and a delay in diagnosis. Many patients have metastases at diagnosis or recur rapidly, and the overall prognosis is poor.[45]

Rarely, breast cancer presents as an axillary nodal metastasis or distant metastasis before cancer is detected in the breast. In most cases, the primary carcinoma is either small or obscured by dense breast tissue. The number of primary carcinomas that remain occult in such cases has been minimized with imaging using mammography, ultrasound, and MRI.

The most common histologic types of breast adenocarcinoma are listed in Table 23-3 . These special types are important to recognize because of their specific clinical associations.

TABLE 23-3 -- Distribution of Histologic Types of Breast Cancer

Total Cancers	Percentage
CARCINOMA IN SITU[*]	**15–30**
Ductal carcinoma in situ	80
Lobular carcinoma in situ	20
INVASIVE CARCINOMA	**70–85**
No-special-type carcinoma (“ductal”)	79
Lobular carcinoma	10
Tubular/cribriform carcinoma	6
Mucinous (colloid) carcinoma	2
Medullary carcinoma	2
Papillary carcinoma	1
Metaplastic carcinoma	<1

The data on invasive carcinomas are modified from Dixon JM et al.: Long-term survivors after breast cancer. Br J Surg 72:445, 1985.

[*] The proportion of in situ carcinomas detected depends on the percentage of women undergoing mammographic screening and ranges from less than 5% in unscreened populations to almost 50% in populations that are well screened. Current observed numbers are between these two extremes.

Invasive Carcinoma, No Special Type (NST; Invasive Ductal Carcinoma)

Invasive carcinomas of no special type include the majority of carcinomas (70% to 80%).

Morphology. On gross examination, most tumors are firm to hard and have an irregular border (Fig. 23-21B). When cut or scraped, they typically produce a characteristic grating sound (similar to cutting a water chestnut) due to small, central pinpoint foci or streaks of chalky-white elastotic stroma and occasional small foci of calcification. Less frequently, carcinomas have a well-circumscribed

border and a softer consistency.

There is a wide range of histologic appearances. Well-differentiated carcinomas show prominent tubule formation, small round nuclei, and rare mitotic figures (Fig. 23-22A). Moderately differentiated carcinomas may have tubules, but solid clusters or single infiltrating cells are also present. These tumors have a greater degree of nuclear pleomorphism and contain mitotic figures (Fig. 23-22B). Poorly differentiated carcinomas often invade as ragged nests or solid sheets of cells with enlarged irregular nuclei. A high proliferation rate and areas of tumor necrosis are common (Fig. 23-22C).

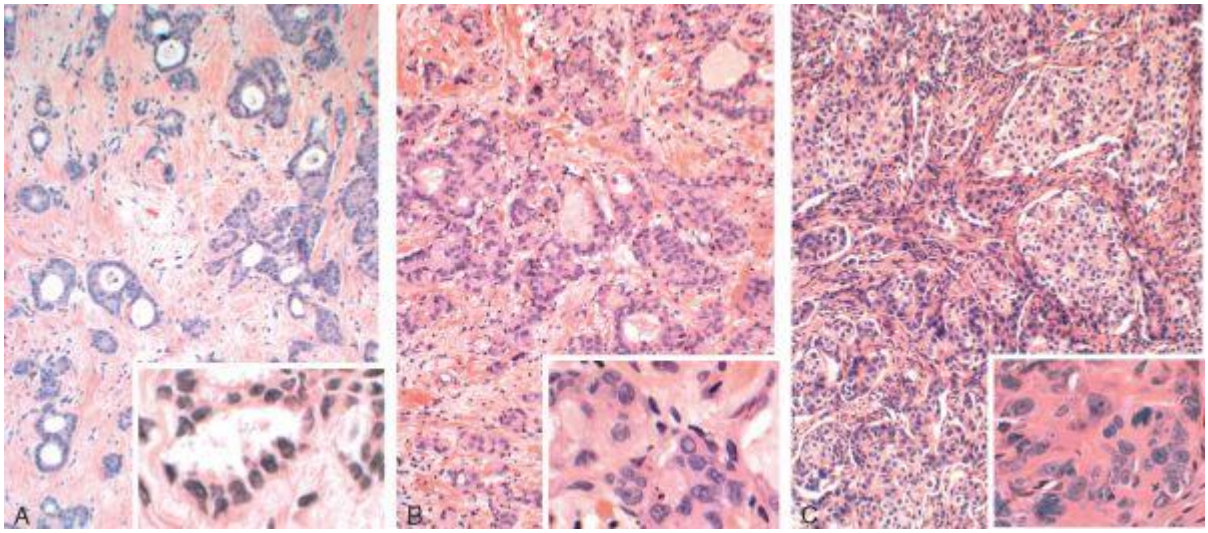

FIGURE 23-22 **A**, A well-differentiated invasive carcinoma of no special type consists of tubules or a cribriform pattern of cells with small monomorphic nuclei. **B**, A moderately differentiated carcinoma shows less tubule formation and more solid nests of cells and pleomorphic nuclei. **C**, This poorly differentiated invasive carcinoma of no special type infiltrates as ragged sheets of pleomorphic cells with numerous mitotic figures and central areas of tumor necrosis.

Recently developed techniques that examine the DNA, RNA, and proteins of carcinomas globally have provided a framework for new molecular classifications of this group of breast cancers (Fig. 23-23). Gene expression profiling, which can measure the relative quantities of mRNA for essentially every gene, has identified five major patterns of gene expression in the NST group: luminal A, luminal B, normal, basal-like, and HER2 positive.[46] These molecular classes correlate with prognosis and response to therapy, and thus have taken on clinical importance.

- *"Luminal A"* (40% to 55% of NST cancers): This is the largest group and consists of cancers that are ER positive and HER2/neu negative. The gene signature is dominated by the dozens of genes under the control of ER (see Fig. 23-23). ER-positive carcinomas also show increased transcription of genes thought to be characteristic of normal luminal cells. The majority are well- or moderately differentiated, and most occur in postmenopausal women.
  These cancers are generally slow growing and respond well to hormonal treatments. Conversely, only a small number will respond to standard chemotherapy. Commercial tests, some already available for use with formalin-fixed tissues, have been developed to identify this and other molecular classes.[47] In addition, clinical trials are attempting to identify different types or combinations of chemotherapeutic agents that may be efficacious for ER-positive cancers.
- *"Luminal B"* (15% to 20% of NST cancers): This group of cancers also expresses ER but is generally of

higher grade, has a higher proliferative rate, and often overexpresses HER2/neu. They are sometimes referred to as *triple-positive* cancers. They compose a major group of ER-positive cancers that are more likely to have lymph node metastases and that may respond to chemotherapy.

- *"Normal breast–like"* (6% to 10% of NST cancers): This is a small group of usually well-differentiated ER-positive, HER2/neu-negative cancers characterized by the similarity of their gene expression pattern to normal tissue. It is not yet clear whether or not this is a specific tumor expression pattern.
- *"Basal-like"* (13% to 25% of NST cancers): These cancers are notable for the absence of ER, PR, and HER2/neu and the expression of markers typical of myoepithelial cells (e.g., basal keratins, P-cadherin, p63, or laminin), progenitor cells, or putative stem cells (e.g., cytokeratins 5 and 6) (see Fig. 23-23). "Basal" was chosen as a general term that covers all of these cell types.
  By strict definition this group is defined by their gene expression profile. Basal-like cancers are a subgroup of ER-PR-HER2/neu "triple-negative" carcinomas.[48,][49] Members of this group include medullary carcinomas, metaplastic carcinomas (e.g., spindle cell carcinomas or matrix-producing carcinomas), and carcinomas with a central fibrotic focus.
  Basal-like cancers are of particular interest because of their distinct genetic and epidemiologic features. Many carcinomas arising in women with *BRCA1* mutations are of this type. There is also an increased incidence in certain ethnic populations and in young women.
  These cancers are generally high grade and have a high proliferation rate. They are associated with an aggressive course, frequent metastasis to viscera and the brain, and a poor prognosis. However, approximately 15% to 20% will have a pathologic complete response to chemotherapy; cure may be possible in this chemosensitive subgroup.
- *"HER2 positive"* (7% to 12% of NST cancers): This group comprises ER-negative carcinomas that overexpress HER2/neu protein. In over 90% of HER2/neu positive cancers, overexpression is due to amplification of the segment of DNA on 17q21 that includes the *HER2/neu* gene and varying numbers of adjacent genes. This amplicon dominates the gene signature of this group (see Fig. 23-23). HER2/neu assays, which include measurement of gene copy number by fluorescence in situ hybridization, mRNA level by gene arrays, and protein by immunohistochemistry, are all abnormal in the majority of these cancers. In rare cases, HER2/neu protein overexpression may occur as a result of mechanisms other than gene amplification.[50] These cancers are usually poorly differentiated, have a high proliferation rate, and are associated with a high frequency of brain metastasis.

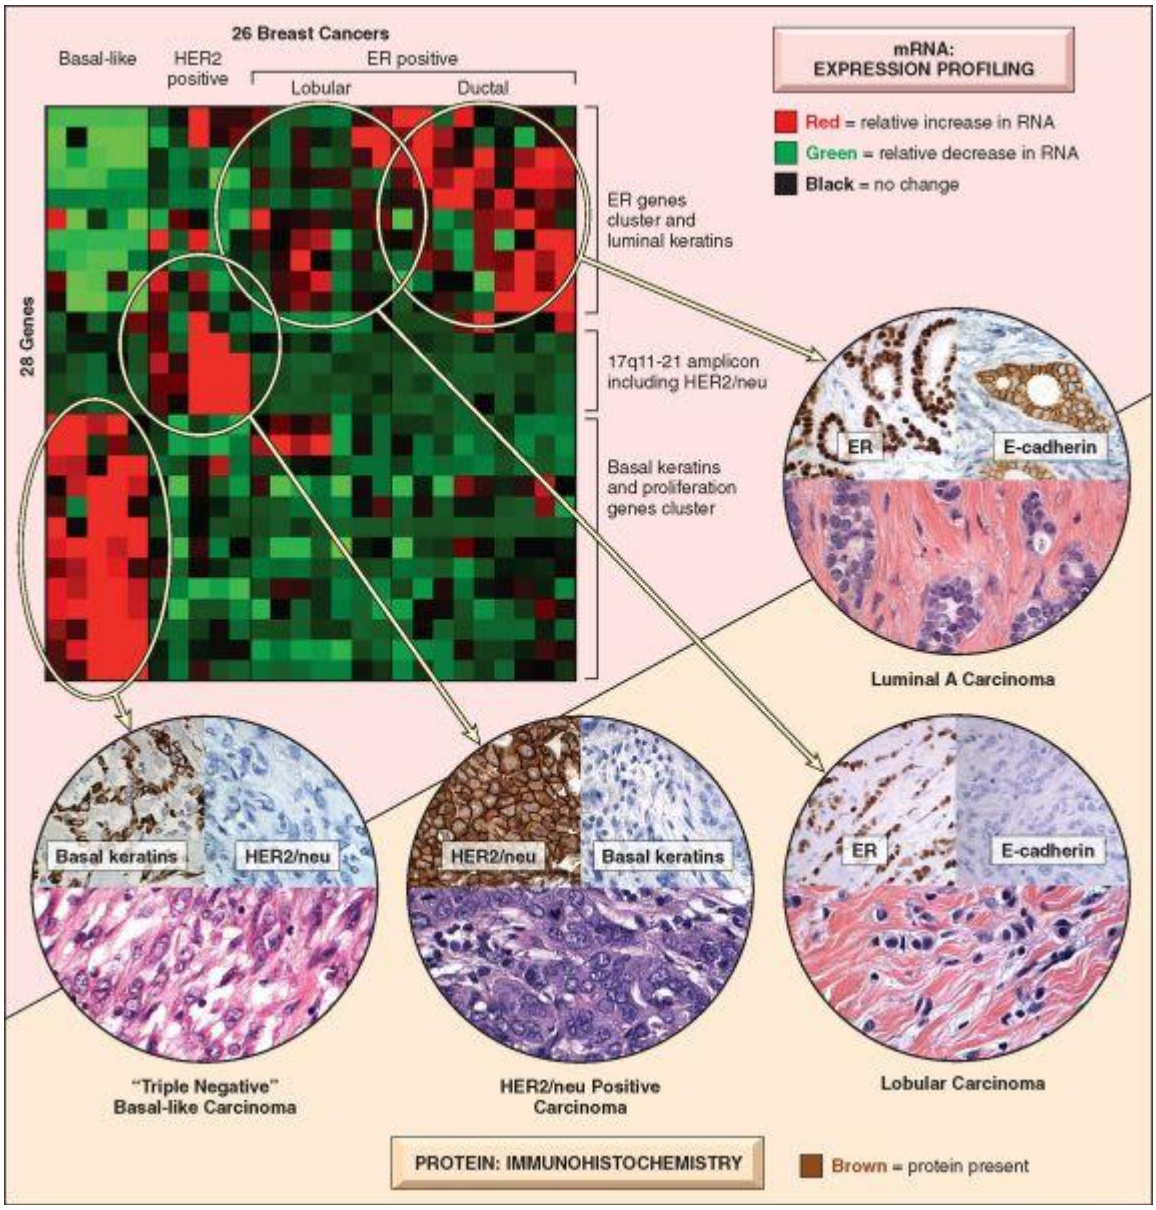

FIGURE 23-23 Gene expression portraits of breast carcinomas. Alterations in DNA, messenger RNA (mRNA), and protein expression identify breast cancer subtypes previously recognized by morphology (e.g., lobular carcinomas) and define new subtypes ("luminal A," "HER2/neu positive," and "basal-like"). *(Array data courtesy of Dr. Andrea Richardson, Brigham and Women's Hospital, Boston, MA, as modified from Signoretti S et al.: Oncogenic role of the ubiquitin ligase subunit skp2 in human breast cancer. J Clin Invest 110:633, 2002.)*

Trastuzumab (Herceptin) is a humanized monoclonal antibody specific to HER2/neu. The combination of trastuzumab and chemotherapy is highly effective in treating carcinomas that overexpress HER2/neu. Demonstrating the first genetargeted therapeutic agent for a solid tumor, these results have created great excitement within the community of physicians and scientists involved with treating cancer patients. Unfortunately, trastuzumab does not cross the blood-brain barrier, leaving patients susceptible to metastatic disease to this site. Newer agents, such as the dual tyrosine kinase inhibitor lapatinib, that targets both EGFR and HER2/neu, will hopefully overcome these limitations.[51] Other genes on the same segment of amplified DNA may influence the sensitivity of HER2 tumors to these agents.

Invasive Lobular Carcinoma

Invasive lobular carcinomas usually present as a palpable mass or a mammographic density with irregular borders. However, in about one fourth of cases the tumor infiltrates the tissue diffusely and causes little desmoplasia. Such tumors are difficult to detect by palpation and may cause only very subtle mammographic changes. Metastases can also be difficult to detect clinically and radiologically because of this type of invasion.

Lobular carcinomas have been reported to have a greater incidence of bilaterality. However, many studies have been biased by the greater likelihood of performing contralateral surgery in women with lobular carcinoma. The actual fraction of women who develop invasive carcinomas in the contralateral breast is only 5% to 10%, which is similar to the incidence for NST carcinomas.

Morphology. The histologic hallmark is the presence of dyscohesive infiltrating tumor cells, often arranged in single file or in loose clusters or sheets (see Fig. 23-23). Tubule formation is absent. The cytologic appearance is identical to the cells of atypical lobular hyperplasia and LCIS. Signet-ring cells containing an intracytoplasmic mucin droplet are common. Desmoplasia may be minimal or absent.

Invasive lobular carcinoma is graded using the same criteria as those applied to other breast carcinomas.[52] Well-differentiated and moderately differentiated invasive lobular carcinomas are usually diploid, ER positive, and associated with LCIS. HER2/neu overexpression is very rare. These cancers have a gene expression profile similar to luminal A cancers (see Fig. 23-23).[53] In contrast, poorly differentiated lobular carcinomas are generally aneuploid, often lack hormone receptors, and may overexpress HER2/neu. If matched by grade and stage, lobular carcinomas have the same prognosis as NST carcinomas.

Lobular carcinomas have a different pattern of metastasis than other breast cancers. Metastasis tends to occur to the peritoneum and retroperitoneum, the leptomeninges (carcinoma meningitis), the gastrointestinal tract, and the ovaries and uterus.[53] In some cases, metastatic lobular carcinoma may be mistaken for signet ring carcinoma of the GI tract, which it closely resembles. The morphologic resemblance of these two tumors is not coincidental, but rather reflects a common underlying molecular etiology. Both lobular carcinoma and signet ring carcinoma of the gastrointestinal tract are characterized by the loss of E-cadherin, a cell adhesion molecule that functions as a tumor suppressor. In lobular carcinoma, biallelic loss of expression of *CDH1*, the gene that encodes E-cadherin, stems from a combination of deletions, mutations, and promoter silencing via methylation. Loss of E-cadherin is also seen in atypical lobular hyperplasia and LCIS, indicating that this alteration is a relatively early event in the development of lobular carcinoma. Rare patients with heterozygous germline mutations in *CDH1* are at very high risk of developing lobular carcinoma (if female) and gastric signet ring carcinoma (males and females), emphasizing the close molecular relationship between these two tumors and the importance of E-cadherin loss in their pathogenesis.[54,][55]

Medullary Carcinoma

Medullary carcinoma is most common in women in the sixth decade and presents as a well-circumscribed mass. It may closely mimic a benign lesion clinically and radiologically, or present as a rapidly growing mass.

Morphology. These tumors produce little desmoplasia and are distinctly more yielding on palpation and cutting than typical breast carcinomas. The tumor is soft, fleshy (*medulla* is Latin for "marrow"), and well circumscribed. Histologically, the carcinoma is characterized by (1) solid, syncytium-like sheets of large cells with vesicular, pleomorphic nuclei, and prominent nucleoli, which compose more than 75% of the tumor mass; (2) frequent mitotic figures; (3) a moderate to marked lymphoplasmacytic infiltrate surrounding and within the tumor; and (4) a pushing (noninfiltrative) border (Fig. 23-24C). All medullary carcinomas are poorly differentiated. DCIS is minimal or absent.

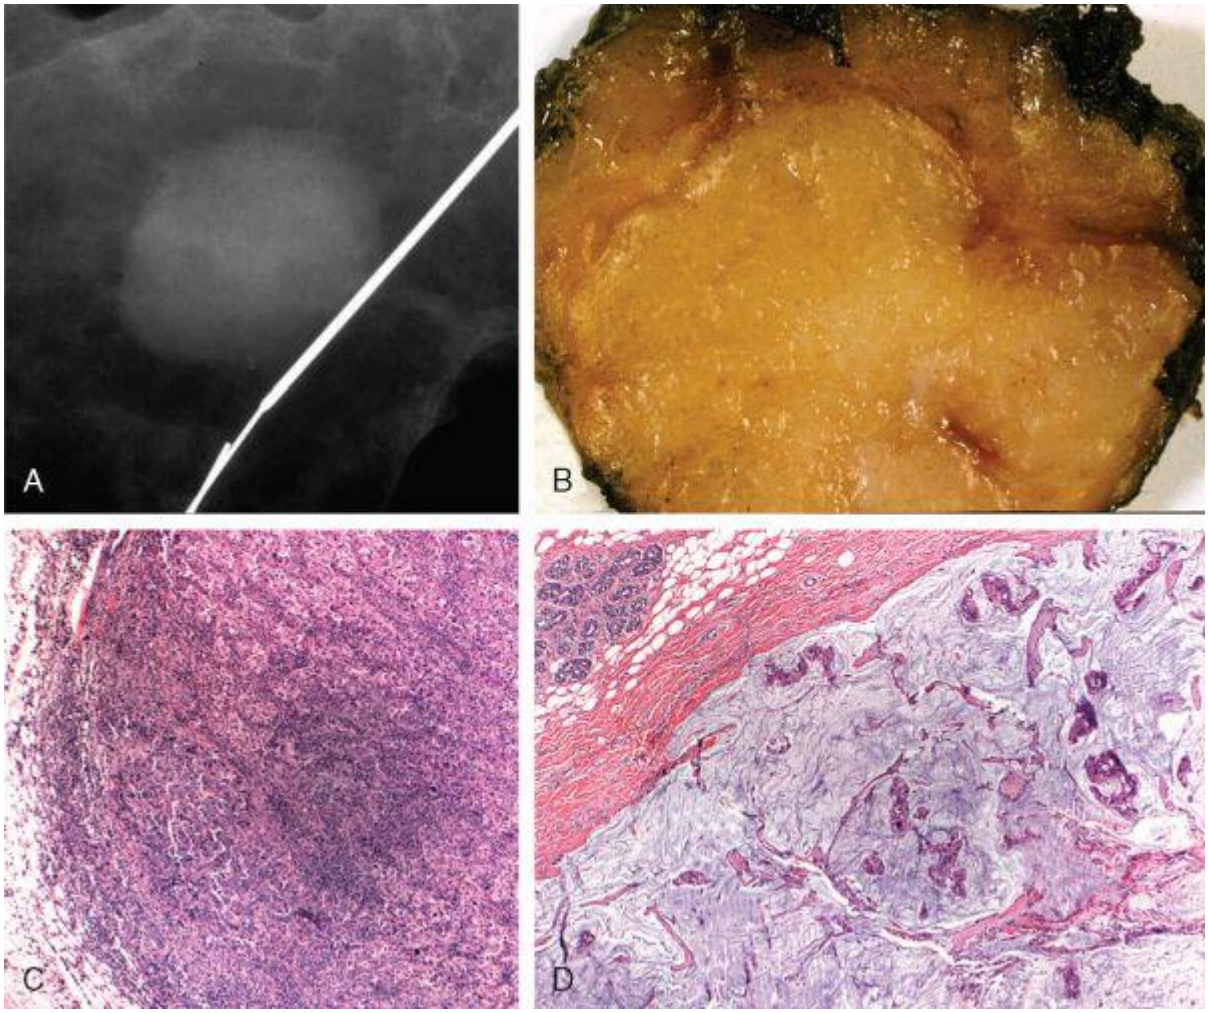

FIGURE 23-24 Invasive carcinoma variants. **A**, The specimen radiogram shows a well-circumscribed mass. The majority of such masses are benign, but approximately 6% are carcinomas. **B**, Grossly, this carcinoma has a pushing border and a fleshy appearance. **C**, Medullary carcinoma. Note the pushing border, the sheetlike growth of the pleomorphic tumor cells, and the prominent lymphoplasmacytic infiltrate. **D**, Mucinous (colloid) carcinoma. The malignant cells lie within pools of extracellular mucin. The tumor also has a pushing border and is very deceptively soft in texture.

Medullary carcinomas have a slightly better prognosis than do NST carcinomas, despite the almost universal presence of poor prognostic factors, including high nuclear grade, aneuploidy, absence of hormone receptors, and high proliferative rates. HER2/neu overexpression is not observed. Lymph node metastases are infrequent and rarely involve multiple nodes. The syncytial growth pattern and pushing

borders may stem from the overexpression of adhesion molecules, such as intercellular cell adhesion molecule and E-cadherin, which could potentially limit metastatic potential.[53]

Medullary carcinomas have a basal-like gene expression profile.[56] Among cancers arising in *BRCA1* carriers, 13% are of medullary type, and up to 60% have a subset of medullary features (see Table 23-3). Although, the majority of medullary carcinomas are not associated with germline *BRCA1* mutations, hypermethylation of the *BRCA1* promoter is observed in 67% of medullary carcinomas, suggesting an association of this morphology with underlying gene expression.

Mucinous (Colloid) Carcinoma

These carcinomas occur in older women (median age 71) and tend to grow slowly over the course of many years.

Morphology. The tumor is soft or rubbery and has the consistency and appearance of pale gray-blue gelatin. The borders are pushing or circumscribed. The tumor cells are arranged in clusters and small islands of cells within large lakes of mucin (Fig. 23-24D).

Mucinous carcinomas are usually diploid, well to moderately differentiated, and ER positive. Lymph node metastases are uncommon. The overall prognosis is slightly better than that of NST carcinomas.

Tubular Carcinoma

Tubular carcinomas are typically detected as small irregular mammographic densities in women in their late 40s. They are uncommon, but constitute up to 10% of tumors that are smaller than 1 cm in size. In a significant minority of cases, tumors are multifocal within one breast or detected bilaterally.

Morphology. These tumors consist exclusively of well-formed tubules and are sometimes mistaken for benign sclerosing lesions (Fig. 23-25). However, the myoepithelial cell layer is absent, placing the tumor cells in direct contact with the stroma. A cribriform pattern is sometimes seen. Apocrine snouts are typical, and calcifications may be present within the lumens. Tubular carcinomas are frequently associated with atypical lobular hyperplasia, LCIS, or low-grade DCIS.[8]

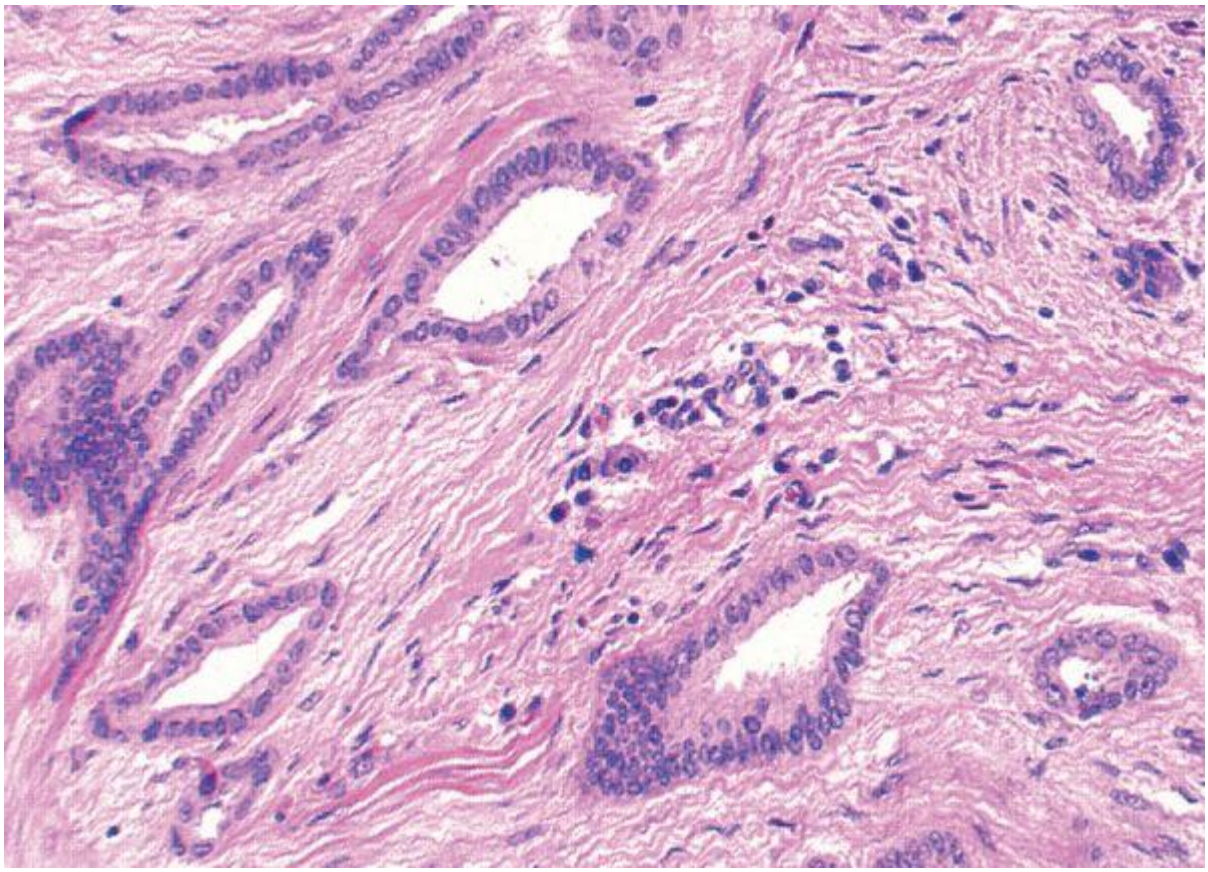

FIGURE 23-25 Tubular carcinoma. This carcinoma is composed of well-formed angulated tubules lined by a single layer of cells with small uniform nuclei.

More than 95% of all tubular carcinomas are diploid, ER positive, and HER2/neu negative. By definition, all are well differentiated. Axillary metastases occur in fewer than 10% of cases unless multiple foci of invasion are present. This subtype is important to recognize because of its excellent prognosis.

Invasive Papillary Carcinoma

Invasive papillary carcinomas and invasive micropapillary carcinomas are rare, representing 1% or fewer of all invasive cancers. Papillary or micropapillary architecture is more commonly seen in DCIS. Invasive papillary carcinomas are usually ER positive and have a favorable prognosis. In contrast, invasive micropapillary carcinomas are more likely to be ER negative and HER2 positive. Lymph node metastases are very common, and the prognosis is poor.

Metaplastic Carcinoma

"Metaplastic carcinoma" includes a variety of rare types of breast cancer (<1% of all cases), such as matrix-producing carcinomas, squamous cell carcinomas, and carcinomas with a prominent spindle cell component. They are ER-PR-HER2/neu "triple negative," often express myoepithelial proteins, and appear to be related to the basal-like carcinomas. Lymph node metastases are infrequent, but the prognosis is generally poor.

PROGNOSTIC AND PREDICTIVE FACTORS

The outcome for women with breast cancer varies widely. Many women have a normal life expectancy, whereas others have only a 10% chance of being alive in 5 years. Except in women who present with distant metastasis (<10%) or with inflammatory carcinoma (<5%) (in whom the prognosis is poor regardless of other findings), *prognosis is determined by the pathologic examination of the primary carcinoma and the axillary lymph nodes*. Prognostic information is important in counseling patients about the likely outcome of their disease, choosing appropriate treatment, and the design of clinical trials.

Major prognostic factors that are the strongest predictors of death from breast cancer are incorporated into the American Joint Committee on Cancer (AJCC) staging system,[57] which is used to divide patients into five stages (0 to IV) that are correlated with survival (Table 23-4). The major prognostic factors are as follows:

1. **Invasive carcinoma versus in situ disease**. By definition, in situ carcinoma is confined to the ductal system and cannot metastasize. Breast cancer deaths associated with DCIS are due to the subsequent development of invasive carcinoma or areas of invasion that were not detected at the time of diagnosis. The great majority of women with adequately treated DICS are cured. In contrast, at least half of invasive carcinomas have metastasized locally or distantly at the time of diagnosis.
2. **Distant metastases**. Once distant metastases are present, cure is unlikely, although long-term remissions and palliation can be achieved, especially in women with hormonally responsive tumors. As mentioned earlier, the tumor type influences the timing and location of metastases.[58,][59]
3. **Lymph node metastases**. *Axillary lymph node status is the most important prognostic factor for invasive carcinoma in the absence of distant metastases*. The clinical assessment of lymph node status is unreliable due to both false positives (e.g., palpable reactive nodes) and false negatives (e.g., lymph nodes with small metastatic deposits). Therefore, biopsy is necessary for accurate assessment. With no nodal involvement, the 10-year disease-free survival rate is close to 70% to 80%; the rate falls to 35% to 40% with one to three positive nodes, and to 10% to 15% when more than 10 nodes are positive.
   Lymphatic vessels in most breast carcinomas drain first to one or two *sentinel nodes*, which can be identified with radiotracer or colored dyes. If a biopsy restricted to the sentinel nodes is negative for metastasis, it is unlikely that other more distant nodes will be involved and the patient can be spared the morbidity of a complete axillary dissection. For these reasons, sentinel node biopsy has been adopted in many centers as part of the assessment of lymph node status. In some tumors of the medial breast, the sentinel node is an intrathoracic internal mammary node. These nodes are generally not biopsied owing to the morbidity associated with the procedure.
   Macrometastases (greater than 0.2 cm) are of proven prognostic importance. Through more sensitive approaches, including serial sectioning of lymph nodes, immunohistochemistry for keratins, and RT-PCR–based detection of tumor-specific mRNA, increased numbers of women with micrometastases (0.2 cm or less) are being identified. The clinical significance of these small metastases is unclear and is being addressed by current clinical trials.
   Approximately 10% to 20% of women without axillary lymph node metastases have a recurrence outside of the breast and about the same number die from breast cancer. In these patients, metastasis may occur via the internal mammary lymph nodes or hematogenously.
4. **Tumor size**. The size of an invasive carcinoma is the second most important prognostic factor. The risk of axillary lymph node metastases increases with the size of the primary tumor, but both are independent prognostic factors. Women with node-negative carcinomas <1 cm in size have a 10-year survival rate of over 90%, whereas survival drops to 77% for cancers >2 cm.
   Unfortunately, breast self-examination does not lower breast cancer mortality,[60] suggesting that by the time breast cancers become palpable (typically when at least 2 to 3 cm), tumors capable of metastasizing have already done so. Mammographically detected cancers are smaller and less likely to have metastasized.
5. **Locally advanced disease**. Carcinomas invading into skin or skeletal muscle are usually large and may be difficult to treat surgically. With increased awareness of breast cancer detection, such cases have fortunately decreased in frequency and are now rare at initial presentation.
6. **Inflammatory carcinoma**. Breast cancers presenting with breast swelling and skin thickening due to dermal

lymphatic involvement have a particularly poor prognosis. The 3-year survival rate is only 3% to 10%. Less than 3% of cancers are in this group, but the incidence is higher in African American women and younger women.[61]

TABLE 23-4 -- AJCC Staging[*]

Stage	T: Primary Cancer	Lymph Nodes (LNs)	M: Distant Metastasis	5-Year Survival (%)
0	DCIS or LCIS	No metastases	Absent	92
I	Invasive carcinoma ≤2 cm	No metastases	Absent	87
II	Invasive carcinoma >2 cm	No metastases	Absent	75
	Invasive carcinoma <5 cm	1 to 3 positive LNs	Absent	
III	Invasive carcinoma >5 cm	1 to 3 positive LNs	Absent	46
	Any size invasive carcinoma	≥4 positive LNs	Absent	
	Invasive carcinoma with skin or chest wall involvement or inflammatory carcinoma	0 to >10 positive LNs	Absent	
IV	Any size invasive carcinoma	Negative or positive lymph nodes	Present	13

DCIS, ductal carcinoma in situ; LCIS, lobular carcinoma in situ.

[*] The groups listed in the table are based on the characteristics of the primary carcinoma and the axillary lymph nodes. For rare women with involved internal mammary lymph nodes or supraclavicular lymph nodes, there are additional staging criteria.[57]

Minor Prognostic and Predictive Factors

In addition to the six factors used by the AJCC, a number of other factors are predictive of outcome; some of these also direct therapies against particular molecular targets.

- **Histologic subtype**. The 30-year survival rate of women with special types of invasive carcinomas (tubular, mucinous, medullary, lobular, and papillary) is greater than 60%, compared with less than 20% for women with NST cancers. With the exception of medullary carcinoma, most of these carcinomas will be well to moderately differentiated, ER positive, and HER2/neu negative. This favorable prognosis probably does not apply to unusual special-type carcinomas without these characteristics.
- **Histologic grade**. The most commonly used grading system, the Nottingham Histologic Score (also referred to as Scarff-Bloom-Richardson), combines nuclear grade, tubule formation, and mitotic rate to classify invasive carcinomas into three groups that are highly correlated with survival.[52] Survival for patients with well-differentiated grade 1 carcinomas (approximately 20% of the total) gradually declines to 70% at 24 years. In contrast, most deaths for poorly differentiated grade 3 carcinomas (approximately 46% of the total) occur in the first 10 years, and 45% of patients survive long-term. Women with moderately differentiated grade 2 carcinomas (approximately 35% of the total) have better survival initially, but their long-term survival is only slightly better than grade 3 carcinomas.
- **Estrogen and progesterone receptors**. Current assays use immunohistochemistry to detect nuclear hormone receptors, a finding that is correlated with a better outcome and is an important predictor of response to hormonal therapy (see Fig. 23-23). Eighty percent of carcinomas that are ER and PR positive respond to hormonal manipulation, whereas only about 40% of those with either ER or PR alone respond. ER-positive cancers are less likely to respond to chemotherapy. Conversely, cancers that fail to express either ER or PR have a less than 10% likelihood of responding to hormonal therapy but are more likely to respond to chemotherapy.
- **HER2/neu**. HER2/neu overexpression is associated with poorer survival, but its main importance is as a predictor of response to agents that target this transmembrane protein (e.g., trastuzumab or lapatinib). Several different assays are used to determine *HER/neu* gene amplification and protein overexpression (see

Fig. 23-23).

- **Lymphovascular invasion**. Tumor cells are present within vascular spaces (either lymphatics or small capillaries) in about half of all invasive carcinomas. This finding is strongly associated with the presence of lymph node metastases. It is a poor prognostic factor for overall survival in women without lymph node metastases and a risk factor for local recurrence. As already mentioned, extensive plugging of the lymphovascular spaces of the dermis with carcinoma cells (inflammatory carcinoma) bodes a very poor prognosis.
- **Proliferative rate**. Proliferation can be measured by mitotic counts (e.g., as part of histologic grading), by immunohistochemical detection of cellular proteins produced during the cell cycle (e.g., cyclins, Ki-67), by flow cytometry (as the S-phase fraction), or by thymidine labeling index. Carcinomas with high proliferation rates have a poorer prognosis but may respond better to chemotherapy.
- **DNA content**. The amount of DNA per tumor cell can be determined by flow-cytometric analysis or by image analysis of tissue sections. Tumors with a DNA index of 1 have the same total amount of DNA as normal diploid cells, although marked karyotypic changes may be present. Aneuploid tumors are those with abnormal DNA indices and have a slightly worse prognosis.
- **Response to neoadjuvant therapy**. Most patients complete their surgery and subsequently receive systemic treatment (referred to as adjuvant therapy). Neoadjuvant therapy is an alternative approach in which the patient is treated before surgery. Although this approach does not improve survival, the degree that the tumor responds to chemotherapy is a strong prognostic factor. Clinical and radiologic examinations are useful to monitor changes during treatment, but often underestimate or overestimate the amount of residual carcinoma. Cancers most likely to respond well are poorly differentiated, ER negative, and have areas of necrosis. The subgroup of patients who achieve a pathologic complete response (i.e., no residual cancer in the breast or lymph nodes) have a greater than 95% long-term survival, in contrast to the poor prognosis of this group as a whole.[62] Pathologic response can be used as a short-term end point for clinical trials (which thus can yield useful information with fewer patients in shorter periods of time) and is being linked to research studies investigating the molecular basis of tumor sensitivity or resistance to therapy.
- **Gene expression profiling**. Expression profiling has been shown to predict survival and recurrence-free interval, and also identifies patients who are most likely to benefit from particular types of chemotherapy. Methods that require rapidly frozen tissue will be difficult to apply in clinical practice, but alternative approaches that use formalin-fixed paraffin-embedded tissues are beginning to enter clinical practice.[47]

Although gene expression profiles provide a vast amount of information about carcinomas, they are not well correlated with tumor size or lymph node status—two of the strongest prognostic factors.[63] This suggests that while patterns of gene expression likely determine metastatic potential, time and chance also influence whether and when metastasis occurs. It is likely that future means of estimating prognosis will involve some combination of these “old” and “new” factors.

Current therapeutic approaches directed at local and regional control consist of combinations of surgery (mastectomy or breast conservation) and postoperative radiation, whereas attempts at systemic control rely on hormonal treatment, chemotherapy, or both. Axillary node dissection or sentinel node sampling is performed for prognostic purposes, but the axilla can also be treated with radiation alone. Newer therapeutic strategies include inhibitors of membrane-bound growth factor receptors (e.g., HER2/neu), stromal proteases, and angiogenesis.

Such therapies are based on models of breast cancer dissemination that have evolved as our understanding of its biology has changed. Earlier models proposed that breast cancer spreads in a contiguous fashion by direct extension from breast to nodes and could therefore be cured by en bloc surgical resection. However, radical surgery, including mastectomies with removal of pectoralis muscles, internal mammary nodes, and even supraclavicular nodes, failed to decrease mortality. A subsequent model, based on studies demonstrating that breast-conserving surgery and radiation were equivalent to radical mastectomy, postulated that all cancers had spread systemically by the time of diagnosis and that local or regional treatment was unimportant for overall survival. In the current era of

increased detection of early-stage carcinomas by mammography, a third model that combines the first two is thought to be a more appropriate guide to therapy.[64]

STROMAL TUMORS

The two types of stroma in the breast, intralobular and interlobular (see the introductory section on the normal female breast), give rise to distinct types of neoplasms. The breastspecific biphasic tumors fibroadenoma and phyllodes tumor arise from intralobular stroma. This specialized stroma may elaborate growth factors for epithelial cells, resulting in the proliferation of the non-neoplastic epithelial component of these tumors. Interlobular stroma is the source of the same types of tumors found in connective tissue in other sites of the body (e.g., lipomas and angiosarcomas) as well as tumors arising more commonly in the breast (e.g., pseudoangiomatous stromal hyperplasia, myofibroblastomas, and fibrous tumors).

Fibroadenoma

This is the most common benign tumor of the female breast. Most occur in women in their 20s and 30s, and they are frequently multiple and bilateral. Young women usually present with a palpable mass and older women with a mammographic density (Fig. 23-26A) or mammographic calcifications. The epithelium of the fibroadenoma is hormonally responsive, and an increase in size due to lactational changes during pregnancy, which may be complicated by infarction and inflammation, can mimic carcinoma. The stroma often becomes densely hyalinized after menopause and may calcify. Large lobulated (“popcorn”) calcifications have a characteristic mammographic appearance, but small calcifications may appear clustered and require biopsy to exclude carcinoma.

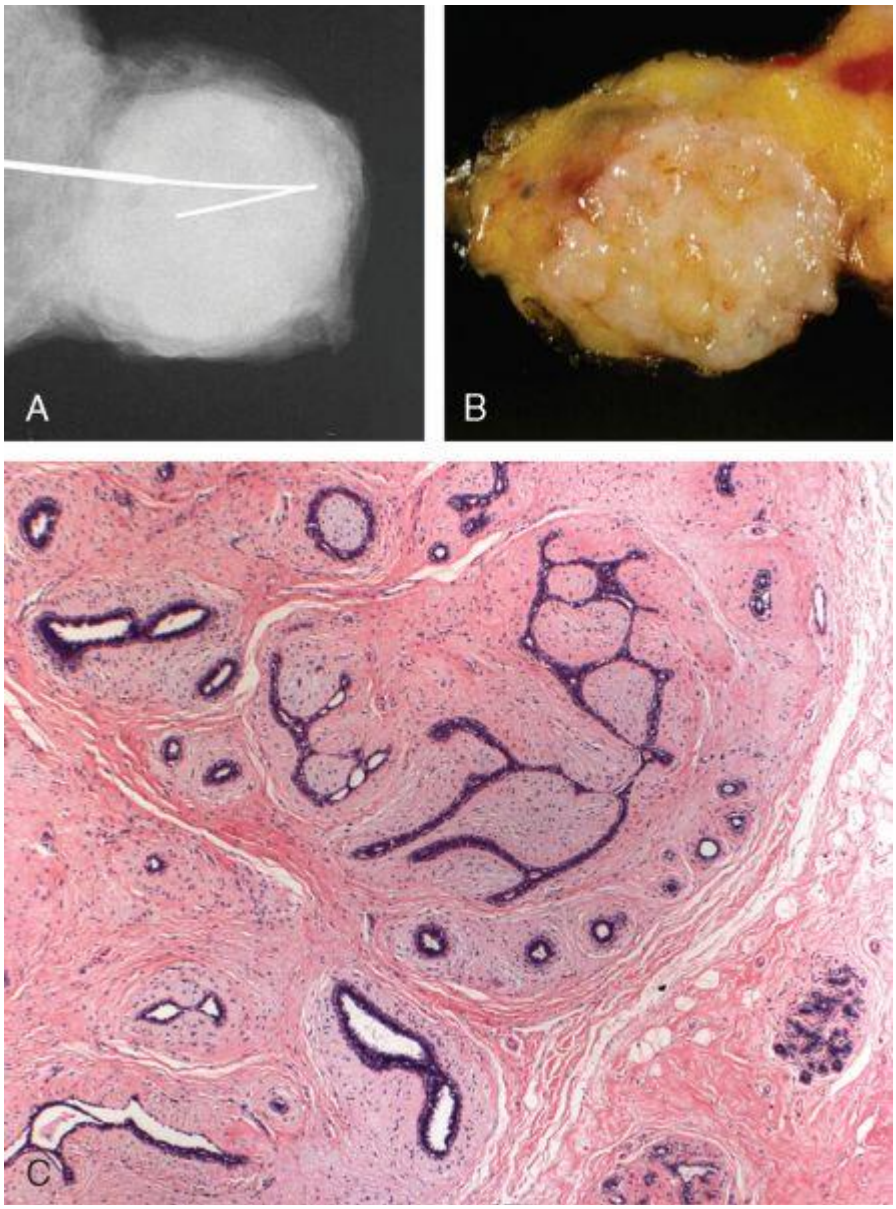

FIGURE 23-26 Fibroadenoma. **A**, The radiogram shows a characteristically well-circumscribed mass. **B**, Grossly, a rubbery, white, well-circumscribed mass is clearly demarcated from the surrounding yellow adipose tissue. The absence of adipose tissue accounts for the radiodensity of the lesion. **C**, The proliferation of intralobular stroma surrounds, pushes, and distorts the associated epithelium. The border is sharply delimited from the surrounding tissue.

Morphology. Fibroadenomas grow as spherical nodules that are usually sharply circumscribed and freely movable. They vary in size from less than 1 cm to large tumors that can replace most of the breast. The tumors are well-circumscribed, rubbery, grayish white nodules that bulge above the surrounding tissue and often contain slitlike spaces (Fig. 23-26B).

The delicate, cellular, and often myxoid stroma resembles normal intralobular stroma. The epithelium may be surrounded by stroma or compressed and distorted by it (Fig. 23-26C). In older women, the stroma typically becomes densely hyalinized and the epithelium atrophic.

Some fibroadenomas are polyclonal hyperplasias of lobular stroma due to some type of stimulus. For example, almost half of women receiving cyclosporin A after renal transplantation develop fibroadenomas. In this setting the tumors are frequently multiple and bilateral. Regression may occur after cessation of cyclosporin treatment. Other fibroadenomas are benign neoplasms associated with clonal cytogenetic aberrations that are confined to the stromal component. No consistent cytogenetic changes have been found.

Fibroadenomas were originally grouped with other "proliferative changes without atypia" in conferring a mild increase in the risk of subsequent cancer. However, in one study the increased risk was limited to fibroadenomas associated with cysts larger than 0.3 cm, sclerosing adenosis, epithelial calcifications, or papillary apocrine change ("complex fibroadenomas") (see Table 23-1).[65]

Phyllodes Tumor

Phyllodes tumors, like fibroadenomas, arise from intralobular stroma. Although they can occur at any age, most present in the sixth decade, 10 to 20 years later than the peak age for fibroadenomas.[66] The majority are detected as palpable masses, but a few are found by mammography. The term *cystosarcoma phyllodes* is sometimes used for these lesions. However, the term *phyllodes tumor* is preferred, since the majority of these tumors behave in a relatively benign fashion, and most are not cystic.

Morphology. The tumors vary in size from a few centimeters to massive lesions involving the entire breast. The larger lesions often have bulbous protrusions (*phyllodes* is Greek for "leaflike") due to the presence of nodules of proliferating stroma covered by epithelium (Fig. 23-27). In some tumors these protrusions extend into a cystic space. This growth pattern can also occasionally be seen in larger fibroadenomas and is not an indication of malignancy. Phyllodes tumors are distinguished from the more common fibroadenomas on the basis of cellularity, mitotic rate, nuclear pleomorphism, stromal overgrowth, and infiltrative borders. Low-grade lesions resemble fibroadenomas but are more cellular and contain mitotic figures. High-grade lesions may be difficult to distinguish from other soft-tissue sarcomas and may have foci of mesenchymal differentiation (e.g., rhabdomyosarcoma or liposarcoma). The frequency of chromosomal changes increases with grade and the majority of high-grade lesions are reported to have amplification of EGFR.[67] Recurrent phyllodes tumors are often of a higher grade than the presenting lesion.

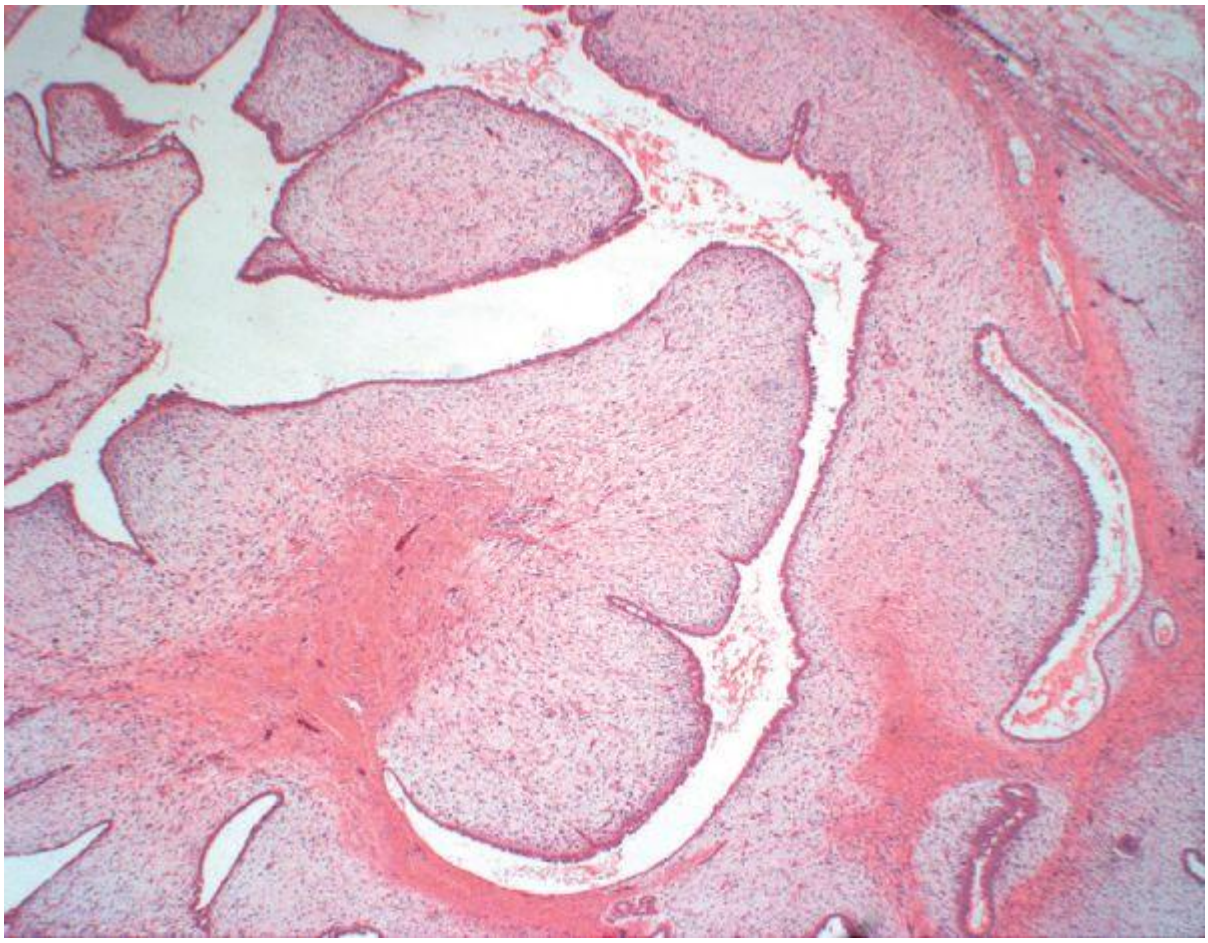

FIGURE 23-27 Phyllodes tumor. Compared to a fibroadenoma, there is increased stromal cellularity, cytologic atypia, and stromal overgrowth, giving rise to the typical leaflike architecture.

Phyllodes tumors must be excised with wide margins or by mastectomy to avoid local recurrences. Axillary lymph node dissection is not indicated, because the incidence of nodal metastases (as for other stromal malignancies) is exceedingly small. The majority are low-grade tumors that may recur locally but only rarely metastasize. Rare high-grade lesions behave aggressively, with frequent local recurrences and distant hematogenous metastases in about one third of cases. Only the stromal component metastasizes.

Benign Stromal Lesions

Tumors of the interlobular stroma of the breast are composed of stromal cells without an accompanying epithelial component. Pseudoangiomatous stromal hyperplasia and fibrous tumors present as circumscribed palpable masses or mammographic densities in premenopausal women or older women on hormone replacement therapy and are benign proliferations of interlobular fibroblasts and myofibroblasts. Myofibroblastoma consists of myofibroblasts and is unusual in that it is the only breast tumor that is more common in males. Lipomas and hamartomas are often palpable but can also be detected mammographically as fat-containing lesions. The only importance of these lesions is to distinguish them from malignancies.

Fibromatosis is a clonal proliferation of fibroblasts and myofibroblasts. It presents as an irregular, infiltrating mass that can involve both skin and muscle. Though locally aggressive, this lesion does not metastasize. Most cases are sporadic, but some occur as part of familial adenomatous polyposis, hereditary desmoid syndrome, and Gardner syndrome. You will recall that familial adenomatous polyposis is caused by mutations in the adenomatosis polyposis coli (*APC*) gene, which negatively regulates the nuclear translocation of β-catenin. The abnormal presence of β-catenin in the nucleus is a useful diagnostic feature.[68]

Malignant Stromal Tumors

Malignant stromal tumors include angiosarcoma, rhabdomyosarcoma, liposarcoma, leiomyosarcoma, chondrosarcoma, and osteosarcoma. Sarcomas usually present as bulky palpable masses. Lymph node metastases are rare; hematogenous spread to the lung is commonly seen.

Angiosarcomas of the breast can be sporadic or arise as a complication of radiation therapy.[69] Most sporadic angiosarcomas occur in young women (mean age 35), are of high grade, and have a poor prognosis. There is an approximate 0.3% risk of sarcoma after radiation therapy for breast cancer, with most cases arising 5 to 10 years after treatment. Two thirds are angiosarcomas, most of which arise in the overlying skin. Angiosarcomas can also arise in the skin of an arm rendered chronically lymphedematous by prior mastectomy and lymph node dissection (Stewart-Treves syndrome). Fortunately, this complication has become much less common with better surgical techniques.

OTHER MALIGNANT TUMORS OF THE BREAST

Malignant tumors may arise from the skin of the breast, sweat glands, sebaceous glands, and hair shafts; these tumors are identical to their counterparts found in skin elsewhere. Lymphomas may arise primarily in the breast, or the breasts may be secondarily involved by systemic lymphomas. Most are of diffuse large B-cell type. Young women with Burkitt lymphoma may present with massive bilateral breast involvement and are often pregnant or lactating. Metastases to the breast are rare, and most commonly arise from a contralateral breast carcinoma. The most frequent nonmammary metastases are from melanomas and lung cancers.

3.13.2 The Male Breast

The normal male breast consists of the nipple and a rudimentary duct system ending in terminal buds without lobule formation. Only two processes occur with sufficient frequency to merit consideration.

3.13.2.1 Gynecomastia

Gynecomastia (enlargement of the male breast) may be unilateral or bilateral and presents as a button-like subareolar enlargement. In advanced cases, the swelling can simulate the adolescent female breast. The lesion must be differentiated only from rare carcinomas of the male breast.

Morphology. There is an increase in dense collagenous connective tissue and marked micropapillary epithelial hyperplasia of the duct lining (Fig. 23-28). The individual epithelial cells are fairly regular, columnar to cuboidal cells with regular nuclei. Lobule formation is rare.

FIGURE 23-28 Gynecomastia. Terminal ducts (without lobule formation) are lined by a multilayered epithelium with small papillary tufts. There is typically surrounding periductal hyalinization and fibrosis.

Like the female breast, the male breast is subject to hormonal influences, and gynecomastia may occur as a result of an imbalance between estrogens, which stimulate breast tissue, and androgens, which counteract these effects. It is encountered under a variety of normal and abnormal circumstances, including puberty, in the very aged, or at any time during adult life when there is cause for hyperestrinism. The most important of these is cirrhosis of the liver, since this organ is responsible for metabolizing estrogen. In older males, gynecomastia may be due to a relative increase in adrenal estrogens as the androgenic function of the testis fails. Drugs such as alcohol, marijuana, heroin, antiretroviral therapy, anabolic steroids used by some athletes and body builders, and some psychoactive agents have also been associated with gynecomastia. Rarely, gynecomastia may occur as part of Klinefelter syndrome (XXY karyotype) or in association with functioning testicular neoplasms, such as Leydig cell and, rarely, Sertoli cell tumors.

3.13.2.2 Carcinoma

Carcinoma arising in the male breast is a rare occurrence.[70] The overall incidence in men is only 1% of that in women, which translates to a lifetime risk of 0.11% (as compared with about 13% in women). There are about 1500 cases and 400 deaths each year. Risk factors are similar to those in women and include first-degree relatives with breast cancer, decreased testicular function (e.g., Klinefelter

syndrome), exposure to exogenous estrogens, increasing age, infertility, obesity, prior benign breast disease, exposure to ionizing radiation, and residency in Western countries. Gynecomastia does not seem to be a risk factor. From 4% to 14% of cases in males are attributed to germline *BRCA2* mutations. There is a 60% to 76% chance of a *BRCA2* mutation in families with at least one affected male. Male breast cancer is also observed in *BRCA1* families, though not as frequently (see Table 23-2). From 3% to 8% of cases are associated with Klinefelter syndrome.

The pathology of male breast cancer is remarkably similar to that of cancers seen in women. The same histologic subtypes of invasive cancer are present, although papillary carcinomas (both invasive and in situ) are more common and lobular carcinomas are less common. The expression of molecular markers is similar, with the exception that ER positivity is more common in male breast cancer (81% of tumors). Unlike in women, the incidence of ER-positive tumors does not increase with age. Prognostic factors are similar in men and women.

Because breast epithelium in men is limited to large ducts near the nipple, carcinomas usually present as a palpable subareolar mass, 2 to 3 cm in size. Nipple discharge is a common symptom. The carcinoma is situated close to the overlying skin and underlying thoracic wall, and even small carcinomas can invade these structures and ulcerate through the skin. Dissemination follows the same pattern as in women, and axillary lymph node involvement is present in about half of cases at the time of diagnosis. Distant metastases to the lungs, brain, bone, and liver are common. Although men present at higher stages, prognosis is similar in men and women when they are matched by stage. Most cancers are treated locally with mastectomy and axillary node dissection. The same systemic treatment guidelines are used for men and women, and response rates are similar.

3.14 24. The Endocrine System

3.14.1 Pituitary Gland

ANIRBAN MAITRA

The endocrine system consists of a highly integrated and widely distributed group of organs that orchestrate a state of metabolic equilibrium, or homeostasis, among the various organs of the body. Signaling by extracellular secreted molecules can be classified into three types—autocrine, paracrine, or endocrine—on the basis of the distance over which the signal acts. In endocrine signaling, the secreted molecules, which are frequently called *hormones*, act on target cells that are distant from their site of synthesis. An endocrine hormone is frequently carried by the blood from its site of release to its target. In response, the target tissue often secretes factors that down-regulate the activity of the gland that produces the stimulating hormone, a process known as *feedback inhibition*.

Several processes can disturb the normal activity of the endocrine system, including impaired synthesis or release of hormones, abnormal interactions between hormones and their target tissues, and abnormal responses of target organs. Endocrine diseases can be generally classified as (1) diseases of *underproduction or overproduction* of hormones and their resulting biochemical and clinical consequences and (2) diseases associated with the development of *mass lesions*. Such lesions might be nonfunctional, or they might be associated with overproduction or underproduction of hormones. The study of endocrine diseases requires integration of morphologic findings with biochemical measurements of the levels of hormones, their regulators, and other metabolites.

PITUITARY GLAND

The pituitary gland is composed of two morphologically and functionally distinct components: the anterior lobe (adenohypophysis) and the posterior lobe (neurohypophysis). The *anterior pituitary*

constitutes about 80% of the gland. The production of most pituitary hormones is controlled predominantly by positive-acting releasing factors from the hypothalamus (Fig. 24-1), which are carried to the anterior pituitary by a portal vascular system. Prolactin is the major exception; its primary hypothalamic control is inhibitory, through the action of dopamine. Pituitary growth hormone also differs in that it receives both stimulatory and inhibitory influences via the hypothalamus. In routine histologic sections of the anterior pituitary, a colorful array of cells is present that contain eosinophilic cytoplasm (acidophil), basophilic cytoplasm (basophil), or poorly staining cytoplasm (chromophobe) cells (Fig. 24-2). Specific antibodies against the pituitary hormones identify five cell types:

1. *Somatotrophs*, producing growth hormone (GH): These acidophilic cells constitute half of all the hormone-producing cells in the anterior pituitary.
2. *Lactotrophs* (mammotrophs), producing prolactin: These acidophilic cells secrete prolactin, which is essential for lactation.
3. *Corticotrophs:* These basophilic cells produce adrenocorticotropic hormone (ACTH), pro-opiomelanocortin (POMC), melanocyte-stimulating hormone (MSH), endorphins, and lipotropin.
4. *Thyrotrophs:* These pale basophilic cells produce thyroid-stimulating hormone (TSH).
5. *Gonadotrophs:* These basophilic cells produce both follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH stimulates the formation of graafian follicles in the ovary, and LH induces ovulation and the formation of corpora lutea in the ovary. The same two hormones also regulate spermatogenesis and testosterone production in males.

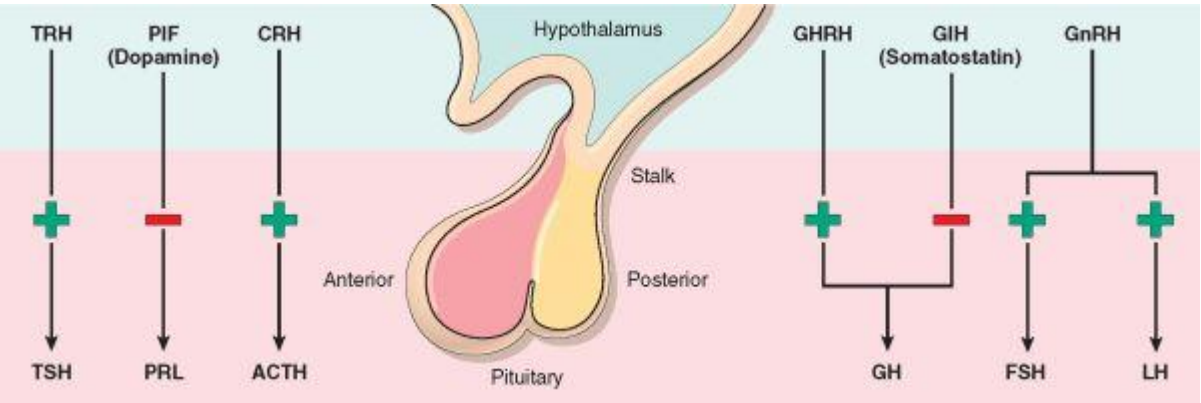

FIGURE 24-1 Hormones released by the anterior pituitary. The adenohypophysis (anterior pituitary) releases five hormones that are in turn under the control of various stimulatory and inhibitory hypothalamic releasing factors. TSH, thyroid-stimulating hormone (thyrotropin); PRL, prolactin; ACTH, adrenocorticotropic hormone (corticotropin); GH, growth hormone (somatotropin); FSH, follicle-stimulating hormone; LH, luteinizing hormone. The stimulatory releasing factors are TRH (thyrotropin-releasing hormone), CRH (corticotropin-releasing hormone), GHRH (growth hormone–releasing hormone), GnRH (gonadotropin-releasing hormone). The inhibitory hypothalamic influences comprise PIF (prolactin inhibitory factor or dopamine) and growth hormone inhibitory factor (GIH or somatostatin).

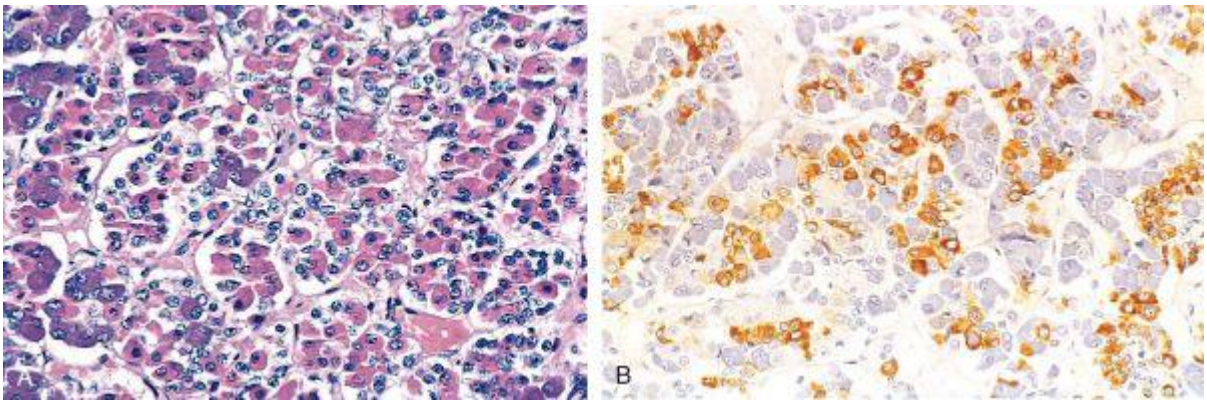

FIGURE 24-2 A, Photomicrograph of normal pituitary. The gland is populated by several distinct cell populations containing a variety of stimulating (tropic) hormones. Each of the hormones has different staining characteristics, resulting in a mixture of cell types in routine histologic preparations. **B**, Immunostain for human growth hormone.

The *posterior pituitary* consists of modified glial cells (termed *pituicytes*) and axonal processes extending from the hypothalamus through the pituitary stalk to the posterior lobe (*axon terminals*). The two peptide hormones secreted from the posterior pituitary—*oxytocin* and *antidiuretic hormone* (ADH, also called *vasopressin*)—are actually synthesized in the hypothalamus and are stored within the axon terminals residing in the posterior pituitary. In response to appropriate stimuli, the pre-formed hormones are released directly into the systemic circulation through the venous channels of the pituitary. For example, dilatation of the cervix in pregnancy results in massive oxytocin release, leading to contraction of the uterine smooth muscle, facilitating parturition (uterine labor). Similarly, oxytocin released upon nipple stimulation in the postnatal period acts on the smooth muscles surrounding the lactiferous ducts of the mammary glands and facilitates lactation. Synthetic oxytocin can be administered during pregnancy for artificial induction of labor. The most important function of ADH is to conserve water by restricting diuresis during periods of dehydration and hypovolemia. Decreased blood pressure, sensed by *baroreceptors* (pressure-sensing receptors) in the cardiac atria and carotids, stimulates ADH release. An increase in plasma osmotic pressure detected by *osmoreceptors* also tiggers ADH secretion. In contrast, states of hypervolemia and increased atrial distention result in inhibition of ADH secretion.

3.14.1.1 Clinical Manifestations of Pituitary Disease

The manifestations of pituitary disorders are as follows:

Hyperpituitarism: Arising from excess secretion of trophic hormones. The causes of hyperpituitarism include pituitary adenoma, hyperplasia and carcinomas of the anterior pituitary, secretion of hormones by nonpituitary tumors, and certain hypothalamic disorders. The symptoms of hyperpituitarism are discussed in the context of individual tumors below.

Hypopituitarism: Arising from deficiency of trophic hormones. This may be caused by destructive processes, including *ischemic injury, surgery or radiation, inflammatory reactions*, and *nonfunctional pituitary adenomas*.

Local mass effects: Among the earliest changes referable to mass effect are *radiographic abnormalities of the sella turcica*, including sellar expansion, bony erosion, and disruption of the diaphragma sella. Because of the close proximity of the optic nerves and chiasm to the sella, expanding pituitary lesions often compress decussating fibers in the optic chiasm. This gives rise to *visual field abnormalities*, classically in the form of defects in the lateral (temporal) visual fields, so-called *bitemporal hemianopsia*. In addition, a variety of other visual field abnormalities may be caused by asymmetric growth of many tumors. Like any expanding intracranial mass, pituitary adenomas can produce signs and symptoms of *elevated intracranial pressure*, including headache, nausea, and vomiting. On occasion, acute hemorrhage into an adenoma is associated

with clinical evidence of rapid enlargement of the lesion, a situation appropriately termed *pituitary apoplexy*. Acute pituitary apoplexy is a neurosurgical emergency, since it can cause sudden death (see below).

Diseases of the posterior pituitary often come to clinical attention because of increased or decreased secretion of ADH.

3.14.1.2 Pituitary Adenomas & Hyperpituitarism

The most common cause of hyperpituitarism is an adenoma arising in the anterior lobe. Pituitary adenomas are classified on the basis of hormone(s) produced by the neoplastic cells, which are detected by immunohistochemical stains (Table 24-1). Some pituitary adenomas can secrete two hormones (GH and prolactin being the most common combination), and rarely, pituitary adenomas are plurihormonal. Pituitary adenomas can be *functional* (i.e., associated with hormone excess and clinical manifestations thereof) or *nonfunctioning* (i.e., immunohistochemical and/or ultrastructural demonstration of hormone production at the tissue level, without clinical symptoms of hormone excess). Less common causes of hyperpituitarism include pituitary carcinomas and some hypothalamic disorders. Large pituitary adenomas, and particularly nonfunctioning ones, may cause hypopituitarism as they encroach on and destroy adjacent anterior pituitary parenchyma.

TABLE 24-1 -- Classification of Pituitary Adenomas

Pituitary Cell Type	Hormone	Tumor Type	Associated Syndrome[*]
Corticotroph	ACTH and other POMC-derived peptides	ACTH cell (corticotroph) adenoma	Cushing syndrome Nelson syndrome
Somatotroph	GH	GH cell (somatotroph) adenoma	Gigantism (children) Acromegaly (adults)
Lactotroph	Prolactin	Prolactin cell (lactotroph) adenoma	Galactorrhea and amenorrhea (in females) Sexual dysfunction, infertility
Mammosomatotroph	Prolactin, GH	Mammosomatotroph	Combined features of GH and prolactin excess
Thyrotroph	TSH	TSH cell (thyrotroph) adenoma	Hyperthyroidism
Gonadotroph	FSH, LH	Gonadotroph, “null cell,” oncocytic adenomas	Hypogonadism, mass effects, and hypopituitarism

Adapted from Ezzat S, Asa SL: Mechanisms of disease: the pathogenesis of pituitary tumors. Nat Clin Prac Endocrinol Metab 2:200–230, 2006.

ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; POMC, pro-opiomelanocortin; TSH, thyroid-stimulating hormone.

[*] Note that nonfunctional adenomas in each category typically present with *mass effects* accompanied by *hypopituitarism* due to destruction of normal pituitary parenchyma. These features are particularly common with gonadotroph adenomas.

Pituitary adenomas are usually found in adults, with a peak incidence from 35 to 60 years of age. They are designated, somewhat arbitrarily, *microadenomas* if they are less than 1 cm in diameter and *macroadenomas* if they exceed 1 cm in diameter. Silent and hormone-negative adenomas are likely to

come to clinical attention at a later stage than those associated with endocrine abnormalities and are therefore more likely to be macroadenomas. A meta-analysis of autopsy studies estimates the population prevalence of pituitary adenomas to be about 14%, although the vast majority of these lesions are incidentally diagnosed microadenomas ("pituitary incidentaloma").[1]

With recent advances in molecular techniques, substantial insight has been gained into *the genetic abnormalities associated with pituitary adenomas*[2] (Table 24-2):

- G-protein mutations are possibly the best-characterized molecular abnormalities in pituitary adenomas. G proteins are described in Chapter 3 ; here we will review their function in the context of endocrine neoplasms. G proteins play a critical role in signal transduction, transmitting signals from particular *cell surface receptors* (e.g., GHRH receptor) to *intracellular effectors* (e.g., adenyl cyclase), which then generate *second messengers* (e.g., cyclic adenosine monophosphate, cAMP). These are heterotrimeric proteins, composed of a specific α-subunit that binds guanine nucleotide and interacts with both cell surface receptors and intracellular effectors (Fig. 24-3); the β- and γ-subunits are noncovalently bound to the specific α-subunit. G_s is a stimulatory G protein that has a pivotal role in signal transduction in several endocrine organs, including the pituitary. The α-subunit of G_s ($G_s\alpha$) is encoded by the *GNAS* gene, located on chromosome 20q13. In the basal state, G_s exists in an inactive state, with guanosine diphosphate (GDP) bound to the guanine nucleotide-binding site of $G_s\alpha$. On interaction with the ligand-bound cell surface receptor, GDP dissociates, and guanosine triphosphate (GTP) binds to $G_s\alpha$, activating the G protein. The activation of $G_s\alpha$ results in the generation of cAMP, which acts as a potent mitogenic stimulus for a variety of endocrine cell types (such as pituitary somatotrophs and corticotrophs, thyroid follicular cells, parathyroid cells), promoting cellular proliferation and hormone synthesis and secretion. The activation of $G_s\alpha$, and resultant generation of cAMP, are *transient* because of an intrinsic GTPase activity in the α-subunit, which hydrolyzes GTP into GDP. *A mutation in the* α*-subunit that interferes with its intrinsic GTPase activity will therefore result in constitutive activation of* $G_s\alpha$, *persistent generation of cAMP, and unchecked cellular proliferation* (see Fig. 24-3). Approximately 40% of somatotroph cell adenomas bear *GNAS* mutations that abrogate the GTPase activity of $G_s\alpha$. In addition, *GNAS* mutations have also been described in a minority of corticotroph adenomas; in contrast, *GNAS* mutations are absent in thyrotroph, lactotroph, and gonadotroph adenomas, since their respective hypothalamic release hormones do not mediate their action via cAMP-dependent pathways.
- The overwhelming majority of pituitary adenomas are sporadic in nature, and only approximately 5% of cases arise as a result of an inherited predisposition. *Four genes have been identified thus far as a cause of familial pituitary adenomas*: *MEN1, CDKN1B, PRKAR1A*, and *AIP*.[3] Germline inactivating mutations of the *MEN1* gene on chromosome 11q13 are responsible for multiple endocrine neoplasia syndrome, type 1 (MEN-1, discussed in detail below). The gene product of *MEN1* is the tumor suppressor protein menin, and individuals with MEN-1 syndrome develop tumors in multiple endocrine organs, including the pituitary. Approximately a third of patients with MEN-1 develop pituitary adenomas, most commonly GH-, prolactin-, or ACTH-secreting tumors. In contrast, somatic mutations of *MEN1* are rare in sporadic pituitary tumors. The gene product of *CDKN1B* on chromosome 12p13 is the cell cycle checkpoint regulator p27 or KIP1; germline mutations of *CDKN1B* are responsible for a subset of patients with a "MEN-1 like" syndrome who lack *MEN1* abnormalities.[4] The *protein kinase A regulatory subunit 1*α (*PRKAR1A*) gene on chromosome 17q24 is mutated in patients with Carney complex, an autosomal-dominant disorder characterized by pituitary and other endocrine tumors. This gene encodes a tumor suppressor that regulates the activity of protein kinase A, a downstream mediator of cAMP-dependent signaling. Thus, loss of PRKAR1A protein function leads to inappropriate activation of cAMP cellular targets, further underscoring the importance of this second-messenger pathway in pituitary neoplasia. The *aryl hydrocarbon receptor interacting protein* (*AIP*) on chromosome 11q is a recently described pituitary adenoma predisposition gene. Patients with germline *AIP* mutations often present with acromegaly due to an underlying GHsecreting adenoma, and are typically younger (<35 years of age) at the time of diagnosis than sporadic GH adenoma patients.[5] The precise mechanism by which the AIP protein acts as a tumor suppressor in the pituitary is not known. Not all persons with germline *AIP* mutations have a positive family history of pituitary tumors, as a result of incomplete penetrance. Immunohistochemistry for AIP is recommended in GH adenomas arising in younger patients, as mutations associated with adenoma typically cause absence of protein expression. Somatic mutations of these four genes are rarely encountered in sporadic pituitary adenomas.
- Molecular abnormalities associated with aggressive behavior include aberrations in cell cycle checkpoint genes, such as overexpression of cyclin D1, mutations of *p53*, and epigenetic silencing of the retinoblastoma gene (*RB1*). In addition, activating mutations of the *HRAS* oncogene are observed in rare

pituitary carcinomas (see below).

TABLE 24-2 -- Genetic Alterations in Pituitary Tumors

Gene	Mechanism of Alteration	Pituitary Tumor Subtype
GAIN OF FUNCTION		
$G_s\alpha$	Activating mutation	GH adenomas
Protein kinase A (PKA)[*]	Germline inactivating mutations of *PRKARIA* (Carney complex), a negative regulator of PKA	GH and prolactin adenomas
Cyclin D1	Overexpression	Aggressive adenomas
HRAS	Activating mutation	Pituitary carcinomas
LOSS OF FUNCTION		
Menin[*]	Germline inactivating mutations of *MEN1* (multiple endocrine neoplasia, type 1)	GH, prolactin, and ACTH adenomas
CDKN1B (p27/KIP1)[*]	Germline inactivating mutations of CDKN1B ("MEN-1-like" syndrome)	ACTH adenomas
Aryl hydrocarbon receptor interacting protein (AIP)[*]	Germline mutations of *AIP* (pituitary adenoma predisposition [PAP] syndrome)	GH adenomas
Retinoblastoma (RB) protein	Methylation of *RB* gene promoter	Aggressive adenomas

ACTH, adrenocorticotrophic hormone; GH, growth hormone.

[*] Genetic alterations associated with *familial* predisposition to pituitary adenomas.

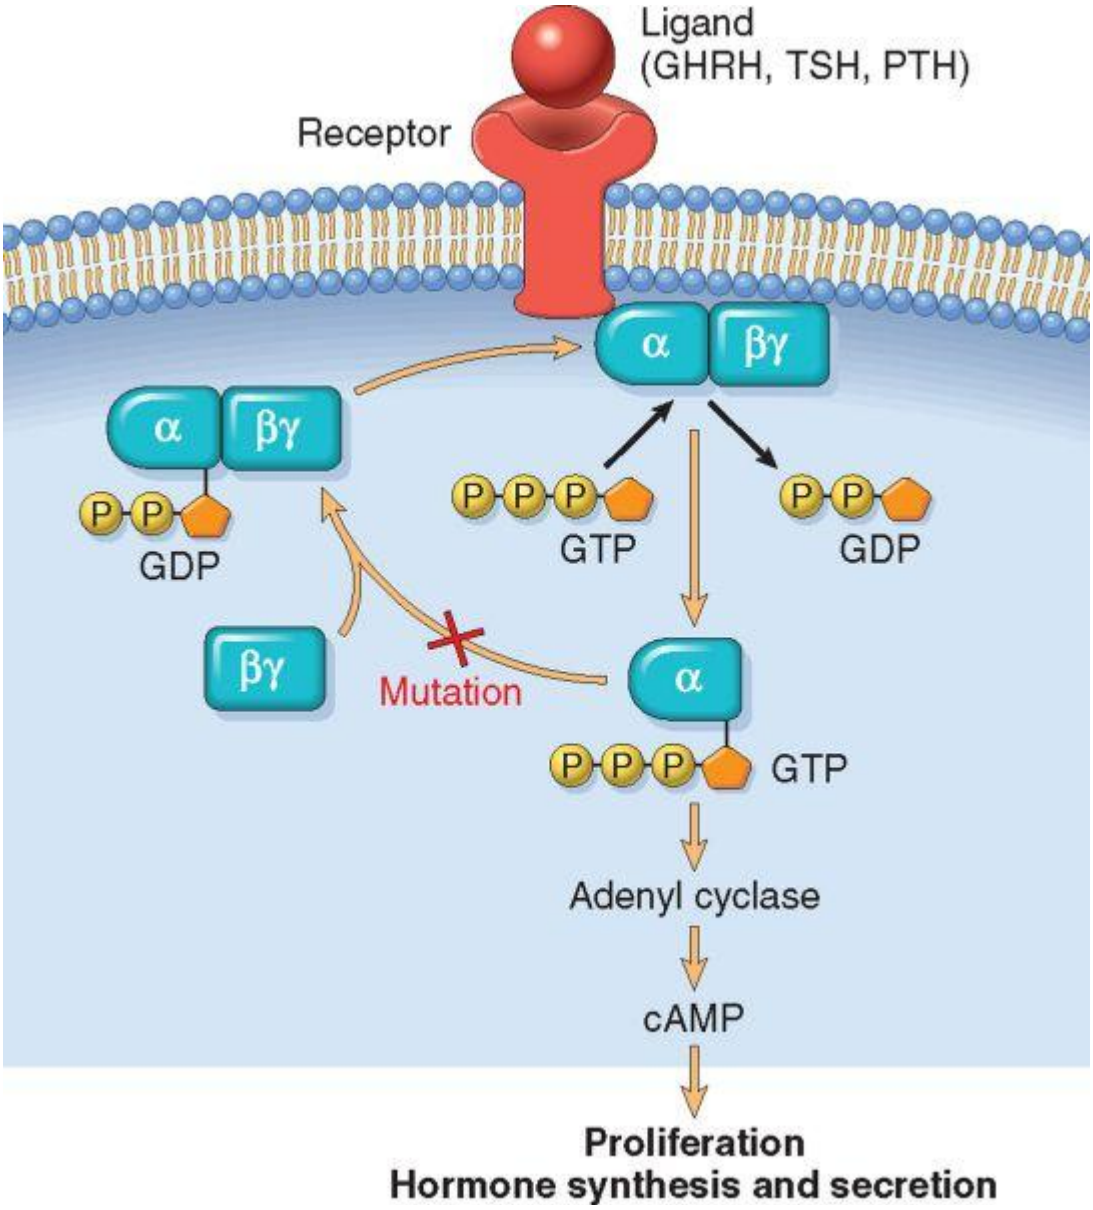

FIGURE 24-3 G-protein signaling in endocrine neoplasia. Mutations that lead to G-protein hyperactivity are seen in a variety of endocrine neoplasms, including pituitary, thyroid, and parathyroid adenomas. G proteins play a critical role in signal transduction, transmitting signals from cell surface receptors (GHRH, TSH, or PTH receptor) to intracellular effectors (e.g., adenyl cyclase), which then generate second messengers (cAMP, cyclic adenosine monophosphate). GDP, guanosine diphosphate; GTP, guanosine triphosphate; P_i, inorganic phosphate. See Figure 24-1 for other abbreviations.

Morphology. The **typical pituitary adenoma** is a soft, well-circumscribed lesion that may be confined to the sella turcica. Larger lesions typically extend superiorly through the diaphragm sella into the suprasellar region, where they often compress the optic chiasm and adjacent structures, such as some of the cranial nerves (Fig. 24-4). As these adenomas expand, they frequently erode the sella turcica and anterior clinoid processes. In as many as 30% of cases, the adenomas are not grossly encapsulated and infiltrate neighboring tissues such as the cavernous and sphenoid sinuses, dura, and on occasion, the brain itself. Such lesions are termed **invasive adenomas**. Not unexpectedly, macroadenomas tend to be invasive more frequently than smaller tumors. Foci of hemorrhage and

necrosis are also more common in these larger adenomas.

Histologically, typical pituitary adenomas are composed of relatively uniform, polygonal cells arrayed in sheets or cords. Supporting connective tissue, or reticulin, is sparse, accounting for the soft, gelatinous consistency of many of these lesions. Mitotic activity is usually sparse. The cytoplasm of the constituent cells may be acidophilic, basophilic, or chromophobic, depending on the type and amount of secretory product within the cells, but it is generally uniform throughout the tumor. **This cellular monomorphism and the absence of a significant reticulin network distinguish pituitary adenomas from non-neoplastic anterior pituitary parenchyma** (Fig. 24-5). The biologic behavior of the adenoma cannot always be reliably predicted from its histologic appearance. A subset of pituitary adenomas demonstrates brisk mitotic activity and staining of greater than 3% of the nuclei with the proliferation marker Ki-67; these tumors typically also demonstrate extensive nuclear p53 immunoreactivity in the neoplastic cells, a feature that correlates with the presence of *p53* mutations. It is recommended that adenomas with this profile be classified as **atypical adenomas**, since these tumors have a higher propensity for aggressive behavior, including invasion and recurrence.

FIGURE 24-4 Pituitary adenoma. This massive, nonfunctional adenoma has grown far beyond the confines of the sella turcica and has distorted the overlying brain. Nonfunctional adenomas tend to be larger at the time of diagnosis than those that secrete a hormone.

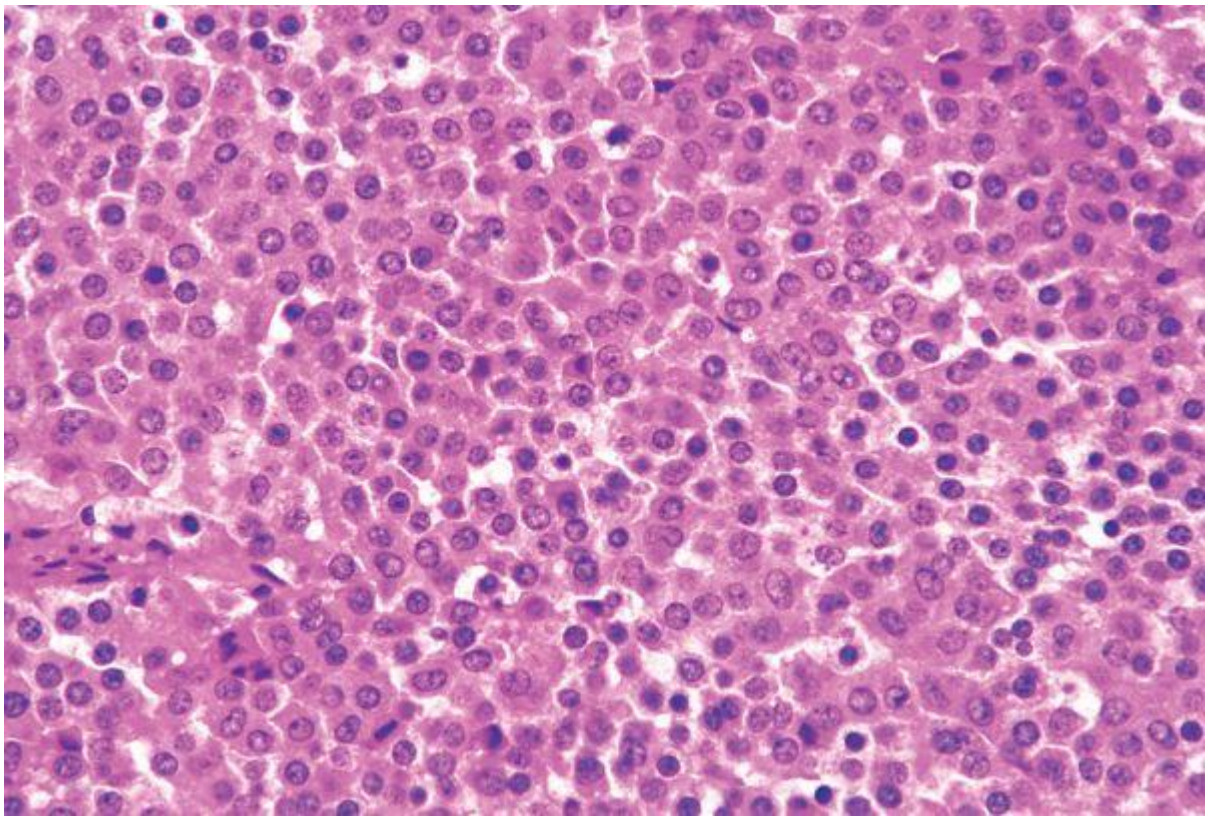

FIGURE 24-5 Pituitary adenoma. The monomorphism of these cells contrasts markedly with the mixture of cells seen in the normal anterior pituitary. Note also the absence of reticulin network.

Clinical Course.

The signs and symptoms of pituitary adenomas include endocrine abnormalities and mass effects. The effects of excessive secretion of anterior pituitary hormones are mentioned below, when the specific types of pituitary adenoma are described. Local mass effects may be encountered in any type of pituitary tumor and have been discussed previously under clinical manifestations of pituitary disease. Briefly, these include *radiographic abnormalities of the sella turcica, visual field abnormalities*, signs and symptoms of elevated *intracranial pressure*, and occasionally *hypopituitarism*. Acute hemorrhage into an adenoma is sometimes associated with *pituitary apoplexy*, as was noted above.

With this general introduction to pituitary adenomas, we proceed to a discussion of the individual types of tumors.

PROLACTINOMAS

Prolactinomas (lactotroph adenomas) are the most frequent type of hyperfunctioning pituitary adenoma, accounting for about 30% of all clinically recognized cases. These lesions range from small microadenomas to large, expansile tumors associated with substantial mass effect. Microscopically, the overwhelming majority of prolactinomas are composed of weakly acidophilic or chromophobic cells *(sparsely granulated prolactinoma)*; rare prolactinomas are strongly acidophilic *(densely granulated prolactinoma)* (Fig. 24-6). Prolactin can be demonstrated within the secretory granules in the cytoplasm of the cells using immunohistochemical stains. Prolactinomas have a propensity to undergo

dystrophic calcification, ranging from isolated psammoma bodies to extensive calcification of virtually the entire tumor mass ("pituitary stone"). Prolactin secretion by functioning adenomas is usually efficient (even microadenomas secrete sufficient prolactin to cause hyperprolactinemia) and *proportional*, in that serum prolactin concentrations tend to correlate with the size of the adenoma.

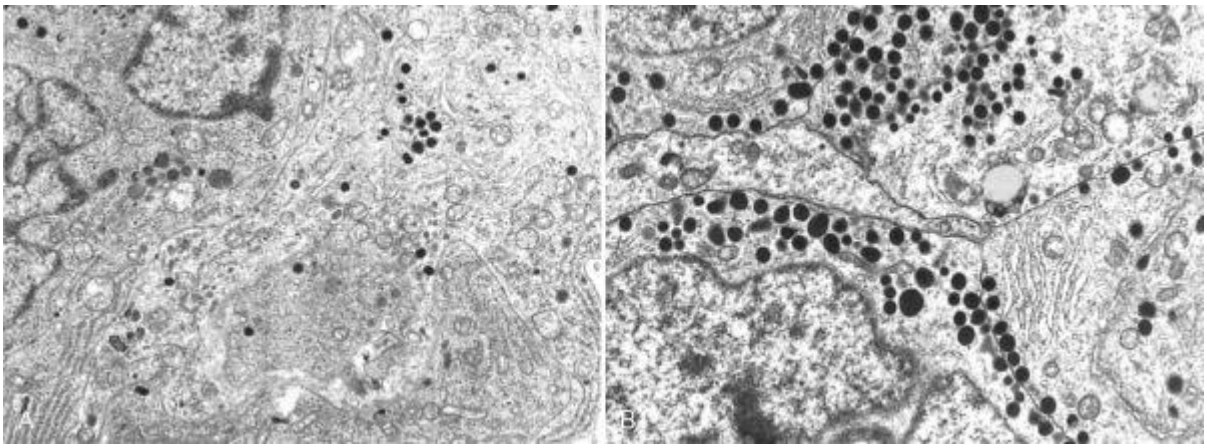

FIGURE 24-6 Ultrastructural features of prolactinomas. **A**, Electron micrograph of a sparsely granulated prolactinoma. The tumor cells contain abundant granular endoplasmic reticulum (indicative of active protein synthesis) and small numbers of electron-dense secretory granules. **B**, Electron micrograph of densely granulated growth hormone–secreting adenoma. The tumor cells are filled with numerous large, electron-dense secretory granules. *(Courtesy of Dr. Eva Horvath, St. Michael's Hospital, Toronto, ON, Canada.)*

Increased serum levels of prolactin, or *prolactinemia*, cause amenorrhea, galactorrhea, loss of libido, and infertility. The diagnosis of an adenoma is made more readily in women than in men, especially between the ages of 20 and 40 years, presumably because of the sensitivity of menses to disruption by hyperprolactinemia. Prolactinoma underlies almost a quarter of cases of amenorrhea. In contrast, in men and older women, the hormonal manifestations may be subtle, allowing the tumors to reach considerable size (macroadenomas) before being detected clinically.

Hyperprolactinemia may result from causes other than prolactin-secreting pituitary adenomas. Physiologic hyperprolactinemia occurs in pregnancy; serum prolactin levels increase throughout pregnancy, reaching a peak at delivery. Prolactin levels are also elevated by nipple stimulation, as occurs during suckling in lactating women, and as a response to many types of stress. Pathologic hyperprolactinemia can also result from *lactotroph hyperplasia*, such as when there is interference with normal dopamine inhibition of prolactin secretion. This may occur as a result of damage to the dopaminergic neurons of the hypothalamus, damage to the pituitary stalk (e.g., due to head trauma), or drugs that block dopamine receptors on lactotroph cells. Any mass in the suprasellar compartment may disturb the normal inhibitory influence of the hypothalamus on prolactin secretion, resulting in hyperprolactinemia. *Therefore, a mild elevation in serum prolactin in a person with a pituitary adenoma does not necessarily indicate a prolactin-secreting tumor*. Other causes of hyperprolactinemia include several classes of drugs (such as dopamine antagonists), estrogens, renal failure, and hypothyroidism. Prolactinomas are treated by surgery or, more commonly, with bromocriptine, a dopamine receptor agonist that causes the lesions to diminish in size.

GROWTH HORMONE CELL (SOMATOTROPH) ADENOMAS

GH-secreting tumors are the second most common type of functioning pituitary adenoma. Somatotroph cell adenomas may be quite large by the time they come to clinical attention because the manifestations of excessive GH may be subtle. Histologically, pure GH cell–containing adenomas are also classified into two subtypes: *densely granulated* and *sparsely granulated*. The densely granulated adenomas are composed of cells that are monomorphic and acidophilic in routine sections, retain strong cytoplasmic GH reactivity on immunohistochemistry, and demonstrate cytokeratin staining in a perinuclear distribution. In contrast, the sparsely granulated variants are composed of chromophobe cells with considerable nuclear and cytologic pleomorphism and focal, weak staining for GH. Bihormonal *mammosomatotroph* adenomas that express both GH and prolactin are being increasingly recognized with the availability of better immunohistochemical reagents; morphologically, most bihormonal adenomas resemble the densely granulated pure somatotroph adenomas.

Persistently elevated levels of GH stimulate the hepatic secretion of insulin-like growth factor 1 (IGF-1 or somatomedin C), which causes many of the clinical manifestations. If a somatotrophic adenoma appears in children before the epiphyses have closed, the elevated levels of GH (and IGF-1) result in *gigantism*. This is characterized by a generalized increase in body size with disproportionately long arms and legs. If the increased levels of GH are present after closure of the epiphyses, patients develop *acromegaly*. In this condition, growth is most conspicuous in skin and soft tissues; viscera (thyroid, heart, liver, and adrenals); and bones of the face, hands, and feet. Bone density may be increased (hyperostosis) in both the spine and the hips. Enlargement of the jaw results in protrusion (prognathism), with broadening of the lower face. The hands and feet are enlarged with broad, sausage-like fingers. In most instances gigantism is also accompanied by evidence of acromegaly. These changes develop for decades before being recognized, hence the opportunity for the adenomas to reach substantial size. GH excess is also correlated with a variety of other disturbances, including gonadal dysfunction, diabetes mellitus, generalized muscle weakness, hypertension, arthritis, congestive heart failure, and an increased risk of gastrointestinal cancers.

The diagnosis of pituitary GH excess relies on documentation of elevated serum GH and IGF-1 levels. *In addition, failure to suppress GH production in response to an oral load of glucose is one of the most sensitive tests for acromegaly*. The underlying pituitary adenoma can be either removed surgically or treated via pharmacologic means. The latter includes somatostatin analogs (recall that somatostatin has an inhibitory effect on pituitary GH secretion) or the use of GH receptor antagonists, which prevent hormone binding to target organs such as the liver. When effective control of high GH levels is achieved, the characteristic tissue overgrowth and related symptoms gradually recede, and the metabolic abnormalities improve.

ACTH CELL (CORTICOTROPH) ADENOMAS

Corticotroph adenomas are usually small microadenomas at the time of diagnosis. These tumors are most often basophilic *(densely granulated)* and occasionally chromophobic *(sparsely granulated)*. Both variants stain positively with periodic acid–Schiff (PAS) because of the presence of carbohydrate in POMC, the ACTH precursor molecule; in addition, they demonstrate variable immunoreactivity for POMC and its derivatives, including ACTH and β-endorphin.

Excess production of ACTH by the corticotroph adenoma leads to adrenal hypersecretion of cortisol and the development of *hypercortisolism* (also known as *Cushing syndrome*). This syndrome is discussed in more detail later with the diseases of the adrenal gland. It can be caused by a wide variety of conditions in addition to ACTH-producing pituitary tumors. When the hypercortisolism is due to excessive production of ACTH by the pituitary, the process is designated *Cushing disease*. Large destructive adenomas can develop in patients after surgical removal of the adrenal glands for treatment of Cushing syndrome. This condition, known as *Nelson syndrome*, occurs most often because of a loss of the

inhibitory effect of adrenal corticosteroids on a preexisting corticotroph microadenoma. Because the adrenals are absent in persons with this disorder, hypercortisolism does not develop. In contrast, patients present with mass effects of the pituitary tumor. In addition, there can be hyperpigmentation because of the stimulatory effect of other products of the ACTH precursor molecule on melanocytes.

OTHER ANTERIOR PITUITARY ADENOMAS

Pituitary adenomas may elaborate more than one hormone. For example, prolactin may be demonstrable by immunolabeling of somatotroph adenomas. In other cases, unusual plurihormonal adenomas are capable of secreting multiple hormones; these tumors are usually aggressive. A few comments are made about several of the less frequent functioning tumors.

Gonadotroph (LH-producing and FSH-producing) adenomas can be difficult to recognize because they secrete hormones inefficiently and variably, and the secretory products usually do not cause a recognizable clinical syndrome (*non-functioning adenomas*, see below). Gonadotroph adenomas are most frequently found in middle-aged men and women when they become large enough to cause neurologic symptoms, such as impaired vision, headaches, diplopia, or pituitary apoplexy. Pituitary hormone deficiencies can also be found, most commonly impaired secretion of LH. This causes decreased energy and libido in men (due to reduced testosterone) and amenorrhea in premenopausal women. Thus, gonadotroph adenomas are paradoxically associated with secondary gonadal hypofunction. The neoplastic cells usually demonstrate immunoreactivity for the common gonadotropin α-subunit and the specific β-FSH and β-LH subunits; FSH is usually the predominant secreted hormone.

Thyrotroph (TSH-producing) adenomas are rare, accounting for approximately 1% of all pituitary adenomas. Thyrotroph adenomas are a rare cause of hyperthyroidism.

Nonfunctioning pituitary adenomas are a heterogeneous group that constitutes approximately 25% to 30% of all pituitary tumors. Their lineage can be established by immunohistochemical staining for hormones or by biochemical demonstration of cell type-specific transcription factors. In the past, many such tumors have been called *silent variants* or *null-cell adenomas*. Not surprisingly, the typical presentation of nonfunctioning adenomas is mass effects. These lesions may also compromise the residual anterior pituitary sufficiently to cause hypopituitarism. This may occur as a result of gradual enlargement of the adenoma or after abrupt enlargement of the tumor because of acute hemorrhage (pituitary apoplexy).

Pituitary carcinomas are quite rare, accounting for less than 1% of pituitary tumors. The demonstration of craniospinal or systemic metastases is a sine qua non of a pituitary carcinoma. The majority of pituitary carcinomas are functional neoplasms, with prolactin and ACTH being the most common secreted products. Metastases usually appear late in the course, following multiple local recurrences.

3.14.1.3 Hypopituitarism

Hypopituitarism refers to decreased secretion of pituitary hormones, which can result from diseases of the hypothalamus or of the pituitary. Hypofunction of the anterior pituitary occurs when approximately 75% of the parenchyma is lost or absent. This may be congenital or the result of a variety of acquired abnormalities that are intrinsic to the pituitary. *Hypopituitarism accompanied by evidence of posterior pituitary dysfunction in the form of diabetes insipidus (see below) is almost always of hypothalamic origin*. Most cases of hypofunction arise from destructive processes directly involving the anterior pituitary, although other mechanisms have been identified.

- *Tumors and other mass lesions:* Pituitary adenomas, other benign tumors arising within the sella, primary and metastatic malignancies, and cysts can cause hypopituitarism. Any mass lesion in the sella can cause damage by exerting pressure on adjacent pituitary cells.

- *Traumatic brain injury and subarachnoid hemorrhage* are among the most common causes of pituitary hypofunction.
- *Pituitary surgery or radiation:* Surgical excision of a pituitary adenoma may inadvertently extend to the nonadenomatous pituitary. Radiation of the pituitary, used to prevent regrowth of residual tumor after surgery, can damage the nonadenomatous pituitary.
- *Pituitary apoplexy:* As has been mentioned, this is a sudden hemorrhage into the pituitary gland, often occurring into a pituitary adenoma. In its most dramatic presentation, apoplexy causes the sudden onset of excruciating headache, diplopia due to pressure on the oculomotor nerves, and hypopituitarism. In severe cases, it can cause cardiovascular collapse, loss of consciousness, and even sudden death. Thus, pituitary apoplexy is a neurosurgical emergency.
- *Ischemic necrosis of the pituitary and Sheehan syndrome: Sheehan syndrome*, or postpartum necrosis of the anterior pituitary, is the most common form of clinically significant ischemic necrosis of the anterior pituitary. During pregnancy the anterior pituitary enlarges to almost twice its normal size. This physiologic expansion of the gland is not accompanied by an increase in blood supply from the low-pressure venous system; hence, there is relative anoxia. Further reduction in blood supply caused by obstetric hemorrhage or shock may precipitate infarction of the anterior lobe. The posterior pituitary, because it receives its blood directly from arterial branches, is much less susceptible to ischemic injury and is therefore usually not affected. Pituitary necrosis may also be encountered in other conditions, such as disseminated intravascular coagulation and (more rarely) sickle cell anemia, elevated intracranial pressure, traumatic injury, and shock of any origin. Whatever the pathogenesis, the ischemic area is resorbed and replaced by a nubbin of fibrous tissue attached to the wall of an empty sella.
- *Rathke cleft cyst:* These cysts, lined by ciliated cuboidal epithelium with occasional goblet cells and anterior pituitary cells, can accumulate proteinaceous fluid and expand, compromising the normal gland.
- *Empty sella syndrome:* Any condition that destroys part or all of the pituitary gland, such as ablation of the pituitary by surgery or radiation, can result in an *empty sella*. The *empty sella syndrome* refers to the presence of an enlarged, empty sella turcica. There are two types: (1) In a *primary* empty sella, there is a defect in the diaphragma sella that allows the arachnoid mater and cerebrospinal fluid to herniate into the sella, resulting in expansion of the sella and compression of the pituitary. Classically, affected patients are obese women with a history of multiple pregnancies. The empty sella syndrome may be associated with visual field defects and occasionally with endocrine anomalies, such as *hyperprolactinemia*, as a result of interruption of inhibitory hypothalamic effects. Loss of functioning parenchyma can be severe enough to result in hypopituitarism. (2) In a *secondary* empty sella, a mass, such as a pituitary adenoma, enlarges the sella, but then it is either surgically removed or undergoes spontaneous necrosis, leading to loss of pituitary function. Hypopituitarism can result from the treatment or spontaneous infarction.
- *Genetic defects:* Congenital deficiency of transcription factors required for normal pituitary function is a rare cause of hypopituitarism. For example, mutation of the pituitary-specific homeobox gene *POU1F1* (previously known as *PIT-1*) results in combined pituitary hormone deficiency, characterized by deficiencies of GH, prolactin, and TSH.
- *Hypothalamic lesions*: As mentioned above, hypothalamic lesions can also affect the pituitary by interfering with the delivery of pituitary hormone–releasing factors. In contrast to diseases that involve the pituitary directly, hypothalamic abnormalities can also diminish the secretion of ADH, resulting in diabetes insipidus (discussed later). Hypothalamic lesions that cause hypopituitarism include *tumors*, including benign lesions that arise in the region of the hypothalamus, such as craniopharyngiomas, and malignant tumors that metastasize to this site, such as breast and lung carcinomas. Hypothalamic hormone deficiency can ensue when brain or nasopharyngeal tumors are treated with radiation.
- *Inflammatory disorders and infections*, such as sarcoidosis or tuberculous meningitis, can cause deficiencies of anterior pituitary hormones and diabetes insipidus.

The clinical manifestations of anterior pituitary hypofunction can be protean, and depend on the specific hormone(s) that are lacking. Children can develop growth failure *(pituitary dwarfism)* due to growth hormone deficiency. Gonadotropin (LH and FSH) deficiency leads to amenorrhea and infertility in women and decreased libido, impotence, and loss of pubic and axillary hair in men. TSH and ACTH deficiencies result in symptoms of hypothyroidism and hypoadrenalism, respectively, and are discussed later in the chapter. Prolactin deficiency results in failure of postpartum lactation. The anterior pituitary is also a rich source of MSH, synthesized from the same precursor molecule that produces ACTH; therefore, one of the manifestations of hypopituitarism includes pallor due to a loss of stimulatory effects of MSH on melanocytes.

3.14.1.4 Posterior Pituitary Syndromes

The clinically relevant posterior pituitary syndromes involve ADH and include *diabetes insipidus* and *secretion of inappropriately high levels of ADH*.

- *Diabetes insipidus*. ADH deficiency causes diabetes insipidus, a condition characterized by excessive urination (polyuria) due to an inability of the kidney to resorb water properly from the urine. It can result from a variety of processes, including head trauma, tumors, and inflammatory disorders of the hypothalamus and pituitary as well as surgical procedures involving these organs. The condition can also arise spontaneously, in the absence of an underlying disorder. Diabetes insipidus from ADH deficiency is designated as *central* to differentiate it from *nephrogenic* diabetes insipidus, which is a result of renal tubular unresponsiveness to circulating ADH. The clinical manifestations of the two diseases are similar and include the excretion of large volumes of dilute urine with an inappropriately low specific gravity. Serum sodium and osmolality are increased as a result of excessive renal loss of free water, resulting in thirst and polydipsia. Patients who can drink water can generally compensate for urinary losses; patients who are obtunded, bedridden, or otherwise limited in their ability to obtain water may develop life-threatening dehydration.
- *Syndrome of inappropriate ADH (SIADH) secretion*. ADH excess causes resorption of excessive amounts of free water, resulting in *hyponatremia*. The most frequent causes of SIADH include the secretion of ectopic ADH by malignant neoplasms (particularly small-cell carcinomas of the lung), drugs that increase ADH secretion, and a variety of central nervous system disorders, including infections and trauma.[6] The clinical manifestations of SIADH are dominated by hyponatremia, cerebral edema, and resultant neurologic dysfunction. Although total body water is increased, blood volume remains normal, and peripheral edema does not develop.

3.14.1.5 Hypothalamic Suprasellar Tumors

Neoplasms in this location may induce hypofunction or hyperfunction of the anterior pituitary, diabetes insipidus, or combinations of these manifestations. The most commonly implicated lesions are *gliomas* (sometimes arising in the chiasm; see Chapter 28) and *craniopharyngiomas*. The craniopharyngioma is thought to be derived from vestigial remnants of Rathke pouch. These slow-growing tumors account for 1% to 5% of intracranial tumors; a small minority of these lesions arise within the sella, but most are suprasellar, with or without intrasellar extension. A bimodal age distribution is observed, with one peak in childhood (5 to 15 years) and a second peak in adults 65 years or older. Patients usually come to attention because of headaches and visual disturbances, while children might present with growth retardation due to pituitary hypofunction and GH deficiency. Abnormalities of the *WNT signaling pathway*, including activating β-catenin mutations, have been reported in craniopharyngiomas.

Morphology. Craniopharyngiomas average 3 to 4 cm in diameter; they may be encapsulated and solid, but more commonly they are cystic and sometimes multiloculated. In their strategic location, they often encroach on the optic chiasm or cranial nerves, and not infrequently they bulge into the floor of the third ventricle and base of the brain. Two distinct histologic variants are recognized: **adamantinomatous craniopharyngioma** (most often observed in children) and **papillary craniopharyngioma** (most often observed in adults). The adamantinomatous type frequently contains radiologically demonstrable calcifications; the papillary variant calcifies only rarely.

Adamantinomatous craniopharyngioma consists of nests or cords of stratified squamous epithelium embedded in a spongy "reticulum" that becomes more prominent in the internal layers. "Palisading" of the squamous epithelium is frequently observed at the periphery. Compact, lamellar keratin formation ("wet keratin") is a diagnostic feature of this tumor (Fig. 24-7). As was mentioned above, **dystrophic calcification** is a frequent finding. Additional features include cyst formation, fibrosis, and chronic inflammatory reaction. The cysts of adamantinomatous craniopharyngiomas often contain a cholesterol-rich, thick brownish-yellow fluid that has been compared to "machine oil."

These tumors extend fingerlets of epithelium into adjacent brain, where they elicit a brisk glial reaction.

Papillary craniopharyngiomas contain both solid sheets and papillae lined by well-differentiated squamous epithelium. These tumors usually lack keratin, calcification, and cysts. The squamous cells of the solid sections of the tumor lack the peripheral palisading and do not typically generate a spongy reticulum in the internal layers.

Patients with craniopharyngiomas, especially those < 5 cm in diameter, have an excellent recurrencefree and overall survival. Larger lesions are more invasive but this does not impact on the prognosis. Malignant transformation of craniopharyngiomas into squamous carcinomas is exceptionally rare and usually occurs after irradiation.

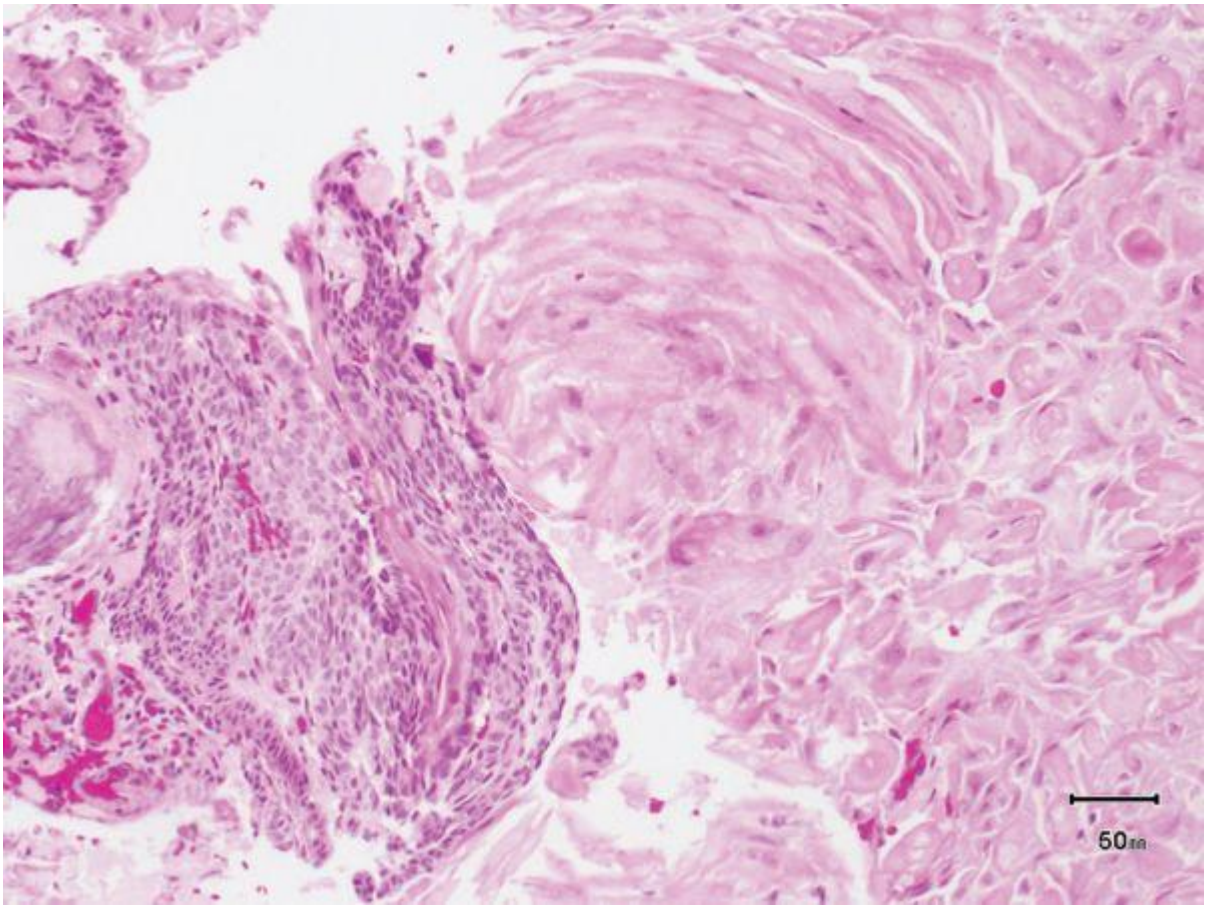

FIGURE 24-7 Adamantinomatous craniopharyngioma, demonstrating characteristic compact, lamellar "wet" keratin (right half of photomicrograph) and cords of squamous epithelium with peripheral palisading on the left. *(Courtesy of Dr. Charles Eberhart, Department of Pathology, Johns Hopkins University, Baltimore, MD.)*

3.14.2 Thyroid Gland

The thyroid gland consists of two bulky lateral lobes connected by a relatively thin isthmus, usually located below and anterior to the larynx. The thyroid is divided by thin fibrous septae into lobules composed of about 20 to 40 evenly dispersed follicles, lined by a cuboidal to low columnar epithelium, and filled with PAS-positive thyroglobulin. In response to hypothalamic factors, TSH *(thyrotropin)* is released by thyrotrophs in the anterior pituitary into the circulation. The binding of TSH to its receptor

on the thyroid follicular epithelium results in conformational change and activation of the receptor, allowing it to associate with a G_s protein (Fig. 24-8). Activation of the G protein eventually results in an increase in intracellular cAMP levels, which stimulates thyroid growth, and hormone synthesis and release via cAMP-dependent protein kinases. The dissociation of thyroid hormone synthesis and release from the controlled influence of TSH-signaling pathways results in so-called *thyroid autonomy* and hyperfunction (see below).

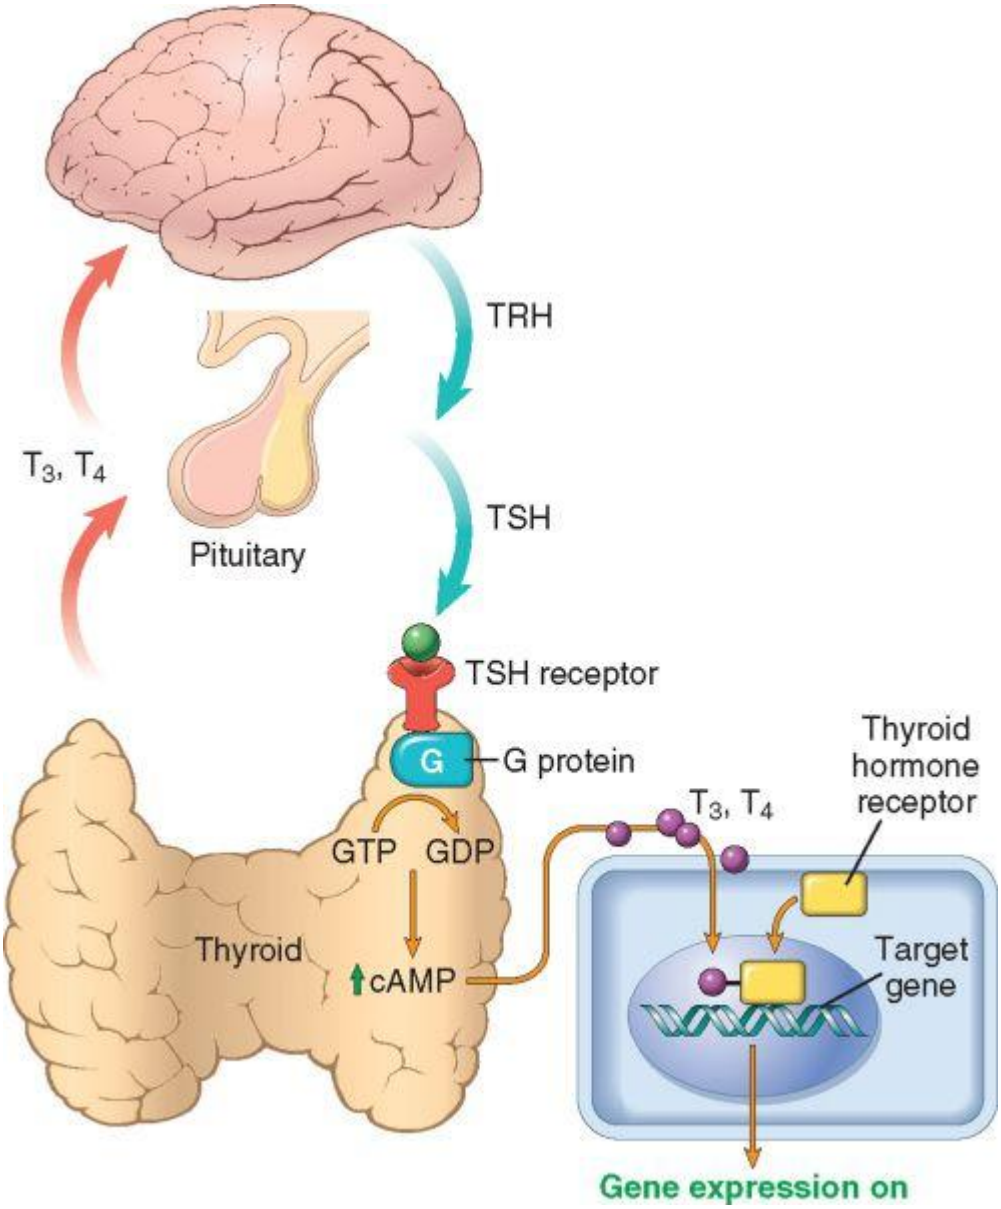

FIGURE 24-8 Homeostasis in the hypothalamus-pituitary-thyroid axis and mechanism of action of thyroid hormones. Secretion of thyroid hormones (T_3 and T_4) is controlled by trophic factors secreted by both the hypothalamus and the anterior pituitary. Decreased levels of T_3 and T_4 stimulate the release of thyrotropin-releasing hormone (TRH) from the hypothalamus and thyroid-stimulating hormone (TSH) from the anterior pituitary, causing T_3 and T_4 levels to rise. Elevated T_3 and T_4 levels, in turn, feed back to suppress the secretion of both TRH and TSH. TSH binds to the TSH receptor on the thyroid follicular epithelium, which causes activation of G proteins, and cAMP-mediated synthesis and release of thyroid hormones (T_3 and T_4). In the periphery, T_3 and T_4 interact with the thyroid hormone receptor (TR) to form a hormone-receptor complex that translocates to the nucleus and binds to so-called thyroid response elements (TREs) on target genes to initiate transcription.

Thyroid follicular epithelial cells convert thyroglobulin into *thyroxine (T_4)* and lesser amounts of *triiodothyronine (T_3)*. T_4 and T_3 are released into the systemic circulation, where most of these peptides are reversibly bound to circulating plasma proteins, such as thyroxine-binding globulin and transthyretin, for transport to peripheral tissues. The binding proteins serve to maintain the serum unbound ("free") T_3 and T_4 concentrations within narrow limits yet ensure that the hormones are readily available to the tissues. In the periphery, the majority of free T_4 is deiodinated to T_3; the latter binds to thyroid hormone nuclear receptors in target cells with tenfold greater affinity than does T_4 and has proportionately greater activity. *The interaction of thyroid hormone with its nuclear thyroid hormone receptor (TR) results in the formation of a multiprotein hormone-receptor complex that binds to thyroid hormone response elements (TREs) in target genes, regulating their transcription* (see Fig. 24-8). Thyroid hormone has diverse cellular effects, including up-regulation of carbohydrate and lipid catabolism and stimulation of protein synthesis in a wide range of cells. The net result of these processes is an increase in the basal metabolic rate. One of the most important functions of thyroid hormone is its critical role in brain development in the fetus and neonate (see below).

The function of the thyroid gland can be inhibited by a variety of chemical agents, collectively referred to as *goitrogens*. Because they suppress T_3 and T_4 synthesis, the level of TSH increases, and subsequent hyperplastic enlargement of the gland (*goiter*) follows. The antithyroid agent *propylthiouracil* inhibits the oxidation of iodide and thus blocks production of the thyroid hormones; parenthetically, propylthiouracil also inhibits the peripheral deiodination of circulating T_4 into T_3, thus ameliorating symptoms of thyroid hormone excess (see below). Iodide, when given to individuals with thyroid hyperfunction, also blocks the release of thyroid hormones but through different mechanisms. Iodides in large doses inhibit proteolysis of thyroglobulin. Thus, thyroid hormone is synthesized and incorporated within increasing amounts of colloid, but it is not released into the blood.

The thyroid gland follicles also contain a population of *parafollicular cells*, or C cells, which synthesize and secrete the hormone *calcitonin*. This hormone promotes the absorption of calcium by the skeletal system and inhibits the resorption of bone by osteoclasts.

Diseases of the thyroid include conditions associated with excessive release of thyroid hormones (hyperthyroidism), those associated with thyroid hormone deficiency (hypothyroidism), and mass lesions of the thyroid. We first consider the clinical consequences of disturbed thyroid function, then focus on the disorders that generate these problems.

3.14.2.1 Hyperthyroidism

Thyrotoxicosis is a hypermetabolic state caused by elevated circulating levels of free T_3 and T_4. Because it is caused most commonly by hyperfunction of the thyroid gland, it is often referred to as *hyperthyroidism*. However, in certain conditions the oversupply is related to either excessive release of preformed thyroid hormone (e.g., in thyroiditis) or to an extra-thyroidal source, rather than hyperfunction of the gland (Table 24-3). *Thus, strictly speaking, hyperthyroidism is only one (albeit the most common) cause of thyrotoxicosis*. The terms *primary* and *secondary hyperthyroidism* are sometimes used to designate hyperthyroidism arising from an intrinsic thyroid abnormality and that arising from processes outside of the thyroid, such as a TSH-secreting pituitary tumor. With this caveat, we will follow the common practice of using the terms *thyrotoxicosis* and *hyperthyroidism* interchangeably. The three most common causes of thyrotoxicosis are also associated with hyperfunction of the gland and include the following:

- *Diffuse hyperplasia* of the thyroid associated with Graves disease (accounts for 85% of cases)
- Hyperfunctional *multinodular goiter*
- Hyperfunctional *adenoma* of the thyroid

TABLE 24-3 -- Disorders Associated with Thyrotoxicosis

ASSOCIATED WITH HYPERTHYROIDISM
Primary
Diffuse toxic hyperplasia (Graves disease)
Hyperfunctioning ("toxic") multinodular goiter
Hyperfunctioning ("toxic") adenoma
Iodine-induced hyperthyroidism
Neonatal thyrotoxicosis associated with maternal Graves disease
Secondary
TSH-secreting pituitary adenoma (rare)[*]
NOT ASSOCIATED WITH HYPERTHYROIDISM
Granulomatous (de Quervain) thyroiditis (*painful*)
Subacute lymphocytic thyroiditis (*painless*)
Struma ovarii (ovarian teratoma with ectopic thyroid)
Factitious thyrotoxicosis (exogenous thyroxine intake)

* Associated with increased thyroid-stimulating hormone (TSH); all other causes of thyrotoxicosis associated with decreased TSH.

Clinical Course.

The clinical manifestations of hyperthyroidism are protean and include changes referable to the *hypermetabolic state* induced by excess thyroid hormone and to overactivity of the *sympathetic nervous system* (i.e., an increase in the β-adrenergic "tone").

Excessive levels of thyroid hormone result in *an increase in the basal metabolic rate*. The *skin* of thyrotoxic patients tends to be soft, warm, and flushed because of increased blood flow and peripheral vasodilation to increase heat loss. *Heat intolerance* is common. Sweating is increased because of higher levels of calorigenesis. Increased basal metabolic rate also results in characteristic *weight loss despite increased appetite*.

Cardiac manifestations are among the earliest and most consistent features of hyperthyroidism. Individuals with hyperthyroidism can have an increase in cardiac output, due to both increased cardiac contractility and increased peripheral oxygen requirements. Tachycardia, palpitations, and cardiomegaly are common. Arrhythmias, particularly atrial fibrillation, occur frequently and are more common in older patients. Congestive heart failure may develop, particularly in elderly patients with preexisting cardiac disease. Myocardial changes, such as foci of lymphocytic and eosinophilic infiltration, mild fibrosis in the interstitium, fatty changes in myofibers, and an increase in size and number of mitochondria, have been described. Some individuals with thyrotoxicosis develop reversible *left ventricular dysfunction* and "low-output" heart failure, so-called *thyrotoxic or hyperthyroid cardiomyopathy*.

In the *neuromuscular system*, overactivity of the sympathetic nervous system produces tremor, hyperactivity, emotional lability, anxiety, inability to concentrate, and insomnia. Proximal muscle weakness and decreased muscle mass are common *(thyroid myopathy)*.

Ocular changes often call attention to hyperthyroidism. A wide, staring gaze and lid lag are present because of sympathetic overstimulation of the levator palpebrae superioris (Fig. 24-9). However, true *thyroid ophthalmopathy* associated with proptosis is seen only in Graves disease (see below).

FIGURE 24-9 A person with hyperthyroidism. A wide-eyed, staring gaze, caused by overactivity of the sympathetic nervous system, is one of the features of this disorder. In Graves disease, one of the most important causes of hyperthyroidism, accumulation of loose connective tissue behind the eyeballs, also adds to the protuberant appearance of the eyes.

In the *gastrointestinal system*, sympathetic hyperstimulation of the gut results in hypermotility, malabsorption, and diarrhea.

The *skeletal system* is also affected. Thyroid hormone stimulates bone resorption, increasing porosity of cortical bone and reducing the volume of trabecular bone. The net effect is osteoporosis and an increased risk of fractures in patients with chronic hyperthyroidism.

Other findings include atrophy of skeletal muscle, with fatty infiltration and focal interstitial lymphocytic infiltrates; minimal liver enlargement due to fatty changes in the hepatocytes; and generalized lymphoid hyperplasia and lymphadenopathy in patients with Graves disease.

Thyroid storm is used to designate the abrupt onset of severe hyperthyroidism. This condition occurs most commonly in patients with underlying Graves disease and probably results from an acute elevation in catecholamine levels, as might be encountered during infection, surgery, cessation of antithyroid medication, or any form of stress. Patients are often febrile and present with tachycardia out of

proportion to the fever. Thyroid storm is a medical emergency: A significant number of untreated patients die of cardiac arrhythmias.

Apathetic hyperthyroidism refers to thyrotoxicosis occurring in the elderly, in whom advanced age and various co-morbidities may blunt the typical features of thyroid hormone excess seen in younger patients. The diagnosis of thyrotoxicosis in these individuals is often made during laboratory work-up for unexplained weight loss or worsening cardiovascular disease.

A diagnosis of hyperthyroidism is made using both clinical and laboratory findings. The measurement of serum TSH concentration using sensitive TSH assays provides the most useful single screening test for hyperthyroidism, since its levels are decreased even at the earliest stages, when the disease may still be subclinical. A low TSH value is usually confirmed with measurement of free T_4, which is expectedly increased. In an occasional patient, hyperthyroidism results predominantly from increased circulating levels of T_3 ("T_3 toxicosis"). In these cases, free T_4 levels may be decreased, and direct measurement of serum T_3 may be useful. In rare cases of pituitary-associated (secondary) hyperthyroidism, TSH levels are either normal or raised. Determining TSH levels after the injection of thyrotropin-releasing hormone (TRH stimulation test) is used in the evaluation of cases of suspected hyperthyroidism with equivocal changes in the baseline serum TSH level. A normal rise in TSH after administration of TRH excludes secondary hyperthyroidism. Once the diagnosis of thyrotoxicosis has been confirmed by a combination of TSH assays and free thyroid hormone levels, measurement of radioactive iodine uptake by the thyroid gland may be valuable in determining the etiology. For example, there may be diffusely increased uptake in the whole gland (Graves' disease), increased uptake in a solitary nodule (toxic adenoma), or decreased uptake (thyroiditis).

The therapeutic options for hyperthyroidism include multiple medications, each of which has a different mechanism of action. Typically, these include a β-blocker to control symptoms induced by increased adrenergic tone, a thionamide to block new hormone synthesis, an iodine solution to block the release of thyroid hormone, and agents that inhibit peripheral conversion of T_4 to T_3. Radioiodine, which is incorporated into thyroid tissues, resulting in ablation of thyroid function over a period of 6 to 18 weeks, may also be used.

3.14.2.2 Hypothyroidism

Hypothyroidism is caused by any structural or functional derangement that interferes with the production of adequate levels of thyroid hormone. Hypothyroidism is a fairly common disorder, and by some estimates the population prevalence of overt hypothyroidism is 0.3%, while subclinical hypothyroidism can be found in greater than 4%.[7] The prevalence of hypothyroidism increases with age, and it is nearly tenfold more common in women than in men. It can result from a defect anywhere in the hypothalamic-pituitary-thyroid axis. As in the case of hyperthyroidism, this disorder is divided into *primary* and *secondary* categories, depending on whether the hypothyroidism arises from an intrinsic abnormality in the thyroid itself, or occurs as a result of pituitary and hypothalamic disease (Table 24-4). Primary hypothyroidism accounts for the vast majority of cases of hypothyroidism, and can be accompanied by an enlargement in the size of the thyroid gland (goiter). Primary hypothyroidism can be congenital, acquired, or autoimmune.

TABLE 24-4 -- Causes of Hypothyroidism

PRIMARY
Developmental (thyroid dysgenesis: *PAX8, FOXE1*, TSH receptor mutations)
Thyroid hormone resistance syndrome (*THRB* mutations)

Postablative
Surgery, radioiodine therapy, or external irradiation
Autoimmune hypothyroidism
Hashimoto thyroiditis[*]
Iodine deficiency[*]
Drugs (lithium, iodides, *p*-aminosalicylic acid)[*]
Congenital biosynthetic defect (dyshormonogenetic goiter)[*]
SECONDARY (CENTRAL)
Pituitary failure
Hypothalamic failure (rare)

[*] Associated with enlargement of thyroid ("goitrous hypothyroidism"). Hashimoto thyroiditis and postablative hypothyroidism account for the majority of cases of hypothyroidism in developed countries. *FOXE1*, forkhead box E1; *PAX8*, paired box 8; *THRB*, thyroid hormone receptor β.

Worldwide, *congenital hypothyroidism* is most often the result of *endemic iodine deficiency* in the diet (see below). Other less common forms of congenital hypothyroidism include *inborn errors of thyroid metabolism (dyshormonogenetic goiter)*, wherein any one of the multiple steps leading to thyroid hormone synthesis may be deficient, such as (1) iodide transport into thyrocytes, (2) iodide "organification" (binding of iodide to tyrosine residues of the storage protein, thyroglobulin), and (3) iodotyrosine coupling to form hormonally active T_3 and T_4. Mutations in the *thyroid peroxidase (TPO)* gene are the most common cause of dyshormonogenetic goiter. *Pendred syndrome*, characterized by hypothyroidism and sensorineural deafness, is caused by mutations in the *SLC26A4* gene, whose product, pendrin, is an anion transporter expressed on the apical surface of thyrocytes and in the inner ear.[8] In rare instances there may be complete absence of thyroid parenchyma *(thyroid agenesis)*, or the gland may be greatly reduced in size *(thyroid hypoplasia)*. Germline mutations in transcription factors that are expressed in the developing thyroid and regulate follicular differentiation, such as *thyroid transcription factor-2* (*TTF-2*), also known as *FOXE1*, and *paired box-8* (*PAX-8*), have been reported in individuals with thyroid agenesis. These patients typically present with a constellation of extra-thyroidal malformations. Inactivating germline mutations of the *TSH receptor (TSHR)* is a rare genetic cause of isolated hypothyroidism (note that *activating* somatic mutations of *TSHR* are found in autonomous thyroid nodules, see below). *Thyroid hormone resistance syndrome* is a rare autosomal-dominant disorder caused by inherited mutations in the thyroid hormone receptor, which abolish the ability of the receptor to bind thyroid hormones. Patients demonstrate a generalized resistance to thyroid hormone, despite high circulating levels of T_3 and T_4. Since the pituitary is also resistant to feedback from thyroid hormones, TSH levels tend to be high as well.

Acquired hypothyroidism can be caused by *surgical or radiation-induced ablation* of thyroid parenchyma. A large resection of the gland (total thyroidectomy) for the treatment of hyperthyroidism of a primary neoplasm can lead to hypothyroidism. The gland may also be ablated by radiation, whether in the form of radioiodine administered for the treatment of hyperthyroidism, or exogenous irradiation, such as external radiation therapy to the neck. *Drugs* given intentionally to decrease thyroid secretion (e.g., methimazole and propylthiouracil) can cause acquired hypothyroidism, as can agents used to treat nonthyroid conditions (e.g., lithium, *p*-aminosalicylic acid).

Autoimmune hypothyroidism is the most common cause of hypothyroidism in iodine-sufficient areas of the world. The vast majority of cases of autoimmune hypothyroidism are due to Hashimoto thyroiditis.

Circulating autoantibodies, including *anti-microsomal, anti-thyroid peroxidase*, and *anti-thyroglobulin* antibodies, are found in this disorder, and the thyroid is typically enlarged (goitrous). Autoimmune hypothyroidism can occur in isolation or in conjunction with autoimmune polyendocrine syndrome (APS), types 1 and 2 (see discussion in "Adrenal Glands").

Secondary (or central) hypothyroidism is caused by deficiency of TSH, and far more uncommonly, that of TRH. Any of the causes of hypopituitarism (for example, pituitary tumor, postpartum pituitary necrosis, trauma, and nonpituitary tumors), or of hypothalamic damage from tumors, trauma, radiation therapy, or infiltrative diseases can cause central hypothyroidism.

Classic clinical manifestations of hypothyroidism include cretinism and myxedema.

CRETINISM

Cretinism refers to hypothyroidism that develops in infancy or early childhood. The term *cretin* was derived from the French *chrétien*, meaning "Christian" or "Christlike," and was applied to these unfortunates because they were considered to be so mentally retarded as to be incapable of sinning. In the past this disorder occurred fairly commonly in areas of the world where dietary iodine deficiency is endemic, such as the Himalayas, inland China, Africa, and other mountainous areas. It has become much less frequent in recent years, as a result of the widespread supplementation of foods with iodine. On rare occasions, cretinism may also result from inborn errors in metabolism that interfere with the biosynthesis of normal levels of thyroid hormone (dyshormonogenetic goiter, see above).

Clinical features of cretinism include impaired development of the skeletal system and central nervous system, manifested by severe mental retardation, short stature, coarse facial features, a protruding tongue, and umbilical hernia. The severity of the mental impairment in cretinism seems to be related to the time at which thyroid deficiency occurs in utero. Normally, maternal hormones, including T_3 and T_4, cross the placenta and are critical to fetal brain development. If there is maternal thyroid deficiency before the development of the fetal thyroid gland, mental retardation is severe. In contrast, reduction in maternal thyroid hormones later in pregnancy, after the fetal thyroid has developed, allows normal brain development.

MYXEDEMA

The term *myxedema* is applied to hypothyroidism developing in the older child or adult. Myxedema, or Gull disease, was first linked with thyroid dysfunction in 1873 by Sir William Gull in an article addressing the development of a "cretinoid state" in adults.[9] The clinical manifestations vary with the age of onset of the deficiency. The older child shows signs and symptoms intermediate between those of the cretin and those of the adult with hypothyroidism. In the adult the condition appears insidiously and may take years to reach the level of clinical suspicion.

Clinical features of myxedema are characterized by a slowing of physical and mental activity. The initial symptoms include generalized fatigue, apathy, and mental sluggishness, which may mimic depression in the early stages of the disease. Speech and intellectual functions become slowed. Patients with myxedema are listless, cold intolerant, and frequently overweight. Decreased sympathetic activity results in constipation and decreased sweating. The skin of these patients is cool and pale because of decreased blood flow. Reduced cardiac output probably contributes to shortness of breath and decreased exercise capacity, two frequent complaints in individuals with hypothyroidism. Thyroid hormones regulate the transcription of several sarcolemmal genes, such as *calcium ATPases*, whose encoded products are critical in maintaining efficient cardiac output. In addition, hypothyroidism promotes an atherogenic profile—an increase in total cholesterol and low-density lipoprotein (LDL) levels—probably contributing toward the adverse cardiovascular mortality rates in this disease. Histologically,

there is an accumulation of matrix substances, such as glycosaminoglycans and hyaluronic acid, in skin, subcutaneous tissue, and a number of visceral sites. This results in non-pitting edema, a broadening and coarsening of facial features, enlargement of the tongue, and deepening of the voice.

Laboratory evaluation plays a vital role in the diagnosis of suspected hypothyroidism because of the nonspecific nature of symptoms. Patients with unexplained increase in body weight or hypercholesterolemia should be assessed for potential hypothyroidism. *Measurement of the serum TSH level is the most sensitive screening test for this disorder*. The TSH level is increased in primary hypothyroidism as a result of a loss of feedback inhibition of TRH and TSH production by the hypothalamus and pituitary, respectively. The TSH level is not increased in persons with hypothyroidism due to primary hypothalamic or pituitary disease. *T_4 levels are decreased* in individuals with hypothyroidism of any origin.

3.14.2.3 Thyroiditis

Thyroiditis, or inflammation of the thyroid gland, encompasses a diverse group of disorders characterized by some form of thyroid inflammation. These diseases include conditions that result in acute illness with severe thyroid pain (e.g., infectious thyroiditis, subacute granulomatous thyroiditis) and disorders in which there is relatively little inflammation and the illness is manifested primarily by thyroid dysfunction—subacute lymphocytic thyroiditis and fibrous (Reidel) thyroiditis.

Infectious thyroiditis may be either acute or chronic. Acute infections can reach the thyroid by hematogenous spread or through direct seeding of the gland, such as through a fistula from the piriform sinus adjacent to the larynx. Other infections of the thyroid, including mycobacterial, fungal, and *Pneumocystis* infections, are more chronic and frequently occur in immunocompromised patients. Whatever the cause, the inflammatory involvement may cause sudden onset of neck pain and tenderness in the area of the gland and is accompanied by fever, chills, and other signs of infection. Infectious thyroiditis can be self-limited or can be controlled with appropriate therapy. Thyroid function is usually not significantly affected, and there are few residual effects except for possible small foci of scarring. This section focuses on the more common and clinically significant types of thyroiditis: (1) Hashimoto thyroiditis, (2) granulomatous (de Quervain) thyroiditis, and (3) subacute lymphocytic thyroiditis.

HASHIMOTO THYROIDITIS

Hashimoto thyroiditis is the most common cause of hypothyroidism in areas of the world where iodine levels are sufficient. The name *Hashimoto thyroiditis* is derived from the 1912 report by Hashimoto describing patients with goiter and intense lymphocytic infiltration of the thyroid *(struma lymphomatosa)*.[10] Hashimoto thyroiditis and Graves disease (see below) are the two most common immunologically mediated disorders of the thyroid. Hashimoto thyroiditis is characterized by gradual thyroid failure because of autoimmune destruction of the thyroid gland. This disorder is most prevalent between 45 and 65 years of age and is more common in women than in men, with a female predominance of 10 : 1 to 20 : 1. Although it is primarily a disease of older women, it can occur in children and is a major cause of nonendemic goiter in the pediatric population.

Akin to other autoimmune diseases, Hashimoto thyroiditis has a strong genetic component. This is supported by the concordance of disease in as many as 40% of monozygotic twins, as well as the presence of circulating antithyroid antibodies in approximately 50% of asymptomatic siblings of Hashimoto patients. Increased susceptibility to Hashimoto thyroiditis is associated with polymorphisms in multiple immune regulation–associated genes, the most significant of which is the linkage to *cytotoxic T lymphocyte–associated antigen-4 (CTLA4)* polymorphisms.[11] CTLA4 is a negative regulator of T-cell responses, and not surprisingly, polymorphisms of the *CTLA4* gene that result in reduced protein level or function are associated with a predisposition to autoimmune disease. Another

recently described genetic determinant of susceptibility to Hashimoto thyroiditis is a functional polymorphism in *protein tyrosine phosphatase-22 (PTPN22)* gene that encodes a lymphoid tyrosine phosphatase, which is also thought to inhibit T-cell function.[12] Susceptibility to other autoimmune diseases, such as type 1 diabetes (see below), has been associated with polymorphisms in both *CTLA4* and *PTPN22*.

Pathogenesis.

Hashimoto thyroiditis is caused by a breakdown in self-tolerance to thyroid auto-antigens. This is exemplified by the presence of circulating autoantibodies against thyroglobulin and thyroid peroxidase in the vast majority of Hashimoto patients. The inciting events leading to breakdown in self-tolerance in Hashimoto patients have not been fully elucidated, but possibilities include abnormalities of regulatory T cells (Tregs)[13], or exposure of normally sequestered thyroid antigens (Chapter 6). Induction of thyroid autoimmunity is accompanied by a progressive depletion of thyrocytes by apoptosis and replacement of the thyroid parenchyma by mononuclear cell infiltration and fibrosis. Multiple immunologic mechanisms may contribute to thyroid cell death, including (Fig. 24-10):

- *CD8+ cytotoxic T cell–mediated cell death:* CD8+ cytotoxic T cells may cause thyrocyte destruction.
- *Cytokine-mediated cell death:* Excessive T-cell activation leads to the production of T_H1 inflammatory cytokines such as interferon-γ in the thyroid gland, with resultant recruitment and activation of macrophages and damage to follicles.
- Binding of anti-thyroid antibodies (anti-thyroglobulin, and anti-thyroid peroxidase antibodies) followed by antibody-dependent cell-mediated cytotoxicity (Chapter 6).

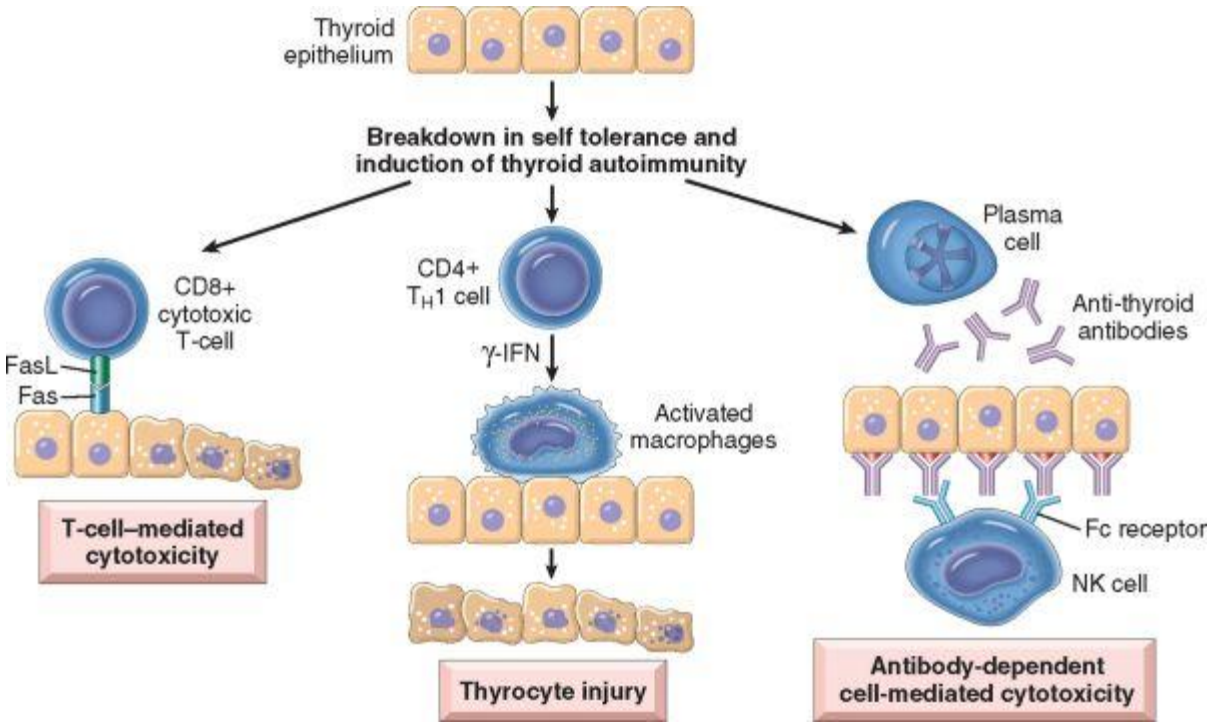

FIGURE 24-10 Pathogenesis of Hashimoto thyroiditis. Breakdown of peripheral tolerance to thyroid auto-antigens, results in progressive autoimmune destruction of thyrocytes by infiltrating cytotoxic T cells, locally released cytokines, or by antibody-dependent cytotoxicity.

Morphology. The thyroid is often diffusely enlarged, although more localized enlargement may be seen in some cases. The capsule is intact, and the gland is well demarcated from adjacent structures. The cut surface is pale, yellowtan, firm, and somewhat nodular. Microscopic examination reveals extensive infiltration of the parenchyma by a **mononuclear inflammatory infiltrate** containing small lymphocytes, plasma cells, and well-developed **germinal centers** (Fig. 24-11). The thyroid follicles are atrophic and are lined in many areas by epithelial cells distinguished by the presence of abundant eosinophilic, granular cytoplasm, termed **Hürthle cells**. This is a metaplastic response of the normally low cuboidal follicular epithelium to ongoing injury. In fine-needle aspiration biopsy samples, the presence of Hürthle cells in conjunction with a heterogeneous population of lymphocytes is characteristic of Hashimoto thyroiditis. In "classic" Hashimoto thyroiditis, interstitial connective tissue is increased and may be abundant. A **fibrous variant** is characterized by severe thyroid follicular atrophy and dense "keloid-like" fibrosis, broad bands of acellular collagen encompassing residual thyroid tissue. Unlike Reidel thyroiditis (see below), the fibrosis does not extend beyond the capsule of the gland. The remnant thyroid parenchyma demonstrates features of chronic lymphocytic thyroiditis.

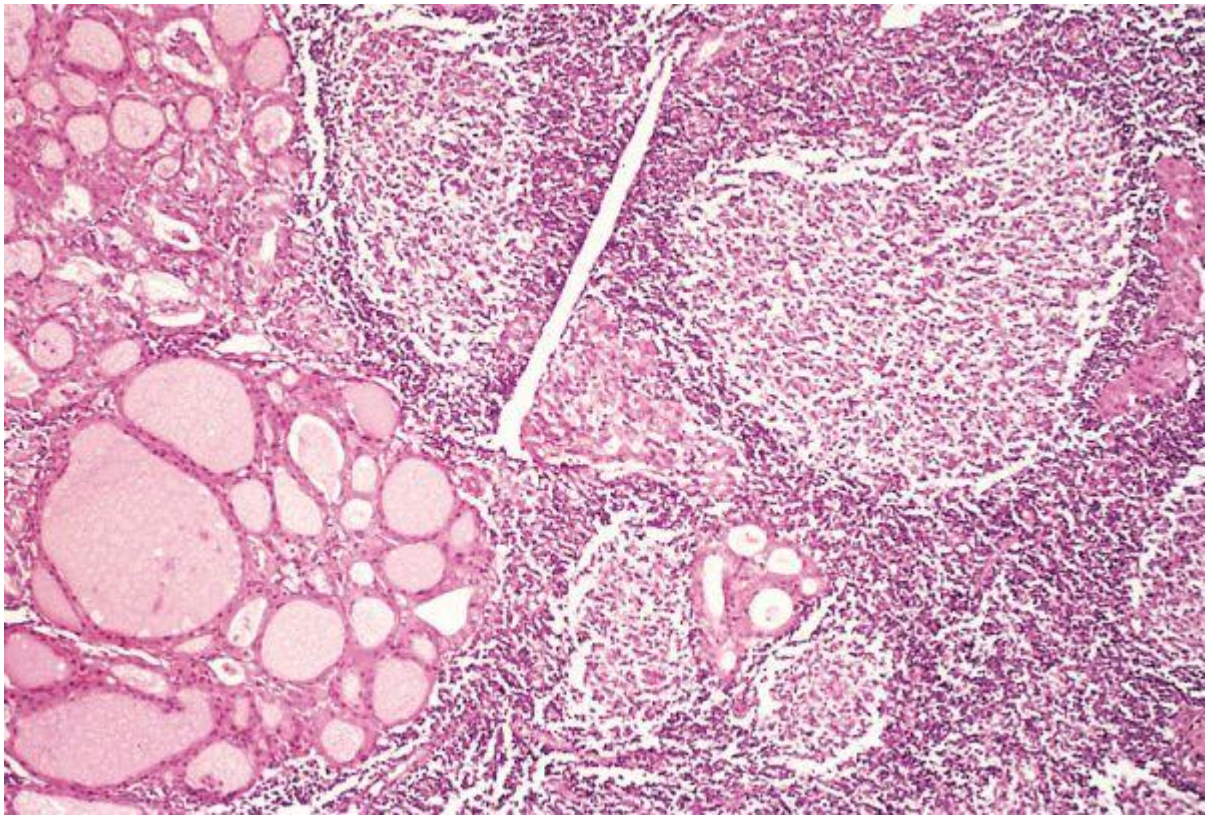

FIGURE 24-11 Hashimoto thyroiditis. The thyroid parenchyma contains a dense lymphocytic infiltrate with germinal centers. Residual thyroid follicles lined by deeply eosinophilic Hürthle cells are also seen.

Clinical Course.

Hashimoto thyroiditis most often comes to clinical attention as painless enlargement of the thyroid, usually associated with some degree of hypothyroidism, in a middle-aged woman. The enlargement of the gland is usually symmetric and diffuse, but in some cases it may be sufficiently localized to raise a

suspicion of neoplasm. In the usual clinical course, hypothyroidism develops gradually. In some cases, however, it may be preceded by transient thyrotoxicosis caused by disruption of thyroid follicles, with secondary release of thyroid hormones ("hashitoxicosis"). During this phase, free T_4 and T_3 levels are elevated, TSH is diminished, and radioactive iodine uptake is decreased. As hypothyroidism supervenes, T_4 and T_3 levels fall, accompanied by a compensatory increase in TSH. Individuals with Hashimoto thyroiditis are at increased risk for developing other autoimmune diseases, both endocrine (type 1 diabetes, autoimmune adrenalitis) and nonendocrine (systemic lupus erythematosus, myasthenia gravis, and Sjögren syndrome; see Chapter 6). They are also at increased risk for the development of B-cell non-Hodgkin lymphomas, especially marginal zone lymphomas of mucosa-associated lymphoid tissues (MALT lymphomas; see Chapter 13). The relationship between Hashimoto disease and thyroid epithelial cancers remains controversial, with some morphologic and molecular studies suggesting a predisposition to papillary carcinomas.

SUBACUTE (GRANULOMATOUS) THYROIDITIS

Subacute thyroiditis, which is also referred to as *granulomatous thyroiditis* or *De Quervain thyroiditis*, occurs much less frequently than does Hashimoto disease. The disorder is most common between the ages of 40 and 50 and, like other forms of thyroiditis, affects women considerably more often than men (4 : 1).

Pathogenesis.

Subacute thyroiditis is believed to be triggered by a *viral infection*. The majority of patients have a history of an upper respiratory infection just before the onset of thyroiditis. The disease has a seasonal incidence, with occurrences peaking in the summer, and clusters of cases have been reported in association with coxsackievirus, mumps, measles, adenovirus, and other viral illnesses. Although the pathogenesis of the disease is unclear, one model suggests that it results from a viral infection that leads to exposure to a viral or thyroid antigen, which is released secondary to virus-induced host tissue damage. This antigen stimulates cytotoxic T lymphocytes, which then damage thyroid follicular cells. In contrast to autoimmune thyroid disease, the immune response is virus-initiated and not self-perpetuating, so the process is limited.

Morphology. The gland may be unilaterally or bilaterally enlarged and firm, with an intact capsule. It may be slightly adherent to surrounding structures. On cut section, the involved areas are firm and yellow-white and stand out from the more rubbery, normal brown thyroid substance. Histologically, the changes are patchy and depend on the stage of the disease. Early in the active inflammatory phase, scattered follicles may be entirely disrupted and replaced by neutrophils forming microabscesses. Later, the more characteristic features appear in the form of aggregates of lymphocytes, activated macrophages, and plasma cells about collapsed and damaged thyroid follicles. **Multinucleate giant cells** enclose naked pools or fragments of colloid (Fig. 24-12), hence the designation **granulomatous thyroiditis**. In later stages of the disease a chronic inflammatory infiltrate and fibrosis may replace the foci of injury. Different histologic stages are sometimes found in the same gland, suggesting waves of destruction over a period of time.

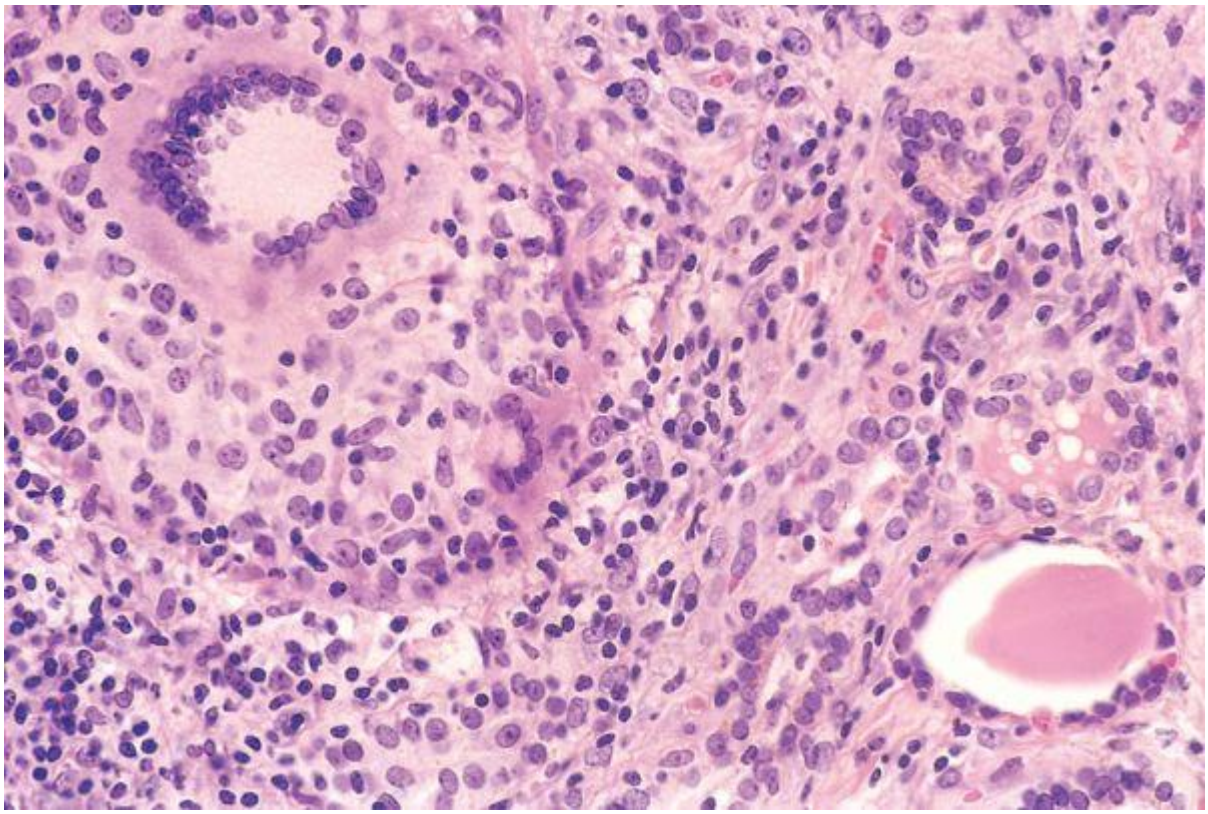

FIGURE 24-12 Granulomatous thyroiditis. The thyroid parenchyma contains a chronic inflammatory infiltrate with a multinucleate giant cell *(above left)* and a colloid follicle *(bottom right)*.

Clinical Course.

Granulomatous (de Quervain) thyroiditis is the most common cause of *thyroid pain*. There is a variable enlargement of the thyroid. The thyroid inflammation and hyperthyroidism are transient, usually diminishing in 2 to 6 weeks, even if the patient is not treated. Nearly all patients have high serum T_4 and T_3 levels and low serum TSH levels during this phase. However, unlike in hyperthyroid states such as Graves disease, radioactive iodine uptake is diminished. After recovery, generally in 6 to 8 weeks, normal thyroid function returns.

SUBACUTE LYMPHOCYTIC (PAINLESS) THYROIDITIS

Subacute lymphocytic thyroiditis, which is also referred to as *painless thyroiditis*, usually comes to clinical attention because of mild hyperthyroidism, goitrous enlargement of the gland, or both. Although it can occur at any age, it is most often seen in middle-aged adults and is more common in women. A disease process resembling painless thyroiditis can occur during the postpartum period in up to 5% of women *(postpartum thyroiditis)*. Painless and postpartum thyroiditides are variants of Hashimoto thyroiditis, since the majority of patients have circulating anti-thyroid peroxidase antibodies or a family history of other autoimmune disorders. As many as a third of cases can evolve into overt hypothyroidism over time, and the thyroid histology is also reminiscent of Hashimoto thyroiditis (see below).

Morphology. Except for possible mild symmetric enlargement, the thyroid appears normal on gross inspection. The most specific histologic features consist of lymphocytic infiltration with hyperplastic germinal centers within the thyroid parenchyma and patchy disruption and collapse of thyroid follicles. Unlike in frank Hashimoto thyroiditis, however, fibrosis and Hürthle cell metaplasia are not prominent features.

Clinical Course.

Individuals with painless thyroiditis can present with a painless goiter, transient overt hyperthyroidism, or both. Some patients transition from a hyperthyroid state to hypothyroidism before recovery. The vast majority (~80%) of individuals with postpartum thyroiditis are euthyroid by 1 year. Postpartum thyroiditis can resemble Graves disease, the incidence of which is also increased in the setting of pregnancy. Infiltrative ophthalmopathy and other manifestations of Graves disease (see below) are, however, not present in the former. As stated, as many as a third of affected individuals eventually progress to overt hypothyroidism over a 10-year period.

Other, less common forms of thyroiditis include *Riedel thyroiditis*, a rare disorder of unknown etiology characterized by extensive fibrosis involving the thyroid and contiguous neck structures. The presence of a hard and fixed thyroid mass clinically simulates a thyroid carcinoma. It may be associated with idiopathic fibrosis in other sites in the body, such as the retroperitoneum. The presence of circulating anti-thyroid antibodies in most patients suggests an autoimmune etiology.

3.14.2.4 Graves Disease

Graves reported in 1835 his observations of a disease characterized by "violent and long continued palpitations in females" associated with enlargement of the thyroid gland.[14] *Graves disease is the most common cause of endogenous hyperthyroidism*. It is characterized by a *triad* of clinical findings:

1. *Hyperthyroidism* due to diffuse, hyperfunctional enlargement of the thyroid
2. Infiltrative *ophthalmopathy* with resultant exophthalmos
3. Localized, infiltrative *dermopathy*, sometimes called *pretibial myxedema*, which is present in a minority of patients

Graves disease has a peak incidence between 20 and 40 years of age. *Women are affected as much as 10 times more frequently than men*. This disorder is said to be present in 1.5% to 2.0% of women in the United States. As previously mentioned, Graves disease (hyperthyroidism) and Hashimoto thyroiditis (hypothyroidism) span two extremes of autoimmune thyroid disorders, and not surprisingly share many underlying tenets. For example, akin to Hashimoto thyroiditis, genetic factors are also important in the etiology of Graves disease, with a concordance rate in monozygotic twins of 30% to 40%, as compared with less than 5% among dizygotic individuals. Like Hashimoto thyroiditis, genetic susceptibility for Graves disease has been linked to polymorphisms in immune-function genes like *CTLA4* and *PTPN22* and the HLA-DR3 allele.[15]

Pathogenesis.

Graves disease is characterized by a breakdown in self-tolerance to thyroid auto-antigens, most importantly the TSH receptor. The result is the production of multiple autoantibodies, including:

- *Thyroid-stimulating immunoglobulin:* This IgG antibody binds to the TSH receptor and mimics the action of TSH, stimulating adenyl cyclase and increasing the release of thyroid hormones. Almost all individuals with

Graves disease have detectable levels of this autoantibody. Thyroid-stimulating immunoglobulin is relatively specific for Graves disease, in contrast to thyroglobulin and thyroid peroxidase antibodies.

- *Thyroid growth-stimulating immunoglobulins:* Also directed against the TSH receptor, thyroid growth-stimulating immunoglobulins have been implicated in the proliferation of thyroid follicular epithelium.
- *TSH-binding inhibitor immunoglobulins*: These anti–TSH receptor antibodies prevent TSH from binding normally to its receptor on thyroid epithelial cells. In so doing, some forms of TSH-binding inhibitor immunoglobulins mimic the action of TSH, resulting in the stimulation of thyroid epithelial cell activity, whereas other forms may actually *inhibit* thyroid cell function. It is not unusual to find the coexistence of stimulating *and* inhibiting immunoglobulins in the serum of the same patient, a finding that could explain why some patients with Graves disease have episodes of hypothyroidism.

The key role of anti–TSH receptor antibodies in the pathogenesis of hyperthyroidism is supported by animal models of Graves disease. Immunization of mice with the TSH receptor results in generation of antibodies that cause thyroid stimulation, thyroid enlargement with lymphocytic infiltration, elevated thyroxine levels, and, in a subset of mice, ocular signs reminiscent of Graves ophthalmopathy (see below).

Autoimmunity also plays a role in the development of the *infiltrative ophthalmopathy* that is characteristic of Graves disease. In Graves ophthalmopathy, the volume of the retro-orbital connective tissues and extraocular muscles is increased for several reasons, including (1) marked infiltration of the retro-orbital space by mononuclear cells, predominantly T cells; (2) inflammatory edema and swelling of extraocular muscles; (3) accumulation of extracellular matrix components, specifically hydrophilic glycosaminoglycans such as hyaluronic acid and chondroitin sulfate; and (4) increased numbers of adipocytes (fatty infiltration). These changes displace the eyeball forward and can interfere with the function of the extraocular muscles. Recent evidence suggests that *orbital preadipocyte fibroblasts* express the TSH receptor and thus become targets of an autoimmune attack. T cells reactive against these fibroblasts secrete cytokines, which stimulate fibroblast proliferation and synthesis of extracellular matrix proteins (glycosaminoglycans) and increase surface TSH receptor expression, perpetuating the autoimmune response. The result is progressive infiltration of the retro-orbital space and ophthalmopathy.

Morphology. The thyroid gland is usually symmetrically enlarged because of **diffuse hypertrophy and hyperplasia** of thyroid follicular epithelial cells (Fig. 24-13A). Increases in weight to over 80 gm are not uncommon. On cut section, the parenchyma has a soft, meaty appearance resembling normal muscle. Histologically, the follicular epithelial cells in untreated cases are tall and more crowded than usual. This crowding often results in the formation of small papillae, which project into the follicular lumen and encroach on the colloid, sometimes filling the follicles (Fig. 24-13B). Such papillae lack fibrovascular cores, in contrast to those of papillary carcinoma (see below). The colloid within the follicular lumen is pale, with scalloped margins. Lymphoid infiltrates, consisting predominantly of T cells, with fewer B cells and mature plasma cells, are present throughout the interstitium; germinal centers are common.

Preoperative therapy alters the morphology of the thyroid in Graves disease. Preoperative administration of iodine causes involution of the epithelium and the accumulation of colloid by blocking thyroglobulin secretion. Treatment with the antithyroid drug propylthiouracil exaggerates the epithelial hypertrophy and hyperplasia by stimulating TSH secretion. Thus, in pretreated patients it is impossible from histologic examination of surgical specimens to evaluate the functional activity of the gland.

Changes in extra-thyroidal tissue include generalized lymphoid hyperplasia. The heart may be

hypertrophied, and ischemic changes may be present, particularly in patients with preexisting coronary artery disease. In patients with ophthalmopathy, the tissues of the orbit are edematous because of the presence of hydrophilic mucopolysaccharides. In addition, there is infiltration by lymphocytes and fibrosis. Orbital muscles are edematous initially but may undergo fibrosis late in the course of the disease. The dermopathy, if present, is characterized by thickening of the dermis due to deposition of glycosaminoglycans and lymphocyte infiltration.

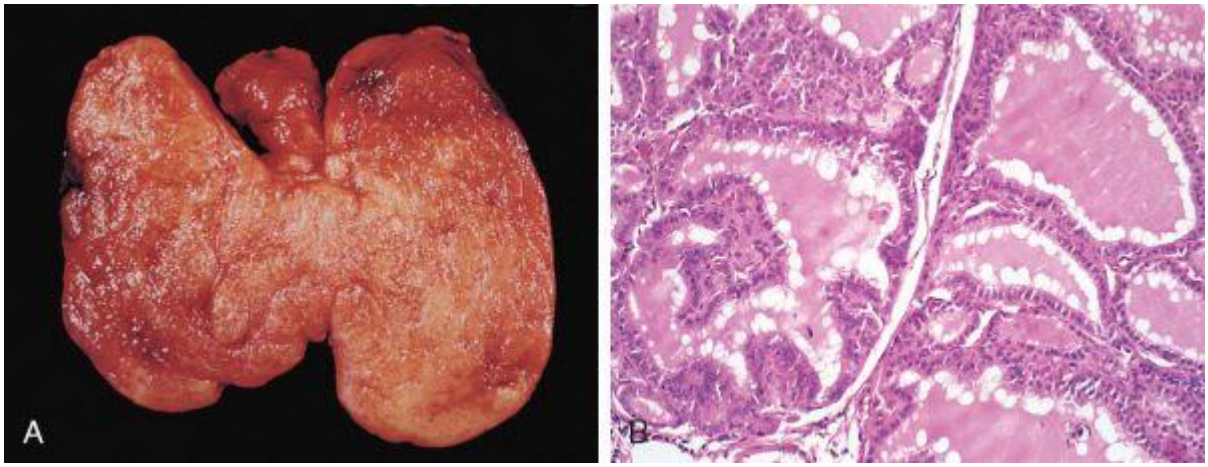

FIGURE 24-13 Graves disease. **A**, There is diffuse symmetric enlargement of the gland and a beefy deep red parenchyma. Compare with gross photograph of multinodular goiter in Figure 24-15 . **B**, Diffusely hyperplastic thyroid in a case of Graves' disease. The follicles are lined by tall, columnar epithelium. The crowded, enlarged epithelial cells project into the lumens of the follicles. These cells actively resorb the colloid in the centers of the follicles, resulting in the scalloped appearance of the edges of the colloid. *(**A**, Reproduced with permission from Lloyd RV et al. (eds): Atlas of Nontumor Pathology: Endocrine Diseases. Washington, DC, American Registry of Pathology, 2002.)*

Clinical Course.

The clinical findings in Graves disease include changes referable to *thyrotoxicosis* as well as those associated uniquely with Graves disease, *diffuse hyperplasia of the thyroid*, *ophthalmopathy*, and *dermopathy*. The degree of thyrotoxicosis varies from case to case and is sometimes less conspicuous than other manifestations of the disease. Diffuse enlargement of the thyroid is present in all cases. The *thyroid enlargement* may be accompanied by increased flow of blood through the hyperactive gland, often producing an audible "bruit." *Sympathetic overactivity* produces a characteristic wide, staring gaze and lid lag. The ophthalmopathy of Graves disease results in abnormal protrusion of the eyeball (*exophthalmos*). The extraocular muscles are often weak. The exophthalmos may persist or progress despite successful treatment of the thyrotoxicosis, sometimes resulting in corneal injury. The infiltrative dermopathy, or *pretibial myxedema*, is most common in the skin overlying the shins, where it presents as scaly thickening and induration. However, it is present only in a minority of patients. Sometimes individuals spontaneously develop thyroid hypofunction. Patients are at increased risk for other autoimmune diseases, such as systemic lupus erythematosus, pernicious anemia, type 1 diabetes, and Addison disease.

Laboratory findings in Graves disease include *elevated free T_4 and T_3* levels and *depressed TSH* levels. Because of ongoing stimulation of the thyroid follicles by thyroid-stimulating immunoglobulins, *radioactive iodine uptake is increased, and radioiodine scans show a diffuse uptake of iodine*.

Graves disease is treated with β-blockers, which address symptoms related to the increased β-adrenergic tone (e.g., tachycardia, palpitations, tremulousness, and anxiety), and by measures aimed at decreasing thyroid hormone synthesis, such as the administration of thionamides (e.g., propylthiouracil), radioiodine ablation, and surgical intervention.

3.14.2.5 Diffuse & Multinodular Goiters

Enlargement of the thyroid, or *goiter*, is the most common manifestation of thyroid disease. *Diffuse and multinodular goiters reflect impaired synthesis of thyroid hormone,* which is most often caused by dietary iodine deficiency. Impairment of thyroid hormone synthesis leads to a compensatory rise in the serum TSH level, which, in turn, causes hypertrophy and hyperplasia of thyroid follicular cells and, ultimately, gross enlargement of the thyroid gland. The compensatory increase in functional mass of the gland is able to overcome the hormone deficiency, ensuring a *euthyroid* metabolic state in most individuals. If the underlying disorder is sufficiently severe (e.g., a congenital biosynthetic defect or endemic iodine deficiency, see below), the compensatory responses may be inadequate to overcome the impairment in hormone synthesis, resulting in *goitrous hypothyroidism*. The degree of thyroid enlargement is proportional to the level and duration of thyroid hormone deficiency.

DIFFUSE NONTOXIC (SIMPLE) GOITER

Diffuse nontoxic (simple) goiter causes enlargement of the entire gland without producing nodularity. Because the enlarged follicles are filled with colloid, the term *colloid goiter* has been applied to this condition. This disorder occurs in both an endemic and a sporadic distribution.

Endemic goiter occurs in geographic areas where the soil, water, and food supply contain low levels of iodine. The term *endemic* is used when goiters are present in more than 10% of the population in a given region. Such conditions are particularly common in mountainous areas of the world, including the Andes and Himalayas, where iodine deficiency is widespread. The lack of iodine leads to decreased synthesis of thyroid hormone and a compensatory increase in TSH, leading to follicular cell hypertrophy and hyperplasia and goitrous enlargement. With increasing dietary iodine supplementation, the frequency and severity of endemic goiter have declined significantly, although as many as 200 million people worldwide continue to be at risk for severe iodine deficiency.

Variations in the prevalence of endemic goiter in regions with similar levels of iodine deficiency point to the existence of other causative influences, particularly dietary substances, referred to as *goitrogens*. The ingestion of substances that interfere with thyroid hormone synthesis at some level, such as vegetables belonging to the Brassicaceae (Cruciferae) family (e.g., cabbage, cauliflower, Brussels sprouts, turnips, and cassava), has been documented to be goitrogenic. Native populations subsisting on cassava root are particularly at risk. Cassava contains a thiocyanate that inhibits iodide transport within the thyroid, worsening any possible concurrent iodine deficiency.

Sporadic goiter occurs less frequently than does endemic goiter. There is a striking female preponderance and a peak incidence at puberty or in young adult life. Sporadic goiter can be caused by several conditions, including the ingestion of substances that interfere with thyroid hormone synthesis. In other instances, goiter may result from hereditary enzymatic defects that interfere with thyroid hormone synthesis, all transmitted as autosomal-recessive conditions (dyshormonogenetic goiter; see above). In most cases, however, the cause of sporadic goiter is not apparent.

Morphology. Two phases can be identified in the evolution of diffuse nontoxic goiter: the **hyperplastic phase** and the phase of **colloid involution**. In the hyperplastic phase, the thyroid gland is diffusely and symmetrically enlarged, although the increase is usually modest, and the gland rarely

exceeds 100 to 150 gm. The follicles are lined by crowded columnar cells, which may pile up and form projections similar to those seen in Graves disease. The accumulation is not uniform throughout the gland, and some follicles are hugely distended, whereas others remain small. If dietary iodine subsequently increases or if the demand for thyroid hormone decreases, the stimulated follicular epithelium involutes to form an enlarged, colloid-rich gland **(colloid goiter)**. In these cases the cut surface of the thyroid is usually brown, somewhat glassy, and translucent. Histologically the follicular epithelium is flattened and cuboidal, and colloid is abundant during periods of involution.

Clinical Course.

As stated above, the vast majority of persons with simple goiters are clinically euthyroid. Therefore, the clinical manifestations are primarily related to *mass effects* from the enlarged thyroid gland (Fig. 24-14). Although serum T_3 and T_4 levels are normal, the serum TSH is usually elevated or at the upper range of normal, as is expected in marginally euthyroid individuals. In children, dyshormonogenetic goiter, caused by a congenital biosynthetic defect, may induce cretinism.

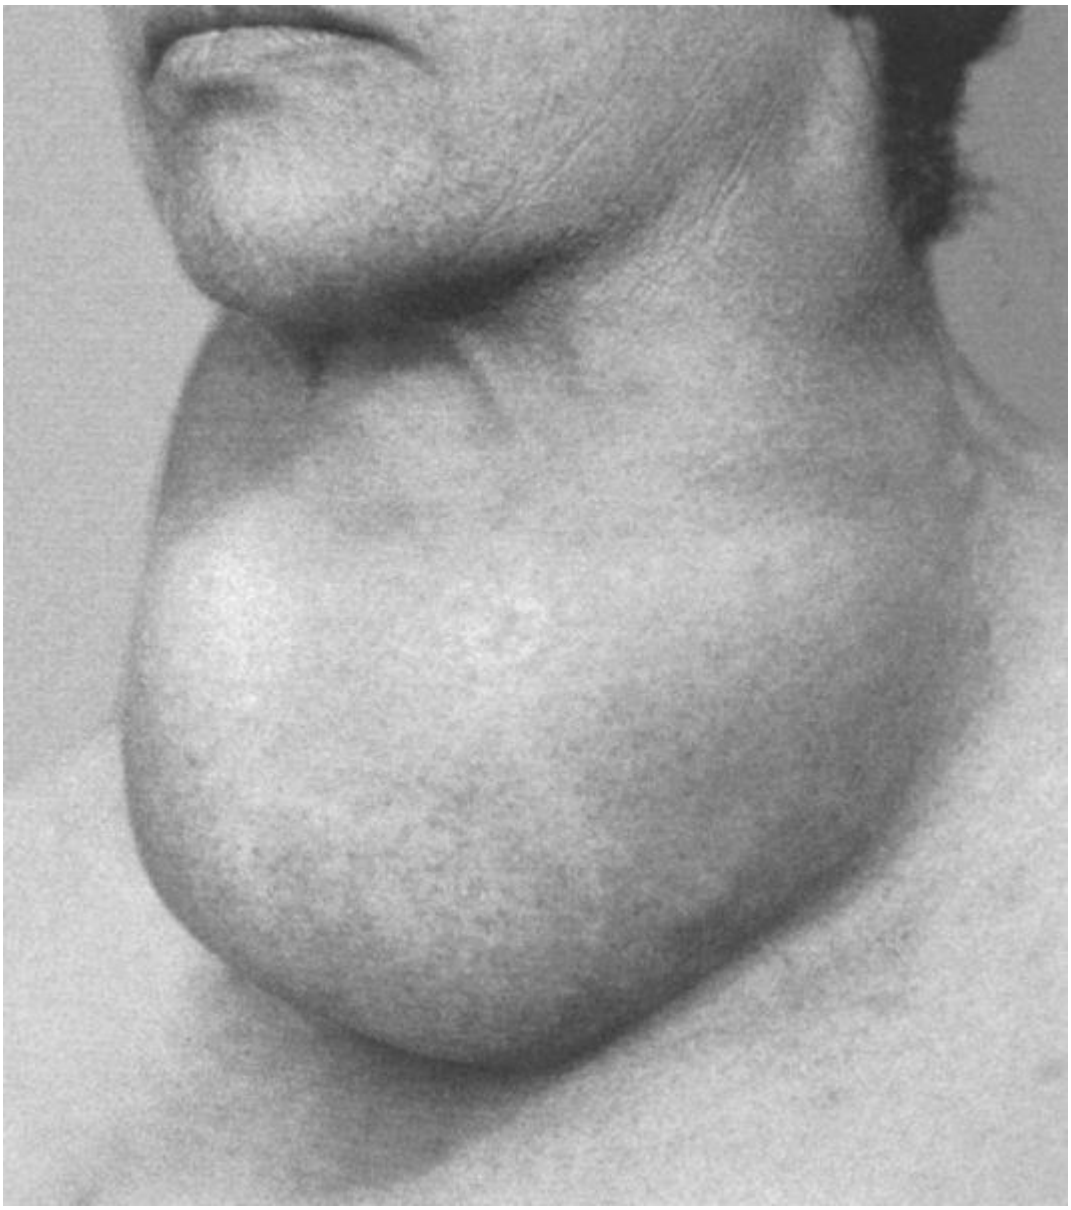

FIGURE 24-14 A 52-year-old woman with a huge colloid goiter who developed compressive symptoms. *(Reproduced with permission from Lloyd RV et al. (eds): Atlas of Nontumor Pathology: Endocrine Diseases. Washington, DC, American Registry of Pathology, 2002.)*

MULTINODULAR GOITER

With time, recurrent episodes of hyperplasia and involution combine to produce a more irregular enlargement of the thyroid, termed *multinodular goiter*. Virtually all long-standing simple goiters convert into multinodular goiters. *Multinodular goiters produce the most extreme thyroid enlargements and are more frequently mistaken for neoplastic involvement than any other form of thyroid disease*. Because they derive from simple goiter, they occur in both sporadic and endemic forms, having the same female-to-male distribution and presumably the same origins but affecting older individuals because they are late complications.

It is believed that multinodular goiters arise because of variations among follicular cells in their response to external stimuli, such as trophic hormones. If some cells in a follicle have a growth advantage, perhaps because of intrinsic genetic abnormalities similar to those that give rise to adenomas, those cells can give rise to clones of proliferating cells. This may result in the formation of a nodule whose continued growth is autonomous, without the external stimulus. Consistent with this model, both polyclonal and monoclonal nodules coexist within the same multinodular goiter, the latter presumably having arisen because of the acquisition of a genetic abnormality favoring growth. Not surprisingly, *mutations affecting proteins of the TSH-signaling pathway that lead to constitutive activation of this pathway have been identified in a subset of autonomous thyroid nodules* (TSH-signaling pathway mutations and their implications are discussed under "Adenomas"). The uneven follicular hyperplasia, generation of new follicles, and uneven accumulation of colloid produce physical stress that leads to rupture of follicles and vessels followed by hemorrhages, scarring, and sometimes calcifications. With scarring, nodularity appears, which may be accentuated by the preexisting stromal framework of the gland.

Morphology. Multinodular goiters are multilobulated, asymmetrically enlarged glands that can reach weights of more than 2000 gm. The pattern of enlargement is quite unpredictable and may involve one lobe far more than the other, producing lateral pressure on midline structures, such as the trachea and esophagus. In other instances the goiter grows behind the sternum and clavicles to produce the so-called **intrathoracic** or **plunging goiter**. Occasionally, most of it is hidden behind the trachea and esophagus; in other instances one nodule may so stand out as to impart the clinical appearance of a solitary nodule. On cut section, irregular nodules containing variable amounts of brown, gelatinous colloid are present (Fig. 24-15A). Older lesions have areas of hemorrhage, fibrosis, calcification, and cystic change. The microscopic appearance includes colloid-rich follicles lined by flattened, inactive epithelium and areas of **follicular hyperplasia**, accompanied by the degenerative changes noted previously. In contrast to follicular neoplasms, a prominent capsule between the hyperplastic nodules and residual compressed thyroid parenchyma is not present (Fig. 24-15B).

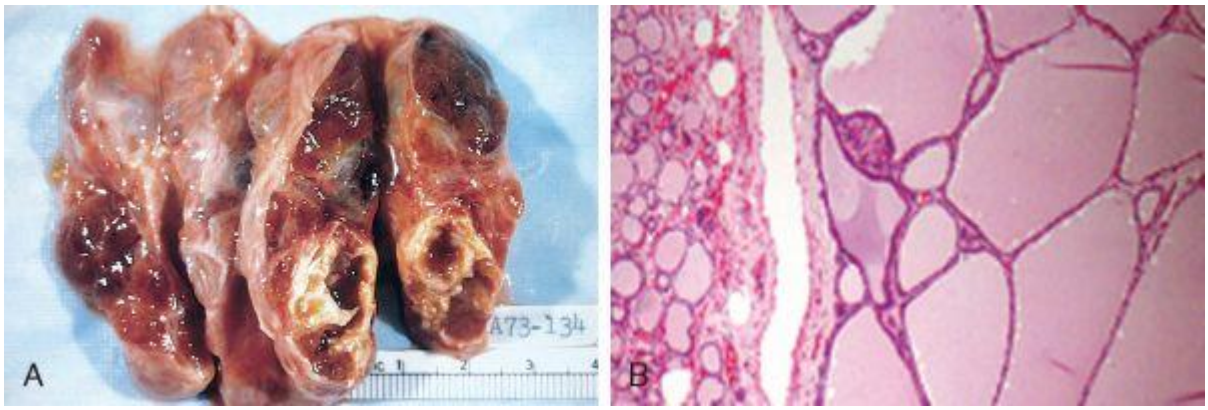

FIGURE 24-15 Multinodular goiter. **A**, Gross morphology demonstrating a coarsely nodular gland, containing areas of fibrosis and cystic change. **B**, Photomicrograph of a hyperplastic nodule, with compressed residual thyroid parenchyma on the periphery. Note absence of a prominent capsule, a distinguishing feature from follicular neoplasms. *(**B**, Courtesy of Dr. William Westra, Department of Pathology, Johns Hopkins University, Baltimore, MD.)*

Clinical Course.

The dominant clinical features of multinodular goiter are those caused by the *mass effects* of the enlarged gland. In addition to the obvious cosmetic effects of a large neck mass, goiters may cause airway obstruction, dysphagia, and compression of large vessels in the neck and upper thorax *(superior vena cava syndrome)*. Most patients are euthyroid or have subclinical hyperthyroidism (identified only by reduced TSH levels), but in a substantial minority of patients an autonomous nodule may develop within a long-standing goiter and produce hyperthyroidism *(toxic multinodular goiter)*. This condition, known as *Plummer syndrome*, is not accompanied by the infiltrative ophthalmopathy and dermopathy of Graves disease. It is estimated that clinically apparent autonomous nodules can develop in approximately 10% of multinodular goiters over a 10-year follow-up. The incidence of malignancy in long-standing multinodular goiters is low (<5%) but not zero, and concern for malignancy arises in goiters that demonstrate sudden changes in size or symptoms (e.g., hoarseness). Dominant nodules in a multinodular goiter can present as a "solitary thyroid nodule" (see below), mimicking a thyroid neoplasm. A radioiodine scan demonstrates uneven iodine uptake (including the occasional "hot" autonomous nodule) consistent with the diffuse parenchymal involvement, and an admixture of hyperplastic and involuting nodules in multinodular goiter. A fine-needle aspiration biopsy is helpful and can often, albeit not always, facilitate the distinction of follicular hyperplasia from a follicular neoplasm (see below).[16]

3.14.2.6 Neoplasms of the Thyroid

The solitary thyroid nodule is a palpably discrete swelling within an otherwise apparently normal thyroid gland. The estimated incidence of solitary palpable nodules in the adult population of the United States varies between 1% and 10%, although it is significantly higher in endemic goitrous regions. Single nodules are about four times more common in women than in men. The incidence of thyroid nodules increases throughout life.

From a clinical standpoint, the possibility of neoplastic disease is of major concern in persons who present with thyroid nodules. Fortunately, the overwhelming majority of solitary nodules of the thyroid prove to be localized, non-neoplastic conditions (e.g., a dominant nodule in multinodular goiter, simple

cysts, or foci of thyroiditis) or benign neoplasms such as follicular adenomas. In fact, *benign neoplasms outnumber thyroid carcinomas by a ratio of nearly 10 : 1*. While under 1% of solitary thyroid nodules are malignant, this still represents about 15,000 new cases of thyroid carcinoma per year in the United States. Fortunately, most of these cancers are indolent, permitting a 90% survival at 20 years. Several clinical criteria provide clues to the nature of a given thyroid nodule:

- *Solitary nodules*, in general, are more likely to be neoplastic than are multiple nodules.
- *Nodules in younger patients* are more likely to be neoplastic than are those in older patients.
- *Nodules in males* are more likely to be neoplastic than are those in females.
- A history of *radiation* treatment to the head and neck region is associated with an increased incidence of thyroid malignancy.
- Functional nodules that take up radioactive iodine in imaging studies *(hot nodules)* are significantly more likely to be benign than malignant.

Such general trends and statistics, however, are of little significance in the evaluation of a given patient, in whom the timely recognition of a malignancy can be lifesaving. Ultimately, it is the morphologic evaluation of a given thyroid nodule, by fine-needle aspiration and histologic study of surgically resected thyroid parenchyma, that provides the most definitive information about its nature. In the following sections we consider the major thyroid neoplasms, including adenoma and carcinoma in its various forms.

ADENOMAS

Adenomas of the thyroid are typically discrete, solitary masses, derived from follicular epithelium, and hence they are also known as *follicular adenomas*. Clinically, follicular adenomas can be difficult to distinguish from dominant nodules of follicular hyperplasia or from the less common follicular carcinomas. In general, follicular adenomas are *not* forerunners to carcinomas; nevertheless, shared genetic alterations support the possibility that at least of subset of follicular carcinomas arise in preexisting adenomas (see below). Although the vast majority of adenomas are nonfunctional, a small proportion produces thyroid hormones and causes clinically apparent thyrotoxicosis. Hormone production in functional adenomas (“toxic adenomas”) is independent of TSH stimulation and represents another example of *thyroid autonomy*, analogous to toxic multinodular goiters. Not surprisingly, both of these benign processes share altered genetic pathways.

Pathogenesis.

A minority (<20%) of *nonfunctioning* follicular adenomas have mutations of *RAS or phosphotidylinositol-3-kinase subunit (PIK3CA),*[17] or bear a *PAX8-PPARG* fusion gene,[18] all of which are genetic alterations shared with follicular carcinomas. These are discussed in further detail under “Carcinomas” (see below).

Somatic mutations of the *TSH receptor signaling pathway* have been found in toxic adenomas, as well as in toxic multinodular goiter. Gain-of-function mutations in one of two components of this signaling system—most often *TSHR* itself or the α-subunit of G_s (*GNAS*)—allow follicular cells to secrete thyroid hormone independent of TSH stimulation (“thyroid autonomy”). This causes symptoms of hyperthyroidism and produces a “hot” thyroid nodule on imaging. Overall, mutations in the TSH receptor signaling pathway seem to be present in slightly over half of toxic thyroid nodules. Notably, *TSHR* and *GNAS* mutations are rare in follicular carcinomas; thus toxic adenomas and toxic multinodular goiter do not seem to be forerunners of malignancy.

Morphology. The typical thyroid adenoma is a solitary, spherical, encapsulated lesion that is well demarcated from the surrounding thyroid parenchyma (Fig. 24-16A). Follicular adenomas average about 3 cm in diameter, but some are much larger (≥10 cm in diameter). In freshly resected specimens the adenoma bulges from the cut surface and compresses the adjacent thyroid. The color ranges from gray-white to red-brown, depending on the cellularity of the adenoma and its colloid content. The neoplastic cells are demarcated from the adjacent parenchyma by a well-defined, intact capsule. **These features are important in making the distinction from multinodular goiters**, which contain multiple nodules on their cut surface even though the patient may present clinically with a solitary dominant nodule. Areas of hemorrhage, fibrosis, calcification, and cystic change, similar to those encountered in multinodular goiters, are common in follicular adenomas, particularly within larger lesions.

Microscopically, the constituent cells often form uniform-appearing follicles that contain colloid (Fig. 24-16B). The follicular growth pattern within the adenoma is usually quite distinct from the adjacent non-neoplastic thyroid. The epithelial cells composing the follicular adenoma reveal little variation in cell and nuclear morphology, and mitotic figures are rare. Extensive mitotic activity, necrosis, or high cellularity warrants careful examination of the capsule to exclude a follicular carcinoma, as well as of the nuclear features to exclude a follicular variant of papillary carcinoma (see below). Occasionally the neoplastic cells acquire brightly eosinophilic granular cytoplasm (oxyphil or Hürthle cell change) (Fig. 24-17); the clinical presentation and behavior of a follicular adenoma with oxyphilia **(Hürthle cell adenoma)** is no different from that of a conventional adenoma. The hallmark of all follicular adenomas is the presence of an intact, well-formed capsule encircling the tumor. **Careful evaluation of the integrity of the capsule is therefore critical in distinguishing follicular adenomas from follicular carcinomas**, which demonstrate capsular and/or vascular invasion (see below).

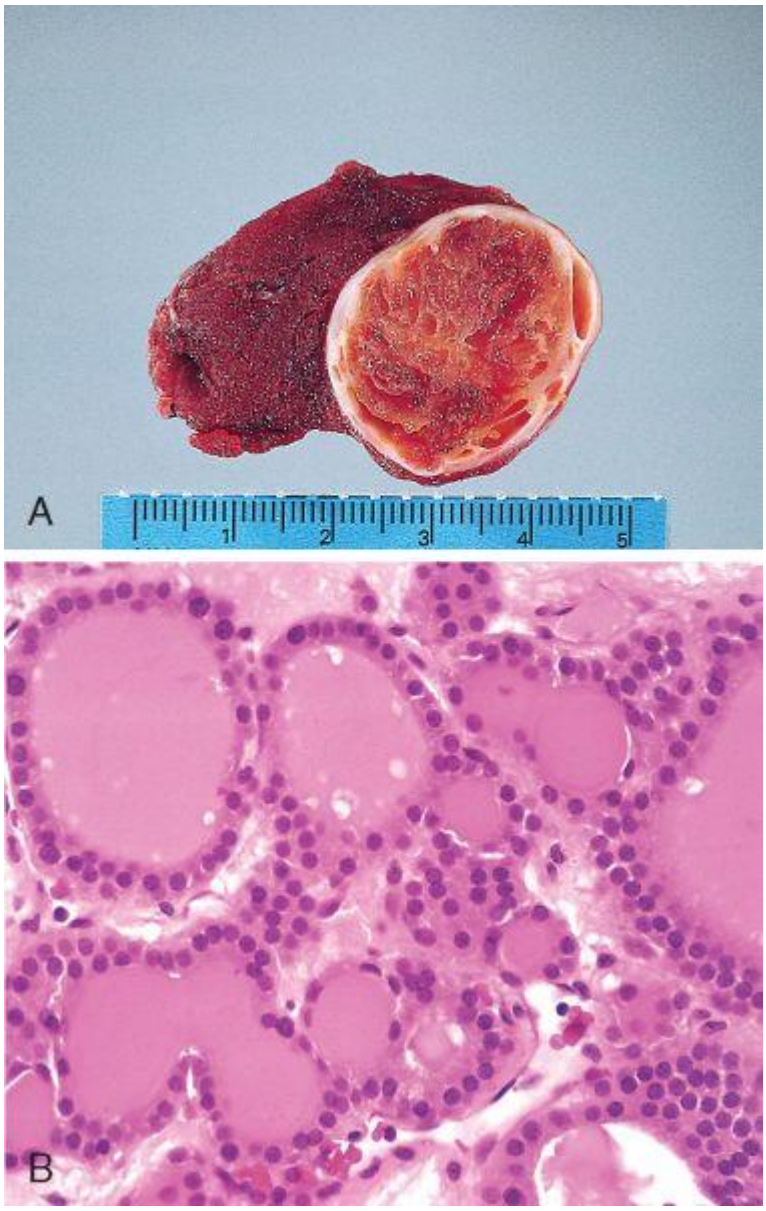

FIGURE 24-16 Follicular adenoma of the thyroid. **A**, A solitary, well-circumscribed nodule is seen. **B**, The photomicrograph shows well-differentiated follicles resembling normal thyroid parenchyma.

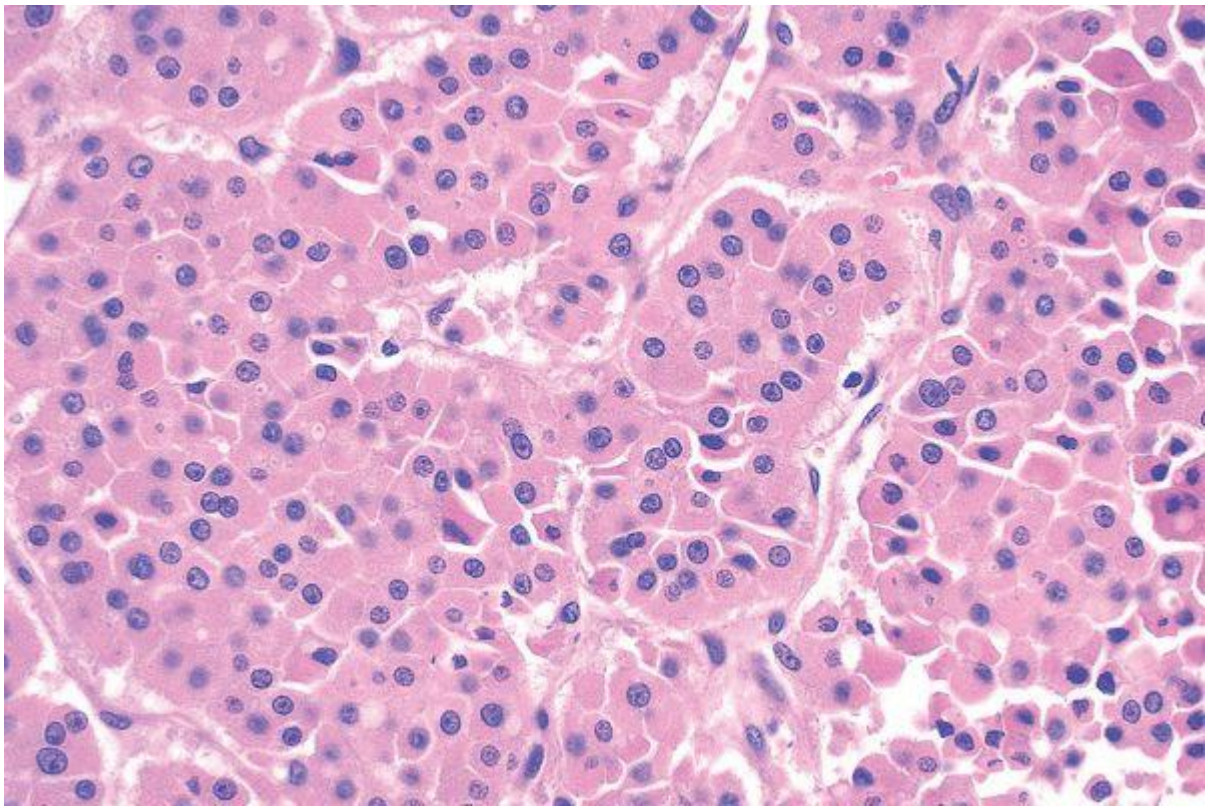

FIGURE 24-17 Hürthle cell (oxyphil) adenoma. A high-power view showing that the tumor is composed of cells with abundant eosinophilic cytoplasm and small regular nuclei. *(Courtesy of Dr. Mary Sunday, Duke University, Durham, NC.)*

Clinical Features.

Many follicular adenomas present as a unilateral painless mass, often discovered during a routine physical examination. Larger masses may produce local symptoms, such as difficulty in swallowing. Nonfunctioning adenomas take up less radioactive iodine than does normal thyroid parenchyma. On radionuclide scanning, therefore, nonfunctioning adenomas usually appear as *cold* nodules relative to the adjacent thyroid tissue. As many as 10% of cold nodules eventually prove to be malignant on histologic analysis. By contrast, malignancy is rare in *hot* nodules (toxic adenomas). Other techniques used in the preoperative evaluation of suspected adenomas are ultrasonography and fine-needle aspiration biopsy. *Because of the need for evaluating capsular integrity, the definitive diagnosis of adenomas can be made only after careful histologic examination of the resected specimen*. Suspected adenomas of the thyroid are therefore removed surgically to exclude malignancy. Follicular adenomas have an excellent prognosis and do not recur or metastasize.

CARCINOMAS

Carcinomas of the thyroid are relatively uncommon in the United States, accounting for about 1.5% of all cancers. A female predominance has been noted among patients who develop thyroid carcinoma in the early and middle adult years. In contrast, cases presenting in childhood and late adult life are distributed equally among males and females. Most thyroid carcinomas (except medullary carcinomas) are derived from the thyroid follicular epithelium, and of these, the vast majority are well-differentiated lesions. The major subtypes of thyroid carcinoma and their relative frequencies include the following:

- Papillary carcinoma (>85% of cases)
- Follicular carcinoma (5% to 15% of cases)
- Anaplastic (undifferentiated) carcinoma (<5% of cases)
- Medullary carcinoma (5% of cases)

Because of the unique clinical and biologic features associated with each variant of thyroid carcinoma, these subtypes are described separately. We begin with a discussion of the molecular pathogenesis of all thyroid cancers.

Pathogenesis

Genetic Factors.

Distinct genetic events are involved in the pathogenesis of the four major histologic variants of thyroid cancer. As stated, medullary carcinomas do not arise from the follicular epithelium. Genetic alterations in the three follicular cell–derived malignancies are clustered along two oncogenic pathways—the mitogen-activated protein (MAP) kinase pathway and the phosphatidylinositol-3-kinase (PI-3K)/AKT pathway (Fig. 24-18). In normal cells, these pathways are transiently activated by binding of soluble growth factor ligands to the extracellular domain of receptor tyrosine kinases, which results in autophosphorylation of the cytoplasmic domain of the receptor, permitting intracellular signal transduction. In thyroid carcinomas, as with many solid cancers (see Chapter 7), gain-of-function mutations along components of these pathways lead to constitutive activation even in the absence of ligand and thus promote carcinogenesis.[17]

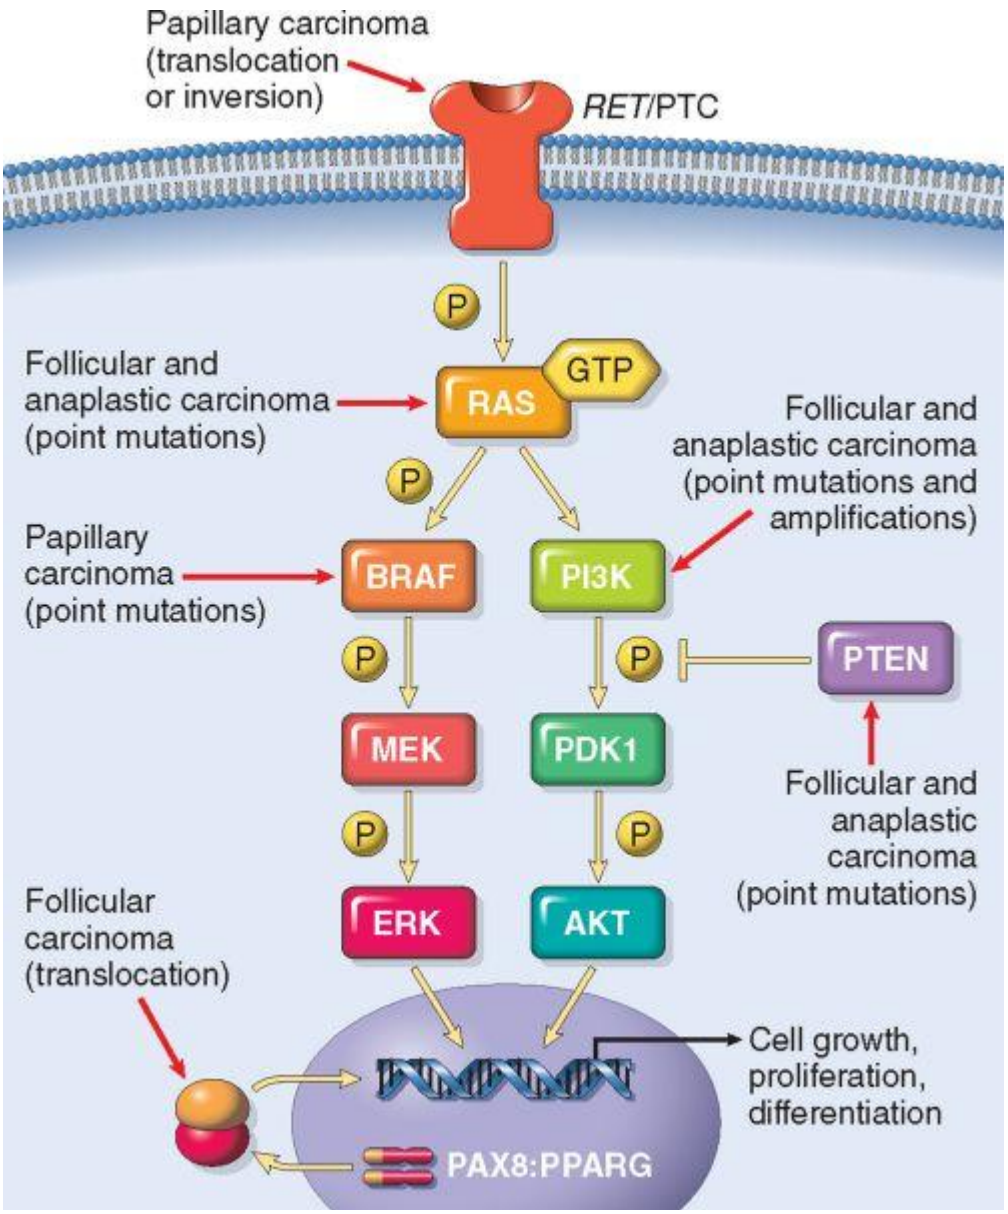

FIGURE 24-18 Genetic alterations in follicular cell–derived malignancies of the thyroid gland.

Papillary Carcinomas.

Activation of the MAP kinase pathway is a feature of most papillary carcinomas and can occur by one of two major mechanisms. The first mechanism involves rearrangements of *RET* or *NTRK1* (neurotrophic tyrosine kinase receptor 1), both of which encode transmembrane receptor tyrosine kinases, and the second mechanism involves activating point mutations in *BRAF*, whose product is an intermediate signaling component in the MAP kinase pathway (see Fig. 24-18). The *RET* gene is located on chromosome 10q11, and the receptor tyrosine kinase it encodes is normally not expressed in thyroid follicular cells. In papillary cancers, either a paracentric inversion of chromosome 10 or a reciprocal translocation between chromosomes 10 and 17 places the tyrosine kinase domain of *RET* under the transcriptional control of genes that are constitutively expressed in the thyroid epithelium. The novel fusion proteins that are so formed are known as *RET*/PTC (*RET*/papillary thyroid carcinoma) and are present in approximately 20% to 40% of papillary thyroid cancers. There are more than 15 fusion

partners of *RET*, and two—designated as *RET*/*PTC1* and *RET*/*PTC2*—are most commonly observed in sporadic papillary cancers. The frequency of *RET*/*PTC* rearrangements is significantly higher in papillary cancers arising in the backdrop of radiation exposure. Irrespective of frequency, the presence of a RET/PTC fusion protein leads to constitutive expression of the tyrosine kinase in thyroid follicular cells, with resultant activation of the MAP kinase pathway. Similarly, paracentric inversions or translocations of *NTRK1* on chromosome 1q21 are present in 5% to 10% of papillary thyroid cancers, and the resultant fusion proteins are constitutively expressed in thyroid cells, leading to activation of MAP kinase and other oncogenic signaling pathways. One third to one half of papillary thyroid carcinomas harbor a gain-of-function mutation in the *BRAF* gene, which is most commonly a valine-to-glutamate change on codon 600 ($BRAF^{V600E}$).[19] The presence of *BRAF* mutations in papillary carcinomas correlates with adverse prognostic factors like metastatic disease and extra-thyroidal extension. The histologic variants of papillary carcinoma demonstrate some unique characteristics vis-vis the frequency or nature of *BRAF* mutation (see below). Since chromosomal rearrangements of the *RET* or *NTRK1* genes and mutations of *BRAF* have redundant effects on the thyroid epithelium (both mechanisms result in activation of the MAP kinase signaling pathway), papillary thyroid carcinomas demonstrate either one or the other molecular abnormality, but not both. *RET*/*PTC* rearrangements and *BRAF* point mutations are not observed in follicular adenomas or carcinomas.

Follicular Carcinomas.

Approximately one third to one half of follicular thyroid carcinomas harbor mutations in the PI-3K/AKT signaling pathway, resulting in constitutive activation of this oncogenic pathway. This subset of cases includes tumors with gain-of-function point mutations of *RAS* and *PIK3CA*, tumors with amplification of *PIK3CA*, and those with loss-of-function mutations of *PTEN*, a tumor suppressor gene and negative regulator of this pathway (see Fig. 24-18). The genetic alterations activating the PI-3K/AKT pathway are almost always mutually exclusive in follicular carcinomas, in line with their functional equivalence. The progressive increase in the prevalence of *RAS* and *PIK3CA* mutations from benign follicular adenomas to follicular carcinomas to anaplastic carcinomas (see below) suggests a shared histogenesis and molecular evolution among these follicular cell–derived tumors. A unique (2;3)(q13;p25) translocation has been described in one third to one half of follicular carcinomas. This translocation creates a fusion gene composed of portions of *PAX8*, a paired homeobox gene that is important in thyroid development, and the peroxisome proliferator-activated receptor gene (*PPARG*), whose gene product is a nuclear hormone receptor implicated in terminal differentiation of cells. Fewer than 10% of follicular adenomas harbor *PAX8-PPARG* fusion genes, and these have not been documented thus far in other thyroid neoplasms.

Anaplastic (Undifferentiated) Carcinomas.

These highly aggressive and lethal tumors can arise de novo, or more commonly, by “dedifferentiation” of a well-differentiated papillary or follicular carcinoma. Molecular alterations present in anaplastic carcinomas include those also seen in well-differentiated carcinomas (e.g., *RAS* or *PIK3CA* mutations), albeit at a significantly higher rate, suggesting that the presence of these mutations might predispose existing thyroid neoplasms to transform.[20] Other genetic “hits,” such as inactivation of *p53* or activating mutations of β-catenin, are essentially restricted to anaplastic carcinomas, and might also relate to their aggressive behavior.

Medullary Thyroid Carcinomas.

Familial medullary thyroid carcinomas occur in multiple endocrine neoplasia type 2 (MEN-2, see below) and are associated with germline *RET* proto-oncogene mutations that lead to constitutive activation of the receptor. *RET* mutations are also seen in approximately one half of nonfamilial (sporadic) medullary

thyroid cancers. Chromosomal rearrangements involving *RET*, such as the *RET/PTC* translocations reported in papillary cancers, are not seen in medullary carcinomas.

Environmental Factors.

The major risk factor predisposing to thyroid cancer is exposure to *ionizing radiation*, particularly during the first 2 decades of life. In keeping with this, there was a marked increase in the incidence of papillary carcinomas among children exposed to ionizing radiation after the Chernobyl nuclear disaster in 1986.[21] *Deficiency of dietary iodine* (and by extension, an association with goiter) is linked with a higher frequency of follicular carcinomas.

Papillary Carcinoma

Papillary carcinomas are the most common form of thyroid cancer, accounting for nearly 85% of primary thyroid malignancies in the United States. They occur throughout life but most often between the ages of 25 and 50, and account for the majority of thyroid carcinomas associated with previous exposure to ionizing radiation. The incidence of papillary carcinoma has increased markedly in the last 30 years, partly because of the recognition of follicular variants (see below) that were misdiagnosed in the past.

Morphology. Papillary carcinomas are solitary or multifocal lesions. Some tumors may be well circumscribed and even encapsulated; others may infiltrate the adjacent parenchyma with ill-defined margins. The lesions may contain areas of fibrosis and calcification and are often cystic. The cut surface sometimes reveals papillary foci that may point to the diagnosis. The microscopic hallmarks of papillary neoplasms include the following (Fig. 24-19):

- Papillary carcinomas can contain branching **papillae** having a fibrovascular stalk covered by a single to multiple layers of cuboidal epithelial cells. In most neoplasms, the epithelium covering the papillae consists of well-differentiated, uniform, orderly cuboidal cells, but at the other extreme are those with fairly anaplastic epithelium showing considerable variation in cell and nuclear morphology. When present, the papillae of papillary carcinoma differ from those seen in areas of hyperplasia in being more complex and having dense fibrovascular cores.
- The nuclei of papillary carcinoma cells contain finely dispersed chromatin, which imparts an **optically clear** or **empty** appearance, giving rise to the designation **ground-glass** or **Orphan Annie eye nuclei**. In addition, invaginations of the cytoplasm may in cross-sections give the appearance of intranuclear inclusions (“pseudo-inclusions”) or intranuclear grooves. **The diagnosis of papillary carcinoma is made based on these nuclear features**, even in the absence of papillary architecture.
- Concentrically calcified structures termed **psammoma bodies** are often present within the lesion, usually within the cores of papillae. These structures are almost never found in follicular and medullary carcinomas, and so, when present in fine-needle aspiration material, they are a strong indication that the lesion is a papillary carcinoma.
- Foci of lymphatic invasion by tumor are often present, but involvement of blood vessels is relatively uncommon, particularly in smaller lesions. Metastases to adjacent cervical lymph nodes are estimated to occur in up to half the cases.

There are over a dozen histologic variants of papillary carcinoma that can mimic other lesions of the thyroid or harbor distinct prognostic implications[22]; their discussion is beyond the scope of this book. The most common variant, and the one most liable to misdiagnosis, is the **follicular variant**, which has the characteristic nuclei of papillary carcinoma but has an almost totally follicular architecture. The incidence of this variant has sharply increased in recent years with greater recognition of its existence among pathologists. The genetic alterations in the follicular variant

demonstrate several distinctions from conventional papillary carcinomas, including a lower frequency of *RET*/*PTC* rearrangements and a significantly higher frequency of *RAS* mutations.[23] Further, the follicular variant often harbors a distinct mutation in *BRAF*, which results in a lower degree of BRAF kinase activation than the mutation present in conventional papillary carcinomas.[24] The follicular variant is more frequently encapsulated and has a lower incidence of lymph node metastases and extra-thyroidal extension than conventional papillary carcinomas. Recent studies suggest that encapsulated follicular variant carcinomas have a favorable prognosis and can be managed with conservative surgical excision, while the more infiltrative tumors associated with metastases should be treated more aggressively.

A **tall-cell variant** is marked by tall columnar cells with intensely eosinophilic cytoplasm lining the papillary structures. These tumors tend to occur in older individuals and have higher frequencies of vascular invasion, extra-thyroidal extension, and cervical and distant metastases than conventional papillary thyroid carcinoma. Tall-cell variant papillary carcinomas harbor *BRAF* mutations in most (55% to 100%) cases, and often have a *RET*/*PTC* translocation. The occurrence of these together may be responsible for the aggressive behavior of this variant.

An unusual **diffuse sclerosing variant** of papillary carcinoma occurs in younger individuals, including children. The tumor demonstrates a prominent papillary growth pattern, intermixed with solid areas containing nests of squamous metaplasia. As the name suggests, there is extensive, diffuse fibrosis throughout the thyroid gland, often associated with a prominent lymphocytic infiltrate, simulating Hashimoto thyroiditis. Lymph node metastases are present in almost all cases. The diffuse sclerosing variant carcinomas lack *BRAF* mutations, but *RET*/*PTC* translocations are found in approximately half the cases.

In passing, we should mention the **papillary microcarcinoma**, which is defined as an otherwise conventional papillary carcinoma less than 1 cm in size, and usually confined to the thyroid gland. These lesions are most often observed as an incidental finding upon surgery. These might well be precursors of the usual papillary cancers.

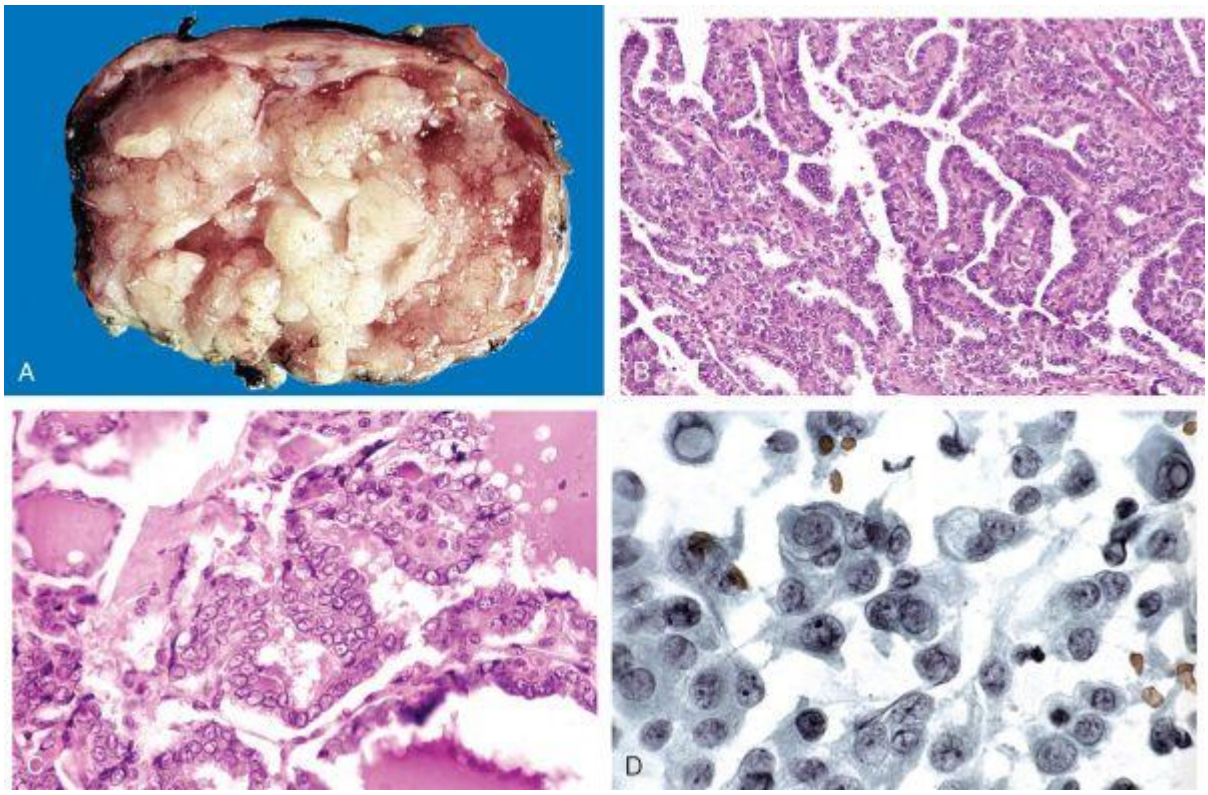

FIGURE 24-19 Papillary carcinoma of the thyroid. **A**, The macroscopic appearance of a papillary carcinoma with grossly discernible papillary structures. This particular example contains well-formed papillae (**B**), lined by cells with characteristic empty-appearing nuclei, sometimes called "Orphan Annie eye" nuclei (**C**). **D**, Cells obtained by fine-needle aspiration of a papillary carcinoma. Characteristic intranuclear inclusions are visible in some of the aspirated cells.

Clinical Course.

Most conventional papillary carcinomas present as asymptomatic thyroid nodules, but the first manifestation may be a mass in a cervical lymph node. Interestingly, the presence of isolated cervical nodal metastases does not seem to have a significant influence on the generally good prognosis of these lesions. The carcinoma, which is usually a single nodule, moves freely during swallowing and is not distinguishable from a benign nodule. Hoarseness, dysphagia, cough, or dyspnea suggests advanced disease. In a minority of patients, hematogenous metastases are present at the time of diagnosis, most commonly in the lung.

A variety of diagnostic tests have been used to help separate benign from malignant thyroid nodules, including radionuclide scanning and fine-needle aspiration. Papillary carcinomas are *cold* masses on scintiscans. Improvements in cytologic analysis have made fine-needle aspiration cytology a reliable test for distinguishing between benign and malignant nodules. The nuclear features are often nicely demonstrable in aspirated specimens.

Papillary thyroid cancers have an excellent prognosis, with a 10-year survival rate in excess of 95%. Between 5% and 20% of patients have local or regional recurrences, and 10% to 15% have distant metastases. The prognosis of someone with papillary thyroid cancers is dependent on several factors including age (in general, the prognosis is less favorable among patients older than 40 years), the presence of extra-thyroidal extension, and presence of distant metastases (stage).

Follicular Carcinoma

Follicular carcinomas account for 5% to 15% of primary thyroid cancers. They are more common in women (3 : 1) and present at an older age than do papillary carcinomas, with a peak incidence between 40 and 60 years of age. Follicular carcinoma is more frequent in areas with dietary iodine deficiency (25% to 40% of thyroid cancers), while its incidence has either decreased or remained stable in iodine-sufficient areas of the world.

Morphology. Follicular carcinomas are single nodules that may be well circumscribed or widely infiltrative (Fig. 24-20A). Sharply demarcated lesions may be exceedingly difficult to distinguish from follicular adenomas by gross examination. Larger lesions may penetrate the capsule and infiltrate well beyond the thyroid capsule into the adjacent neck. They are gray to tan to pink on cut section and, on occasion, are somewhat translucent due to the presence of large, colloid-filled follicles. Degenerative changes, such as central fibrosis and foci of calcification, are sometimes present.

Microscopically, most follicular carcinomas are composed of fairly uniform cells forming small follicles containing colloid, quite reminiscent of normal thyroid (Fig. 24-20B). In other cases follicular differentiation may be less apparent, and there may be nests or sheets of cells without colloid. Occasional tumors are dominated by cells with abundant granular, eosinophilic cytoplasm **(Hürthle cell or oncocytic variant of follicular carcinoma)**. Whatever the pattern, the nuclei lack the features typical of papillary carcinoma, and psammoma bodies are not present. It is important to note the absence of these details, because some papillary carcinomas appear almost entirely follicular. Follicular lesions in which the nuclear features are typical of papillary carcinomas should be treated as papillary cancers. While nuclear features are helpful in distinguishing papillary from follicular neoplasms, they are of little value in distinguishing follicular adenomas from **minimally invasive follicular carcinomas**. This distinction requires extensive histologic sampling of the tumor-capsule-thyroid interface to exclude capsular and/or vascular invasion (Fig. 24-21). The criterion for vascular invasion is applicable only to capsular vessels and vascular spaces beyond the capsule; the presence of tumor plugs within intra-tumoral blood vessels has little prognostic significance. Unlike in papillary cancers, lymphatic spread is uncommon in follicular cancers.

In contrast to minimally invasive follicular cancers, the diagnosis of carcinoma is obvious in **widely invasive follicular carcinomas**, which infiltrate the thyroid parenchyma and extra-thyroidal soft tissues. Histologically, these cancers tend to have a greater proportion of solid or trabecular growth pattern, less evidence of follicular differentiation, and increased mitotic activity.

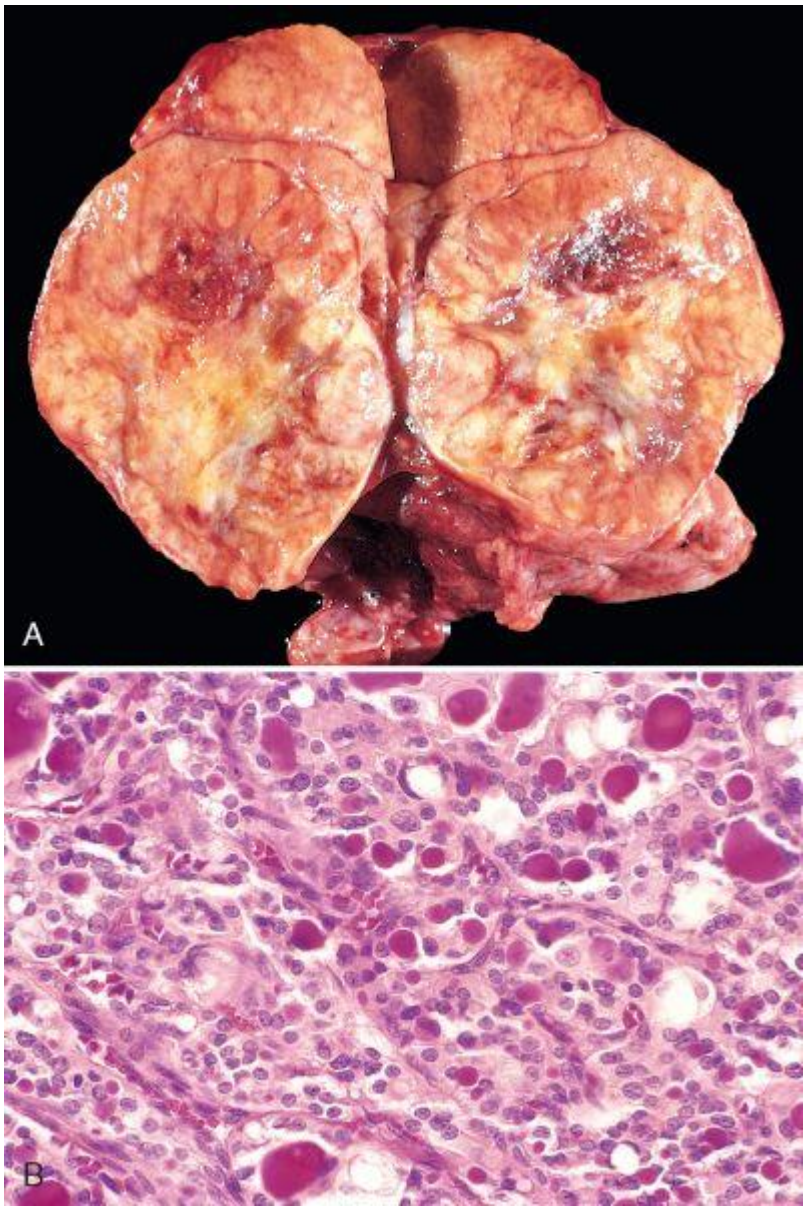

FIGURE 24-20 Follicular carcinoma. **A**, Cut surface of a follicular carcinoma with substantial replacement of the lobe of the thyroid. The tumor has a lighttan appearance and contains small foci of hemorrhage. **B**, A few of the glandular lumens contain recognizable colloid.

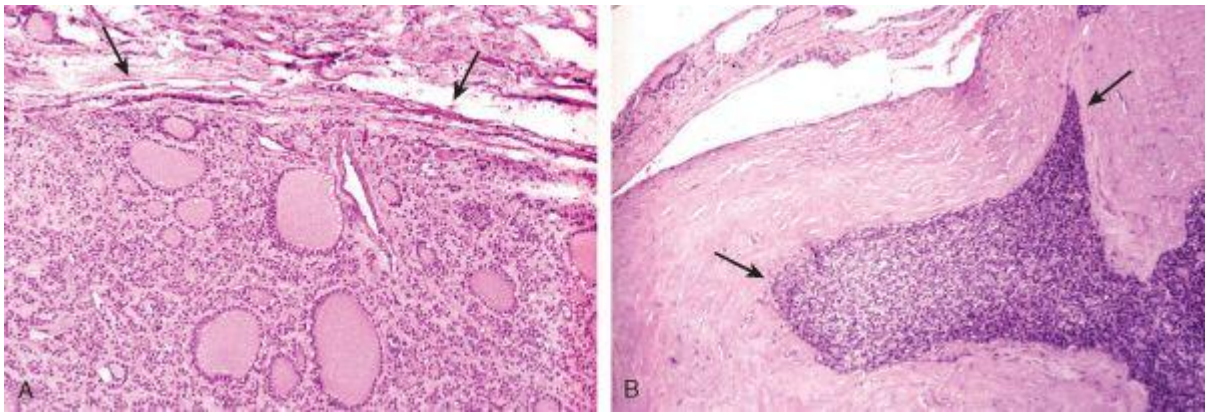

FIGURE 24-21 Capsular integrity in follicular neoplasms. In adenomas (**A**), a fibrous capsule, usually thin but occasionally more prominent, circumferentially surrounds the neoplastic follicles and no capsular invasion is seen *(arrows)*; compressed normal thyroid parenchyma is usually present external to the capsule *(top of the panel)*. In contrast, follicular carcinomas demonstrate capsular invasion (**B**, *arrows*) that may be minimal, as in this case, or widespread. The presence of vascular invasion is another feature of follicular carcinomas.

Clinical Course.

Follicular carcinomas present as slowly enlarging painless nodules. Most frequently they are *cold nodules* on scintigrams, although rare, better differentiated lesions may be hyperfunctional, take up radioactive iodine and appear *warm* on scintiscan. Follicular carcinomas have little propensity for invading lymphatics; therefore, regional lymph nodes are rarely involved, but vascular (hematogenous) dissemination is common, with metastases to bone, lungs, liver, and elsewhere. The prognosis is largely dependent on the extent of invasion and stage at presentation. Widely invasive follicular carcinomas not infrequently present with systemic metastases, and as many as half the patients succumb to their disease within 10 years. This is in stark contrast to minimally invasive follicular carcinoma, with which the 10-year survival rate is greater than 90%. Most follicular carcinomas are treated with total thyroidectomy followed by the administration of radioactive iodine, the rationale being that metastases are likely to take up the radioactive element, which can be used to identify and ablate such lesions. In addition, because any residual follicular carcinoma may respond to TSH stimulation, patients are usually treated with thyroid hormone after surgery to suppress endogenous TSH. Serum thyroglobulin levels are used for monitoring tumor recurrence, since this product should be barely detectable in a patient who is free of disease.

Anaplastic (Undifferentiated) Carcinoma

Anaplastic carcinomas are undifferentiated tumors of the thyroid follicular epithelium, accounting for less than 5% of thyroid tumors. They are aggressive, with a mortality rate approaching 100%. Patients with anaplastic carcinoma are older than those with other types of thyroid cancer, with a mean age of 65 years. Approximately a quarter of patients with anaplastic thyroid carcinomas have a past history of a well-differentiated thyroid carcinoma, and another quarter harbor a concurrent well-differentiated tumor in the resected specimen.

Morphology. Microscopically, these neoplasms are composed of highly anaplastic cells, with variable morphology, including: (1) large, pleomorphic **giant** cells, including occasional osteoclast-like multinucleate giant cells; (2) **spindle** cells with a sarcomatous appearance; and (3) **mixed** spindle and giant cells. Foci of papillary or follicular differentiation may be present in some tumors, suggesting an origin from a better differentiated carcinoma. The neoplastic cells express epithelial markers like cytokeratin, but are usually negative for markers of thyroid differentiation, like thyroglobulin.

Clinical Course.

Anaplastic carcinomas usually present as a rapidly enlarging bulky neck mass. In most cases, the disease has already spread beyond the thyroid capsule into adjacent neck structures or has metastasized to the lungs at the time of presentation. Symptoms related to compression and invasion, such as dyspnea, dysphagia, hoarseness, and cough, are common. There are no effective therapies, and the disease is

almost uniformly fatal. Although metastases to distant sites are common, in most cases death occurs in less than 1 year as a result of aggressive growth and compromise of vital structures in the neck.

Medullary Carcinoma

Medullary carcinomas of the thyroid are *neuroendocrine* neoplasms derived from the parafollicular cells, or C cells, of the thyroid, and account for approximately 5% of thyroid neoplasms. Medullary carcinomas, similar to normal C cells, secrete *calcitonin*, the measurement of which plays an important role in the diagnosis and postoperative follow-up of patients. In some instances the tumor cells elaborate other polypeptide hormones, such as serotonin, ACTH, and vasoactive intestinal peptide (VIP). About 70% of tumors arise sporadically. The remainder occurs in the setting of MEN syndrome 2A or 2B or as familial tumors without an associated MEN syndrome (familial medullary thyroid carcinoma, or FMTC; see "Multiple Endocrine Neoplasia Syndromes"). Recall that *activating point mutations in the RET protooncogene* play an important role in the development of both familial and sporadic medullary carcinomas. Cases associated with MEN types 2A or 2B occur in younger patients, and may even arise during the first decade of life. In contrast, sporadic as well as familial medullary carcinomas are lesions of adulthood, with a peak incidence in the 40s and 50s.

Morphology. Sporadic medullary thyroid carcinomas present as a solitary nodule (Fig. 24-22A). In contrast, **bilaterality and multicentricity are common in familial cases**. Larger lesions often contain areas of necrosis and hemorrhage and may extend through the capsule of the thyroid. The tumor tissue is firm, pale gray to tan, and infiltrative. There may be foci of hemorrhage and necrosis in the larger lesions.

Microscopically, medullary carcinomas are composed of polygonal to spindle-shaped cells, which may form nests, trabeculae, and even follicles. Small, more anaplastic cells are present in some tumors and may be the predominant cell type. Acellular **amyloid deposits**, derived from altered calcitonin polypeptides, are present in the adjacent stroma in many cases (Fig. 24-22B). Calcitonin is readily demonstrable within the cytoplasm of the tumor cells as well as in the stromal amyloid by immunohistochemical methods. As with all neuroendocrine tumors, electron microscopy reveals variable numbers of membrane-bound electron-dense granules within the cytoplasm of the neoplastic cells (Fig. 24-23). One of the peculiar features of familial medullary cancers is the presence of multicentric **C-cell hyperplasia** in the surrounding thyroid parenchyma, a feature that is usually absent in sporadic lesions. While the precise criteria for defining C-cell hyperplasia are not established, the presence of multiple prominent clusters of C cells scattered throughout the parenchyma should raise the specter of a familial tumor, even if that history is not explicitly present. Foci of C-cell hyperplasia are believed to represent the precursor lesions from which medullary carcinomas arise.

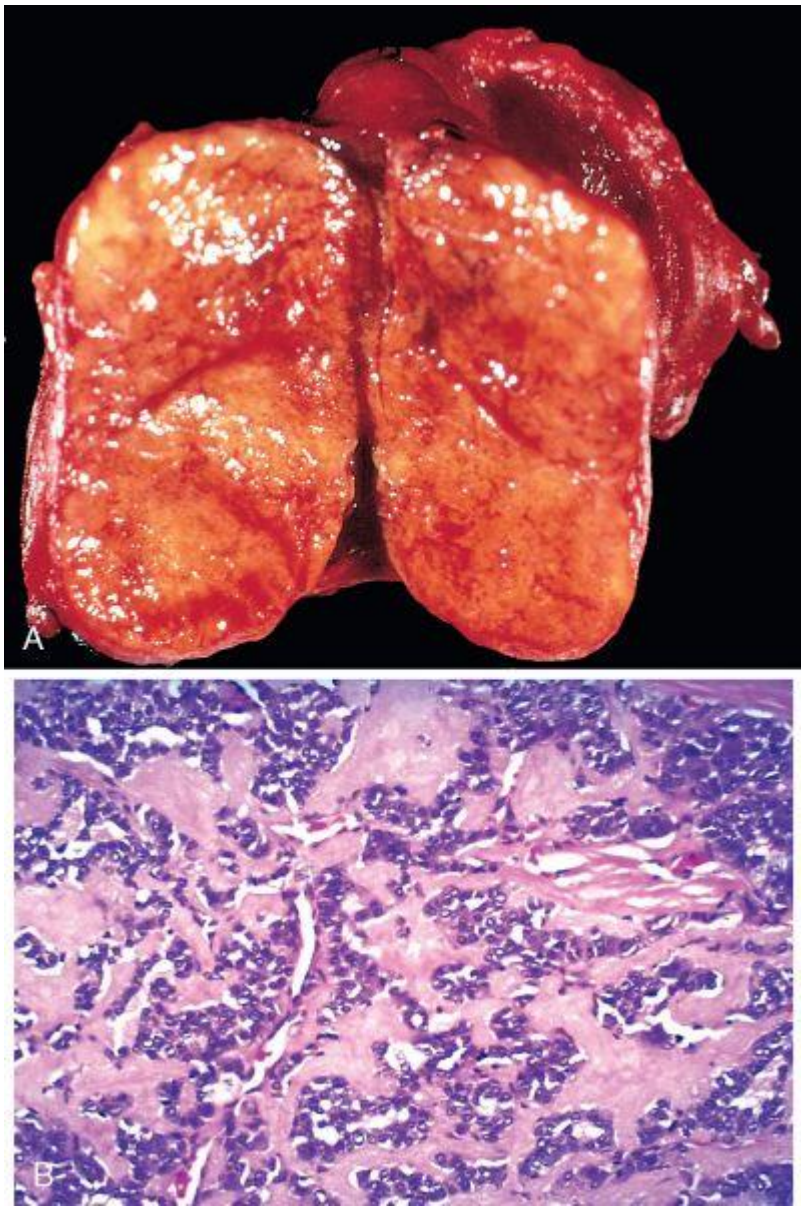

FIGURE 24-22 Medullary carcinoma of thyroid. **A**, These tumors typically show a solid pattern of growth and do not have connective tissue capsules. **B**, Histology demonstrates abundant deposition of amyloid, visible here as homogeneous extracellular material, derived from calcitonin molecules secreted by the neoplastic cells. *(**A**, Courtesy of Dr. Joseph Corson, Brigham and Women's Hospital, Boston, MA.)*

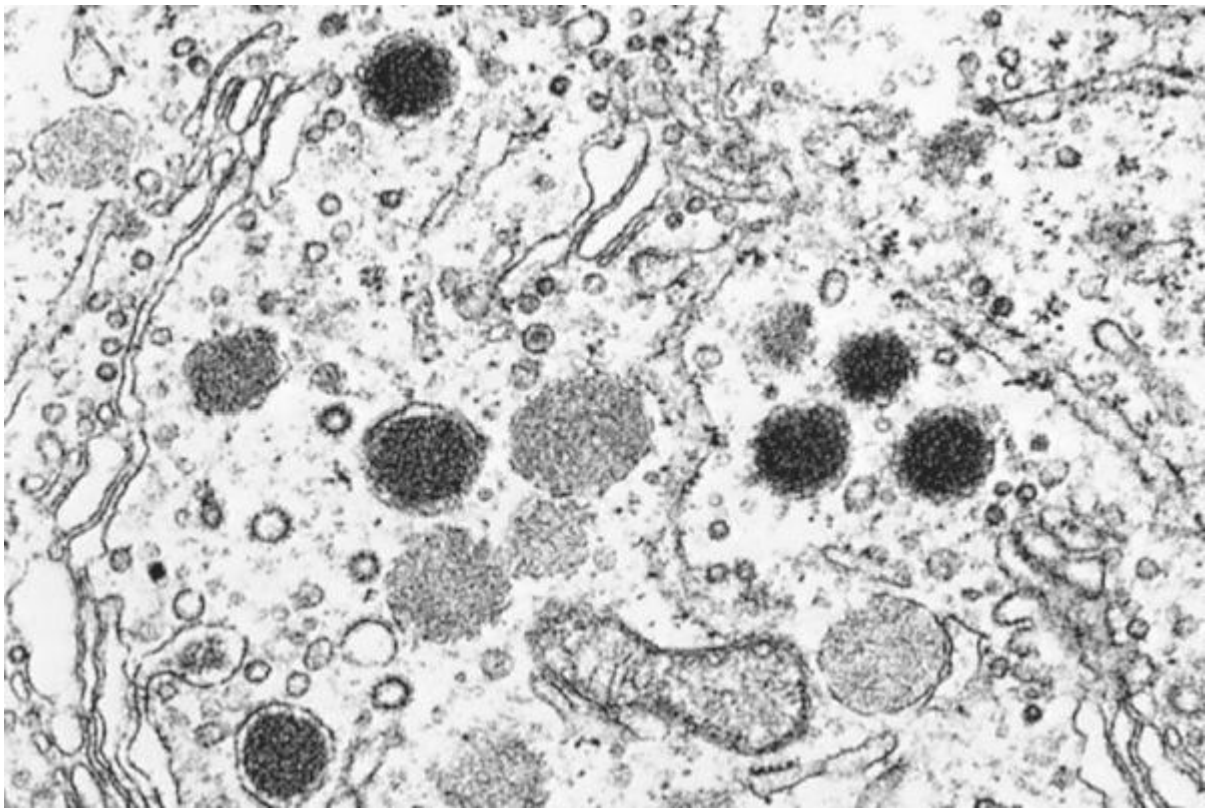

FIGURE 24-23 Electron micrograph of medullary thyroid carcinoma. These cells contain membrane-bound secretory granules that are the sites of storage of calcitonin and other peptides.

Clinical Course.

Sporadic cases of medullary carcinoma come to medical attention most often as a mass in the neck, sometimes associated with local effects such as dysphagia or hoarseness. In some instances, the initial manifestations are those of a paraneoplastic syndrome, caused by the secretion of a peptide hormone (e.g., diarrhea due to the secretion of VIP, or Cushing syndrome due to ACTH). Notably, hypocalcemia is not a prominent feature, despite the presence of raised calcitonin levels. In addition to circulating calcitonin, secretion of carcinoembryonic antigen by the neoplastic cells is a useful biomarker, especially for presurgical assessment of tumor load and in calcitonin-negative tumors. Patients with *familial syndromes* may come to attention because of symptoms localized to the thyroid or as a result of endocrine neoplasms in other organs (e.g., adrenal or parathyroid glands). Medullary carcinomas arising in the context of MEN-2B are generally more aggressive and metastasize more frequently than those occurring in patients with sporadic tumors, MEN-2A, or FMTC. As will be discussed later, all asymptomatic MEN-2 kindred carrying germline *RET* mutations are offered prophylactic thyroidectomy as early as possible to protect against the inevitable development of medullary carcinomas, the major risk factor for poor outcome in these families. Sometimes the only histologic finding in the resected thyroid of asymptomatic carriers is the presence of C-cell hyperplasia or small (<1 cm) "micromedullary" carcinomas. Several promising small-molecule inhibitors of RET tyrosine kinase have recently been developed, and are being tested in individuals with medullary carcinomas.[25]

3.14.2.7 Congenital Anomalies

Thyroglossal duct or cyst is the most common clinically significant congenital anomaly of the thyroid. A persistent sinus tract may remain as a vestigial remnant of the tubular development of the thyroid gland. Parts of this tube may be obliterated, leaving small segments to form cysts. These occur at any age and might not become evident until adult life. Mucinous, clear secretions may collect within these cysts to form either spherical masses or fusiform swellings, rarely over 2 to 3 cm in diameter. These are present in the midline of the neck anterior to the trachea. Segments of the duct and cysts that occur high in the neck are lined by stratified squamous epithelium, which is essentially identical with that covering the posterior portion of the tongue in the region of the foramen cecum. The anomalies that occur in the lower neck more proximal to the thyroid gland are lined by epithelium resembling the thyroidal acinar epithelium. Characteristically, subjacent to the lining epithelium, there is an intense lymphocytic infiltrate. Superimposed infection may convert these lesions into abscess cavities, and rarely, they give rise to cancers.

3.14.3 Parathyroid Glands

The four parathyroid glands are composed mainly of *chief cells*. The chief cells vary from light to dark pink with hematoxylin and eosin stains, depending on their glycogen content. They are polygonal, 12 to 20 μm in diameter, and have central, round, uniform nuclei. In addition, they have secretory granules containing *parathyroid hormone (PTH)*. Sometimes these cells have a *water-clear* appearance due to lakes of glycogen. *Oxyphil cells* and transitional oxyphils are found throughout the normal parathyroid, either singly or in small clusters. They are slightly larger than the chief cells, have acidophilic cytoplasm, and are tightly packed with mitochondria. Glycogen granules are also present in these cells, but secretory granules are sparse or absent. In early infancy and childhood, the parathyroid glands are composed almost entirely of solid sheets of chief cells. The amount of stromal fat increases up to age 25, reaching a maximum of approximately 30% of the gland, and then plateaus.

The activity of the parathyroid glands is controlled by the level of free (ionized) calcium in the bloodstream rather than by trophic hormones secreted by the hypothalamus and pituitary. Normally, decreased levels of free calcium stimulate the synthesis and secretion of PTH. The metabolic functions of PTH in regulating serum calcium levels can be summarized as follows:

- It increases the renal tubular reabsorption of calcium, thereby conserving free calcium.
- It increases the conversion of vitamin D to its active dihydroxy form in the kidneys.
- It increases urinary phosphate excretion, thereby lowering serum phosphate levels.
- It augments gastrointestinal calcium absorption.

The net result of these activities is an increase in the level of free calcium, which, in turn, inhibits further PTH secretion in a classic feedback loop.

Hypercalcemia is one of a number of changes induced by elevated levels of PTH. As was discussed in Chapter 7 , hypercalcemia is also a relatively common complication of malignancy, occurring both with solid tumors, such as lung, breast, head and neck, and renal cancers, and with hematologic malignancies, notably multiple myeloma. In fact, *malignancy is the most common cause of clinically apparent hypercalcemia*, while primary hyperparathyroidism (see below) is a more common cause of asymptomatic elevated blood calcium *(incidental hypercalcemia)*. The prognosis of individuals with malignancy-associated hypercalcemia is generally poor, because it more frequently occurs with advanced cancers. Hypercalcemia of malignancy is due to increased bone resorption and subsequent release of calcium. Bone resorption can occur in tumors that have not metastasized to the bone, as well as in tumors with *osteolytic metastases*. This is because many solid cancers secrete PTH-related protein (PTHrP) (Chapter 7), which promotes the expression of receptor activator of nuclear factor κB ligand

(RANKL) on osteoblasts. RANKL is an osteoclast differentiation factor, which binds to its receptor, RANK, on the surface of osteoclast progenitor cells, and promotes their differentiation into mature osteoclasts, capable of bone resorption. Calcium homeostasis in bones is maintained by the secretion of *osteoprotegerin*, a *decoy receptor* of RANKL, capable of "siphoning" off excess ligand, and thereby preventing unbalanced bone resorption (Chapter 26). PTHrP inhibits osteoprotegerin secretion by osteoblastic cells, thereby altering the RANKL/osteoprotegerin ratio in a direction favoring osteoclastogenesis.[26] Thus, administration of soluble osteoprotegerin and monoclonal antibodies against RANKL have both emerged as promising therapeutic strategies in cancer patients with hypercalcemia of malignancy.

Similar to the other endocrine organs, abnormalities of the parathyroid glands include both hyperfunction and hypofunction. Tumors of the parathyroid glands, in contrast to thyroid tumors, usually come to attention because of excessive secretion of PTH rather than mass effects.

3.14.3.1 Hyperparathyroidism

Hyperparathyroidism occurs in two major forms—*primary* and *secondary*—and, less commonly, *tertiary*. The first condition represents an autonomous, spontaneous overproduction of PTH; the latter two conditions typically occur as secondary phenomena in individuals with chronic renal insufficiency.

PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is one of the most common endocrine disorders, and it is an important cause of *hypercalcemia*. The frequency of the various parathyroid lesions underlying the hyperfunction is as follows:

- Adenoma: 85% to 95%
- Primary hyperplasia (diffuse or nodular): 5% to 10%
- Parathyroid carcinoma: ~1%

Primary hyperparathyroidism is usually a disease of adults and is more common in women than in men by a ratio of nearly 4 : 1. The annual incidence is now estimated to be about 25 cases per 100,000 in the United States and Europe; as many as 80% of patients with this condition are identified in the outpatient setting, when hypercalcemia is discovered incidentally on a serum electrolyte panel. Most cases occur in the 50s or later in life.

The most common cause of primary hyperparathyroidism is a solitary parathyroid adenoma arising in the sporadic (nonfamilial) setting (Fig. 24-24). Although familial syndromes are a distant second, they have provided a unique insight into the pathogenesis of primary hyperparathyroidism. The genetic syndromes associated with *familial primary hyperparathyroidism* include the following:

- *Multiple endocrine neoplasia-1 (MEN-1):* The *MEN1* gene on chromosome 11q13 is a tumor suppressor gene inactivated in a variety of MEN-1–related parathyroid lesions, including parathyroid adenomas and hyperplasia. In addition to familial cases, *MEN1* mutations have also been described in sporadic parathyroid tumors. The MEN-1 syndrome is discussed in further detail below.
- *Multiple endocrine neoplasia-2 (MEN-2):* The MEN-2 syndrome is caused by activating mutations in the tyrosine kinase receptor, *RET*, on chromosome 10q. Primary hyperparathyroidism occurs as a component of MEN-2A, which is discussed in further detail below. *RET* mutations have not been described in sporadic parathyroid lesions outside the context of MEN-2.
- *Familial hypocalciuric hypercalcemia* is an autosomaldominant disorder characterized by enhanced parathyroid function due to decreased sensitivity to extracellular calcium. Inactivating mutations in the

parathyroid *calcium-sensing receptor gene* (*CASR*) on chromosome 3q are a primary cause for this disorder.[27] *CASR* mutations have not been described in sporadic parathyroid tumors.

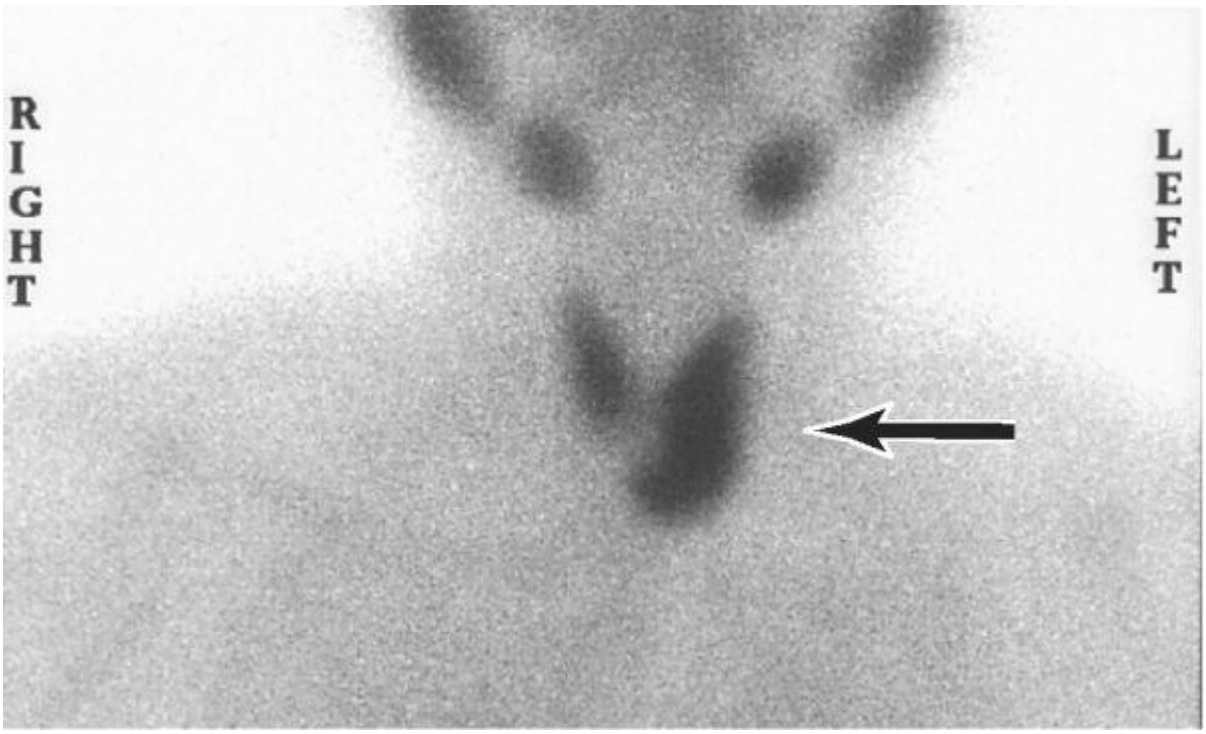

FIGURE 24-24 Parathyroid adenomas are almost always solitary lesions. Technetium-99m-sestamibi radionuclide scan demonstrates an area of increased uptake corresponding to the left inferior parathyroid gland *(arrow)*. This person had a parathyroid adenoma. Preoperative scintigraphy is useful in localizing and distinguishing adenomas from parathyroid hyperplasia, where more than one gland would demonstrate increased uptake.

Most, if not all, *sporadic parathyroid adenomas* are monoclonal, suggesting that they are true neoplasms. Sporadic parathyroid hyperplasia is also monoclonal in many instances, particularly when associated with a persistent stimulus for parathyroid growth (refractory secondary or tertiary parathyroidism; see below). Among the sporadic adenomas there are two molecular defects that have an established role in pathogenesis:

- *Cyclin D1 gene inversions*. Cyclin D1 is a major regulator of the cell cycle. A pericentromeric inversion on chromosome 11 results in relocation of the *cyclin D1* gene (normally on 11q), so that it is positioned adjacent to the 5′-flanking region of the *PTH* gene (on 11p). As a consequence of these changes, a regulatory element from the *PTH* gene 5′-flanking sequence directs overexpression of cyclin D1 protein, forcing the cells to proliferate. Between 10% and 20% of adenomas have this clonal genetic defect. In addition, cyclin D1 is overexpressed in approximately 40% of parathyroid adenomas, suggesting that mechanisms other than *cyclin D1* gene inversion can lead to its activation.
- *MEN1 mutations:* Approximately 20% to 30% of parathyroid tumors not associated with the MEN-1 syndrome have mutations in both copies of the *MEN1* gene. The spectrum of *MEN1* mutations in the sporadic tumors is virtually identical to that in familial parathyroid adenomas.

Morphology. The morphologic changes seen in primary hyperparathyroidism include those in the parathyroid glands as well as those in other organs affected by elevated levels of PTH and calcium. Parathyroid **adenomas** are almost always solitary and, similar to the normal parathyroid glands, may

lie in close proximity to the thyroid gland or in an ectopic site (e.g., the mediastinum). The typical parathyroid adenoma averages 0.5 to 5.0 gm; is a well-circumscribed, soft, tan to reddish-brown nodule; and is invested by a delicate capsule. In contrast to primary hyperplasia, the glands outside the adenoma are usually normal in size or somewhat shrunken because of feedback inhibition by elevated levels of serum calcium. Microscopically, parathyroid adenomas are mostly composed of fairly uniform, polygonal chief cells with small, centrally placed nuclei (Fig. 24-25). At least a few nests of larger oxyphil cells are present as well; uncommonly, entire adenomas may be composed of this cell type **(oxyphil adenomas)**. These may resemble Hürthle cell tumors in the thyroid. A rim of compressed, non-neoplastic parathyroid tissue, generally separated by a fibrous capsule, is often visible at the edge of the adenoma. Mitotic figures are rare, but it is not uncommon to find bizarre and pleomorphic nuclei even within adenomas (so-called **endocrine atypia**); this is not a criterion for malignancy. In contrast to the normal parathyroid parenchyma, adipose tissue is inconspicuous.

Primary hyperplasia may occur sporadically or as a component of MEN syndrome. Although classically all four glands are involved, there is frequently asymmetry with apparent sparing of one or two glands, making the distinction between hyperplasia and adenoma difficult. The combined weight of all glands rarely exceeds 1.0 gm and is often less. Microscopically, the most common pattern seen is that of chief cell hyperplasia, which may involve the glands in a diffuse or multinodular pattern. Less commonly, the constituent cells contain abundant water-clear cells ("water-clear cell hyperplasia"). In many instances there are islands of oxyphils, and poorly developed, delicate fibrous strands may envelop the nodules. As in the case of adenomas, stromal fat is inconspicuous within the foci of hyperplasia.

Parathyroid carcinomas may be circumscribed lesions that are difficult to distinguish from adenomas, or they may be clearly invasive neoplasms. These tumors enlarge one parathyroid gland and consist of gray-white, irregular masses that sometimes exceed 10 gm in weight. The cells are usually uniform and resemble normal parathyroid cells. They are arrayed in nodular or trabecular patterns with a dense, fibrous capsule enclosing the mass. There is general agreement that a **diagnosis of carcinoma based on cytologic detail is unreliable, and invasion of surrounding tissues and metastasis are the only reliable criteria**. Local recurrence occurs in one third of cases, and more distant dissemination occurs in another third.

Morphologic changes in other organs deserving special mention include skeletal and renal lesions. **Skeletal changes** include increased numbers of osteoclasts, which erode bone matrix and mobilize calcium salts, particularly in the metaphyses of long tubular bones. Bone resorption is accompanied by increased osteoblastic activity and the formation of new bony trabeculae. In many cases the resultant bone contains widely spaced, delicate trabeculae reminiscent of those seen in osteoporosis. In more severe cases the cortex is grossly thinned, and the marrow contains increased amounts of fibrous tissue accompanied by foci of hemorrhage and cyst formation **(osteitis fibrosa cystica)** (Chapter 26). Aggregates of osteoclasts, reactive giant cells, and hemorrhagic debris occasionally form masses that may be mistaken for neoplasms (**brown tumors** of hyperparathyroidism). PTH-induced hypercalcemia favors formation of **urinary tract stones** (nephrolithiasis) as well as calcification of the renal interstitium and tubules (nephrocalcinosis). Metastatic calcification secondary to hypercalcemia may also be seen in other sites, including the stomach, lungs, myocardium, and blood vessels.

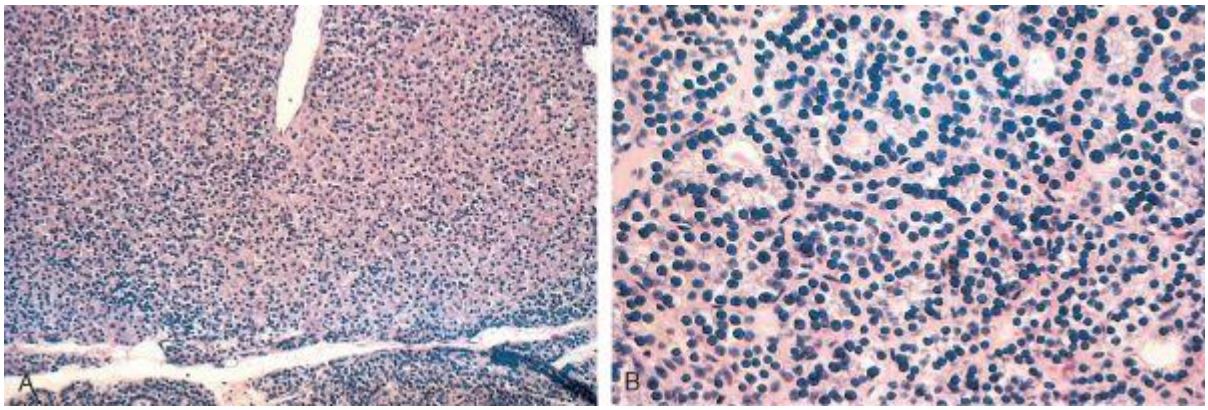

FIGURE 24-25 Parathyroid adenoma. **A**, Solitary chief cell parathyroid adenoma (low-power photomicrograph) revealing clear delineation from the residual gland below. **B**, High-power detail of a chief cell parathyroid adenoma. There is some slight variation in nuclear size but no anaplasia and some slight tendency to follicular formation.

Clinical Course.

Primary hyperparathyroidism may be: (1) asymptomatic and identified after a routine chemistry profile, or (2) associated with the classic clinical manifestations of primary hyperparathyroidism.

Asymptomatic Hyperparathyroidism.

Because serum calcium levels are routinely assessed in the work-up of most patients who need blood tests, clinically silent hyperparathyroidism is often detected early. Hence, many of the classic manifestations, particularly those referable to bone and renal disease, are now seen infrequently in clinical practice. Primary hyperparathyroidism is the most common cause of *asymptomatic* hypercalcemia and indeed the most common manifestation of primary hyperparathyroidism is hypercalcemia. Among many other less common causes of hypercalcemia (Table 24-5), malignancy stands out as the most frequent cause of *clinically apparent* hypercalcemia in adults and must be excluded by appropriate clinical and laboratory investigations in patients with suspected hyperparathyroidism. *In individuals with primary hyperparathyroidism, serum PTH levels are inappropriately elevated for the level of serum calcium, whereas PTH levels are low to undetectable in hypercalcemia caused by of nonparathyroid diseases* (see Table 24-5). In persons with hypercalcemia caused by secretion of PTHrP by certain nonparathyroid tumors, radioimmunoassays specific for PTH and PTHrP can distinguish between the two molecules. Other laboratory alterations referable to PTH excess include hypophosphatemia and increased urinary excretion of both calcium and phosphate. Secondary renal disease may lead to phosphate retention with normalization of serum phosphates.

TABLE 24-5 -- Causes of Hypercalcemia

Raised [PTH]	Decreased [PTH]
Hyperparathyroidism	Hypercalcemia of malignancy[*]
Primary (adenoma > hyperplasia)[*]	Vitamin D toxicity
Secondary[†]	Immobilization
Tertiary[†]	Thiazide diuretics
Familial hypocalciuric hypercalcemia	Granulomatous disease (sarcoidosis)

[PTH], parathyroid hormone concentration.

* Primary hyperparathyroidism is the most common cause of hyper-calcemia overall. Malignancy is the most common cause of *symptomatic* hypercalcemia. Primary hyperparathyroidism and malignancy account for nearly 90% of cases of hypercalcemia.

† Secondary and teriary hyperparathyroidism are most commonly associated with progressive renal failure.

Symptomatic Primary Hyperparathyroidism.

The signs and symptoms of hyperparathyroidism reflect the combined effects of increased PTH secretion and hypercalcemia. Primary hyperparathyroidism is associated with "painful bones, renal stones, abdominal groans, and psychic moans." The constellation of symptoms includes:

- *Bone disease* and bone pain secondary to fractures of bones weakened by osteoporosis or osteitis fibrosa cystica.
- *Nephrolithiasis* (renal stones) in 20% of newly diagnosed patients, with attendant pain and obstructive uropathy. Chronic renal insufficiency and abnormalities in renal function lead to polyuria and secondary polydipsia.
- Gastrointestinal disturbances, including constipation, nausea, peptic ulcers, pancreatitis, and gallstones.
- Central nervous system alterations, including depression, lethargy, and eventually seizures.
- Neuromuscular abnormalities, including weakness and fatigue.
- Cardiac manifestations, including aortic or mitral valve calcifications (or both).

The abnormalities most directly related to hyperparathyroidism are nephrolithiasis and bone disease, whereas those attributable to hypercalcemia include fatigue, weakness, and constipation. The pathogenesis of many of the other manifestations of the disorder remains poorly understood.

SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism is caused by any condition that gives rise to chronic hypocalcemia, which in turn leads to compensatory overactivity of the parathyroid glands. *Renal failure is by far the most common cause of secondary hyperparathyroidism*, although several other diseases, including inadequate dietary intake of calcium, steatorrhea, and vitamin D deficiency, may also cause this disorder. The mechanisms by which chronic renal failure induces secondary hyperparathyroidism are complex and not fully understood. Chronic renal insufficiency is associated with decreased phosphate excretion, which in turn results in hyperphosphatemia. The elevated serum phosphate levels directly depress serum calcium levels and thereby stimulate parathyroid gland activity. In addition, loss of renal substance reduces the availability of α-1-hydroxylase necessary for the synthesis of the active form of vitamin D, which in turn reduces intestinal absorption of calcium (Chapter 9). Because vitamin D has suppressive effects on parathyroid growth and PTH secretion, its relative deficiency compounds the hyperparathyroidism in renal failure.

Morphology. The **parathyroid glands in secondary hyperparathyroidism are hyperplastic**. As in primary hyperparathyroidism, the degree of glandular enlargement is not necessarily symmetric. Microscopically, the hyperplastic glands contain an increased number of chief cells, or cells with more abundant, clear cytoplasm (so-called water-clear cells) in a diffuse or multinodular distribution. Fat cells are decreased in number. **Bone changes** similar to those seen in primary hyperparathyroidism may also be present. **Metastatic calcification** may be seen in many tissues,

including lungs, heart, stomach, and blood vessels.

Clinical Course.

The clinical features of secondary hyperparathyroidism are usually dominated by symptoms of chronic renal failure. Bone abnormalities *(renal osteodystrophy)* and other changes associated with PTH excess are, in general, less severe than are those seen in primary hyperparathyroidism. The vascular calcification associated with secondary hyperparathyroidism may occasionally result in significant ischemic damage to skin and other organs, a process sometimes referred to as *calciphylaxis*. Patients with secondary hyperparathyroidism often respond to dietary vitamin D supplementation, as well as phosphate binders to decrease the prevailing hyperphosphatemia.

In a minority of patients, parathyroid activity may become autonomous and excessive, with resultant hypercalcemia, a process that is sometimes termed *tertiary hyperparathyroidism*. Parathyroidectomy may be necessary to control the hyperparathyroidism in such patients.

3.14.3.2 Hypoparathyroidism

Hypoparathyroidism is far less common than is hyperparathyroidism. Acquired hypoparathyroidism is almost always an inadvertent consequence of surgery; in addition, there are several genetic causes of hypoparathyroidism.

- *Surgically induced hypoparathyroidism* occurs with inadvertent removal of all the parathyroid glands during thyroidectomy, excision of the parathyroid glands in the mistaken belief that they are lymph nodes during radical neck dissection for some form of malignant disease, or removal of too large a proportion of parathyroid tissue in the treatment of primary hyperparathyroidism.
- *Autoimmune hypoparathyroidism* is often associated with chronic mucocutaneous candidiasis and primary adrenal insufficiency; this syndrome is known as autoimmune polyendocrine syndrome type 1 (APS1) and is caused by mutations in the *autoimmune regulator (AIRE)* gene. The syndrome typically presents in childhood with the onset of candidiasis, followed several years later by hypoparathyroidism and then adrenal insufficiency during adolescence. APS1 is discussed further under “Adrenal Glands.”
- *Autosomal-dominant hypoparathyroidism* is caused by gain-of-function mutations in the *calcium-sensing receptor* (*CASR*) gene. Inappropriate CASR activity due to abnormal calcium sensing suppresses PTH, resulting in *hypocalcemia* and *hypercalciuria*.
- *Familial isolated hypoparathyroidism* (FIH) is a rare condition with either autosomal dominant or autosomal recessive patterns of inheritance. Autosomal-dominant FIH is caused by a mutation in the gene encoding PTH precursor peptide, which impairs its processing to the mature hormone. Autosomal-recessive FIH is caused by loss-of-function mutations in the transcription factor gene *glial cells missing-2* (*GCM2*), which is essential for development of the parathyroid.
- *Congenital absence* of parathyroid glands can occur in conjunction with other malformations, such as thymic aplasia and cardiovascular defects, or as a component of the 22q11 deletion syndrome.[28] As discussed in Chapter 5 , when thymic defects are present, the condition is called DiGeorge syndrome.

The major clinical manifestations of hypoparathyroidism are related to the severity and chronicity of the hypocalcemia.

- The hallmark of hypocalcemia is *tetany*, which is characterized by *neuromuscular irritability*, resulting from decreased serum ionized calcium concentration. These symptoms range from circumoral numbness or paresthesias (tingling) of the distal extremities and carpopedal spasm, to life-threatening laryngospasm and generalized seizures. The classic findings on physical examination are *Chvostek sign* and *Trousseau sign*. Chvostek sign is elicited in subclinical disease by tapping along the course of the facial nerve, which induces contractions of the muscles of the eye, mouth, or nose. Trousseau sign refers to carpal spasms produced by occlusion of the circulation to the forearm and hand with a blood pressure cuff for several minutes.
- *Mental status changes* include emotional instability, anxiety and depression, confusional states, hallucinations, and frank psychosis.

- *Intracranial manifestations* include calcifications of the basal ganglia, parkinsonian-like movement disorders, and increased intracranial pressure with resultant papilledema. The paradoxical association of hypocalcemia with calcifications may be because of an increase in phosphate levels, resulting in tissue deposits with locally produced calcium.
- *Ocular disease* takes the form of calcification of the lens and cataract formation.
- *Cardiovascular manifestations* include a conduction defect that produces a characteristic prolongation of the QT interval in the electrocardiogram.
- *Dental abnormalities* occur when hypocalcemia is present during early development. These findings are highly characteristic of hypoparathyroidism and include dental hypoplasia, failure of eruption, defective enamel and root formation, and abraded carious teeth.

3.14.3.3 Pseudohypoparathyroidism

In this condition, hypoparathyroidism occurs because of end-organ resistance to the actions of PTH. Indeed, serum PTH levels are normal or elevated. In one form of pseudohypoparathyroidism, there is multi-hormone end-organ resistance to TSH and FSH/LH, besides PTH. All these hormones signal via G-protein–triggered second messengers, and the disorder results from genetic defects in this pathway. The PTH resistance is the most obvious clinical manifestation, presenting as hypocalcemia, hyperphosphatemia, and elevated circulating PTH. TSH resistance is generally mild, while LH/FSH resistance manifests as hypergonadotropic hypogonadism in females.

3.14.4 The Endocrine Pancreas

The endocrine pancreas consists of about 1 million clusters of cells, the *islets of Langerhans*, which contain four major and two minor cell types. The four main types are β, α, δ, and PP (pancreatic polypeptide) cells. They can be differentiated by the ultrastructural characteristics of their granules, and by their hormone content (Fig. 24-26). *The* β *cell produces insulin*, as will be detailed in the discussion of diabetes. The insulin-containing intracellular granules contain a rectangular crystalline matrix, surrounded by a halo. *The* α *cell secretes glucagon*, inducing hyperglycemia by its glycogenolytic activity in the liver. α-cell granules are round, with closely applied membranes and a dense center. δ cells contain somatostatin, which suppresses both insulin and glucagon release; they have large, pale granules with closely applied membranes. *PP cells contain a unique pancreatic polypeptide* that exerts several gastrointestinal effects, such as stimulation of secretion of gastric and intestinal enzymes and inhibition of intestinal motility. These cells have small, dark granules and not only are present in islets but also are scattered in the exocrine pancreas. The two rare cell types are *D1 cells* and *enterochromaffin cells*. D1 cells elaborate vasoactive intestinal polypeptide (*VIP*), a hormone that induces glycogenolysis and hyperglycemia; it also stimulates gastrointestinal fluid secretion and causes secretory diarrhea. *Enterochromaffin cells synthesize serotonin* and are the source of pancreatic tumors that cause the carcinoid syndrome (Chapter 19).

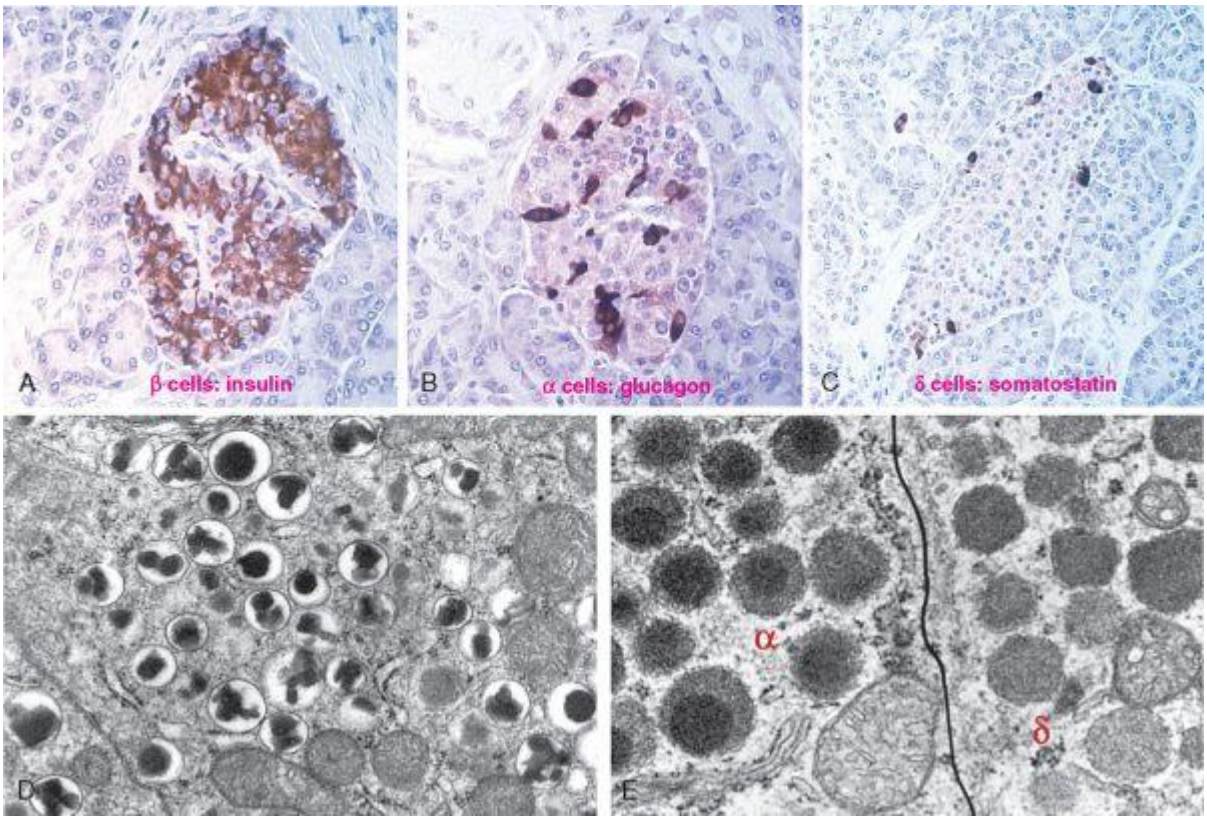

FIGURE 24-26 Hormone production in pancreatic islet cells. Immunoperoxidase staining shows a dark reaction product for insulin in β cells (**A**), glucagon in α cells (**B**), and somatostatin in δ cells (**C**). **D**, Electron micrograph of a β cell shows the characteristic membrane-bound granules, each containing a dense, often rectangular core and distinct halo. **E**, Portions of an α cell *(left)* and a δ cell *(right)* also show granules, but with closely apportioned membranes. The α-cell granule shows a dense, round center. *(Electron micrographs courtesy of Dr. Arthur Like, University of Massachusetts Medical School, Worcester, MA.)*

3.14.4.1 Diabetes Mellitus

Diabetes mellitus is not a single disease entity but rather a *group of metabolic disorders sharing the common underlying feature of hyperglycemia*. Hyperglycemia in diabetes results from defects in insulin secretion, insulin action, or, most commonly, both. The chronic hyperglycemia and attendant metabolic dysregulation may be associated with secondary damage in multiple organ systems, especially the kidneys, eyes, nerves, and blood vessels. According to the American Diabetes Association, diabetes affects over 20 million children and adults, or 7% of the population, in the United States, nearly a third of whom are currently unaware that they have hyperglycemia. Approximately 1.5 million new cases of diabetes are diagnosed each year in the United States, and diabetes is the leading cause of end-stage renal disease, adult-onset blindness, and nontraumatic lower extremity amputations. A staggering 54 million adults in this country have “pre-diabetes,” which is defined as elevated blood sugar that does not reach the criterion accepted for an outright diagnosis of diabetes (see below); individuals with pre-diabetes have an elevated risk for developing frank diabetes. Compared to non-Hispanic whites, Native Americans, African Americans, and Hispanics are 1.5 to 2 times more likely to develop diabetes over their lifetime. The total number of people with diabetes worldwide was estimated to be between 151 million and 171 million at the turn of the century, and is expected to rise to 366 million by 2030. The prevalence of diabetes is increasingly sharply in the developing world as people adopt more sedentary life styles, with India and China being the largest contributors to the world's diabetic load.

DIAGNOSIS

Blood glucose values are normally maintained in a very narrow range, usually 70 to 120 mg/dL. *The diagnosis of diabetes is established by noting elevation of blood glucose by any one of three criteria:*

1. A random glucose concentration greater than 200 mg/dL, with classical signs and symptoms (discussed below)
2. A fasting glucose concentration greater than 126 mg/dL on more than one occasion
3. An abnormal oral glucose tolerance test (OGTT), in which the glucose concentration is greater than 200 mg/dL 2 hours after a standard carbohydrate load

Levels of blood glucose proceed along a continuum. Individuals with fasting glucose concentrations less than 100 mg/dL, or less than 140 mg/dL following an OGTT, are considered to be euglycemic. However, those with fasting glucose concentrations greater than 100 mg/dL but less than 126 mg/dL, or OGTT values greater than 140 mg/dL but less than 200 mg/dL, are considered to have impaired glucose tolerance, also known as "pre-diabetes." Pre-diabetic individuals have a significant risk of progressing to overt diabetes over time, with as many as 5% to 10% advancing to diabetes mellitus per year. In addition, pre-diabetics are at risk for cardiovascular disease, as a result of the abnormal carbohydrate metabolism as well as the coexistence of other risk factors such as low levels of high-density lipoprotein, hypertriglyceridemia, and increased plasminogen activator inhibitor-1 (PAI-1) (see Chapter 11).

CLASSIFICATION

Although all forms of diabetes mellitus share hyperglycemia as a common feature, the underlying abnormalities involved in the development of hyperglycemia vary widely. The previous classification schemes of diabetes mellitus were based on the age at onset of the disease or on the mode of therapy; in contrast, the etiologic classification reflects our greater understanding of the pathogenesis of each variant (Table 24-6). *The vast majority of cases of diabetes fall into one of two broad classes:*

TABLE 24-6 -- Classification of Diabetes Mellitus

1.	**Type 1 diabetes** (β-cell destruction, usually leading to absolute insulin deficiency) Immune-mediated Idiopathic
2.	**Type 2 diabetes** (combination of insulin resistance and β-cell dysfunction)
3.	**Genetic defects of β-cell function** Maturity-onset diabetes of the young (MODY), caused by mutations in: Hepatocyte nuclear factor 4α (*HNF4A*), MODY1 Glucokinase (*GCK*), MODY2 Hepatocyte nuclear factor 1α (*HNF1A*), MODY3 Pancreatic and duodenal homeobox 1 (*PDX1*), MODY4 Hepatocyte nuclear factor 1β (*HNF1B*), MODY5 Neurogenic differentiation factor 1 (*NEUROD1*), MODY6 Neonatal diabetes (activating mutations in *KCNJ11* and *ABCC8*, encoding Kir6.2 and SUR1, respectively) Maternally inherited diabetes and deafness (MIDD) due to mitochondrial DNA mutations (m.3243A→G)

	Defects in proinsulin conversion
	Insulin gene mutations
4.	**Genetic defects in insulin action**
	Type A insulin resistance
	Lipoatrophic diabetes, including mutations in *PPARG*
5.	**Exocrine pancreatic defects**
	Chronic pancreatitis
	Pancreatectomy/trauma
	Neoplasia
	Cystic fibrosis
	Hemachromatosis
	Fibrocalculous pancreatopathy
6.	**Endocrinopathies**
	Acromegaly
	Cushing syndrome
	Hyperthyroidism
	Pheochromocytoma
	Glucagonoma
7.	**Infections**
	Cytomegalovirus
	Coxsackie B virus
	Congenital rubella
8.	**Drugs**
	Glucocorticoids
	Thyroid hormone
	Interferon-α
	Protease inhibitors
	β-adrenergic agonists
	Thiazides
	Nicotinic acid
	Phenytoin (Dilantin)
	Vacor
9.	**Genetic syndromes associated with diabetes**
	Down syndrome
	Kleinfelter syndrome
	Turner syndrome

	Prader-Willi syndrome
10.	**Gestational diabetes mellitus**

American Diabetes Association: Position statement from the American Diabetes Association on the diagnosis and classification of diabetes mellitus. Diabetes Care 31 (Suppl. 1):S55–S60, 2008.

Type 1 diabetes is an autoimmune disease characterized by pancreatic β-cell destruction and an absolute deficiency of insulin. It accounts for approximately 5% to 10% of all cases, and is the most common subtype diagnosed in patients younger than 20 years of age.

Type 2 diabetes is caused by a combination of peripheral resistance to insulin action and an inadequate secretory response by the pancreatic β cells (“relative insulin deficiency”). Approximately 90% to 95% of diabetic patients have type 2 diabetes, and the vast majority of such individuals are overweight. Although classically considered “adult-onset,” the prevalence of type 2 diabetes in children and adolescents is increasing at an alarming pace.[29]

A variety of monogenic and secondary causes are responsible for the remaining cases, and these will be discussed later. It should be stressed that while the major types of diabetes have different pathogenic mechanisms, *the long-term complications affecting the kidneys, eyes, nerves, and blood vessels are the same, as are the principal causes of morbidity and death*. The pathogenesis of the two major types is discussed separately, but first we briefly review normal insulin secretion and the mechanism of insulin signaling, since these aspects are critical to understanding the pathogenesis of diabetes.

GLUCOSE HOMEOSTASIS

Normal glucose homeostasis is tightly regulated by three interrelated processes: glucose production in the liver; glucose uptake and utilization by peripheral tissues, chiefly skeletal muscle; and actions of insulin and counter-regulatory hormones, including glucagon, on glucose uptake and metabolism.

Insulin and glucagon have opposing regulatory effects on glucose homeostasis. During fasting states, low insulin and high glucagon levels facilitate hepatic gluconeogenesis and glycogenolysis (glycogen breakdown) while decreasing glycogen synthesis, thereby preventing hypoglycemia. Thus, fasting plasma glucose levels are determined primarily by hepatic glucose output. Following a meal, insulin levels rise and glucagon levels fall in response to the large glucose load. Insulin promotes glucose uptake and utilization in tissues (discussed later). The skeletal muscle is the major insulin-responsive site for postprandial glucose utilization, and is critical for preventing hyperglycemia and maintaining glucose homeostasis.

Regulation of Insulin Release

The insulin gene is expressed in the β cells of the pancreatic islets (see Fig. 24-26). Preproinsulin is synthesized in the rough endoplasmic reticulum from insulin mRNA and delivered to the Golgi apparatus. There, a series of proteolytic cleavage steps generate mature insulin and a cleavage peptide, *C-peptide*. Both insulin and C-peptide are then stored in secretory granules and secreted in equimolar quantities after physiologic stimulation; thus, C-peptide levels serve as a surrogate for β-cell function, decreasing with loss of β-cell mass in type 1 diabetes, or increasing with insulin resistance–associated hyperinsulinemia.

The most important stimulus for insulin synthesis and release is glucose itself.[30] A rise in blood glucose levels results in glucose uptake into pancreatic β cells, facilitated by an insulinindependent glucose-transporter, GLUT-2 (Fig. 24-27). β cells express an ATP-sensitive K+ channel on the membrane, which comprises two subunits: an inward rectifying K+ channel (Kir6.2) and the sulfonylurea receptor (SUR1), the latter being the binding site for oral hypoglycemic agents (sulfonylureas) used in the treatment of diabetes (see below). Metabolism of glucose by glycolysis generates ATP, resulting in an increase in β-cell cytoplasmic ATP/ADP ratios. This inhibits the activity of the ATP-sensitive K+ channel, leading to membrane depolarization and the influx of extracellular $Ca^{[2]+}$ through voltage-dependent $Ca^{[2]+}$ channels. The resultant increase in intracellular $Ca^{[2]+}$ stimulates secretion of insulin, presumably from stored hormone within the β-cell granules. This is the phase of *immediate release of insulin*. If the secretory stimulus persists, a delayed and protracted response follows that involves *active synthesis of insulin*. Other factors, including intestinal hormones and certain amino acids (leucine and arginine), also stimulate insulin release, but not its synthesis.

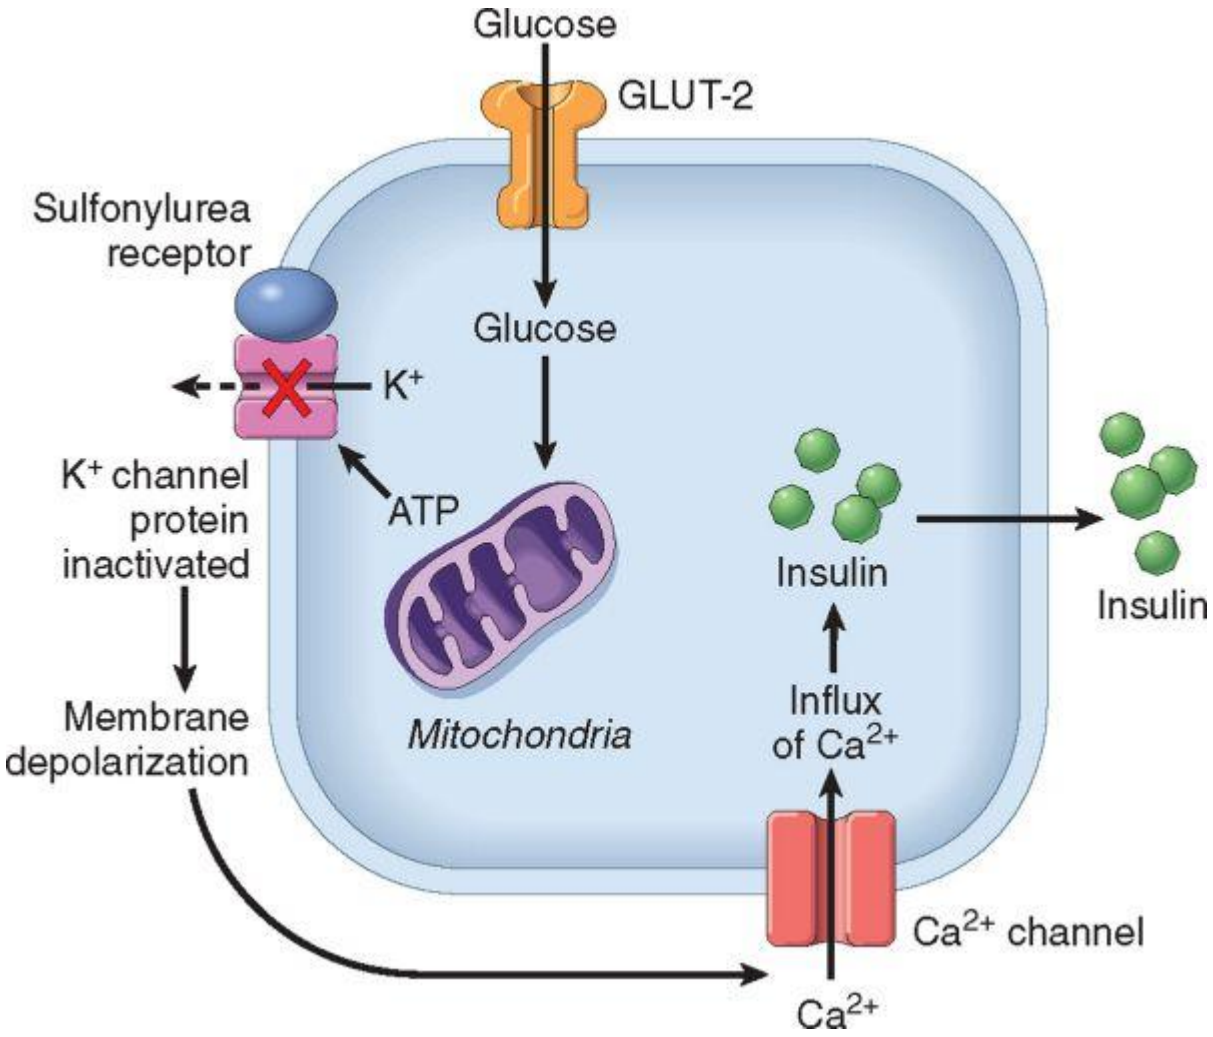

FIGURE 24-27 Insulin synthesis and secretion. Intracellular transport of glucose is mediated by GLUT-2, an insulin-independent glucose transporter in β cells. Glucose undergoes oxidative metabolism in the β cell to yield ATP. ATP inhibits an inward rectifying K+ channel receptor on the β-cell surface; the receptor itself is a dimeric complex of the sulfonylurea receptor (SUR1) and a K+-channel protein (Kir6.2). Inhibition of this receptor leads to membrane depolarization, influx of $Ca^{[2]+}$ ions, and release of stored insulin from β cells. The sulfonylurea class of oral hypoglycemic agents bind to the SUR1 receptor protein.

Insulin is the most potent anabolic hormone known, with multiple synthetic and growth-promoting effects (Fig. 24-28).[31] *Its principal metabolic function is to increase the rate of glucose transport into certain cells in the body, thus providing an increased source of energy*. These cells are the *striated muscle cells* (including myocardial cells) and to a lesser extent, *adipocytes*, which together represent about two thirds of the entire body weight. Glucose uptake in other peripheral tissues, most notably the brain, is insulin independent. In muscle cells, glucose is then either stored as glycogen or oxidized to generate ATP. In adipose tissue, glucose is primarily stored as lipid. Besides promoting lipid synthesis, insulin also inhibits lipid degradation in adipocytes. Similarly, insulin promotes amino acid uptake and protein synthesis, while inhibiting protein degradation. *Thus, the anabolic effects of insulin are attributable to increased synthesis and reduced degradation of glycogen, lipids, and proteins*. In addition, insulin has several *mitogenic* functions, including initiation of DNA synthesis in certain cells and stimulation of their growth and differentiation.

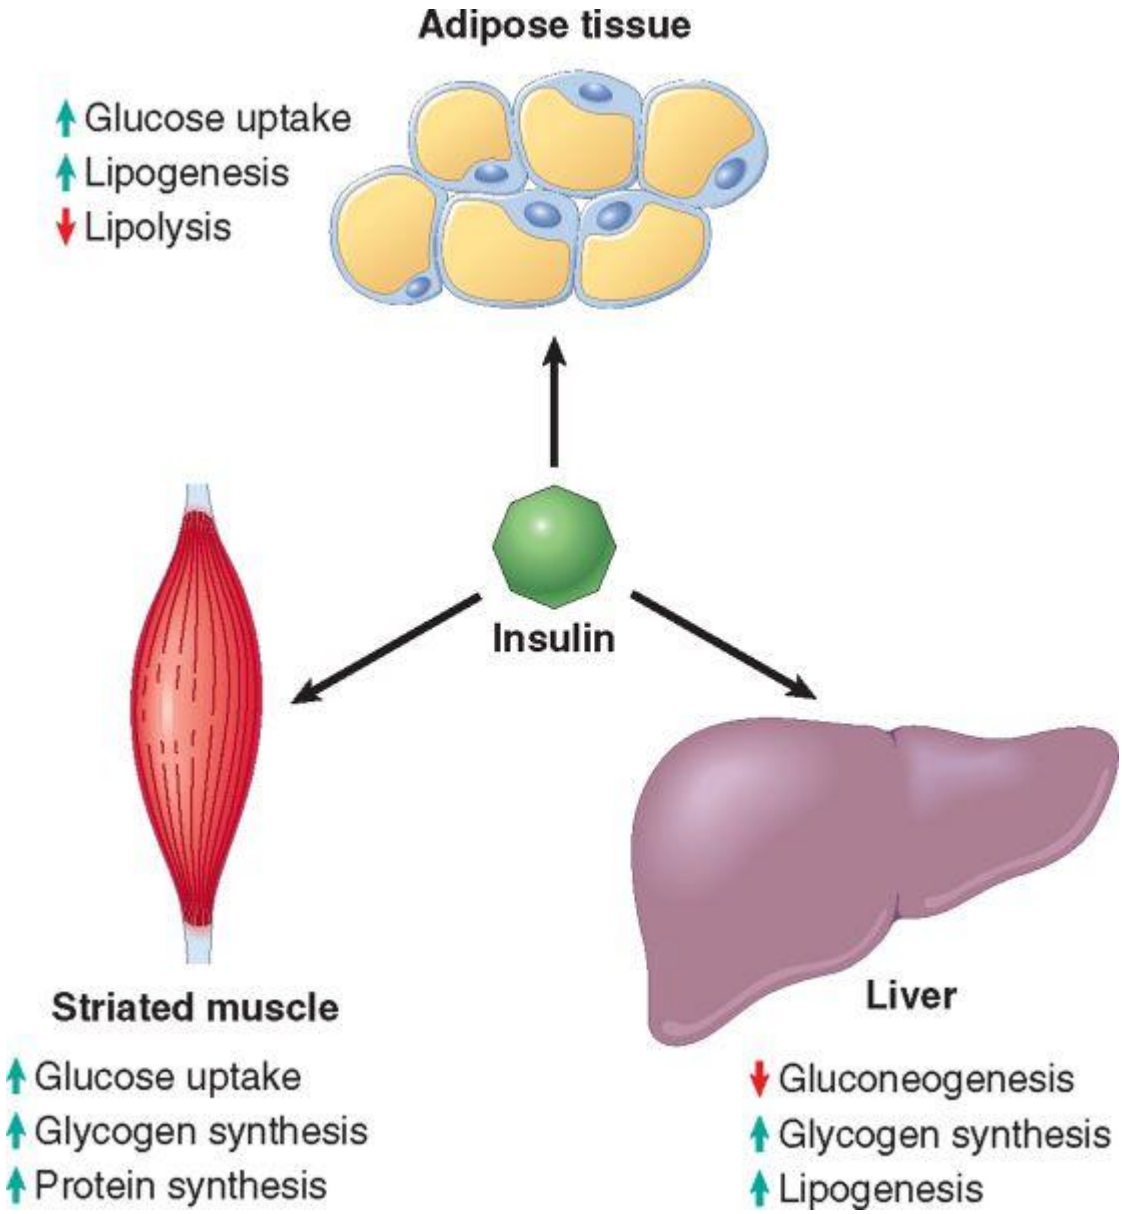

FIGURE 24-28 Metabolic actions of insulin in striated muscle, adipose tissue, and liver.

Elucidation of the insulin signaling pathway has been central to our understanding of the pathogenesis of diabetes. The complete description of this intricate network is beyond the scope of this book, and we will only summarize some of the more pertinent mediators (Fig. 24-29). The *insulin receptor* is a tetrameric protein composed of two α- and two βsubunits. The β-subunit cytosolic domain possesses tyrosine kinase activity. Insulin binding to the α-subunit extracellular domain activates the β-subunit tyrosine kinase, resulting in autophosphorylation of the receptor and the phosphorylation (activation) of several intracellular substrate proteins, such as the family of insulin receptor substrate (IRS) proteins, which includes IRS1–IRS4 and GAB1. The substrate proteins, in turn, activate multiple downstream signaling cascades, including the PI-3K and the MAP kinase pathways, which mediate the metabolic and mitogenic activities of insulin on the cell. Insulin signaling facilitates the trafficking and docking of vesicles containing the glucose transporter protein GLUT-4 to the plasma membrane, which promotes glucose uptake. This process is mediated by AKT, the principal effector of the PI-3K pathway, but also independently by the cytoplasmic protein CBL, which is a direct phosphorylation target of the insulin receptor. Insulin signaling is attenuated in vivo by several endogenous inhibitors that act along components of the pathway. For example, protein tyrosine phosphatase 1B (PTPN1B) dephosphorylates the insulin receptor and inhibits insulin signaling. The phosphatase PTEN can attenuate insulin signaling by blocking AKT activation by the PI-3K pathway.

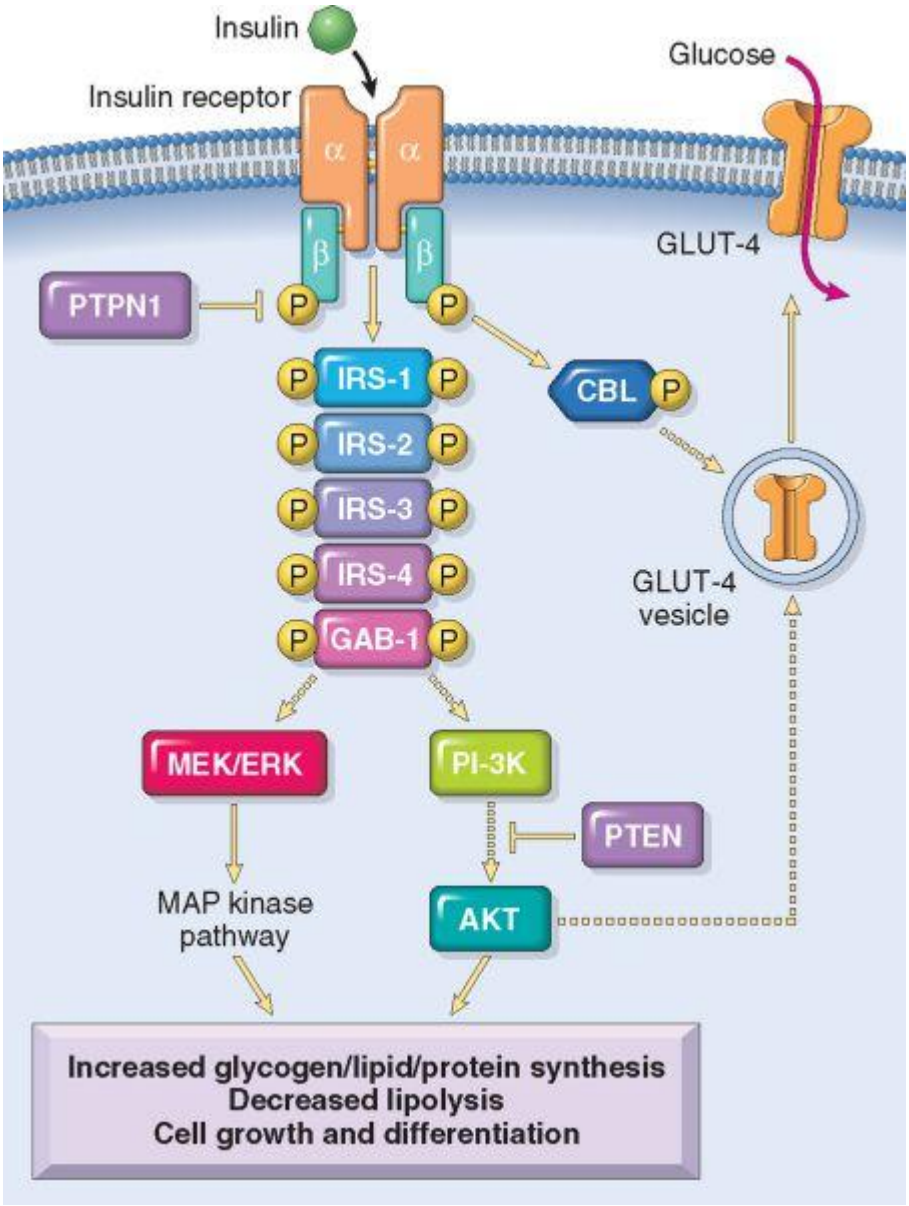

FIGURE 24-29 Insulin action on a target cell. The metabolic actions of insulin include promoting glycogen synthesis by activating glycogen synthase, and enhancing protein synthesis and lipogenesis while inhibiting lipolysis (see text). Dashed arrows represent intermediate proteins and binding partners that are not shown in this overview diagram.

PATHOGENESIS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes is an autoimmune disease in which islet destruction is caused primarily by immune effector cells reacting against endogenous β-cell antigens. Type 1 diabetes most commonly develops in childhood, becomes manifest at puberty, and progresses with age. Since the disease can develop at any age, including late adulthood, the appellation "juvenile diabetes" is now considered obsolete. Similarly, the older moniker "insulin-dependent diabetes mellitus" has been excluded from the recent classification of diabetes because insulin dependence is not a consistent distinguishing feature. Nevertheless, most patients with type 1 diabetes depend on insulin for survival; without insulin they develop serious metabolic complications such as ketoacidosis and coma. A rare form of "idiopathic"

type 1 diabetes has been described in which the evidence for autoimmunity is not definitive.[32] Here we will focus on the typical immune-mediated type 1 diabetes.

As with most autoimmune diseases, the pathogenesis of type 1 diabetes represents interplay of genetic susceptibility and environmental factors.

Genetic Susceptibility.

Epidemiologic studies, such as those demonstrating higher concordance rates for disease in monozygotic vs dizygotic twins, have convincingly established a genetic basis for type 1 diabetes. More recently, genome-wide association studies have identified multiple genetic susceptibility loci for type 1 diabetes, as well as for type 2 diabetes (see below). Over a dozen susceptibility loci for type 1 diabetes are now known.[33,][34] Of these, by far the most important is the *HLA locus* on chromosome 6p21; according to some estimates, the HLA locus contributes as much as 50% of the genetic susceptibility to type 1 diabetes. Ninety to 95% of Caucasians with this disease have either a HLA-DR3 or HLA-DR4 haplotype, in contrast to about 40% of normal subjects; moreover, 40% to 50% of type 1 diabetics are combined DR3/DR4 heterozygotes, in contrast to 5% of normal subjects. Individuals who have either DR3 or DR4 concurrently with a DQ8 haplotype (which corresponds to *DQA1*0301-DQB1*0302* alleles) demonstrate one of the highest inherited risks for type 1 diabetes in sibling studies.[35] Predictably, the polymorphisms in the HLA molecules are located in or adjacent to the peptide-binding pockets, consistent with the notion that disease-associated alleles code for molecules that have particular features of antigen display. However, as we discussed in Chapter 6 , it is still not known if these HLA-disease associations reflect the ability of specific HLA molecules to present self antigens or if they are related to T-cell selection and tolerance.

Several *non-HLA genes* also confer susceptibility to type 1 diabetes. The first disease-associated non-MHC gene to be identified was *insulin*, with variable number of tandem repeats (VNTRs) in the promoter region being associated with disease susceptibility.[36] The mechanism underlying this association is unknown. It is possible that these polymorphisms influence the level of expression of insulin in the thymus, thus altering the negative selection of insulin-reactive T cells (Chapter 6). We have previously mentioned the association between polymorphisms in *CTLA4* and *PTPN22* and autoimmune thyroiditis (see above); both genes are also linked with susceptibility to type 1 diabetes. Both CTLA-4 and PTPN-22 are thought to inhibit T-cell responses, so polymorphisms that interfere with their functional activity are expected to set the stage for excessive T-cell activation. Whether this is the only mechanism of action of these proteins in the development of autoimmune diseases remains an open question. Another recently identified polymorphism is in *CD25*, which encodes the α chain of the IL-2 receptor. It is postulated that the polymorphism reduces the activity of this receptor, which is critical for the maintenance of functional regulatory T cells.[37] Many of the other susceptibility loci identified in type 1 diabetes have been linked to various chromosomal regions but the involved genes are not defined.

Environmental Factors.

There is evidence that environmental factors, especially viral infections, may be involved in triggering islet cell destruction in type 1 diabetes. Epidemiologic associations have been reported between type 1 diabetes and infection with mumps, rubella, coxsackie B, or cytomegalovirus, among others. At least three different mechanisms have been proposed to explain the role of viruses in the induction of autoimmunity. The first is “bystander” damage, wherein viral infections induce islet injury and inflammation, leading to the release of sequestered β-cell antigens and the activation of autoreactive T cells. The second possibility is that the viruses produce proteins that mimic β-cell antigens, and the immune response to the viral protein cross-reacts with the self-tissue (“molecular mimicry”). The third hypothesis suggests that viral infections incurred early in life (“predisposing virus”) might persist in the

tissue of interest, and subsequent re-infection with a related virus ("precipitating virus") that shares antigenic epitopes leads to an immune response against the infected islet cells. This last mechanism, also known as "viral déj vu," might explain the latency between infections and the onset of diabetes. It is unclear whether any of these mechanisms contribute to β-cell damage, and no causative viral infection is established. In fact, some epidemiologic data and studies of experimental models suggest that infections may be protective; the underlying mechanisms of such a protective effect are unknown. An epidemiologic study has also established no causal association between childhood vaccinations and the risk of developing type 1 diabetes.[38]

Mechanisms of β-Cell Destruction

Although the clinical onset of type 1 diabetes is often abrupt, the autoimmune process usually starts many years before the disease becomes evident, with progressive loss of insulin reserves over time[39] (Fig. 24-30). The classic manifestations of the disease (hyperglycemia and ketosis) occur late in its course, after more than 90% of the β cells have been destroyed. Many of the advances in type 1 diabetes pathogenesis have emerged from studies of the nonobese diabetic (NOD) mouse model, which shares features of autoimmune islet destruction observed in the human disease. *The fundamental immune abnormality in type 1 diabetes is a failure of self-tolerance in T-cells*.[40] This failure of tolerance may be a result of some combination of defective clonal deletion of self-reactive T cells in the thymus, as well as defects in the functions of regulatory T cells or resistance of effector T cells to suppression by regulatory cells. Thus, autoreactive T-cells not only survive but are poised to respond to self-antigens. The initial activation of these cells is thought to occur in the peripancreatic lymph nodes, perhaps in response to antigens that are released from damaged islets. The activated T cells then traffic to the pancreas, where they cause β cell injury. Multiple T-cell populations have been implicated in this damage, including T_H1 cells (which may injure β cells by secreted cytokines, including IFN-γ and TNF), and CD8+ CTLs (which directly kill β cells). The islet auto-antigens that are the targets of immune attack may include insulin itself, as well as the β-cell enzyme glutamic acid decarboxylase (GAD), and islet cell autoantigen 512 (ICA512).[41]

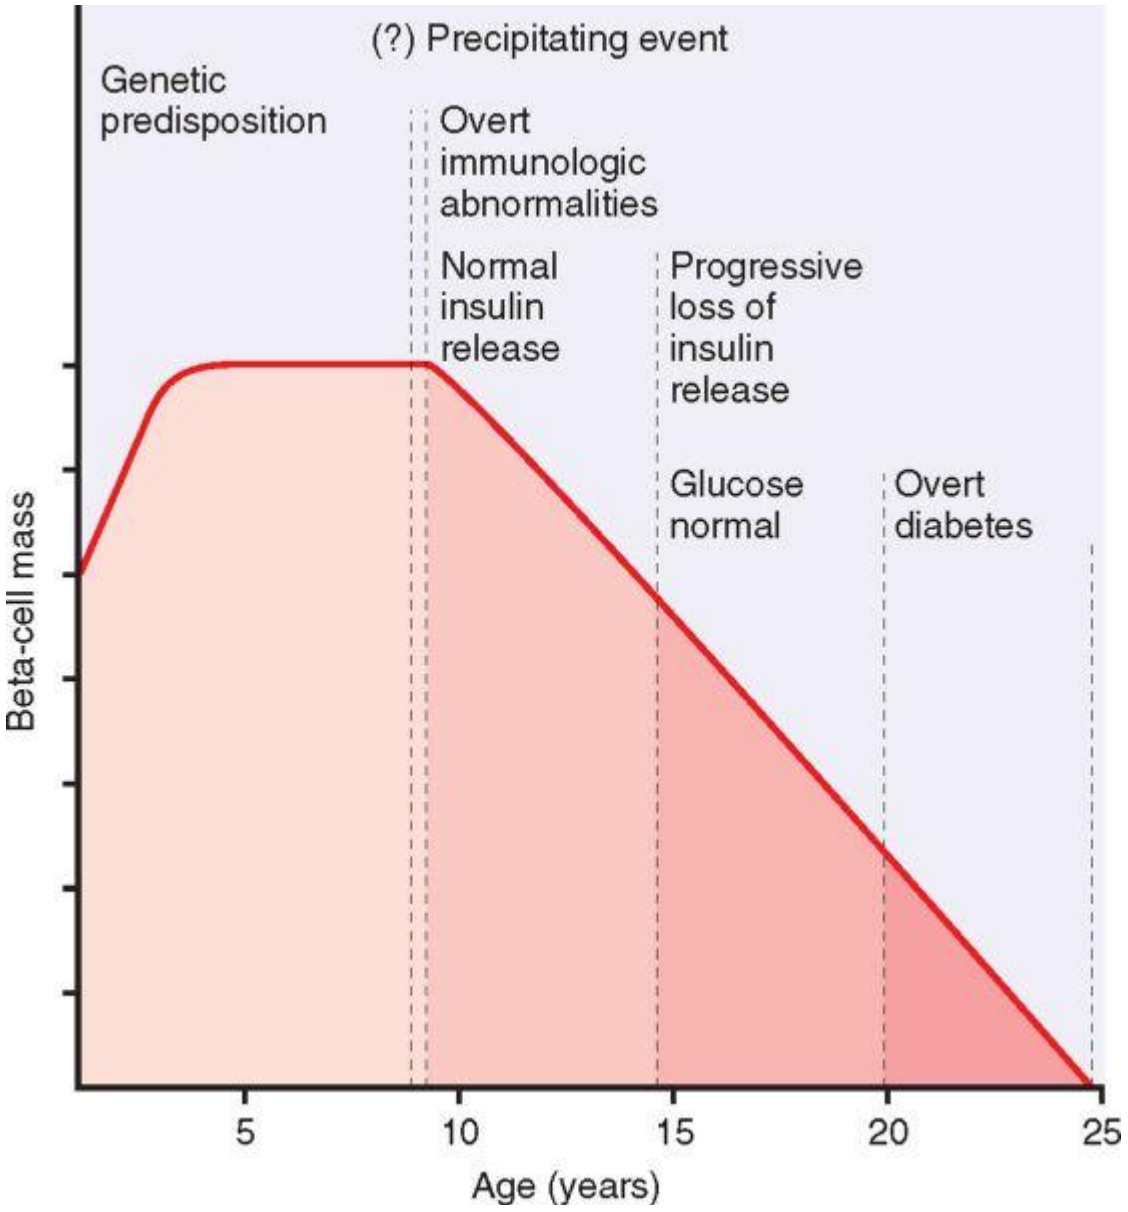

FIGURE 24-30 Stages in the development of type 1 diabetes mellitus. The stages are listed from left to right, and hypothetical β-cell mass is plotted against age. *(From Eisenbarth GE: Type 1 diabetes: a chronic autoimmune disease. N Engl J Med 314:1360, 1986. Copyright © 1986, Massachusetts Medical Society. All rights reserved.)*

A role for antibodies in type 1 diabetes is suspected because of the observation that autoantibodies against islet antigens are found in the vast majority of patients with type 1 diabetes, as well as in asymptomatic family members at risk for progression to overt disease; in fact, the presence of islet cell antibodies is used as a predictive marker for the disease.[42] However, it is not clear if the autoantibodies are involved in causing injury or are produced as a consequence of islet injury.

PATHOGENESIS OF TYPE 2 DIABETES MELLITUS

Type 2 diabetes is a prototypic multifactorial complex disease. Environmental factors, such as a sedentary life style and dietary habits, unequivocally play a role, as will become evident when the

association with obesity is considered. Genetic factors are also involved in the pathogenesis, as evidenced by the disease concordance rate of 35% to 60% in monozygotic twins compared with nearly half that in dizygotic twins. Such concordance is even greater than in type 1 diabetes, suggesting perhaps an even larger genetic component in type 2 diabetes. Furthermore, the lifetime risk for type 2 diabetes in an offspring is more than double if both parents are affected. *Additional evidence for a genetic basis has emerged from recent large-scale genome-wide association studies, which have identified over a dozen susceptibility loci*.[43,][44] The detailed description of these analyses is beyond the scope of this chapter, and only a few pertinent examples will be discussed here. Not surprisingly, polymorphisms in genes associated with β-cell function and insulin secretion seem to confer some of the strongest genetic risk for developing type 2 diabetes. The most reproducible association occurs with *transcription factor 7–like-2 (TCF7L2)* on chromosome 10q, which encodes a transcription factor in the *WNT* signaling pathway. Unlike type 1 diabetes, however, the disease is not linked to genes involved in immune tolerance and regulation (*HLA*, *CTLA4*, etc.), and there is no evidence of an autoimmune basis.

The two metabolic defects that characterize type 2 diabetes are (1) a decreased response of peripheral tissues to insulin (insulin resistance) and (2) β*-cell dysfunction that is manifested as inadequate insulin secretion in the face of insulin resistance and hyperglycemia*. Insulin resistance predates the development of hyperglycemia and is usually accompanied by compensatory β-cell hyperfunction and hyperinsulinemia in the early stages of the evolution of diabetes (Fig. 24-31).

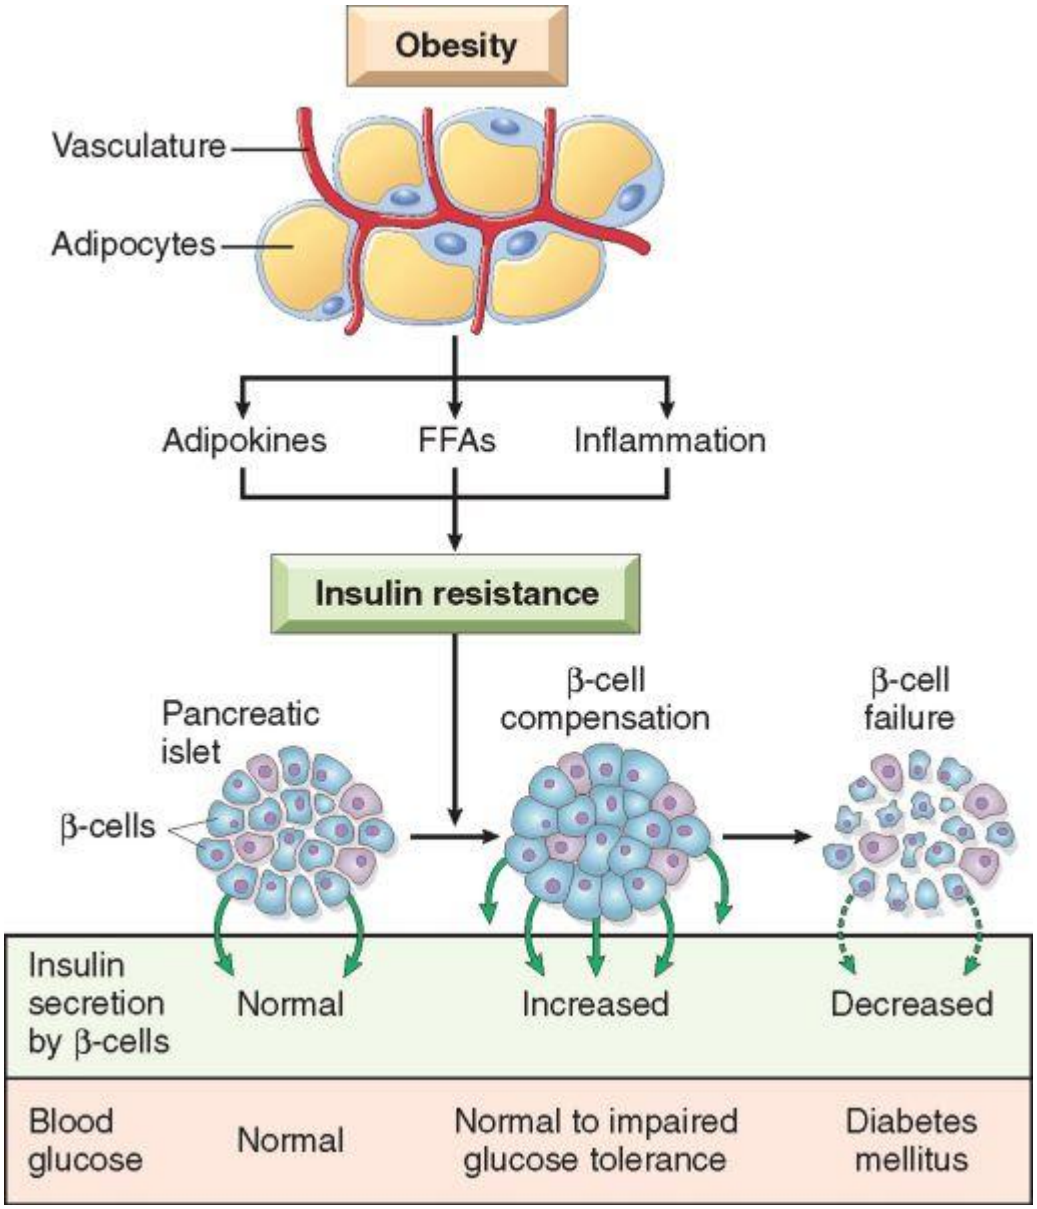

FIGURE 24-31 Development of type 2 diabetes. Insulin resistance associated with obesity is induced by adipokines, free fatty acids, and chronic inflammation in adipose tissue. Pancreatic β cells compensate for insulin resistance by hypersecretion of insulin. However, at some point, β-cell compensation is followed by β-cell failure, and diabetes ensues. *(Reproduced with permission from Kasuga M: Insulin resistance and pancreatic β-cell failure. J Clin Invest 116:1756, 2006.)*

Insulin Resistance

Insulin resistance is defined as the failure of target tissues to respond normally to insulin. It leads to decreased uptake of glucose in muscle, reduced glycolysis and fatty acid oxidation in the liver, and an inability to suppress hepatic gluconeogenesis. Studies in tissue-specific insulin receptor knockout mice suggest that *loss of insulin sensitivity in the hepatocytes is likely to be the largest contributor to the pathogenesis of insulin resistance in vivo*.[45] A variety of functional defects have been reported in the insulin signaling pathway in states of insulin resistance (for example, reduced tyrosine phosphorylation and increased serine phosphorylation of the insulin receptor and IRS proteins), which attenuate signal transduction.[46] *Few factors play as important a role in the development of insulin resistance as obesity*.

Obesity and Insulin Resistance.

The epidemiologic association of obesity with type 2 diabetes has been recognized for decades, with visceral obesity observed in greater than 80% of patients. Obesity has profound effects on sensitivity of tissues to insulin, and as consequence, on systemic glucose homeostasis. Insulin resistance is present even in simple obesity unaccompanied by hyperglycemia, indicating a fundamental abnormality of insulin signaling in states of fatty excess (see metabolic syndrome, below). The risk for diabetes increases as the body mass index (a measure of body fat content) increases. It is not only the absolute amount but also the distribution of body fat that has an effect on insulin sensitivity: central obesity (abdominal fat) is more likely to be linked with insulin resistance than are peripheral (gluteal/subcutaneous) fat depots. *Obesity can adversely impact insulin sensitivity in numerous ways* (see Fig. 24-31).[47]

- *Nonesterified fatty acids (NEFAs)*: Cross-sectional studies have demonstrated an inverse correlation between fasting plasma NEFAs and insulin sensitivity. The level of intracellular triglycerides is often markedly increased in muscle and liver tissues of obese individuals, presumably because excess circulating NEFAs are deposited in these organs. Central adipose tissue is more “lipolytic” than peripheral sites, which might explain the particularly deleterious consequences of this pattern of fat distribution. Excess intracellular NEFAs overwhelm the fatty acid oxidation pathways, leading to accumulation of cytoplasmic intermediates like diacylglycerol (DAG) and ceramide. These “toxic” intermediates can activate serine/threonine kinases, which cause aberrant serine phosphorylation of the insulin receptor and IRS proteins. Recall that, unlike tyrosine modification, phosphorylation at serine residues *attenuates* insulin signaling. Insulin normally inhibits hepatic gluconeogenesis by blocking the activity of phosphoenolpyruvate carboxykinase, the first enzymatic step in this process. Attenuated insulin signaling allows phosphoenolpyruvate carboxykinase to “ramp up” gluconeogenesis. Excess NEFAs also compete with glucose for substrate oxidation, leading to feedback inhibition of glycolytic enzymes, and thereby further exacerbating the existing glucose imbalance.
- *Adipokines:* It is recognized that adipose tissue is not merely a passive storage depot for fat but is a functional endocrine organ that releases hormones in response to changes in the metabolic status. A variety of proteins secreted into the systemic circulation by adipose tissue have been identified, and these are collectively termed *adipokines* (or adipose cytokines). Both pro-hyperglycemic adipokines (e.g., resistin, retinol binding protein 4 [RBP4]) and anti-hyperglycemic adipokines (leptin, adiponectin) have been identified. Leptin and adiponectin improve insulin sensitivity by directly enhancing the activity of the AMP-activated protein kinase (AMPK), an enzyme that promotes fatty acid oxidation, in liver and skeletal muscle. Adiponectin levels are reduced in obesity, thus contributing to insulin resistance. Notably, AMPK is also the target for metformin, a commonly used oral antidiabetic medication.[48]
- *Inflammation:* Adipose tissue also secretes a variety of pro-inflammatory cytokines like tumor necrosis factor, interleukin-6, and macrophage chemoattractant protein-1, the last attracting macrophages to fat deposits. Studies in experimental models have demonstrated that reducing the levels of pro-inflammatory cytokines enhances insulin sensitivity. These cytokines induce insulin resistance by increasing cellular “stress,” which in turn, activates multiple signaling cascades that antagonize insulin action on peripheral tissues.
- *Peroxisome proliferator-activated receptor* γ *(PPAR γ):* PPARγ is a nuclear receptor and transcription factor expressed in adipose tissue, and plays a seminal role in adipocyte differentiation. A class of antidiabetic medications known as thiazolidinediones acts as agonist ligands for PPARγ and improves insulin sensitivity. Activation of PPARγ promotes secretion of anti-hyperglycemic adipokines like adiponectin, and shifts the deposition of NEFAs toward adipose tissue and away from liver and skeletal muscle. As discussed below, rare mutations of *PPARG* that cause profound loss of protein function can result in monogenic diabetes.

β-Cell Dysfunction

In type 2 diabetes, β cells seemingly exhaust their capacity to adapt to the long-term demands of peripheral insulin resistance. In states of insulin resistance like obesity, insulin secretion is initially higher for each level of glucose than in controls. This hyperinsulinemic state is a compensation for peripheral resistance and can often maintain normal plasma glucose for years. Eventually, however, β-cell compensation becomes inadequate, and there is progression to hyperglycemia. *The observation that not all obese individuals with insulin resistance develop overt diabetes suggests that an intrinsic*

predisposition to β-cell failure must also exist. For example, recent studies have shown that allelic variants associated with the highest risk for type 2 diabetes in the diabetogenic gene *TCF7L2* (see above) are associated with reduced insulin secretion from islets, indicating a preexisting propensity toward β-cell failure.[49] The molecular mechanisms underlying β-cell dysfunction in type 2 diabetes are multifactorial and in many instances overlap with those implicated in insulin resistance. Thus, the excess NEFAs and attenuated insulin signaling ("lipotoxicity") predispose to both insulin resistance and β-cell failure. Agents like metformin that enhance fatty acid oxidation through AMPK activation (see above) also improve β-cell function, further highlighting the shared pathogenetic mechanisms between insulin resistance and β-cell failure. Amyloid replacement of islets is a characteristic finding in individuals with long-standing type 2 diabetes and is present in more than 90% of diabetic islets examined. Some believe that the islet amyloid protein is directly cytotoxic to islets, analogous to the role played by amyloid plaques implicated in the pathogenesis of Alzheimer disease (Chapter 28).

MONOGENIC FORMS OF DIABETES

Although genetically defined causes of diabetes are uncommon, they have been intensively studied in the hope of gaining insights into the disease. As Table 24-6 illustrates, monogenic forms of diabetes are classified separately from types 1 and 2. These forms of diabetes result from either a primary defect in β-cell function or a defect in insulin–insulin receptor signaling, as described below.

Genetic Defects in β-Cell Function.

Approximately 1% to 2% of diabetics harbor a *primary defect in β-cell function that occurs without β-cell loss, affecting either β-cell mass and/or insulin production*. This form of monogenic diabetes is caused by a heterogeneous group of genetic defects, and is characterized by (1) autosomal-dominant inheritance, with high penetrance; (2) early onset, usually before age 25 and even in the neonatal period, as opposed to after age 40 for most patients with type 2 diabetes; (3) absence of obesity; and (4) absence of β-cell autoantibodies. Because of genetic heterogeneity, the clinical features vary widely from mild persistent hyperglycemia to severe diabetes requiring insulin for survival.

The largest subgroup of patients in this category was traditionally designated as having "maturity-onset diabetes of the young" (MODY) because of its superficial resemblance to type 2 diabetes and its occurrence in younger patients. MODY can result from hemizygous loss-of-function mutations in one of six genes (see Table 24-6). Glucokinase, implicated in MODY2, is an enzyme that catalyzes the transfer of phosphate from ATP to glucose, which is the first and rate-limiting step in glucose metabolism. β-cell glucokinase controls the entry of glucose into the glycolytic cycle, which, in turn, is coupled to insulin secretion. Mutations of the *glucokinase* (*GCK*) gene increase the glucose threshold that triggers insulin release, causing mild increases in fasting blood glucose *(familial mild fasting hyperglycemia)*. *As many as 50% of carriers of glucokinase mutations develop gestational diabetes mellitus*, defined as any degree of glucose intolerance during pregnancy; conversely, approximately 2% to 5% of women with gestational diabetes mellitus and a first-degree relative with diabetes carry a mutation in the glucokinase gene. The other five genes mutated in MODY encode transcription factors that control insulin expression in β cells and β-cell mass; one such factor, *IPF1* (also known as *PDX1*), plays a central role in the development of the pancreas.

Permanent neonatal diabetes (to be distinguished from transient neonatal hyperglycemic states) occurs as a result of mutations of *KCNJ11* and *ABCC8* genes, which encode the Kir6.2 and SUR1 subunits, respectively, of the ATP-sensitive K+ channel (see Fig. 24-27).[50,][51] You will recall that inactivation of this channel is required for membrane depolarization and physiologic insulin secretion from β cells. Gain-offunction *KCNJ11* or *ABCC8* mutations cause constitutive activation of the K+ channel, membrane hyperpolarization, and hypoinsulinemic diabetes. Permanent neonatal diabetes presents with severe hyperglycemia and ketoacidosis, and a fifth of such patients also demonstrate concurrent

neurologic symptoms like epilepsy. *Maternally inherited diabetes and deafness* results from mitochondrial DNA mutations.[52] Impairment of mitochondrial ATP synthesis in metabolically active islet cells results in decreased insulin secretion. Mitochondrial diabetes is associated with bilateral sensorineural deafness. Finally, mutations within the *insulin gene* itself have recently been described as a form of monogenic diabetes, most commonly presenting in the neonatal period, but also in childhood and adolescence.[53]

Genetic Defects in Insulin Action.

Rare instances of *insulin receptor* mutations that affect receptor synthesis, insulin binding, or receptor tyrosine kinase activity can cause severe insulin resistance, accompanied by hyperinsulinemia and diabetes (type A insulin resistance). Such patients often show a velvety hyperpigmentation of the skin, known as *acanthosis nigricans*. Females with type A insulin resistance frequently have polycystic ovaries and elevated androgen levels. *Lipoatrophic diabetes*, as the name suggests, is hyperglycemia accompanied by loss of adipose tissue, the latter occurring selectively in the subcutaneous fat. This rare group of genetic disorders has in common insulin resistance, diabetes, hypertriglyceridemia, acanthosis nigricans, and abnormal fat deposition in the liver (hepatic steatosis). Multiple subtypes of lipoatrophic diabetes, each ascribed to a different causal mutation, have been reported. Dominant-negative mutations in the DNA-binding domain of PPARG are found in a subset of patients, which interfere with the function of wild-type PPARγ in the nucleus, leading to severe insulin resistance.[54] As discussed above, common *PPARG* polymorphisms are associated with susceptibility to type 2 diabetes, while PPARγ has emerged as a target for therapies that aim to improve insulin sensitivity in this disease.

PATHOGENESIS OF THE COMPLICATIONS OF DIABETES

The morbidity associated with long-standing diabetes of either type results from several serious complications, caused mainly by lesions involving both large- and medium-sized muscular arteries *(macrovascular disease)* and capillary dysfunction in target organs *(microvascular disease)*. Macrovascular disease causes *accelerated atherosclerosis* among diabetics, resulting in increased risk of myocardial infarction, stroke, and lower extremity gangrene. The effects of microvascular disease are most profound in the retina, kidneys, and peripheral nerves, resulting in *diabetic retinopathy*, *nephropathy*, and *neuropathy*, respectively.

The pathogenesis of the long-term complications of diabetes is multifactorial, although persistent hyperglycemia ("glucotoxicity") seems to be a key mediator. Much of the evidence supporting a role for glycemic control in ameliorating the long-term complications of diabetes has come from large randomized trials. The assessment of glycemic control in these trials has been based on the percentage of *glycosylated hemoglobin*, also known as Hb_{A1C}, which is formed by nonenzymatic covalent addition of glucose moieties to hemoglobin in red cells. Unlike blood glucose levels, Hb_{A1C} provides a measure of glycemic control over the lifespan of a red cell (120 days) and is little affected by day-to-day variations. The American Dietetic Association recommends that Hb_{A1C} be maintained below 7% in diabetic patients. It is important to stress that hyperglycemia is not the only factor responsible for the long-term complications of diabetes, and that other underlying abnormalities, such as insulin resistance, and co-morbidities like obesity, also play an important role.

At least three distinct metabolic pathways have been implicated in the deleterious effects of persistent hyperglycemia on peripheral tissues, although the primacy of any one over the others is unclear. The pathways are discussed below.

Formation of Advanced Glycation End Products.

Advanced glycation end products (AGEs) are formed as a result of nonenzymatic reactions between intracellular glucose-derived dicarbonyl precursors (glyoxal, methylglyoxal, and 3deoxyglucosone) with the amino groups of both intracellular and extracellular proteins. The natural rate of AGE formation is greatly accelerated in the presence of hyperglycemia. AGEs bind to a specific receptor (RAGE), which is expressed on inflammatory cells (macrophages and T cells), endothelium, and vascular smooth muscle. The detrimental effects of the AGE-RAGE signaling axis within the vascular compartment include (1) release of pro-inflammatory *cytokines and growth factors* from intimal macrophages; (2) generation of *reactive oxygen species* in endothelial cells; (3) increased *procoagulant activity* on endothelial cells and macrophages; and (4) enhanced *proliferation of vascular smooth muscle cells and synthesis of extracellular matrix*. Not surprisingly, endothelialspecific overexpression of RAGE in diabetic mice accelerates large vessel injury and microangiopathy, while RAGE-null mice show attenuation of these features.[55,][56] Antagonists of RAGE have emerged as a therapeutic strategy in diabetes and are being tested in clinical trials.

In addition to receptor-mediated effects, *AGEs can directly cross-link extracellular matrix proteins*. Cross-linking of collagen type I molecules in large vessels decreases their elasticity, which may predispose these vessels to shear stress and endothelial injury (Chapter 11). Similarly, AGE-induced cross-linking of type IV collagen in basement membrane decreases endothelial cell adhesion and increases extravasation of fluid. Proteins cross-linked by AGEs are resistant to proteolytic digestion. Thus, cross-linking decreases protein removal while enhancing protein deposition. AGE-modified matrix components also trap nonglycated plasma or interstitial proteins. In large vessels, trapping of LDL, for example, retards its efflux from the vessel wall and enhances the deposition of cholesterol in the intima, thus accelerating atherogenesis (Chapter 11). In capillaries, including those of renal glomeruli, plasma proteins such as albumin bind to the glycated basement membrane, accounting in part for the basement membrane thickening that is characteristic of diabetic microangiopathy.

Activation of Protein Kinase C.

Activation of intracellular protein kinase C (PKC) by $Ca^{[2]}+$ ions and the second messenger diacyl glycerol (DAG) is an important signal transduction pathway in many cellular systems. Intracellular hyperglycemia stimulates the de novo synthesis of DAG from glycolytic intermediates, and hence causes activation of PKC. The downstream effects of PKC activation are numerous and include the following.

- Production of proangiogenic vascular endothelial growth factor (VEGF), implicated in the neovascularization characterizing diabetic retinopathy (Chapter 29)
- Elevated levels of the vasoconstrictor endothelin-1 and decreased levels of the vasodilator NO, due to decreased expression of endothelial nitric oxide synthase
- Production of profibrogenic factors like TGF-β, leading to increased deposition of extracellular matrix and basement membrane material
- Production of PAI-1, leading to reduced fibrinolysis and possible vascular occlusive episodes
- Production of pro-inflammatory cytokines by the vascular endothelium

It should be evident that some effects of AGEs and activated PKC are overlapping, and both contribute to the long-term complications of diabetic microangiopathy. Clinical trials using a PKC inhibitor (ruboxistaurin) have yielded promising results in diabetic retinopathy,[57] and this pathway is also under investigation as a therapeutic target in diabetic nephropathy.

Intracellular Hyperglycemia and Disturbances in Polyol Pathways.

In some tissues that do not require insulin for glucose transport (e.g., nerves, lenses, kidneys, blood vessels), persistent hyperglycemia in the extracellular milieu leads to an increase in intracellular glucose. This excess glucose is metabolized by the enzyme aldose reductase to sorbitol, a polyol, and eventually to fructose, in a reaction that uses NADPH (the reduced form of nicotinamide dinucleotide phosphate) as a cofactor. NADPH is also required by the enzyme glutathione reductase in a reaction that regenerates reduced glutathione (GSH). You will recall that GSH is one of the important antioxidant mechanisms in the cell (Chapter 1), and any reduction in GSH increases cellular susceptibility to oxidative stress. In the face of sustained hyperglycemia, progressive depletion of intracellular NADPH by aldol reductase compromises GSH regeneration, increasing cellular susceptibility to oxidative stress. In neurons, persistent hyperglycemia appears to be the major underlying cause of diabetic neuropathy *("glucose neurotoxicity")*.[58] Although clinical trials with aldose reductase inhibitors have been disappointing to date, targeting this pathway as a means for amelioration of diabetic complications remains on the horizon.

MORPHOLOGY OF DIABETES AND ITS LATE COMPLICATIONS

Pathologic findings in the pancreas are variable and not necessarily dramatic. The important morphologic changes are related to the many late systemic complications of diabetes. There is great variability among patients in the time of onset of these complications, their severity, and the particular organ or organs involved. In individuals with tight control of diabetes, the onset might be delayed. In most patients, however, morphologic changes are likely to be found in arteries *(macrovascular disease)*, basement membranes of small vessels *(microangiopathy)*, kidneys *(diabetic nephropathy)*, retina *(retinopathy)*, nerves *(neuropathy)*, and other tissues (Fig. 24-32). These changes are seen in both type 1 and type 2 diabetes.

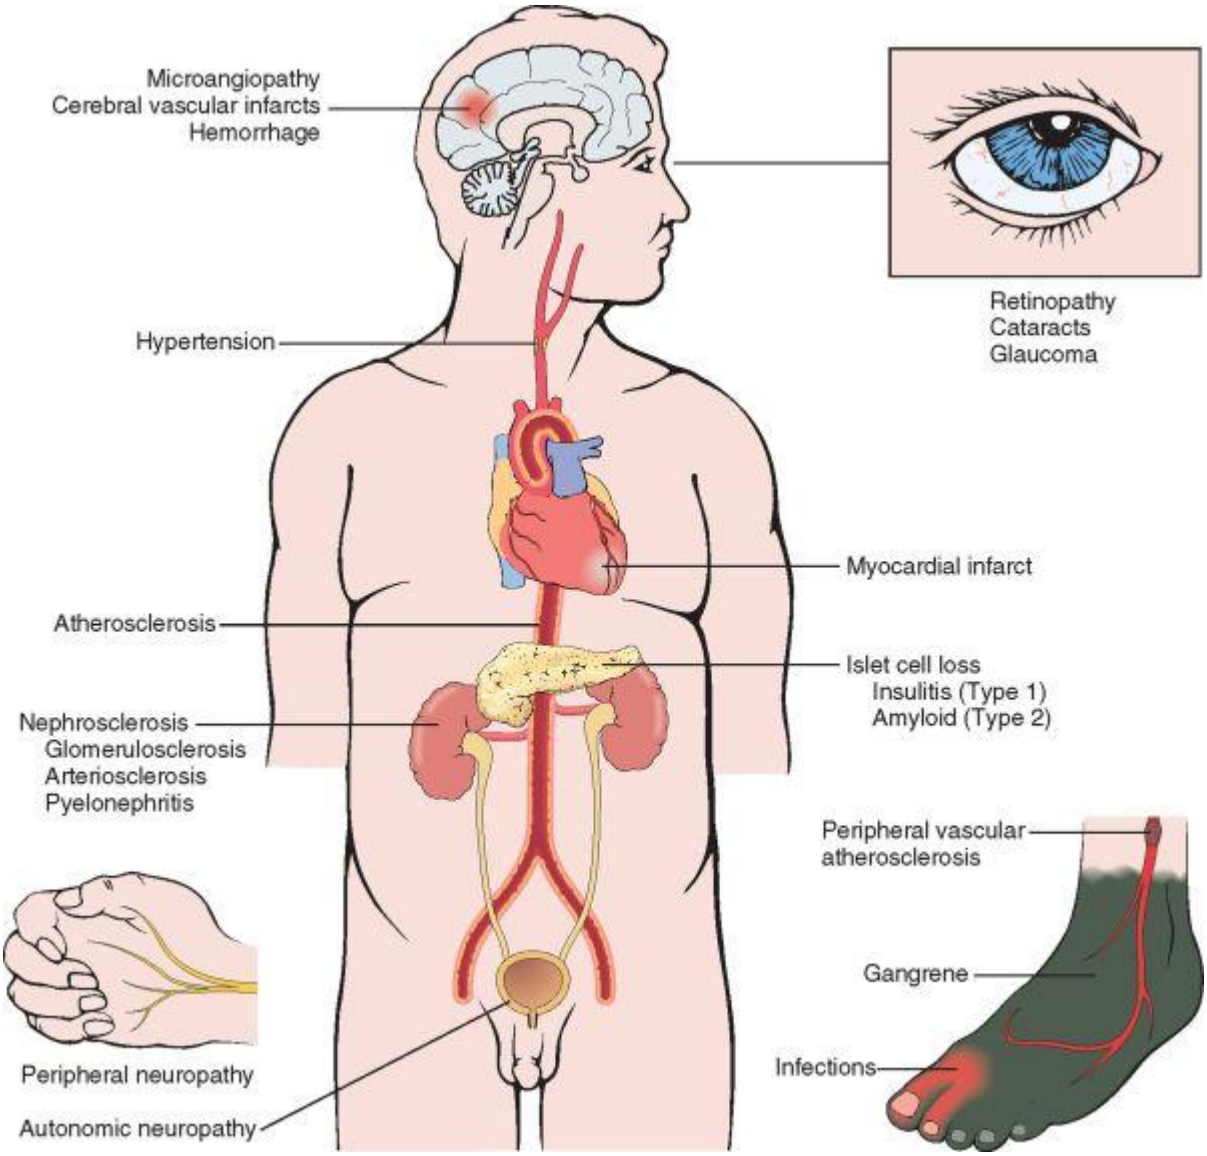

FIGURE 24-32 Long-term complications of diabetes.

Morphology

Pancreas. Lesions in the pancreas are inconstant and rarely of diagnostic value. Distinctive changes are more commonly associated with type 1 than with type 2 diabetes. One or more of the following alterations may be present:

- **Reduction in the number and size of islets**. This is most often seen in type 1 diabetes, particularly with rapidly advancing disease. Most of the islets are small and inconspicuous.
- **Leukocytic infiltrates in the islets** (insulitis) are principally composed of T lymphocytes, as is also seen in animal models of autoimmune diabetes (Fig. 24-33A). Lymphocytic infiltrates may be present in type 1 diabetics at the time of clinical presentation. The distribution of insulitis may be strikingly uneven. Eosinophilic infiltrates may also be found, particularly in diabetic infants who fail to survive the immediate postnatal period.

- **In type 2 diabetes there may be a subtle reduction in islet cell mass**, demonstrated only by special morphometric studies.
- **Amyloid deposition within islets in type 2 diabetes** begins in and around capillaries and between cells. At advanced stages, the islets may be virtually obliterated (Fig. 24-33B); fibrosis may also be observed. Similar lesions may be found in elderly nondiabetics, apparently as part of normal aging.
- **An increase in the number and size of islets** is especially characteristic of nondiabetic newborns of diabetic mothers. Presumably, fetal islets undergo hyperplasia in response to the maternal hyperglycemia.

Diabetic Macrovascular Disease. Diabetes exacts a heavy toll on the vascular system. **Endothelial dysfunction** (see Chapter 11), which predisposes to atherosclerosis and other cardiovascular morbidities, is widespread in diabetes, as a consequence of the deleterious effects of persistent hyperglycemia and insulin resistance on the vascular compartment. The hallmark of diabetic macrovascular disease is **accelerated atherosclerosis** involving the aorta and large- and medium-sized arteries. Except for its greater severity and earlier age at onset, atherosclerosis in diabetics is indistinguishable from that in nondiabetics (Chapter 11). **Myocardial infarction, caused by atherosclerosis of the coronary arteries, is the most common cause of death in diabetics**, and an elevated **risk for cardiovascular disease is even observed in pre-diabetics**. Significantly, myocardial infarction is almost as common in diabetic women as in diabetic men. In contrast, myocardial infarction is uncommon in nondiabetic women of reproductive age. **Gangrene of the lower extremities**, as a result of advanced vascular disease, is about 100 times more common in diabetics than in the general population. The larger renal arteries are also subject to severe atherosclerosis, but the most damaging effect of diabetes on the kidneys is exerted at the level of the glomeruli and the microcirculation. This is discussed later.

Hyaline arteriolosclerosis, the vascular lesion associated with hypertension (Chapters 11 and 20 , is both more prevalent and more severe in diabetics than in nondiabetics, but it is not specific for diabetes and may be seen in elderly nondiabetics without hypertension. It takes the form of an amorphous, hyaline thickening of the wall of the arterioles, which causes narrowing of the lumen (Fig. 24-34). Not surprisingly, in diabetics it is related not only to the duration of the disease but also to the level of blood pressure.

Diabetic Microangiopathy. One of the most consistent morphologic features of diabetes is **diffuse thickening of basement membranes**. The thickening is most evident in the capillaries of the skin, skeletal muscle, retina, renal glomeruli, and renal medulla. However, it may also be seen in such nonvascular structures as renal tubules, the Bowman capsule, peripheral nerves, and placenta. It should be noted that despite the increase in the thickness of basement membranes, **diabetic capillaries are more leaky than normal to plasma proteins. The microangiopathy underlies the development of diabetic nephropathy, retinopathy, and some forms of neuropathy**. An indistinguishable microangiopathy can be found in aged nondiabetic patients but rarely to the extent seen in patients with long-standing diabetes.

Diabetic Nephropathy. The kidneys are prime targets of diabetes. Renal failure is second only to myocardial infarction as a cause of death from this disease. **Three lesions are encountered: (1) glomerular lesions; (2) renal vascular lesions, principally arteriolosclerosis; and (3) pyelonephritis, including necrotizing papillitis**.

The most important glomerular lesions are capillary basement membrane thickening, diffuse mesangial sclerosis, and nodular glomerulosclerosis.

Capillary Basement Membrane Thickening. **Widespread thickening of the glomerular capillary**

basement membrane (GBM) occurs in virtually all cases of diabetic nephropathy and is part and parcel of the diabetic microangiopathy. Pure capillary basement membrane thickening can be detected only by electron microscopy (Fig. 24-35). Careful morphometric studies demonstrate that this thickening begins as early as 2 years after the onset of type 1 diabetes and by 5 years amounts to about a 30% increase. The thickening continues progressively and usually concurrently with mesangial widening. Simultaneously, there is thickening of the tubular basement membranes (Fig 24-36).

Diffuse Mesangial Sclerosis. This lesion consists of **diffuse increase in mesangial matrix**. There can be mild proliferation of mesangial cells early in the disease process, but cell proliferation is not a prominent part of this injury. The mesangial increase is typically associated with the overall thickening of the GBM. The matrix depositions are PAS-positive (Fig. 24-37). As the disease progresses, the expansion of mesangial areas can extend to nodular configurations. The progressive expansion of the mesangium has been shown to correlate well with measures of deteriorating renal function such as increasing proteinuria.

Nodular Glomerulosclerosis. This is also known as **intercapillary glomerulosclerosis or Kimmelstiel-Wilson disease**. The glomerular lesions take the form of ovoid or spherical, often laminated, nodules of matrix situated in the periphery of the glomerulus. The nodules are PAS-positive. They lie within the mesangial core of the glomerular lobules and can be surrounded by patent peripheral capillary loops (Fig 24-37) or loops that are markedly dilated. The nodules often show features of mesangiolysis with fraying of the mesangial/capillary lumen interface, disruption of sites at which the capillaries are anchored into the mesangial stalks, and resultant capillary microaneurysm formation as the untethered capillaries distend outward as a result of intracapillary pressures and flows. Usually, not all the lobules in the individual glomerulus are involved by nodular lesions, but even uninvolved lobules and glomeruli show striking diffuse mesangial sclerosis. As the disease advances, the individual nodules enlarge and may eventually compress and engulf capillaries, obliterating the glomerular tuft. These nodular lesions are frequently accompanied by prominent accumulations of hyaline material in capillary loops (“fibrin caps”) or adherent to Bowman's capsules (“capsular drops”). Both afferent and efferent glomerular hilar arterioles show hyalinosis. As a consequence of the glomerular and arteriolar lesions, the kidney suffers from ischemia, develops tubular atrophy and interstitial fibrosis, and usually undergoes overall contraction in size (Fig. 24-38). Approximately 15% to 30% of individuals with long-term diabetes develop nodular glomerulosclerosis, and in most instances it is associated with renal failure.

Renal atherosclerosis and arteriolosclerosis constitute part of the macrovascular disease in diabetics. The kidney is one of the most frequently and severely affected organs; however, the changes in the arteries and arterioles are similar to those found throughout the body. Hyaline arteriolosclerosis affects not only the afferent but also the efferent arteriole. Such efferent arteriolosclerosis is rarely, if ever, encountered in individuals who do not have diabetes.

Pyelonephritis is an acute or chronic inflammation of the kidneys that usually begins in the interstitial tissue and then spreads to affect the tubules. Both the acute and chronic forms of this disease occur in nondiabetics as well as in diabetics but are more common in diabetics than in the general population, and, once affected, diabetics tend to have more severe involvement. One special pattern of acute pyelonephritis, **necrotizing papillitis** (or papillary necrosis), is much more prevalent in diabetics than in nondiabetics.

***Diabetic Ocular Complications*.**

The ocular involvement may take the form of retinopathy, cataract formation, or glaucoma. The

morphologic features are discussed further in Chapter 29 .

Diabetic Neuropathy.

The central and peripheral nervous systems are not spared by diabetes. The morphology of diabetes in the nervous system is described further in Chapter 27 .

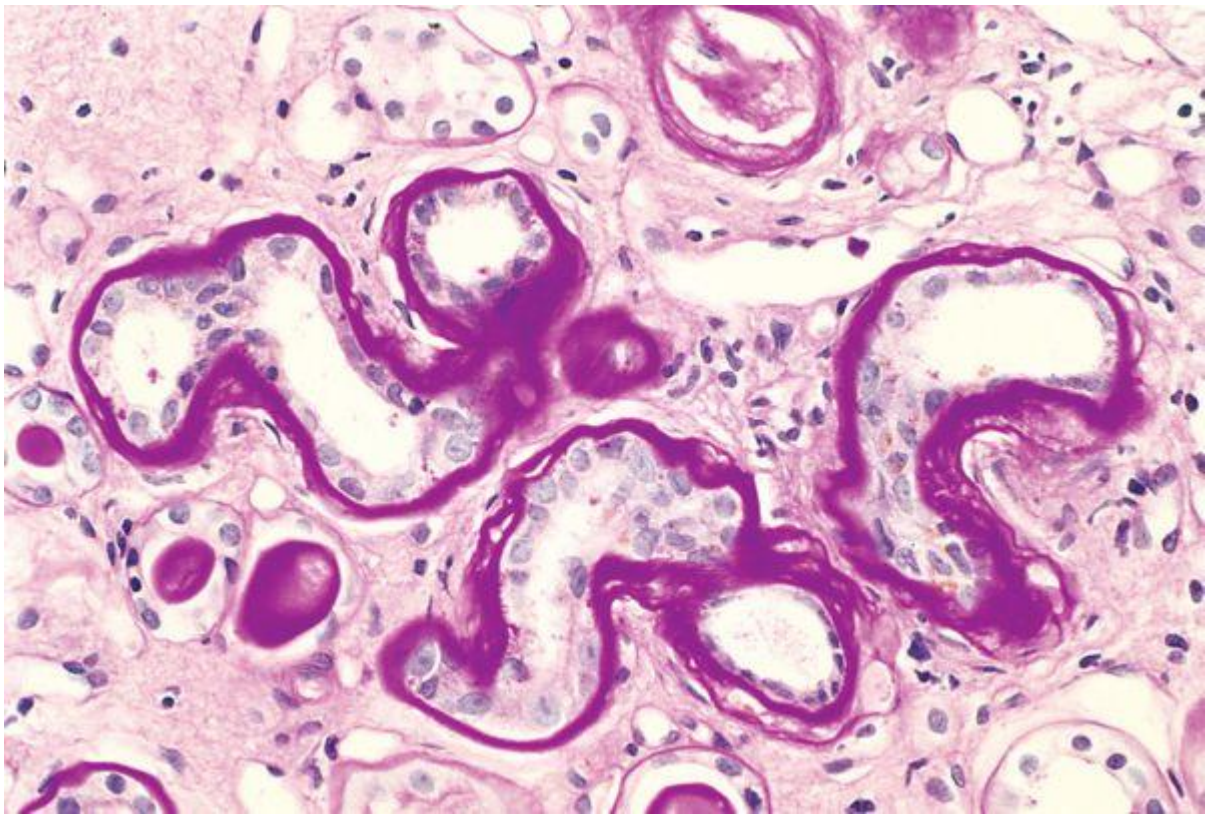

FIGURE 24-36 Renal cortex showing thickening of tubular basement membranes in a diabetic patient (PAS stain).

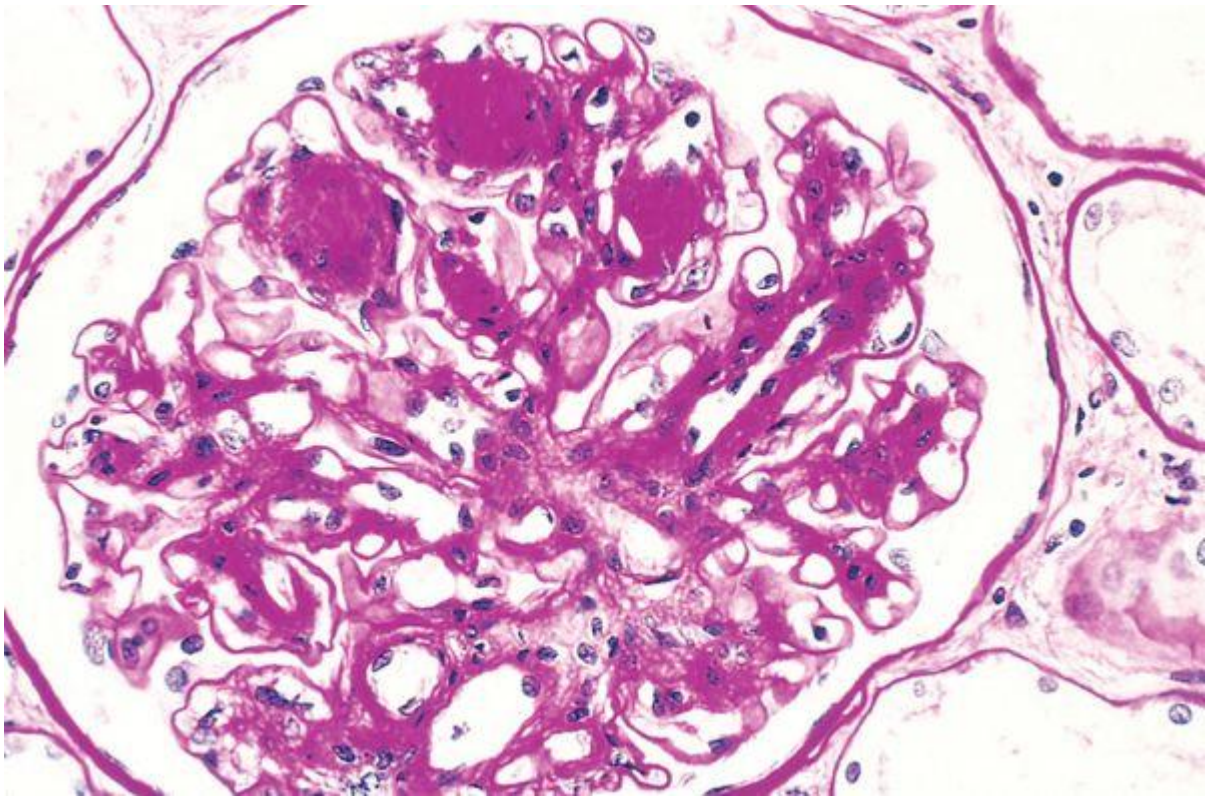

FIGURE 24-37 Diffuse and nodular diabetic glomerulosclerosis (PAS stain). Note the diffuse increase in mesangial matrix and characteristic acellular PAS-positive nodules.

FIGURE 24-38 Nephrosclerosis in a patient with long-standing diabetes. The kidney has been bisected to demonstrate both diffuse granular transformation of the surface *(left)* and marked thinning of the cortical tissue *(right)*. Additional features include some irregular depressions, the result of pyelonephritis, and an incidental cortical cyst *(far right)*.

CLINICAL FEATURES OF DIABETES

It is difficult to sketch with brevity the diverse clinical presentations of diabetes mellitus. Only a few characteristic patterns will be presented.

Type 1 diabetes was formerly thought to occur primarily in those under age 18 but is now known to occur at any age. In the initial 1 or 2 years following the onset of overt type 1 diabetes, the exogenous insulin requirements may be minimal because of ongoing endogenous insulin secretion (referred to as

the *honeymoon period*). Thereafter, any residual β-cell reserve is exhausted and insulin requirements increase dramatically. Although β-cell destruction is a prolonged process, the transition from impaired glucose tolerance to overt diabetes may be abrupt, and is often brought on by an event, such as infection, that is also associated with increased insulin requirements.

The onset is marked by polyuria, polydipsia, polyphagia, and, when severe, ketoacidosis, all resulting from metabolic derangements. Since insulin is a major anabolic hormone in the body, *deficiency of insulin results in a catabolic state that affects not only glucose metabolism but also fat and protein metabolism*. Unopposed secretion of counter-regulatory hormones (glucagon, growth hormone, epinephrine) also plays a role in these metabolic derangements. The assimilation of glucose into muscle and adipose tissue is sharply diminished or abolished. Not only does storage of glycogen in liver and muscle cease, but also reserves are depleted by glycogenolysis. The resultant hyperglycemia exceeds the renal threshold for reabsorption, and glycosuria ensues. The glycosuria induces an osmotic diuresis and thus *polyuria*, causing a profound loss of water and electrolytes (Fig. 24-39). The obligatory renal water loss combined with the hyperosmolarity resulting from the increased levels of glucose in the blood tends to deplete intracellular water, triggering the osmoreceptors of the thirst centers of the brain. In this manner, intense thirst *(polydipsia)* appears. With a deficiency of insulin the scales swing from insulin-promoted anabolism to catabolism of proteins and fats. Proteolysis follows, and the gluconeogenic amino acids are removed by the liver and used as building blocks for glucose. The catabolism of proteins and fats tends to induce a negative energy balance, which in turn leads to increasing appetite *(polyphagia)*, thus completing the classic triad of diabetes: *polyuria, polydipsia*, and *polyphagia*. Despite the increased appetite, catabolic effects prevail, resulting in weight loss and muscle weakness. *The combination of polyphagia and weight loss is paradoxical and should always raise the suspicion of diabetes*.

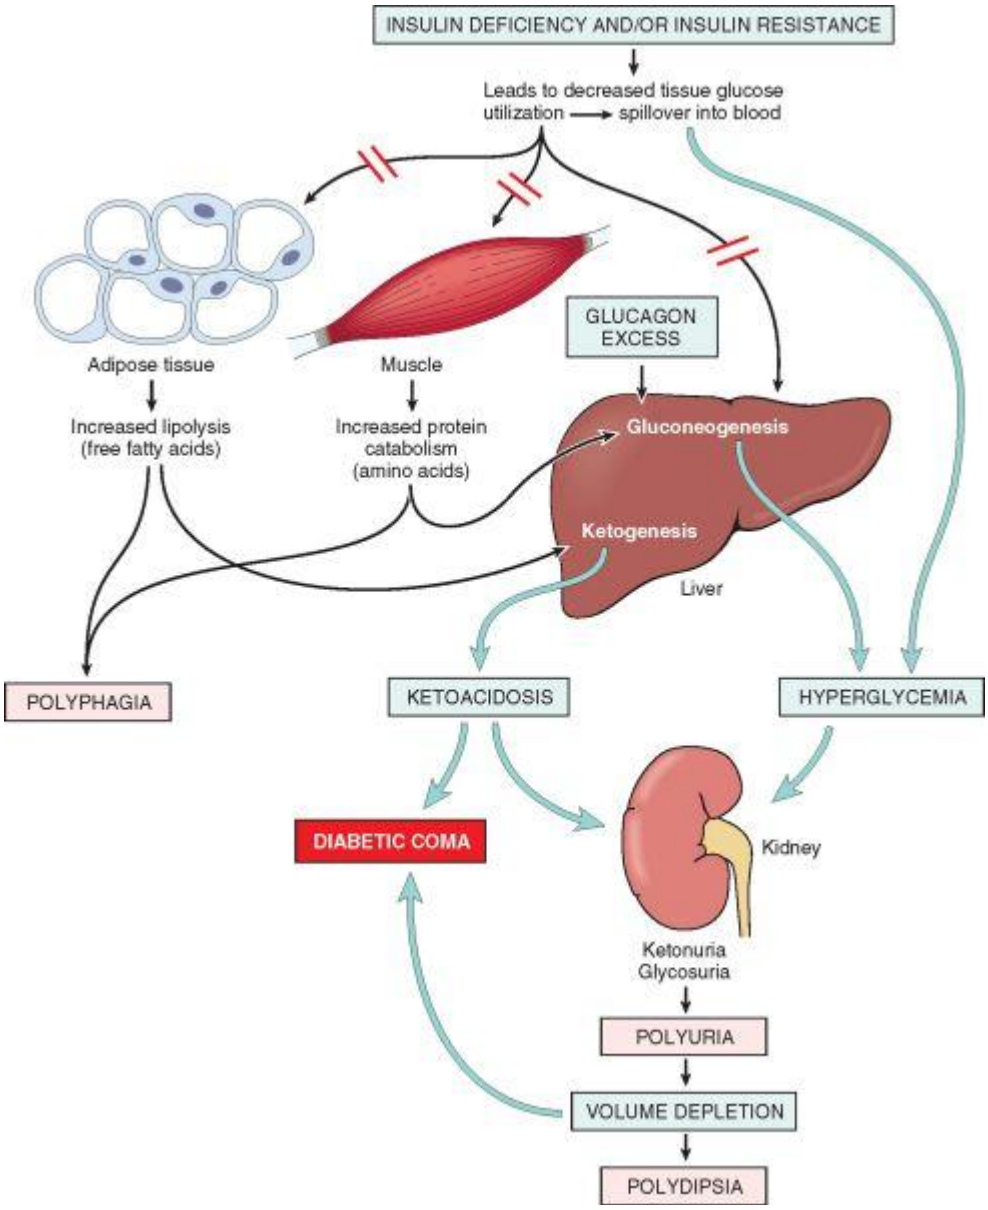

FIGURE 24-39 Sequence of metabolic derangements underlying the clinical manifestations of diabetes. An absolute insulin deficiency leads to a catabolic state, culminating in ketoacidosis and severe volume depletion. These cause sufficient central nervous system compromise to lead to coma and eventual death if left untreated.

Diabetic ketoacidosis is a serious complication of type 1 diabetes but may also occur in type 2 diabetes, though not as commonly and not to as marked an extent. These patients have marked insulin deficiency, and the release of the catecholamine hormone *epinephrine* blocks any residual insulin action and stimulates the secretion of glucagon. The insulin deficiency coupled with glucagon excess decreases peripheral utilization of glucose while increasing gluconeogenesis, severely exacerbating hyperglycemia (the plasma glucose levels are usually in the range of 500 to 700 mg/dL). The hyperglycemia causes an osmotic diuresis and dehydration characteristic of the ketoacidotic state. The second major effect of an alteration in the insulin-to-glucagon ratio is activation of the ketogenic machinery. Insulin deficiency stimulates lipoprotein lipase, with resultant breakdown of adipose stores, and an increase in levels of free fatty acids. When these free fatty acids reach the liver, they are esterified to fatty acyl coenzyme A.

Oxidation of fatty acyl coenzyme A molecules within the hepatic mitochondria produces *ketone bodies* (acetoacetic acid and β-hydroxybutyric acid). The rate at which ketone bodies are formed may exceed the rate at which acetoacetic acid and β-hydroxybutyric acid can be utilized by peripheral tissues, leading to *ketonemia* and *ketonuria*. If the urinary excretion of ketones is compromised by dehydration, systemic *metabolic ketoacidosis* results. Release of ketogenic amino acids by protein catabolism aggravates the ketotic state.

Type 2 diabetes mellitus may also present with polyuria and polydipsia, but unlike in type 1 diabetes, patients are often older (over 40 years) and frequently obese. However, with the increase in obesity and sedentary life style in our society, type 2 diabetes is now seen in children and adolescents with increasing frequency. In some cases medical attention is sought because of unexplained weakness or weight loss. *Most frequently, however, the diagnosis is made after routine blood or urine testing in asymptomatic persons*. The infrequency of ketoacidosis and milder presentation in type 2 diabetes is presumably because of higher portal vein insulin levels in these patients than in type 1 diabetics, which prevents unrestricted hepatic fatty acid oxidation and keeps the formation of ketone bodies in check. In the decompensated state, these patients may develop *hyperosmolar nonketotic coma* due to severe dehydration resulting from sustained osmotic diuresis (particularly in patients who do not drink enough water to compensate for urinary losses from chronic hyperglycemia). Typically, the patient is an elderly diabetic who is disabled by a stroke or an infection and is unable to maintain adequate water intake. Furthermore, the absence of ketoacidosis and its symptoms (nausea, vomiting, respiratory difficulties) delays the seeking of medical attention until severe dehydration and coma occur. Table 24-7 summarizes some of the pertinent clinical, genetic, and histopathologic features that distinguish type 1 and type 2 diabetes.

TABLE 24-7 -- Type 1 Versus Type 2 Diabetes Mellitus

	Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
CLINICAL		
	Onset: usually childhood and adolescence	Onset: usually adult; increasing incidence in childhood and adolescence
	Normal weight or weight loss preceding diagnosis	Vast majority are obese (80%)
	Progressive decrease in insulin levels	Increased blood insulin (early); normal or moderate decrease in insulin (late)
	Circulating islet autoantibodies (anti-insulin, anti-GAD, anti-ICA512)	No islet auto-antibodies
	Diabetic ketoacidosis in absence of insulin therapy	Nonketotic hyperosmolar coma more common
GENETICS		
	Major linkage to MHC class I and II genes; also linked to polymorphisms in *CTLA4* and *PTPN22*, and insulin gene VNTRs	No HLA linkage; linkage to candidate diabetogenic and obesity-related genes (*TCF7L2*, *PPARG*, *FTO*, etc.)
PATHOGENESIS		
	Dysfunction in regulatory T cells (Tregs) leading to breakdown in self-tolerance to islet auto-antigens	Insulin resistance in peripheral tissues, failure of compensation by β-cells
		Multiple obesity-associated factors (circulating nonesterified fatty acids, inflammatory mediators, adipocytokines) linked to pathogenesis of insulin resistance
PATHOLOGY		
	Insulitis (inflammatory infiltrate of T cells and macrophages)	No insulitis; amyloid deposition in islets

Type 1 Diabetes Mellitus	Type 2 Diabetes Mellitus
β-cell depletion, islet atrophy	Mild β-cell depletion

HLA, human leukocyte antigen; MHC, major histocompatibility complex; VNTRs, variable number of tandem repeats.

In both types it is the long-term effects of diabetes, more than the acute metabolic complications, that are responsible for the overwhelming majority of the morbidity and mortality.[59,][60] In most instances these complications appear approximately 15 to 20 years after the onset of hyperglycemia.

- *Macrovascular complications such as myocardial infarction, renal vascular insufficiency, and cerebrovascular accidents are the most common causes of mortality in long-standing diabetes*.[61] Diabetics have a two to four times greater incidence of coronary artery disease, and a fourfold higher risk of dying from cardiovascular complications than nondiabetics. Diabetes is often accompanied by underlying conditions that favor the development of adverse cardiovascular events. For example, *hypertension* is found in approximately 75% of individuals with type 2 diabetes and potentiates the effects of hyperglycemia and insulin resistance on endothelial dysfunction and atherosclerosis. Another cardiovascular risk frequently seen in diabetics is *dyslipidemia*, which includes both increased triglycerides and LDL levels and decreased levels of the “protective” lipoprotein, high-density lipoprotein (Chapter 11). Insulin resistance is believed to contribute to “diabetic dyslipidemia” by favoring the hepatic production of atherogenic lipoproteins and by suppressing the uptake of circulating lipids in peripheral tissues. Finally, diabetics have elevated levels of PAI-1, which is an inhibitor of fibrinolysis and therefore acts as a procoagulant in the formation of atherosclerotic plaques.
- *Diabetic nephropathy* is a leading cause of end-stage renal disease in the United States. Approximately 30% to 40% of all diabetics develop clinical evidence of nephropathy, but a considerably smaller fraction of patients with type 2 diabetes progress to end-stage renal disease. However, because of the much greater prevalence of type 2 diabetes, these patients constitute slightly over half the diabetic patients starting dialysis each year. The frequency of diabetic nephropathy is greatly influenced by the genetic makeup of the population in question; for example, Native Americans, Hispanics, and African Americans have a greater risk of developing end-stage renal disease than do non-Hispanic whites with type 2 diabetes. The earliest manifestation of diabetic nephropathy is the appearance of low amounts of albumin in the urine (>30 mg/day, but <300 mg/day), that is, *microalbuminuria*. Notably, microalbuminuria is also a marker for greatly increased cardiovascular morbidity and mortality for persons with either type 1 or type 2 diabetes. Therefore, all patients with microalbuminuria should be screened for macrovascular disease, and aggressive intervention should be undertaken to reduce cardiovascular risk factors. Without specific interventions, approximately 80% of type 1 diabetics and 20% to 40% of type 2 diabetics will develop *overt nephropathy with macroalbuminuria* (>300 mg of urinary albumin per day) over 10 to 15 years, usually accompanied by the appearance of hypertension. The progression from overt nephropathy to end-stage renal disease can be highly variable. By 20 years, more than 75% of type 1 diabetics and approximately 20% of type 2 diabetics with overt nephropathy will develop end-stage renal disease, requiring dialysis or renal transplantation. Diabetic nephropathy is also discussed in Chapter 20 .
- *Visual impairment*, sometimes even total blindness, is one of the more feared consequences of long-standing diabetes. Approximately 60% to 80% of patients develop some form of *diabetic retinopathy* approximately 15 to 20 years after diagnosis. The fundamental lesion of retinopathy—neovascularization—is attributable to hypoxia-induced overexpression of VEGF in the retina. Indeed, current treatment for this condition includes intravitreous injection of anti-angiogenic agents. Diabetic retinopathy, described in Chapter 29 , consists of a constellation of changes that together are considered by many ophthalmologists to be virtually diagnostic of the disease. In addition to retinopathy, diabetics also have an increased propensity for *glaucoma* and *cataract formation*, both of which contribute to visual impairment in diabetes.
- *Diabetic neuropathy* can elicit a variety of clinical syndromes, afflicting the central nervous system, peripheral sensorimotor nerves, and the autonomic nervous system (Chapter 27). The most frequent pattern of involvement is a *distal symmetric polyneuropathy* of the lower extremities that affects both motor and sensory function, but particularly the latter. Over time the upper extremities may be involved as well,

thus approximating a “glove and stocking” pattern of polyneuropathy. Other forms include *autonomic neuropathy*, which produces disturbances in bowel and bladder function and sometimes sexual impotence, and *diabetic mononeuropathy*, which may manifest as sudden footdrop, wristdrop, or isolated cranial nerve palsies.

- *Diabetics are plagued by enhanced susceptibility to infections of the skin and to tuberculosis, pneumonia, and pyelonephritis*. Such infections cause the deaths of about 5% of diabetics. In an individual with diabetic neuropathy, a trivial infection in a toe may be the first event in a long succession of complications (gangrene, bacteremia, pneumonia) that may ultimately lead to death. The basis of enhanced susceptibility is multifactorial, and includes decreased neutrophil functions (chemotaxis, adherence to the endothelium, phagocytosis, and microbicidal activity), and impaired cytokine production by macrophages. The vascular compromise also reduces delivery of circulating cells and molecules that are required for host defense.

In recent years increasingly sedentary life styles and poor eating habits have contributed to the simultaneous escalation of diabetes and obesity worldwide, which some have termed as the *diabesity* epidemic.[62] Sadly, obesity and diabetes have now percolated even to children exposed to “junk” food and lacking adequate exercise. The term *metabolic syndrome* (previously called “syndrome X”) has been applied to an increasingly common condition wherein abdominal obesity and insulin resistance are accompanied by a constellation of risk factors for cardiovascular disease like abnormal lipid profiles.[63] Persons with metabolic syndrome benefit greatly from changes in their life style, including dietary modification and weight reduction; a similar benefit is observed in individuals with frank type 2 diabetes.[64] As the incidence of communicable diseases has declined and expected life span has increased, diabetes has become a major public health problem, and it continues to be one of the top 10 “killers” in the United States. The American Diabetes Association estimates that the total costs from diabetes to the United States economy is an astounding $132 billion dollars, including $92 billion from direct medical costs and the additional $40 billion from indirect costs such as disability, work loss, and premature mortality. There is hope, however, since the role of primary prevention of type 2 diabetes by life-style and dietary alterations, and secondary prevention of diabetic complications by strict glycemic control, has become increasingly recognized. It is also hoped that islet cell transplantation, stem cell therapies, and immune modulators may result in a cure for those afflicted with type 1 diabetes.

3.14.4.2 Pancreatic Endocrine Neoplasms

The preferred term for tumors of the pancreatic islet cells (“islet cell tumors”) is *pancreatic endocrine neoplasms*. They are rare in comparison with tumors of the exocrine pancreas, accounting for only 2% of all pancreatic neoplasms. They are most common in adults and can occur anywhere along the length of the pancreas, embedded in the substance of the pancreas or arising in the immediate peripancreatic tissues. They resemble in appearance their counterparts, carcinoid tumors, found elsewhere in the alimentary tract (Chapter 17). These tumors may be single or multiple and benign or malignant. Pancreatic endocrine neoplasms often elaborate pancreatic hormones, but some may be totally nonfunctional.

Like any other endocrine neoplasms in the body (see below), it is difficult to predict the biologic behavior of a pancreatic endocrine neoplasm based on light microscopic criteria alone. *Unequivocal criteria for malignancy* include metastases, vascular invasion, and local infiltration. The functional status of the tumor has some impact on prognosis, since approximately 90% of insulinomas are benign, while 60% to 90% of other functioning and nonfunctioning pancreatic endocrine neoplasms are malignant. Fortunately, insulinomas are the most common subtype of pancreatic endocrine neoplasms.

The three most common and distinctive clinical syndromes associated with functional pancreatic endocrine neoplasms are (1) *hyperinsulinism,* (2) *hypergastrinemia and the Zollinger-Ellison syndrome*, and (3) *MEN* (described in detail later).

HYPERINSULINISM (INSULINOMA)

β-cell tumors (insulinomas) are the most common of pancreatic endocrine neoplasms. They may be responsible for the elaboration of sufficient insulin to induce clinically significant hypoglycemia. The characteristic clinical picture is dominated by hypoglycemic episodes, which (1) occur with blood glucose levels below 50 mg/dL of serum; (2) consist principally of central nervous system manifestations such as confusion, stupor, and loss of consciousness; and (3) are precipitated by fasting or exercise and are promptly relieved by feeding or parenteral administration of glucose.

Morphology. Insulinomas are most often found within the pancreas and are generally benign. Most are solitary, although multiple tumors may be encountered. Bona fide carcinomas, making up only about 10% of cases, are diagnosed on the basis of local invasion and distant metastases. On rare occasions an insulinoma may arise in ectopic pancreatic tissue. In such cases, electron microscopy reveals the distinctive granules of β-cells (see Fig. 24-26).

Solitary tumors are usually small (often <2 cm in diameter) and are encapsulated, pale to red-brown nodules located anywhere in the pancreas. Histologically, these benign tumors look remarkably like giant islets, with preservation of the regular cords of monotonous cells and their orientation to the vasculature. Not even the malignant lesions present much evidence of anaplasia, and they may be deceptively encapsulated. **Deposition of amyloid** in the extracellular tissue is a characteristic feature of many insulinomas (Fig. 24-40).

Hyperinsulinism may also be caused by **focal or diffuse hyperplasia of the islets**. This change is found occasionally in adults but is far more commonly encountered as congenital hyperinsulinism with hypoglycemia in neonates and infants. Several clinical scenarios may result in islet hyperplasia (previously known as *nesidioblastosis*), including maternal diabetes, Beckwith-Wiedemann syndrome (Chapter 10), and rare mutations in the β-cell K+-channel protein or sulfonylurea receptor.[65] In maternal diabetes, the fetal islets respond to the hyperglycemia by increasing their size and number. In the postnatal period, these hyperactive islets may be responsible for serious episodes of hypoglycemia. This phenomenon is usually transient.

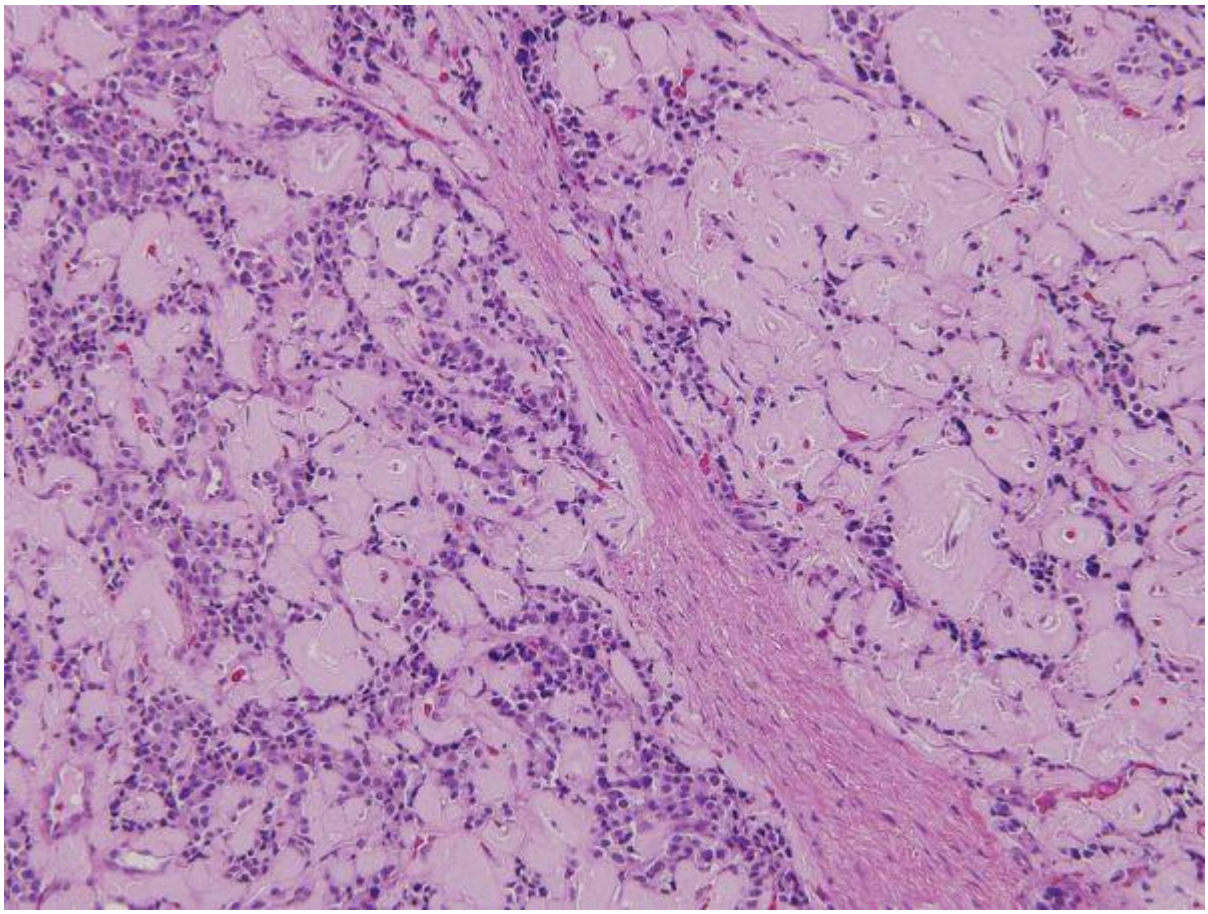

FIGURE 24-40 Pancreatic endocrine neoplasm ("islet cell tumor"). The neoplastic cells are monotonous and demonstrate minimal pleomorphism or mitotic activity. There is abundant amyloid deposition, characteristic of an insulinoma. Clinically, the patient had episodic hypoglycemia.

Clinical Features.

While up to 80% of islet cell tumors may demonstrate excessive insulin secretion, the hypoglycemia is mild in all but about 20%, and many cases never become clinically symptomatic. The critical laboratory findings in insulinomas are high circulating levels of insulin and a high insulin-to-glucose ratio. Surgical removal of the tumor is usually followed by prompt reversal of the hypoglycemia.

It is important to note that *there are many other causes of hypoglycemia besides insulinomas*. The differential diagnosis of this metabolic abnormality includes such conditions as abnormal insulin sensitivity, diffuse liver disease, inherited glycogenoses, and ectopic production of insulin by certain retroperitoneal fibromas and fibrosarcomas. Depending on the clinical circumstances, hypoglycemia induced by self-injection of insulin should also be considered.

ZOLLINGER-ELLISON SYNDROME (GASTRINOMAS)

Marked hypersecretion of gastrin usually has its origin in gastrin-producing tumors *(gastrinomas)*, which are just as likely to arise in the duodenum and peripancreatic soft tissues as in the pancreas (so-called gastrinoma triangle). There has been lack of agreement regarding the cell of origin for these tumors, although it seems likely that endocrine cells of either the gut or the pancreas could be the source.

Zollinger and Ellison first called attention to the *association of pancreatic islet cell lesions, hypersecretion of gastric acid and severe peptic ulceration,* which are present in 90% to 95% of patients.

Morphology. Gastrinomas may arise in the pancreas, the peripancreatic region, or the wall of the duodenum. **Over half of gastrin-producing tumors are locally invasive or have already metastasized at the time of diagnosis**. In approximately 25% of patients, gastrinomas arise in conjunction with other endocrine tumors, as part of the MEN-1 syndrome (see below); MEN-1–associated gastrinomas are frequently multifocal, while sporadic gastrinomas are usually single. As with insulin-secreting tumors of the pancreas, gastrin-producing tumors are histologically bland and rarely show marked anaplasia.

In the Zollinger-Ellison syndrome, hypergastrinemia gives rise to extreme gastric acid secretion, which in turn causes **peptic ulceration** (Chapter 17). The duodenal and gastric ulcers are often multiple; although they are identical to those found in the general population, they are often unresponsive to therapy. In addition, ulcers may occur in unusual locations such as the jejunum; when intractable jejunal ulcers are found, Zollinger-Ellison syndrome should be considered.

Clinical Features.

More than 50% of the patients have diarrhea; in 30%, it is the presenting symptom. Treatment of Zollinger-Ellison syndrome involves control of gastric acid secretion by use of H+,K+-ATPase inhibitors (Chapter 17) and excision of the neoplasm. Total resection of the neoplasm, when possible, eliminates the syndrome. Patients with hepatic metastases have a significantly shortened life expectancy, with progressive tumor growth leading to liver failure usually within 10 years.

OTHER RARE PANCREATIC ENDOCRINE NEOPLASMS

α-*cell tumors (glucagonomas)* are associated with increased serum levels of glucagon and a syndrome consisting of mild diabetes mellitus, a characteristic skin rash (necrolytic migratory erythema), and anemia. They occur most frequently in perimenopausal and postmenopausal women and are characterized by extremely high plasma glucagon levels.

δ-*cell tumors (somatostatinomas)* are associated with diabetes mellitus, cholelithiasis, steatorrhea, and hypochlorhydria. They are exceedingly difficult to localize preoperatively. High plasma somatostatin levels are required for diagnosis.

VIPoma (watery diarrhea, hypokalemia, achlorhydria, or WDHA syndrome) is an endocrine tumor that induces a characteristic syndrome, caused by release of vasoactive intestinal peptide (VIP) from the tumor. Some of these tumors are locally invasive and metastatic. A VIP assay should be performed on all patients with severe secretory diarrhea. Neural crest tumors, such as neuroblastomas, ganglioneuroblastomas, and ganglioneuromas (Chapter 10) and pheochromocytomas (see below) can also be associated with the VIPoma syndrome.

Pancreatic carcinoid tumors producing serotonin and an atypical carcinoid syndrome are exceedingly rare. *Pancreatic polypeptide-secreting endocrine tumors* are endocrinologically asymptomatic, despite the presence of high levels of the hormone in plasma.

Some pancreatic and extra-pancreatic endocrine tumors produce two or more hormones. In addition to insulin, gluca-gon, and gastrin, pancreatic endocrine tumors may produce ACTH, MSH, ADH, serotonin, and norepinephrine. These *multihormonal tumors* are to be distinguished from the MEN

syndromes (discusssed later), in which a multiplicity of hormones is produced by tumors in several different glands.

3.14.5 Adrenal Glands

3.14.5.1 Adrenal Cortex

The *adrenal glands* are paired endocrine organs consisting of both cortex and medulla, which differ in their development, structure, and function. Beneath the capsule of the adrenal is the narrow layer of zona glomerulosa. An equally narrow zona reticularis abuts the medulla. Intervening is the broad zona fasciculata, which makes up about 75% of the total cortex. The *adrenal cortex* synthesizes three different types of steroids: (1) *glucocorticoids* (principally cortisol), which are synthesized primarily in the zona fasciculata and to a lesser degree in the zona reticularis; (2) *mineralocorticoids*, the most important being aldosterone, which is generated in the zona glomerulosa; and (3) *sex steroids* (estrogens and androgens), which are produced largely in the zona reticularis. The *adrenal medulla* is composed of chromaffin cells, which synthesize and secrete *catecholamines*, mainly epinephrine. Catecholamines have many effects that allow rapid adaptations to changes in the environment.

Diseases of the adrenal cortex can be conveniently divided into those associated with hyperfunction and those associated with hypofunction.

ADRENOCORTICAL HYPERFUNCTION (HYPERADRENALISM)

Just as there are three basic types of corticosteroids elaborated by the adrenal cortex, so there are three distinctive hyperadrenal syndromes: (1) *Cushing syndrome*, characterized by an excess of cortisol; (2) *hyperaldosteronism*; and (3) *adrenogenital* or virilizing syndromes caused by an excess of androgens. The clinical features of these syndromes overlap somewhat because of the overlapping functions of some of the adrenal steroids.

Hypercortisolism (Cushing Syndrome)

Pathogenesis.

This disorder is caused by any condition that produces elevated glucocorticoid levels. Cushing syndrome can be broadly divided into *exogenous* and *endogenous* causes. *The vast majority of cases of Cushing syndrome are the result of the administration of exogenous glucocorticoids* ("iatrogenic" Cushing syndrome).[66] The endogenous causes can, in turn, be divided into those that are *ACTH dependent* and those that are *ACTH independent* (Table 24-8).

TABLE 24-8 -- Endogenous Causes of Cushing Syndrome

Cause	Relative Frequency (%)	Ratio of Females to Males
ACTH-DEPENDENT		
Cushing disease (pituitary adenoma; rarely CRH-dependent pituitary hyperplasia)	70	3.5:1.0
Ectopic corticotropin syndrome (ACTH-secreting pulmonary small-cell carcinoma, bronchial carcinoid)	10	1:1
ACTH-INDEPENDENT		
Adrenal adenoma	10	4:1
Adrenal carcinoma	5	1:1
Macronodular hyperplasia (ectopic expression of hormone receptors,	<2	1:1

Cause	Relative Frequency (%)	Ratio of Females to Males
including GIPR, LHR, vasopressin and serotonin receptors)		
Primary pigmented nodular adrenal disease (*PRKARIA* and *PDE11* mutations)	<2	1:1
McCune-Albright syndrome (*GNAS* mutations)	<2	1:1

Adapted with permission from Newell-Price J et al.: Cushing syndrome. Lancet 367:1605–1616, 2006.

ACTH, adrenocorticotropic hormone; GIPR, gastric inhibitory polypeptide receptor; LHR, luteinizing hormone receptor; *PRKAR1A*, protein kinase A regulatory subunit 1α; *PDE11*, phosphodiesterase 11A.

Note: These etiologies are responsible for endogenous Cushing syndrome. The most common overall cause of Cushing syndrome is exogenous glucocorticoid administration (iatrogenic Cushing syndrome).

ACTH-secreting pituitary adenomas account for approximately 70% of cases of endogenous hypercortisolism. In recognition of Harvey Cushing, the neurosurgeon who first published the full description of this syndrome, the pituitary form is referred to as *Cushing disease*.[67] The disorder affects women about four times more frequently than men and occurs most frequently in young adults. In the vast majority of cases it is caused by an *ACTH-producing pituitary microadenoma*; some corticotroph tumors qualify as macroadenomas (>10 mm). Rarely, the anterior pituitary contains areas of *corticotroph cell hyperplasia* without a discrete adenoma. Corticotroph cell hyperplasia may be primary or arise secondarily from excessive stimulation of ACTH release by a hypothalamic corticotrophin-releasing hormone (CRH)–producing tumor. The adrenal glands in individuals with Cushing disease are characterized by variable degrees of nodular cortical hyperplasia (discussed later), caused by the elevated levels of ACTH. The cortical hyperplasia, in turn, is responsible for hypercortisolism.

Secretion of ectopic ACTH by nonpituitary tumors accounts for about 10% of ACTH-dependent Cushing syndrome. In many instances the responsible tumor is a *small-cell carcinoma of the lung*, although other neoplasms, including carcinoids, medullary carcinomas of the thyroid, and islet cell tumors, have been associated with the syndrome. In addition to tumors that elaborate ectopic ACTH, an occasional neuroendocrine neoplasm produces ectopic CRH, which, in turn, causes ACTH secretion and hypercortisolism. As in the pituitary variant, the adrenal glands undergo bilateral cortical hyperplasia, but the rapid downhill course of patients with these cancers often cuts short the adrenal enlargement. This variant of Cushing syndrome is more common in men and usually occurs in the 40s and 50s.

Primary adrenal neoplasms, such as adrenal adenoma (~10%) and carcinoma (~5%) are the most common underlying causes for *ACTH-independent* Cushing syndrome. The biochemical sine qua non of ACTH-independent Cushing syndrome is elevated serum levels of cortisol with low levels of ACTH. Cortical carcinomas tend to produce more marked hypercortisolism than adenomas or hyperplasias. In instances of a unilateral neoplasm, the uninvolved adrenal cortex and the cortex in the opposite gland undergo atrophy because of suppression of ACTH secretion.

The overwhelming majority of hyperplastic adrenals are ACTH dependent, and *primary cortical hyperplasia (i.e., ACTH-independent hyperplasia) is uncommon*. In *macronodular hyperplasia* the nodules are usually greater than 3 mm in diameter. Macronodular hyperplasia is typically a sporadic (nonsyndromic) condition observed in adults. It is now known that, although the condition is ACTH independent, it is not entirely "autonomous." Specifically, cortisol production is regulated by non-ACTH circulating hormones, as a result of ectopic overexpression of their corresponding receptors in

the adrenocortical cells. For example, overexpression of the receptors for gastric inhibitory peptide, LH, ADH, and serotonin are often found within the hyperplastic tissues.[68] The mechanism by which these receptors for non-ACTH hormones are overexpressed in adrenocortical tissues is, however, not known. A subset of macronodular hyperplasia arises in the setting of McCune-Albright syndrome, characterized by germline activating mutations in *GNAS*, which encodes a stimulatory $G_s\alpha$ (Chapter 26). In addition, primary cortical hyperplasias may result from mutations in other genes that control intracellular levels of cAMP. These include the *PRKR1A* gene (see below) and the *phosphodiesterase 11A* (*PDE11A*) gene.[69]

Morphology. The main lesions of Cushing syndrome are found in the pituitary and adrenal glands. The **pituitary** shows changes regardless of the cause. The most common alteration, resulting from high levels of endogenous or exogenous glucocorticoids, is termed **Crooke hyaline change**. In this condition the normal granular, basophilic cytoplasm of the ACTH-producing cells in the anterior pituitary becomes homogeneous and paler. This alteration is the result of the accumulation of intermediate keratin filaments in the cytoplasm.

Depending on the cause of the hypercortisolism the **adrenals** have one of the following abnormalities: (1) cortical atrophy, (2) diffuse hyperplasia, (3) macronodular or micronodular hyperplasia, and (4) an adenoma or carcinoma. In patients in whom the syndrome results from exogenous glucocorticoids, suppression of endogenous ACTH results in bilateral **cortical atrophy**, due to a lack of stimulation of the zonae fasciculata and reticularis by ACTH. The zona glomerulosa is of normal thickness in such cases, because this portion of the cortex functions independently of ACTH. In contrast, in cases of endogenous hypercortisolism, the adrenals either are hyperplastic or contain a cortical neoplasm. **Diffuse hyperplasia** is found in individuals with ACTH-dependent Cushing syndrome (Fig. 24-41). Both glands are enlarged, either subtly or markedly, weighing up to 30 gm. The adrenal cortex is diffusely thickened and variably nodular, although the latter is not as pronounced as seen in cases of ACTH-independent nodular hyperplasia. Microscopically, the hyperplastic cortex demonstrates an expanded "lipid-poor" zona reticularis, comprising compact, eosinophilic cells, surrounded by an outer zone of vacuolated "lipid-rich" cells, resembling those seen in the zona fasciculata. Any nodules present are usually composed of vacuolated "lipid-rich" cells, which accounts for the yellow color of diffusely hyperplastic glands. In contrast, in **macronodular hyperplasia** the adrenals are almost entirely replaced by prominent nodules of varying sizes (≤3 cm), which contain an admixture of lipid-poor and lipid-rich cells. Unlike diffuse hyperplasia, the areas between the macroscopic nodules also demonstrate evidence of microscopic nodularity. **Micronodular hyperplasia** is composed of 1- to 3-mm darkly pigmented (brown to black) micronodules, with atrophic intervening areas (Fig. 24-42). The pigment is believed to be lipofuscin, a wear-and-tear pigment (Chapter 1).

Primary adrenocortical neoplasms causing Cushing syndrome may be malignant or benign. Functional adenomas or carcinomas of the adrenal cortex as the source of cortisol are not morphologically distinct from nonfunctioning adrenal neoplasms (described later). Both the benign and the malignant lesions are more common in women in their 30s to 50s. Adrenocortical **adenomas** are yellow tumors surrounded by thin or well-developed capsules, and most weigh less than 30 gm. Microscopically, they are composed of cells that are similar to those encountered in the normal zona fasciculata. The **carcinomas** associated with Cushing syndrome, by contrast, tend to be larger than the adenomas. These tumors are unencapsulated masses frequently exceeding 200 to 300 gm in weight, having all of the anaplastic characteristics of cancer, as will be detailed later. With functioning tumors, both benign and malignant, the adjacent adrenal cortex and that of the contralateral adrenal gland are atrophic, as a result of suppression of endogenous ACTH by high cortisol levels.

FIGURE 24-41 Diffuse hyperplasia of the adrenal contrasted with normal adrenal gland. In cross-section the adrenal cortex is yellow and thickened, and a subtle nodularity is seen (contrast with Figure 24-46). Both adrenal glands were diffusely hyperplastic in this patient with ACTH-dependent Cushing syndrome.

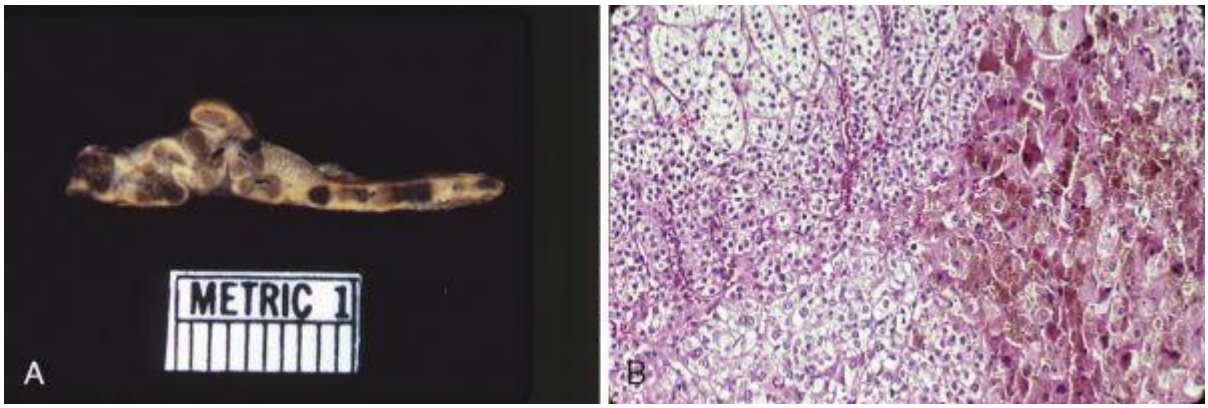

FIGURE 24-42 A, Primary pigmented nodular adrenocortical disease showing prominent pigmented nodules in the adrenal gland. **B**, On histologic examination the nodules are composed of cells containing lipofuscin pigment, seen in the right part of the field. *(Photographs courtesy of Dr. Aidan Carney, Department of Medicine, Mayo Clinic, Rochester, MN.)*

Clinical Course.

Developing slowly over time, Cushing syndrome can be quite subtle in its early manifestations. Early stages of the disorder may present with hypertension and weight gain (Table 24-9). With time the more characteristic central pattern of adipose tissue deposition becomes apparent in the form of truncal obesity, moon facies, and accumulation of fat in the posterior neck and back *(buffalo hump)*. Hypercortisolism causes selective atrophy of fast-twitch (type 2) myofibers, resulting in decreased muscle mass and proximal limb weakness. Glucocorticoids induce gluconeogenesis and inhibit the uptake of glucose by cells, with resultant *hyperglycemia*, *glucosuria* and *polydipsia (secondary diabetes)*. The catabolic effects cause loss of collagen and resorption of bones. Consequently the *skin is thin, fragile, and easily bruised*; wound healing is poor; and cutaneous striae are particularly common in the abdominal area (Fig. 24-43). Bone resorption results in the development of *osteoporosis*, with consequent backache and increased susceptibility to fractures. Persons with Cushing syndrome are at increased risk for a variety of infections, because glucocorticoids suppress the immune response. Additional manifestations include several *mental disturbances*, including mood swings, depression, and frank psychosis, as well as *hirsutism* and *menstrual abnormalities*.

TABLE 24-9 -- Clinical Features of Cushing Syndrome

Obesity or weight gain	95%[*]
Facial plethora	90%
Rounded face	90%
Decreased libido	90%
Thin skin	85%
Decrease in linear growth in children	70–80%
Menstrual irregularity	80%
Hypertension	75%
Hirsutism	75%
Depression/emotional liability	70%

Obesity or weight gain	95%[*]
Easy bruising	65%
Glucose intolerance	60%
Weakness	60%
Osteopenia or fracture	50%
Nephrolithiasis	50%

Adapted from Newell-Price J et al.: Cushing syndrome. Lancet 367:1605–1616, 2006.

[*] 100% in children.

FIGURE 24-43 A patient with Cushing syndrome demonstrating central obesity, "moon facies," and abdominal striae. *(Reproduced with permission from Lloyd RV et al.: Atlas of Nontumor Pathology: Endocrine Diseases. Washington, DC, American Registry of Pathology, 2002.)*

Cushing syndrome is diagnosed in the laboratory with the following: (1) the 24-hour urine free-cortisol concentration, which is increased, and (2) loss of normal diurnal pattern of cortisol secretion. Determining the cause of Cushing syndrome depends on the serum ACTH and measurement of urinary steroid excretion after administration of dexamethasone (dexamethasone suppression test). The results of these tests fall into three general patterns:

1. In pituitary Cushing syndrome, the most common form, ACTH levels are elevated and cannot be suppressed by the administration of a low dose of dexamethasone. Hence, there is no reduction in urinary excretion of 17-hydroxycorticosteroids. After higher doses of injected dexamethasone, however, the pituitary responds by reducing ACTH secretion, which is reflected by suppression of urinary steroid secretion.
2. Ectopic ACTH secretion results in an elevated level of ACTH, but its secretion is completely insensitive to low or high doses of exogenous dexamethasone.
3. When Cushing syndrome is caused by an adrenal tumor, the ACTH level is quite low because of feedback inhibition of the pituitary. As with ectopic ACTH secretion, both low-dose and high-dose dexamethasone fail to suppress cortisol excretion.

Primary Hyperaldosteronism

Hyperaldosteronism is the generic term for a group of closely related conditions characterized by chronic excess aldosterone secretion. Hyperaldosteronism may be primary, or it may be secondary to an extra-adrenal cause. *Primary hyperaldosteronism* stems from an autonomous overproduction of aldosterone, with resultant suppression of the renin-angiotensin system and *decreased plasma renin activity*. Blood pressure elevation is the most common manifestation of primary hyperaldosteronism, which is caused by one of three mechanisms (Fig. 24-44):

- *Bilateral idiopathic hyperaldosteronism* (IHA), characterized by bilateral nodular hyperplasia of the adrenal glands, is the most common underlying cause of primary hyperaldosteronism, accounting for about 60% of cases. Individuals with IHA tend to be older and to have less severe hypertension than those presenting with adrenal neoplasms. The pathogenesis of IHA remains unclear.
- *Adrenocortical neoplasm*, either an aldosterone-producing adenoma (the most common cause) or, rarely, an adrenocortical carcinoma. In approximately 35% of cases, primary hyperaldosteronism is caused by a solitary aldosterone-secreting adenoma, a condition referred to as *Conn syndrome*.[70] This syndrome occurs most frequently in adult middle life and is more common in women than in men (2 : 1). Multiple adenomas may be present in an occasional patient.
- *Glucocorticoid-remediable hyperaldosteronism* is an uncommon cause of primary familial hyperaldosteronism. In some families, it is caused by a chimeric gene resulting from fusion between *CYP11B1* (the *11*β*-hydroxylase* gene) and *CYP11B2* (the *aldosterone synthase* gene). This leads to a sustained production of hybrid steroids in addition to both cortisol and aldosterone. The activation of aldosterone secretion is under the influence of ACTH and hence is suppressible by exogenous administration of dexamethasone.

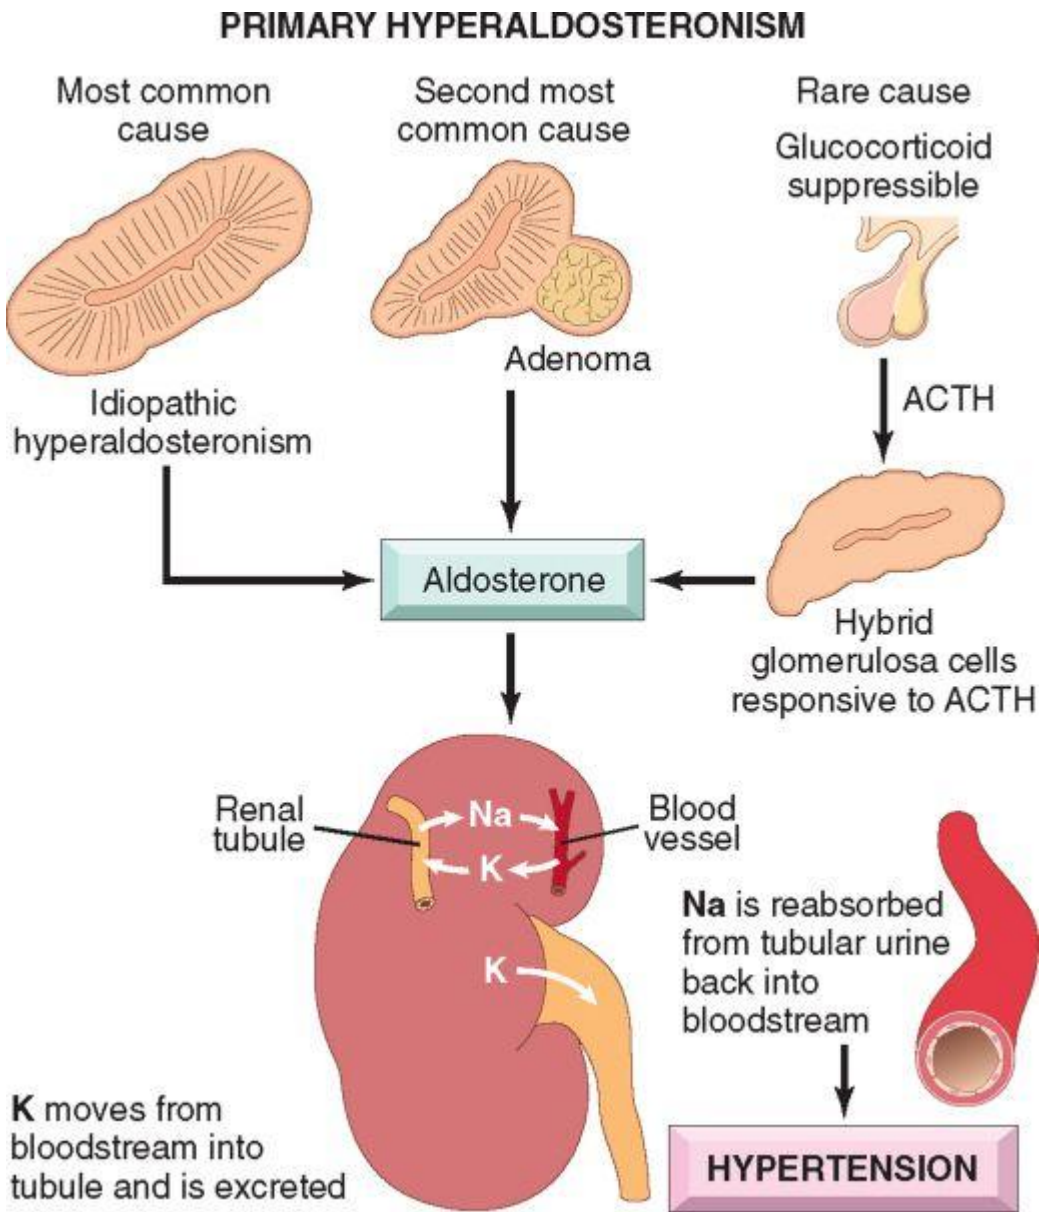

FIGURE 24-44 The major causes of primary hyperaldosteronism and its principal effects on the kidney.

In *secondary hyperaldosteronism*, in contrast, aldosterone release occurs in response to activation of the renin-angiotensin system (Chapter 11). It is characterized by *increased levels of plasma renin* and is encountered in conditions such as the following:

- Decreased renal perfusion (arteriolar nephrosclerosis, renal artery stenosis)
- Arterial hypovolemia and edema (congestive heart failure, cirrhosis, nephrotic syndrome)
- Pregnancy (due to estrogen-induced increases in plasma renin substrate)

Morphology. Aldosterone-producing adenomas are almost always solitary, small (<2 cm in diameter), well-circumscribed lesions, more often found on the left than on the right. They tend to

occur in the 30s and 40s, and in women more often than in men. These lesions are often buried within the gland and do not produce visible enlargement, a point to be remembered in interpreting sonographic or scanning images. They are bright yellow on cut section and, surprisingly, are composed of lipid-laden cortical cells that more closely resemble fasciculata cells than glomerulosa cells (the normal source of aldosterone). In general, the cells tend to be uniform in size and shape and resemble mature cortical cells; occasionally, there is modest nuclear and cellular pleomorphism (see Fig. 24-50). A characteristic feature of aldesterone-producing adenomas is the presence of eosinophilic, laminated cytoplasmic inclusions, known as **spironolactone bodies**, found after treatment with the antihypertensive drug spironolactone. In contrast to cortical adenomas associated with Cushing syndrome, those associated with hyperaldosteronism do not usually suppress ACTH secretion. Therefore, the adjacent adrenal cortex and that of the contralateral gland are not atrophic.

Bilateral idiopathic hyperplasia is marked by diffuse and focal hyperplasia of cells resembling those of the normal zona glomerulosa. The hyperplasia is often wedge-shaped, extending from the periphery toward the center of the gland. Bilateral enlargement can be subtle in idiopathic hyperplasia, and as a rule, an adrenocortical adenoma should be carefully excluded as the cause for hyperaldosteronism.

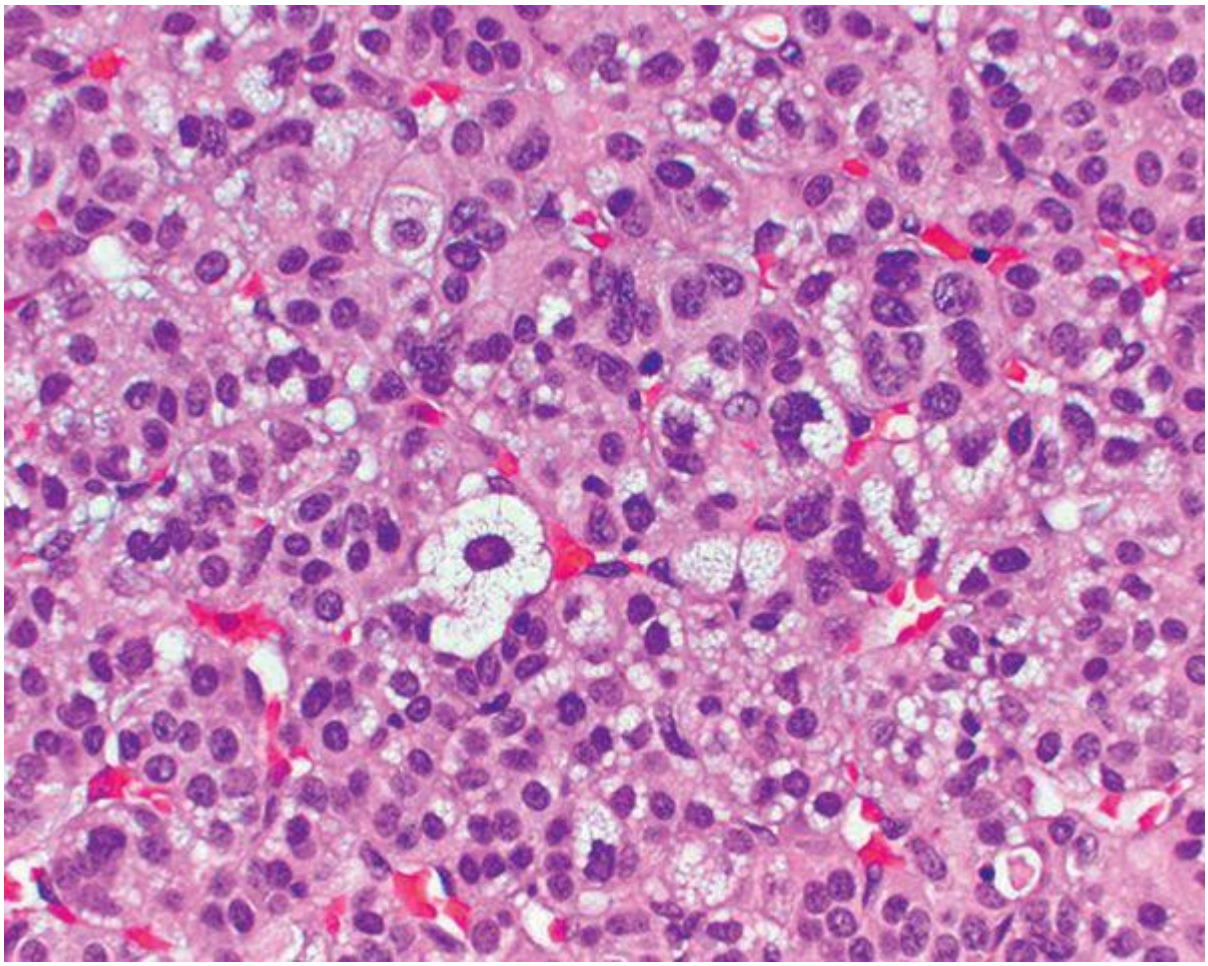

FIGURE 24-50 Histologic features of an adrenal cortical adenoma. The neoplastic cells are vacuolated because of the presence of intracytoplasmic lipid. There is mild nuclear pleomorphism. Mitotic activity and necrosis are not seen.

Clinical Course.

The clinical sine qua non of hyperaldosteronism is hypertension. With an estimated prevalence rate of 5% to 10% among nonselected hypertensive patients, primary hyperaldosteronism may be the most common cause of secondary hypertension (i.e., hypertension secondary to an identifiable cause). The prevalence of hyperaldosteronism increases with the severity of hypertension, reaching nearly 20% in patients who are classified as having treatment-resistant hypertension. Through its effects on the renal mineralocorticoid receptor, aldosterone promotes sodium reabsorption, which secondarily increases the reabsorption of water, expanding the extracellular fluid volume and elevating cardiac output. In addition, *aldosterone contributes to endothelial dysfunction* by decreasing glucose-6-phospate dehydrogenase levels, which, in turn, reduces endothelial nitric oxide synthesis and causes oxidative stress.[71] The long-term effects of hyperaldosteronism-induced hypertension are cardiovascular compromise (e.g., left ventricular hypertrophy and reduced diastolic volumes) and an increase in the prevalence of adverse events such as stroke and myocardial infarction. *Hypokalemia* was considered a mandatory feature of primary hyperaldosteronism, but increasing numbers of normokalemic patients are now diagnosed. Hypokalemia results from renal potassium wasting and, when present, can cause a variety of neuromuscular manifestations, including weakness, paresthesias, visual disturbances, and occasionally frank tetany. The diagnosis of primary hyperaldosteronism is confirmed by elevated ratios of plasma aldosterone concentration to plasma renin activity; if this screening test is positive, a confirmatory *aldosterone suppression test* must be performed, since many unrelated causes can alter the plasma aldosterone and renin ratios.

In primary hyperaldosteronism, the therapy varies according to cause. Adenomas are amenable to surgical excision. In contrast, surgical intervention is not very beneficial in patients with primary hyperaldosteronism due to bilateral hyperplasia, which often occurs in children and young adults. These patients are best managed medically with an aldosterone antagonist such as spironolactone. The treatment of secondary hyperaldosteronism rests on correcting the underlying cause stimulating the renin-angiotensin system.

Adrenogenital Syndromes

Disorders of sexual differentiation, such as virilization or feminization, can be caused by primary gonadal disorders (Chapter 22) and several primary adrenal disorders. The adrenal cortex secretes two compounds—dehydroepiandrosterone and androstenedione—that can be converted to testosterone in peripheral tissues. Unlike gonadal androgens, ACTH regulates adrenal androgen formation (Fig. 24-45); thus, excess secretion can occur either as a “pure” syndrome or as a component of Cushing disease. The adrenal causes of androgen excess include *adrenocortical neoplasms* and a group of disorders that have been designated *congenital adrenal hyperplasia (CAH)*.

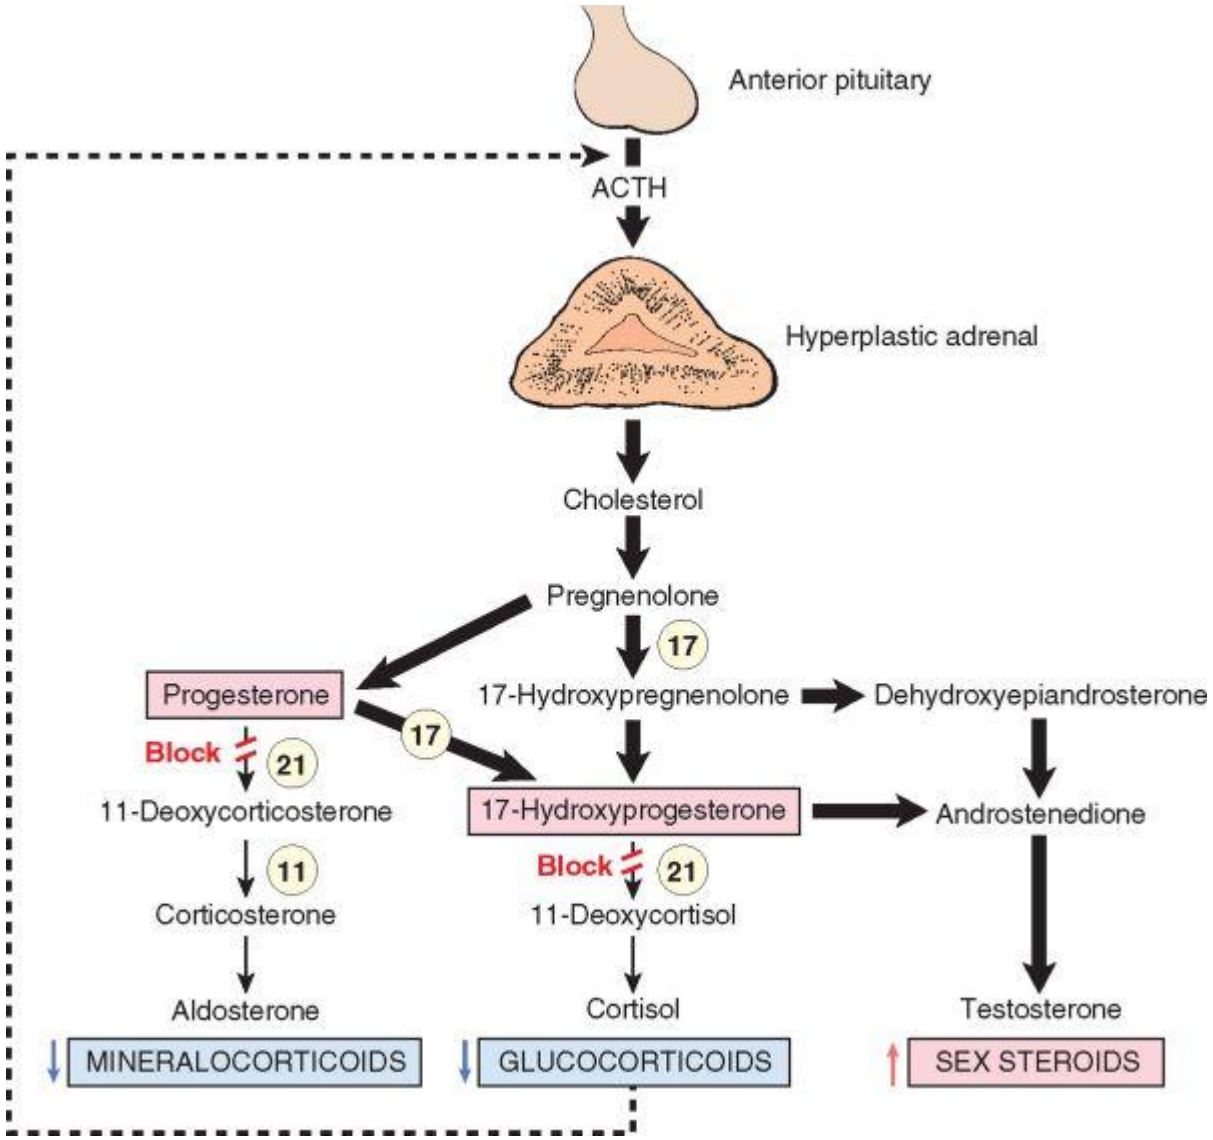

FIGURE 24-45 Consequences of C-21 hydroxylase deficiency. 21-Hydroxylase deficiency impairs the synthesis of both cortisol and aldosterone. The resultant decrease in feedback inhibition *(dashed line)* causes increased secretion of ACTH, resulting ultimately in adrenal hyperplasia and increased synthesis of testosterone. The sites of action of 11-, 17-, and 21-hydroxylase are shown by the numbers in circles.

Adrenocortical neoplasms associated with virilization are more likely to be *androgen-secreting adrenal carcinomas* than adenomas. Such tumors are often also associated with hypercortisolism ("mixed syndrome"). They are morphologically identical to other cortical neoplasms and will be discussed later.

CAH represents a group of autosomal-recessive, inherited metabolic errors, each characterized by a deficiency or total lack of a particular enzyme involved in the biosynthesis of cortical steroids, particularly cortisol. Steroidogenesis is then channeled into other pathways, leading to increased production of androgens, which accounts for virilization. Simultaneously, the deficiency of cortisol results in increased secretion of ACTH, resulting in adrenal hyperplasia. Certain enzyme defects may also impair aldosterone secretion, adding *salt wasting* to the virilizing syndrome. Other enzyme deficiencies may be incompatible with life or, in rare instances, may involve only the aldosterone

pathway without involving cortisol synthesis. Thus, there is a spectrum of these syndromes; the following remarks focus on the most common.

21-Hydroxylase Deficiency.

The defective conversion of progesterone to 11-deoxycorticosterone by 21-hydroxylase (the product of *CYP21A2*) accounts for over 90% of cases of CAH. Figure 24-45 illustrates normal adrenal steroidogenesis and the consequences of 21-hydroxylase deficiency, which may range from a total lack to a mild loss, depending on the nature of the *CYP21A2* mutation. Three distinctive syndromes have been described: (1) salt-wasting (classic) adrenogenitalism, (2) simple virilizing adrenogenitalism, and (3) nonclassic adrenogenitalism, a mild disease that may be entirely asymptomatic or associated only with symptoms of androgen excess during childhood or puberty.

The carrier frequency of the classic form is approximately 1 in 120, while the carrier frequency of the nonclassic or mild form may be higher, depending on the ethnic group; Hispanics and Ashkenazi Jewish populations have the highest carrier frequencies. The incidence of classic 21-hydroxylase deficiency varies somewhat between populations, with a worldwide mean of around 1 in 13,000 newborns. The mechanism of *CYP21A2* gene inactivation in 21-hydroxylase deficiency involves recombination with a neighboring pseudogene on chromosome 6p21 called *CYP21A1* (a *pseudogene* is an inactive homologous gene created by ancestral duplication in a localized region of the genome).[72] In the majority of cases of CAH, portions of the *CYP21A1* pseudogene replace all or part of the active *CYP21A2* gene. The introduction of nonfunctional sequences from *CYP21A1* into the *CYP21A2* sequence has the same effect as inactivating mutations in *CYP21A2*.

The *salt-wasting syndrome* results from an inability to convert progesterone into deoxycorticosterone because of a total lack of the hydroxylase. Thus, there is virtually no synthesis of mineralocorticoids, and concomitantly, there is a block in the conversion of hydroxyprogesterone into deoxycortisol resulting in deficient cortisol synthesis. This pattern usually comes to light soon after birth, because in utero the electrolytes and fluids can be maintained by the maternal kidneys. There is *salt wasting, hyponatremia*, and *hyperkalemia*, which induce acidosis, *hypotension*, cardiovascular collapse, and possibly death. The concomitant block in cortisol synthesis and excess production of androgens, however, lead to virilization, which is easily recognized in the female at birth or in utero but is difficult to recognize in the male. Males with this disorder are generally unrecognized at birth but come to clinical attention 5 to 15 days later because of some salt-losing crisis.

Simple virilizing adrenogenital syndrome without salt wasting (presenting as genital ambiguity) occurs in approximately a third of patients with 21-hydroxylase deficiency. These patients generate sufficient mineralocorticoid for salt reabsorption and prevent a salt-wasting "crisis." However, the lowered glucocorticoid level fails to cause feedback inhibition of ACTH secretion. Thus, the level of testosterone is increased, with resultant progressive virilization.

Nonclassic or late-onset adrenal virilism is significantly more common than the classic patterns already described. There is only a partial deficiency in 21-hydroxylase function, which accounts for the later onset. Individuals with this syndrome may be virtually asymptomatic or have mild manifestations, such as hirsutism, acne, and menstrual irregularities. Nonclassic CAH cannot be diagnosed on routine newborn screening, and the diagnosis is usually rendered by demonstration of biosynthetic defects in steroidogenesis.

Morphology. In all cases of CAH the adrenals are bilaterally hyperplastic, sometimes increasing to 10 to 15 times their normal weights because of the sustained elevation in ACTH. The adrenal cortex

is thickened and nodular, and on cut section the widened cortex appears brown, because of total depletion of all lipid. The proliferating cells are mostly compact, eosinophilic, lipid-depleted cells, intermixed with lipid-laden clear cells. Hyperplasia of corticotroph (ACTH-producing) cells is present in the anterior pituitary in most persons with CAH.

Clinical Course.

The clinical features of these disorders are determined by the specific enzyme deficiency and include abnormalities related to *androgen excess*, with or without *aldosterone* and *glucocorticoid deficiency*. CAH affects not only adrenal cortical enzymes but also products synthesized in the medulla. High levels of intra-adrenal glucocorticoids are required to facilitate medullary catecholamine (epinephrine and norepinephrine) synthesis. In patients with severe salt-wasting 21-hydroxylase deficiency, a combination of low cortisol levels and developmental defects of the medulla *(adrenomedullary dysplasia)* profoundly affects catecholamine secretion, further predisposing these individuals to hypotension and circulatory collapse.[73]

Depending on the nature and severity of the enzymatic defect, the onset of clinical symptoms may occur in the perinatal period, later childhood, or, less commonly, adulthood. For example, in 21-hydroxylase deficiency excessive androgenic activity causes signs of masculinization in females, ranging from clitoral hypertrophy and pseudohermaphroditism in infants, to oligomenorrhea, hirsutism, and acne in postpubertal females. In males, androgen excess is associated with enlargement of the external genitalia and other evidence of precocious puberty in prepubertal patients and oligospermia in older males.

CAH should be suspected in any neonate with ambiguous genitalia; severe enzyme deficiency in infancy can be a life-threatening condition with vomiting, dehydration, and salt wasting. Individuals with CAH are treated with exogenous glucocorticoids, which, in addition to providing adequate levels of glucocorticoids, also suppress ACTH levels and thus decrease the excessive synthesis of the steroid hormones responsible for many of the clinical abnormalities. Mineralocorticoid supplementation is required in the salt-wasting variants of CAH. With the availability of routine neonatal metabolic screens for CAH and the feasibility of molecular testing for antenatal detection of 21-hydroxylase mutations, the outcome for even the most severe variants has improved significantly.

ADRENOCORTICAL INSUFFICIENCY

Adrenocortical insufficiency, or hypofunction, may be caused by either primary adrenal disease (primary hypoadrenalism) or decreased stimulation of the adrenals due to a deficiency of ACTH (secondary hypoadrenalism) (Table 24-10). The patterns of adrenocortical insufficiency can be considered under the following headings: (1) primary *acute* adrenocortical insufficiency (adrenal crisis), (2) primary *chronic* adrenocortical insufficiency *(Addison disease)*, and (3) secondary adrenocortical insufficiency.

TABLE 24-10 -- Adrenocortical Insufficiency

PRIMARY INSUFFICIENCY
Loss of Cortex
Congenital adrenal *hypo*plasia
X-linked adrenal hypoplasia (*DAX1* gene on Xp21)
“Miniature”-type adrenal hypoplasia (unknown cause)
Adrenoleukodystrophy (*ALD* gene on Xq28)

Autoimmune adrenal insufficiency
Autoimmune polyendocrinopathy syndrome type 1 (*AIRE1* gene on 21q22)
Autoimmune polyendocrinopathy syndrome type 2 (polygenic)
Isolated autoimmune adrenalitis (polygenic)
Infection
Acquired immune deficiency syndrome
Tuberculosis
Fungi
Acute hemorrhagic necrosis (*Waterhouse-Friderichsen syndrome*)
Amyloidosis, sarcoidosis, hemochromatosis
Metastatic carcinoma
Metabolic Failure in Hormone Production
Congenital adrenal *hyper*plasia (cortisol and aldosterone deficiency with virilization)
Drug- and steroid-induced inhibition of ACTH or cortical cell function
SECONDARY INSUFFICIENCY
Hypothalamic Pituitary Disease
Neoplasm, inflammation (sarcoidosis, tuberculosis, pyogens, fungi)
Hypothalamic Pituitary Suppression
Long-term steroid administration
Steroid-producing neoplasms

ACTH, adrenocorticotropic hormone.

Primary Acute Adrenocortical Insufficiency

Acute adrenal cortical insufficiency occurs in a variety of clinical settings.

- As a *crisis* in individuals with chronic adrenocortical insufficiency precipitated by any form of stress that requires an immediate increase in steroid output from glands incapable of responding
- In patients maintained on exogenous corticosteroids, in whom *rapid withdrawal of steroids* or failure to increase steroid doses in response to an acute stress may precipitate an adrenal crisis, as a result of the inability of the atrophic adrenals to produce glucocorticoid hormones
- As a result of *massive adrenal hemorrhage*, which damages the adrenal cortex sufficiently to cause acute adrenocortical insufficiency—as occurs in newborns following prolonged and difficult delivery with considerable trauma and hypoxia. Newborns are particularly vulnerable because they are often deficient in prothrombin for at least several days after birth. It also occurs in some patients maintained on anticoagulant therapy, in postsurgical patients who develop disseminated intravascular coagulation and consequent hemorrhagic infarction of the adrenals, and as a complication of bacteremic infection; in this last setting, it is called *Waterhouse-Friderichsen syndrome*.[74,][75]

Waterhouse-Friderichsen Syndrome

This uncommon but catastrophic syndrome is characterized by the following:

- Overwhelming bacterial infection, classically *Neisseria meningitidis* septicemia but occasionally caused by other highly virulent organisms, such as *Pseudomonas* species, pneumococci, *Haemophilus influenzae*, or even staphylococci
- Rapidly progressive hypotension leading to shock
- Disseminated intravascular coagulation associated with widespread purpura, particularly of the skin
- Rapidly developing adrenocortical insufficiency associated with massive bilateral adrenal hemorrhage

Waterhouse-Friderichsen syndrome can occur at any age but is somewhat more common in children. The basis for the adrenal hemorrhage is uncertain but could be attributable to direct bacterial seeding of small vessels in the adrenal, the development of disseminated intravascular coagulation, endotoxin-induced vasculitis, or some form of hypersensitivity vasculitis. *Whatever the basis, the adrenals are converted to sacs of clotted blood, which virtually obscures all underlying detail* (Fig. 24-46). Histologic examination reveals that the hemorrhage starts within the medulla near thin-walled venous sinusoids, then suffuses peripherally into the cortex, often leaving islands of recognizable cortical cells (Fig. 24-47). When it is recognized promptly and treated effectively with antibiotics, recovery is possible, but the clinical course is usually abrupt and devastating. Prompt recognition and appropriate therapy must be instituted immediately, or death follows within hours to a few days.

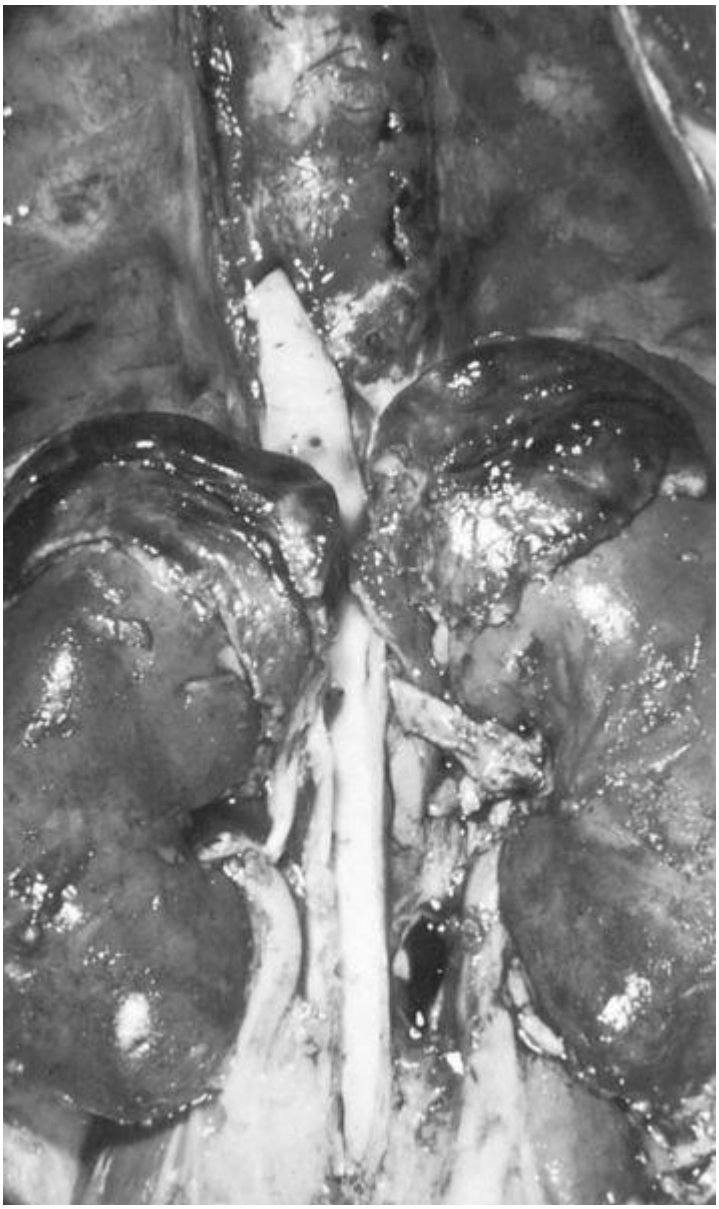

FIGURE 24-46 Waterhouse-Friderichsen syndrome in a child. The dark, hemorrhagic adrenal glands are distended with blood.

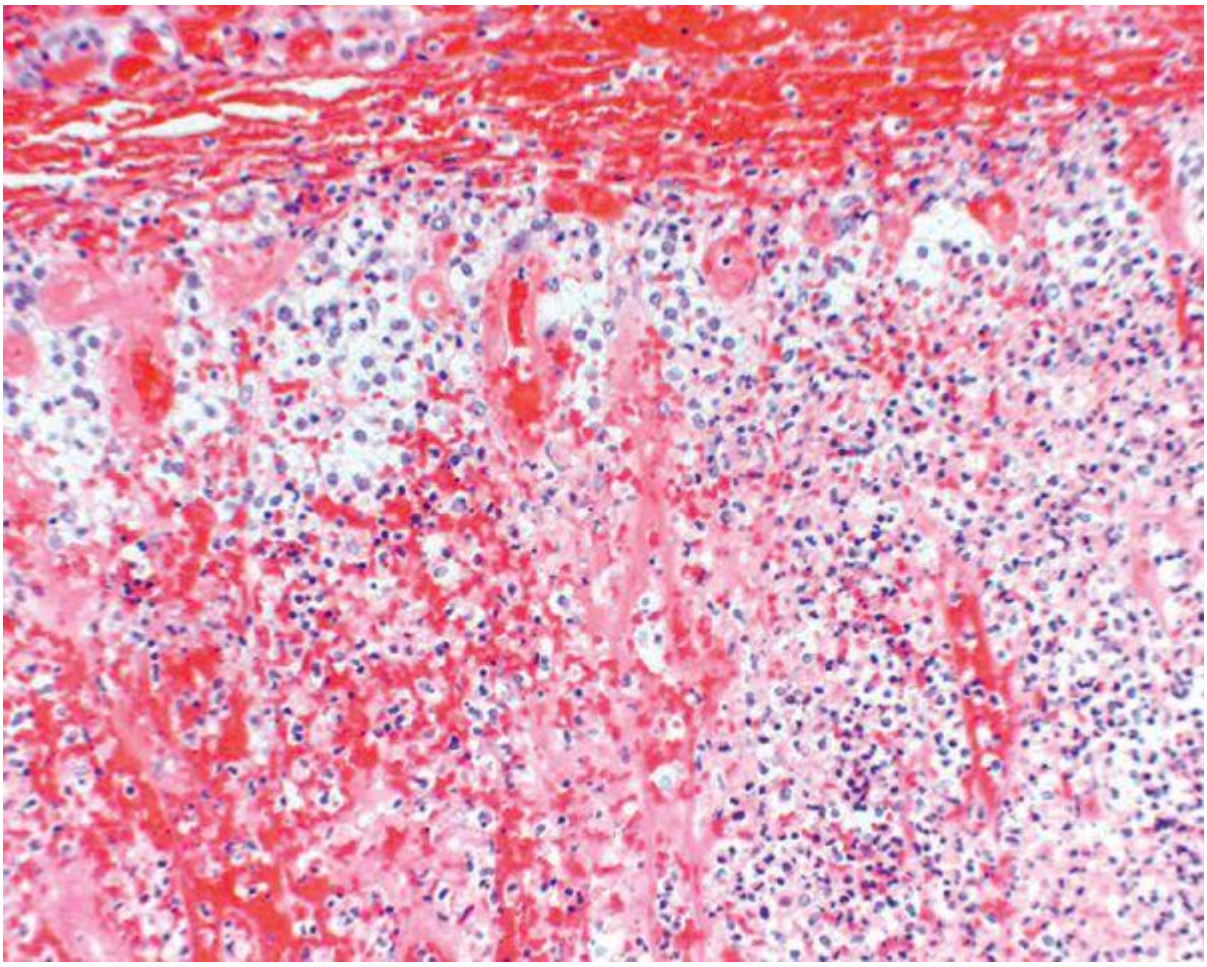

FIGURE 24-47 Waterhouse-Friderichsen syndrome. At autopsy, the adrenals were grossly hemorrhagic and shrunken; microscopically, little residual cortical architecture is discernible.

Primary Chronic Adrenocortical Insufficiency (Addison Disease)

In an article published in 1855, Thomas Addison described a group of patients suffering from a constellation of symptoms, including "general languor and debility, remarkable feebleness of the heart's action, and a peculiar change in the color of the skin" associated with disease of the "suprarenal capsules" or, in more current terminology, the adrenal glands.[76] Addison disease, or chronic adrenocortical insufficiency, is an uncommon disorder resulting from progressive destruction of the adrenal cortex. In general, clinical manifestations of adrenocortical insufficiency do not appear until at least 90% of the adrenal cortex has been compromised. The causes of chronic adrenocortical insufficiency are listed in Table 24-10 . Although all races and both sexes may be affected, certain causes of Addison disease (such as autoimmune adrenalitis) are much more common in whites and in women.

Pathogenesis.

A large number of diseases may affect the adrenal cortex, including lymphomas, amyloidosis, sarcoidosis, hemochromatosis, fungal infections, and adrenal hemorrhage, but more than 90% of all cases are attributable to one of four disorders: *autoimmune adrenalitis, tuberculosis, AIDS, or metastatic cancers*.

Autoimmune adrenalitis accounts for 60% to 70% of cases; it is by far the most common cause of primary adrenal insufficiency in developed countries. As the name implies, there is autoimmune destruction of steroidogenic cells. Autoantibodies to several key steroidogenic enzymes (21-hydroxylase, 17-hydroxylase) have been detected in these patients. Autoimmune adrenalitis can occur in one of two clinical settings:

- *Autoimmune polyendocrine syndrome type 1* (APS1) is also known as autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy. APS1 is characterized by chronic mucocutaneous candidiasis and abnormalities of skin, dental enamel, and nails (ectodermal dystrophy) occurring in association with a combination of organ-specific autoimmune disorders (autoimmune adrenalitis, autoimmune hypoparathyroidism, idiopathic hypogonadism, pernicious anemia) that result in immune destruction of target organs. APS1 is caused by mutations in the autoimmune regulator *(AIRE)* gene on chromosome 21q22. AIRE is expressed primarily in the thymus, where it functions as a transcription factor that promotes the expression of many peripheral tissue antigens. Self-reactive T cells that recognize these antigens undergo clonal deletion (Chapter 6).[77] In the absence of AIRE function, central tolerance to peripheral tissue antigens is compromised, promoting autoimmunity.
- *Autoimmune polyendocrine syndrome type 2* (APS2) usually starts in early adulthood and presents as a combination of adrenal insufficiency and autoimmune thyroiditis or type 1 diabetes. Unlike in APS1, mucocutaneous candidiasis, ectodermal dysplasia, and autoimmune hypoparathyroidism do not occur.

Infections, particularly tuberculosis and those produced by fungi, may also cause primary chronic adrenocortical insufficiency. Tuberculous adrenalitis, which once accounted for as much as 90% of Addison disease, has become less common with the development of antituberculous agents. With the resurgence of tuberculosis in most urban centers and the persistence of the disease in developing countries, however, this cause of adrenal insufficiency must be kept in mind. When present, tuberculous adrenalitis is usually associated with active infection in other sites, particularly in the lungs and genitourinary tract. Among the fungi, disseminated infections caused by *Histoplasma capsulatum* and *Coccidioides immitis* may result in chronic adrenocortical insufficiency. AIDS sufferers are at risk for developing adrenal insufficiency from several infectious (cytomegalovirus, *Mycobacterium avium-intercellulare*) and noninfectious (Kaposi sarcoma) complications.

Metastatic neoplasms involving the adrenals are another cause of adrenal insufficiency. The adrenals are a fairly common site for metastases in patients with disseminated carcinomas. Although adrenal function is preserved in most such patients, the metastatic tumors occasionally destroy enough adrenal cortex to produce a degree of adrenal insufficiency. Carcinomas of the lung and breast are the source of a majority of metastases, although many other neoplasms, including gastrointestinal carcinomas, malignant melanoma, and hematopoietic neoplasms, may also metastasize to the adrenals.

Genetic causes of adrenal insufficiency include congenital adrenal hypoplasia (*adrenal hypoplasia congenita*) and *adrenoleukodystrophy*. Adrenoleukodystrophy is described in Chapter 28 . Congenital adrenal hypoplasia is a rare X-linked disease caused by mutations in a gene that encodes a transcription factor implicated in adrenal development.

Morphology. The anatomic changes in the adrenal glands depend on the underlying disease. **Primary autoimmune adrenalitis** is characterized by irregularly shrunken glands, which may be difficult to identify within the suprarenal adipose tissue. Histologically the cortex contains only scattered residual cortical cells in a collapsed network of connective tissue. A variable lymphoid infiltrate is present in the cortex and may extend into the adjacent medulla, although the medulla is otherwise preserved (Fig. 24-48). In cases of **tuberculous and fungal disease** the adrenal architecture is effaced by a granulomatous inflammatory reaction identical to that encountered in other sites of infection. When hypoadrenalism is caused by **metastatic carcinoma**, the adrenals are

enlarged, and their normal architecture is obscured by the infiltrating neoplasm.

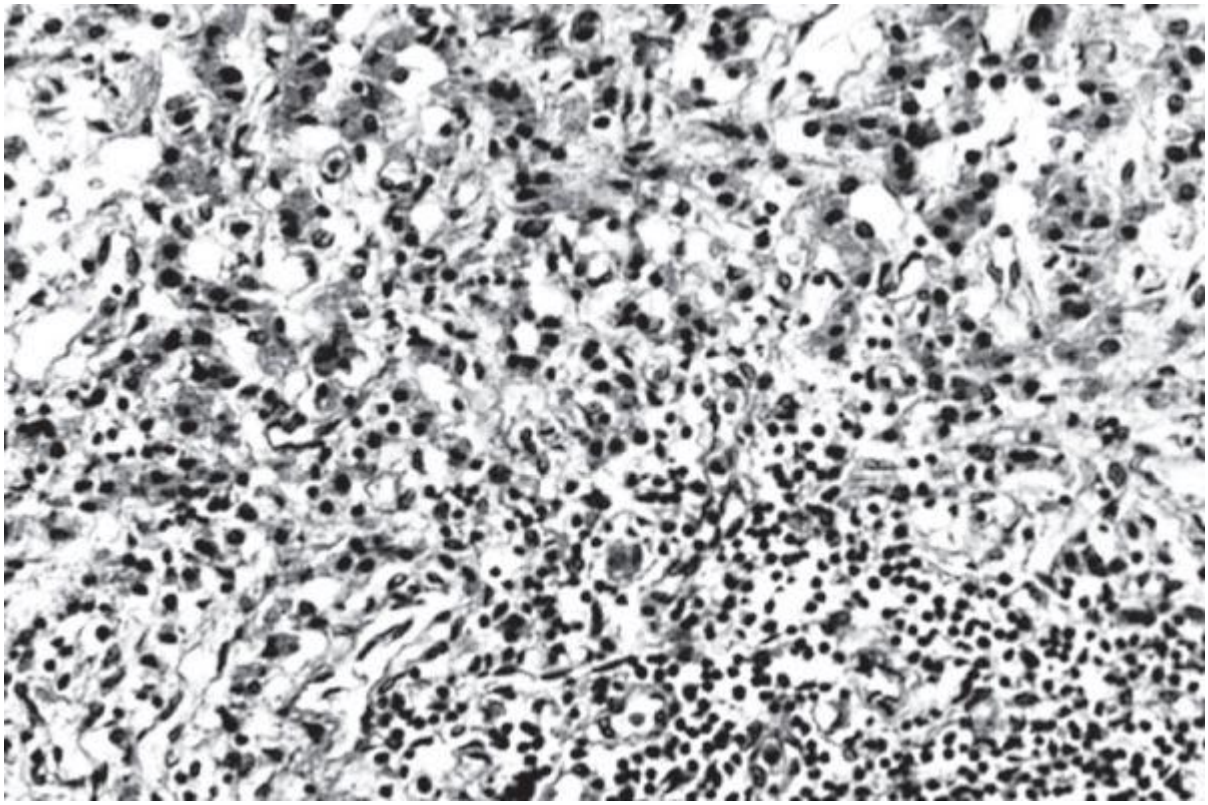

FIGURE 24-48 Autoimmune adrenalitis. In addition to loss of all but a subcapsular rim of cortical cells, there is an extensive mononuclear cell infiltrate.

Clinical Course.

Addison disease begins insidiously and does not come to attention until the levels of circulating glucocorticoids and mineralocorticoids are significantly decreased. The initial manifestations include *progressive weakness and easy fatigability*, which may be dismissed as nonspecific complaints. *Gastrointestinal* disturbances are common and include anorexia, nausea, vomiting, weight loss, and diarrhea. In individuals with primary adrenal disease, *hyperpigmentation* of the skin, particularly of sun-exposed areas and at pressure points, such as the neck, elbows, knees, and knuckles, is quite characteristic. This is caused by elevated levels of pro-opiomelanocortin (POMC), which is derived from the anterior pituitary and is a precursor of both ACTH and melanocyte stimulating hormone (MSH). By contrast, hyperpigmentation is not seen in persons with adrenocortical insufficiency caused by primary pituitary or hypothalamic disease. Decreased mineralocorticoid activity in persons with primary adrenal insufficiency results in potassium retention and sodium loss, with consequent *hyperkalemia, hyponatremia, volume depletion, and hypotension*. Hypoglycemia may occasionally occur as a result of glucocorticoid deficiency and impaired gluconeogenesis. Stresses such as infections, trauma, or surgical procedures in such patients can precipitate an acute adrenal crisis, manifested by intractable vomiting, abdominal pain, hypotension, coma, and vascular collapse. Death occurs rapidly unless corticosteroid therapy begins immediately.

Secondary Adrenocortical Insufficiency

Any disorder of the hypothalamus and pituitary, such as metastatic cancer, infection, infarction, or irradiation, that reduces the output of ACTH leads to a syndrome of hypoadrenalism that has many similarities to Addison disease. Analogously, prolonged administration of exogenous glucocorticoids suppresses the output of ACTH and adrenal function. *With secondary disease the hyperpigmentation of primary Addison disease is lacking, because levels of melanocyte-stimulating hormone are not elevated*. The manifestations also differ in that secondary hypoadrenalism is characterized by deficient cortisol and androgen output but normal or near-normal aldosterone synthesis. Thus, in adrenal insufficiency secondary to pituitary malfunction, marked hyponatremia and hyperkalemia are not seen.

ACTH deficiency can occur alone, but in some instances, it is only one component of panhypopituitarism, associated with multiple primary trophic hormone deficiencies. Secondary disease can be differentiated from Addison disease by demonstration of low levels of plasma ACTH. In patients with primary disease the destruction of the adrenal cortex precludes a response to exogenously administered ACTH, whereas in those with secondary hypofunction there is a prompt rise in plasma cortisol levels.

Morphology. In cases of hypoadrenalism secondary to hypothalamic or pituitary disease **(secondary hypoadrenalism)**, depending on the severity of ACTH deficiency, the adrenals may be moderately to markedly decreased in size. The small, flattened glands usually retain their yellow color as a result of a small amount of residual lipid. The cortex may be reduced to a thin ribbon composed largely of zona glomerulosa. The medulla is unaffected.

ADRENOCORTICAL NEOPLASMS

It should be evident from the preceding sections that functional adrenal neoplasms may be responsible for any of the various forms of hyperadrenalism. Adenomas and carcinomas are about equally common in adults; in children, carcinomas predominate. While most cortical neoplasms are sporadic, two familial cancer syndromes are associated with a predisposition for developing adrenocortical carcinomas: Li-Fraumeni syndrome, wherein patients harbor germline *p53* mutations (Chapter 7), and Beckwith-Wiedemann syndrome, an imprinting disorder (Chapter 10). *Functional adenomas are most commonly associated with hyperaldosteronism and Cushing syndrome, whereas a virilizing neoplasm is more likely to be a carcinoma*. However, not all adrenocortical neoplasms elaborate steroid hormones. *Functional and nonfunctional adrenocortical neoplasms cannot be distinguished on the basis of morphologic features*. Determination of functionality is based on clinical evaluation, and measurement of hormones or hormone metabolites in the blood.

Morphology. Most **adrenocortical adenomas** are clinically silent and are usually incidental findings at autopsy or during abdominal imaging for an unrelated cause (see the discussion of adrenal "incidentalomas" below). Some experts believe that all adrenal adenomas should, by definition, demonstrate clinical or biochemical evidence of hyperfunction and that incidentally discovered "tumors" are best classified as hyperplasia. In either case the typical cortical adenoma is a well-circumscribed, nodular lesion up to 2.5 cm in diameter that expands the adrenal (Fig. 24-49). In contrast to functional adenomas, which are associated with atrophy of the adjacent cortex, the cortex adjacent to nonfunctional adenomas is normal. On cut surface, adenomas are usually yellow to yellow-brown because of the presence of lipid. Microscopically, adenomas are composed of cells similar to those populating the normal adrenal cortex. The nuclei tend to be small, although some degree of pleomorphism may be encountered even in benign lesions ("endocrine atypia"). The cytoplasm of the neoplastic cells ranges from eosinophilic to vacuolated, depending on their lipid content (Fig. 24-50). Mitotic activity is generally inconspicuous.

Adrenocortical carcinomas are rare neoplasms that can occur at any age, including childhood. They are more likely to be functional than adenomas and are often associated with virilism or other clinical manifestations of hyperadrenalism. In most cases adrenocortical carcinomas are large, invasive lesions, many exceeding 20 cm in diameter, which efface the native adrenal gland (Fig. 24-51). The less common, smaller, and better circumscribed lesions may be difficult to distinguish from an adenoma. On cut surface, adrenocortical carcinomas are typically variegated, poorly demarcated lesions containing areas of necrosis, hemorrhage, and cystic change. Adrenal cancers have a strong tendency to invade the adrenal vein, vena cava, and lymphatics. Metastases to regional and periaortic nodes are common, as is distant hematogenous spread to the lungs and other viscera. Bone metastases are unusual. The median patient survival is about 2 years. Microscopically, adrenocortical carcinomas may be composed of well-differentiated cells, resembling those seen in cortical adenomas, or bizarre, monstrous giant cells (Fig. 24-52), which may be difficult to distinguish from those of an undifferentiated carcinoma metastatic to the adrenal. Between these extremes are found cancers with moderate degrees of anaplasia, some composed predominantly of spindle cells. Carcinomas, particularly those of bronchogenic origin, may metastasize to the adrenals, and may be difficult to differentiate from primary cortical carcinomas. Of note, carcinomas metastatic to the adrenal cortex are significantly more frequent than a primary adrenocortical carcinoma.

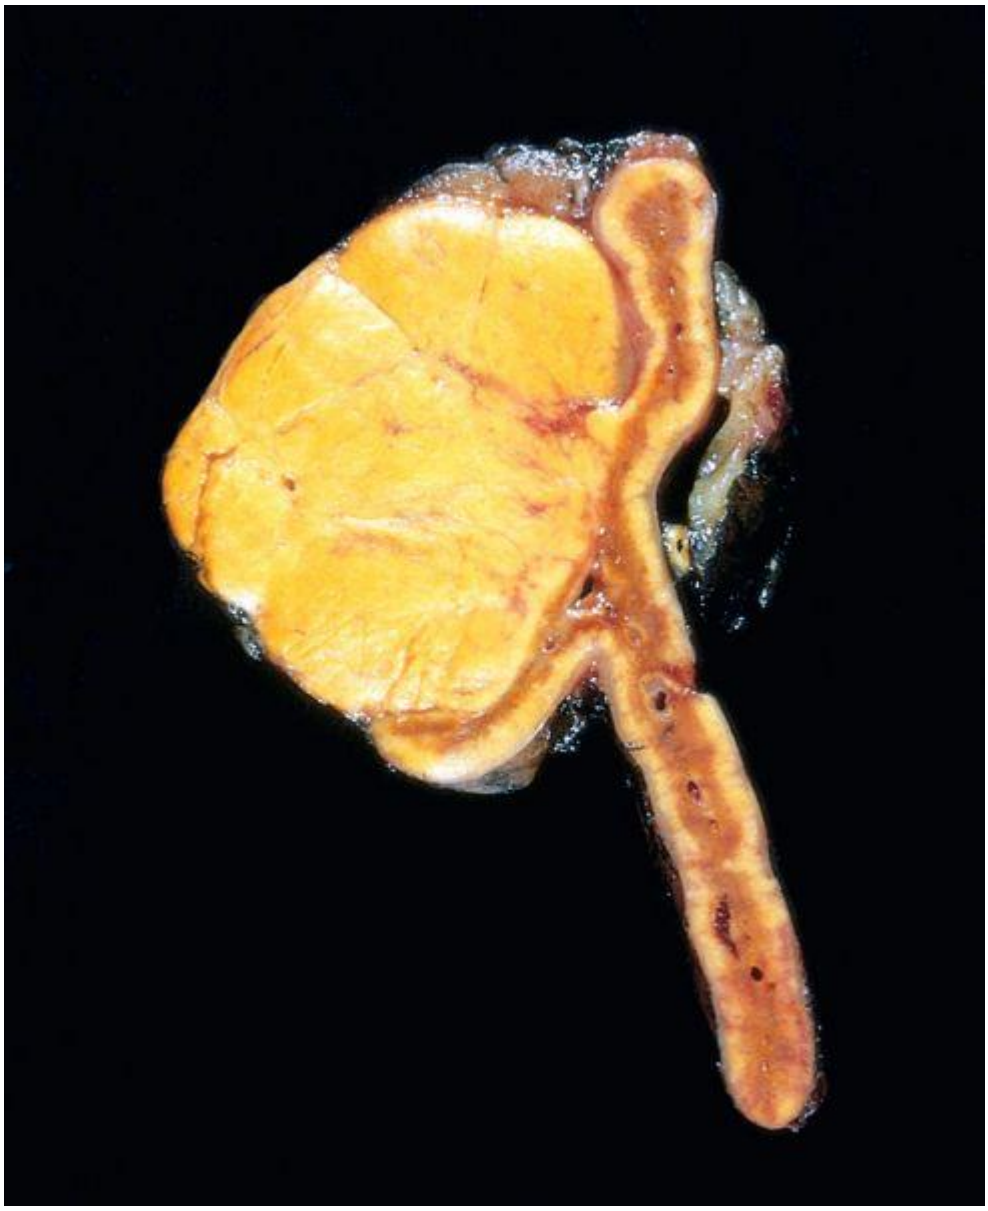

FIGURE 24-49 Adrenal cortical adenoma. The adenoma is distinguished from nodular hyperplasia by its solitary, circumscribed nature. The functional status of an adrenal cortical adenoma cannot be predicted from its gross or microscopic appearance.

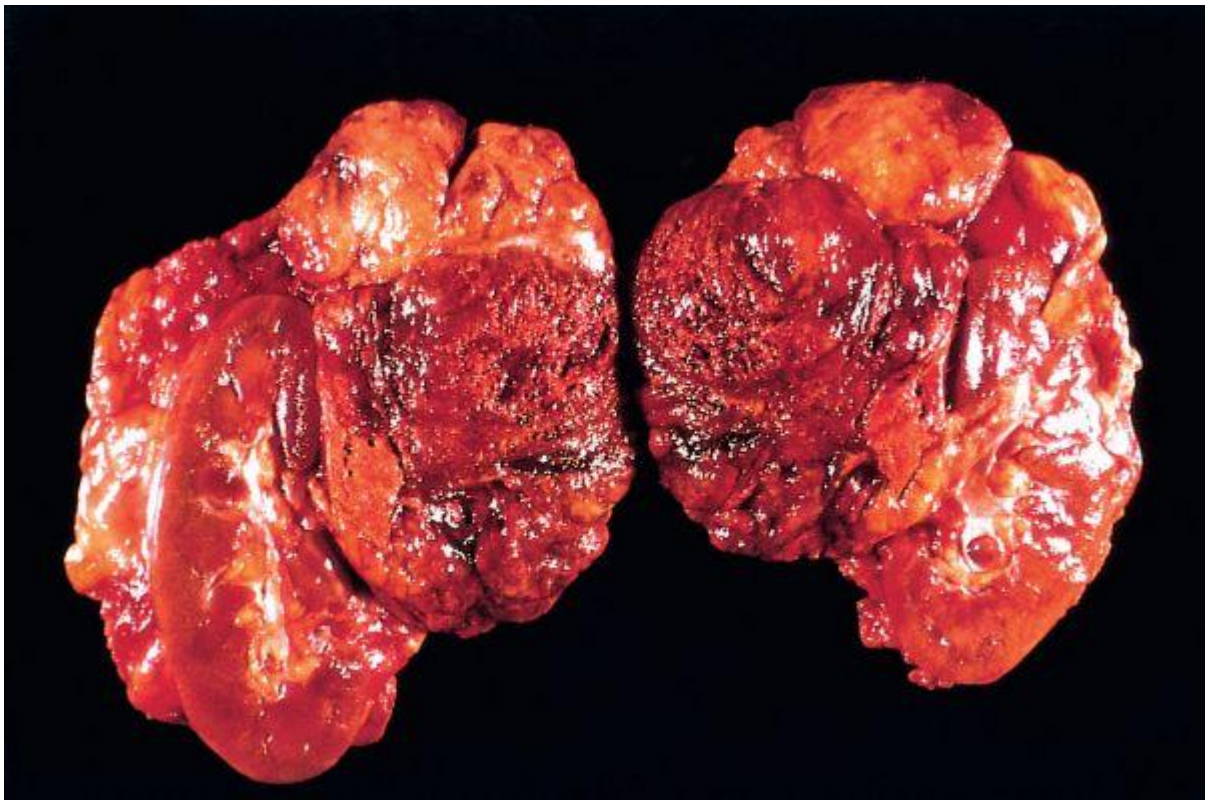

FIGURE 24-51 Adrenal carcinoma. The hemorrhagic and necrotic tumor dwarfs the kidney and compresses the upper pole.

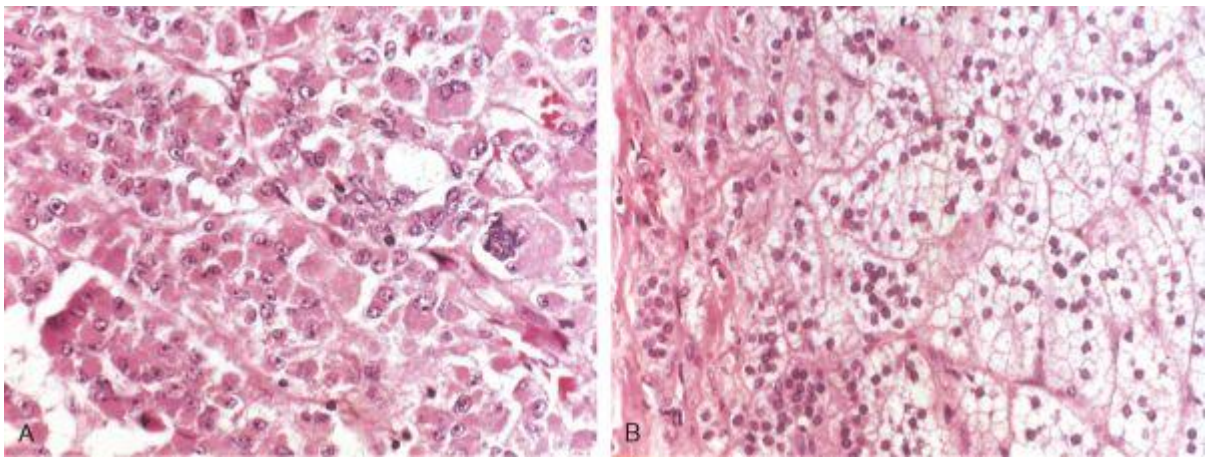

FIGURE 24-52 Adrenal carcinoma (**A**) revealing marked anaplasia, contrasted with normal adrenal cortical cells (**B**).

OTHER LESIONS OF THE ADRENAL

Adrenal cysts are relatively uncommon; however, with the use of sophisticated abdominal imaging techniques, the frequency of detection of these lesions seems to be increasing. Larger cysts may produce

an abdominal mass and flank pain. Both cortical and medullary neoplasms may undergo necrosis and cystic degeneration and may present as "nonfunctional cysts."

Adrenal myelolipomas are unusual benign lesions composed of mature fat and hematopoietic cells. Although most of these lesions represent incidental findings, occasional myelolipomas may reach massive proportions. Histologically, mature adipocytes are admixed with aggregates of hematopoietic cells belonging to all three lineages. Foci of myelolipomatous change may be seen in cortical tumors and in adrenals with cortical hyperplasia.

The term *adrenal incidentaloma* is a half-facetious moniker that has crept into the medical lexicon as advancements in medical imaging have led to the incidental discovery of adrenal masses in asymptomatic individuals or in individuals in whom the presenting complaint is not directly related to the adrenal gland.[78] The estimated population prevalence of "incidentalomas" discovered by imaging is approximately 4%, with an age-dependent increase in prevalence. Fortunately, *the vast majority of adrenal incidentalomas are small nonsecreting cortical adenomas of no clinical importance*.

3.14.5.2 Adrenal Medulla

The adrenal medulla is developmentally, functionally, and structurally distinct from the adrenal cortex. It is composed of specialized neural crest (neuroendocrine) cells, termed *chromaffin* cells, and their supporting (sustentacular) cells. The adrenal medulla is the major source of catecholamines (epinephrine, norepinephrine) in the body. Neuroendocrine cells similar to chromaffin cells are widely dispersed in an extra-adrenal system of clusters and nodules that, together with the adrenal medulla, make up the *paraganglion system*. These extra-adrenal paraganglia are closely associated with the autonomic nervous system and can be divided into three groups based on their anatomic distribution: (1) branchiomeric, (2) intravagal, and (3) aorticosympathetic. The branchiomeric and intravagal paraganglia associated with the parasympathetic system are located close to the major arteries and cranial nerves of the head and neck and include the carotid bodies (Chapter 16). The intravagal paraganglia, as the term implies, are distributed along the vagus nerve. The aorticosympathetic chain is found in association with segmental ganglia of the sympathetic system and therefore is distributed mainly alongside of the abdominal aorta. The organs of Zuckerkandl, close to the aortic bifurcation, belong to this group.

The most important diseases of the adrenal medulla are neoplasms, which include neoplasms of chromaffin cells *(pheochromocytomas)* and neuronal neoplasms *(neuroblastic tumors)*. Neuroblastomas and other neuroblastic tumors are further discussed in Chapter 10 .

PHEOCHROMOCYTOMA

Pheochromocytomas are neoplasms composed of chromaffin cells, which synthesize and release catecholamines and in some instances peptide hormones. It is important to recognize these tumors because they are a rare cause of surgically correctable hypertension. Traditionally, pheochromocytomas have been associated with a *"rule of 10s"*.

- *10% of pheochromocytomas are extra-adrenal*, occurring in sites such as the organs of Zuckerkandl and the carotid body. Pheochromocytomas that develop in extra-adrenal paraganglia are designated *paragangliomas* and are discussed in Chapter 16 .
- *10% of sporadic adrenal pheochromocytomas are bilateral*; this figure may rise to as high as 50% in cases that are associated with familial syndromes (see below).
- *10% of adrenal pheochromocytomas are biologically malignant*, defined by the presence of metastatic disease. Notably, malignancy is more common (20% to 40%) in extra-adrenal paragangliomas, and in tumors arising in the setting of certain germline mutations (see below).

- *10% of adrenal pheochromocytomas are not associated with hypertension*. Of the 90% that present with hypertension, approximately two thirds have “paroxysmal” episodes associated with sudden rise in blood pressure and palpitations, which can, on occasion, be fatal.
- One “traditional” 10% rule that has now been modified pertains to familial cases. It is now recognized that *as many as 25% of individuals with pheochromocytomas and paragangliomas harbor a germline mutation* in one of at least six known genes (Table 24-11).[79] Patients with germline mutations are typically younger at presentation than those with sporadic tumors and more often harbor bilateral disease. The incidence of malignancy is higher (~30%) in tumors that arise on the backdrop of germline *SDHB* mutations. The three succinate dehydrogenase complex subunit genes (*SDHB, SDHC*, and *SDHD*) encode proteins involved in mitochondrial electron transport and oxygen sensing. It is postulated that loss of function in one or more of these subunits leads to stabilization of the oncogenic transcription factor hypoxia-inducible factor 1α (HIF-1α), promoting tumorigenesis.[80] Notably, stabilization of HIF-1α is also the most likely mechanism underlying cancer predisposition in patients with von Hippel-Lindau (VHL) syndrome, since the VHL protein normally targets HIF-1α for destruction.

TABLE 24-11 -- Familial Syndromes Associated with Pheochromocytoma and Extra-Adrenal Paragangliomas

Syndrome	Gene	Associated Lesion	Other Features
Multiple endocrine neoplasia, type 2A (MEN-2A)	*RET*	Pheochromocytoma	Medullary thyroid carcinoma
			Parathyroid hyperplasia
Multiple endocrine neoplasia, type 2B (MEN-2B)	*RET*	Pheochromocytoma	Medullary thyroid carcinoma
			Marfanoid habitus
			Mucocutaneous GNs
Neurofibromatosis, type 1 (NF1)	*NF1*	Pheochromocytoma	Neurofibromatosis
			Café-au-lait spots
			Optic nerve glioma
Von Hippel-Lindau (VHL)	*VHL*	Pheochromocytoma, paraganglioma *(uncommon)*	Renal cell carcinoma
			Hemangioblastoma
			Pancreatic endocrine neoplasm
Familial paraganglioma 1	*SDHD*	Pheochromocytoma, paraganglioma	
Familial paraganglioma 3	*SDHC*	Paraganglioma	
Familial paraganglioma 4	*SDHB*	Pheochromocytoma, paraganglioma	

Adapted with permission from Elder EE et al.: Pheochromocytoma and functional paraganglioma syndrome: no longer the 10% tumor. J Surg Oncol 89:193–201, 2005.

GN, ganglioneuroma; *NF1*, neurofibromin; *SDHB*, succinate dehydrogenase complex, subunit B; *SDHC*, succinate dehydrogenase complex, subunit C; *SDHD*, succinate dehydrogenase complex, subunit D.

Morphology. Pheochromocytomas range from small, circumscribed lesions confined to the adrenal (Fig. 24-53) to large hemorrhagic masses weighing kilograms. The average weight of a pheochromocytoma is 100 gm, but weights from just over 1 gm to almost 4000 gm have been reported. The larger tumors are well demarcated by either connective tissue or compressed cortical or

medullary tissue. Richly vascularized fibrous trabeculae within the tumor produce a lobular pattern. In many tumors, remnants of the adrenal gland can be seen, stretched over the surface or attached at one pole. On section, the cut surfaces of smaller pheochromocytomas are yellowtan. Larger lesions tend to be hemorrhagic, necrotic, and cystic and typically efface the adrenal gland. Incubation of fresh tissue with a potassium dichromate solution turns the tumor a dark brown color due to oxidation of stored catecholamines, thus the term **chromaffin**.

The histologic pattern in pheochromocytoma is quite variable. The tumors are composed of polygonal to spindle-shaped chromaffin cells or chief cells, clustered with the sustentacular cells into small nests or alveoli **(zellballen)** by a rich vascular network (Fig. 24-54). Uncommonly, the dominant cell type is a spindle or small cell; various patterns can be found in any one tumor. The cytoplasm has a finely granular appearance, best demonstrated with silver stains, due to the presence of granules containing catecholamines. The nuclei are usually round to ovoid, with a stippled "salt and pepper" chromatin that is characteristic of neuroendocrine tumors. Electron microscopy reveals variable numbers of membrane-bound, electron-dense secretory granules (Fig. 24-55). Immunoreactivity for neuroendocrine markers (chromogranin and synaptophysin) is seen in the chief cells, while the peripheral sustentacular cells stain with antibodies against S-100, a calcium-binding protein expressed by a variety of mesenchymal cell types.

Determining malignancy in pheochromocytomas can be vexing. **There is no histologic feature that reliably predicts clinical behavior**. Several histologic features, such as numbers of mitoses, confluent tumor necrosis, and spindle cell morphology, have been associated with an aggressive behavior and increased risk of metastasis, but these are not entirely reliable. Tumors with "benign" histologic features may metastasize, while bizarrely pleomorphic tumors may remain confined to the adrenal gland. In fact, cellular and nuclear pleomorphism, including the presence of giant cells, and mitotic figures are often seen in benign pheochromocytomas, while cellular monotony is paradoxically associated with an aggressive behavior. Even capsular and vascular invasion may be encountered in benign lesions. **Therefore, the definitive diagnosis of malignancy in pheochromocytomas is based exclusively on the presence of metastases**. These may involve regional lymph nodes as well as more distant sites, including liver, lung, and bone.

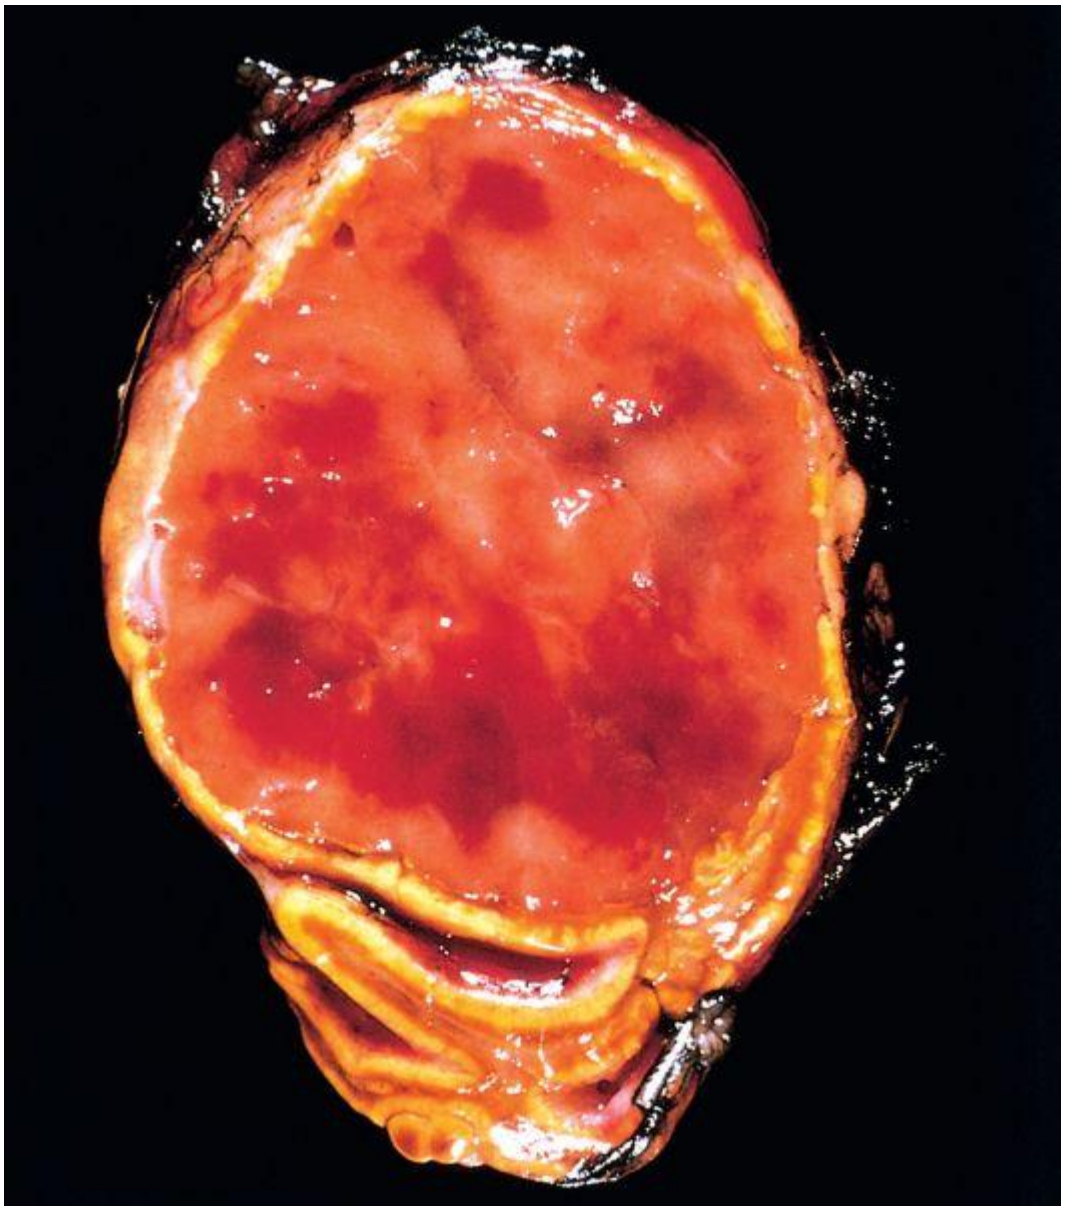

FIGURE 24-53 Pheochromocytoma. The tumor is enclosed within an attenuated cortex and demonstrates areas of hemorrhage. The comma-shaped residual adrenal is seen below. *(Courtesy of Dr. Jerrold R. Turner, Department of Pathology, University of Chicago Hospitals, Chicago, IL.)*

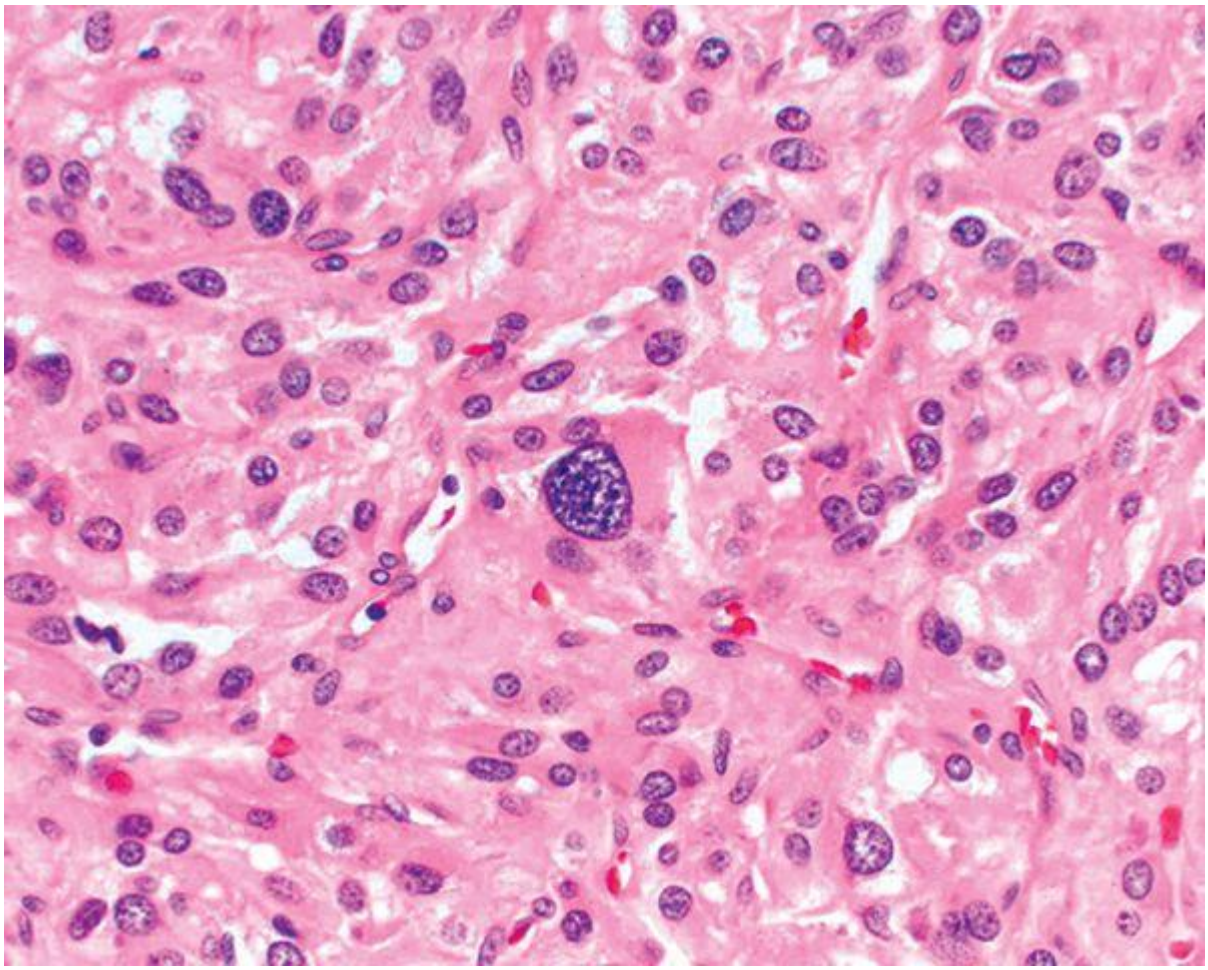

FIGURE 24-54 Pheochromocytoma demonstrating characteristic nests of cells ("zellballen") with abundant cytoplasm. Granules containing catecholamine are not visible in this preparation. It is not uncommon to find bizarre cells even in pheochromocytomas that are biologically benign. *(Courtesy of Dr. Jerrold R. Turner, Department of Pathology, University of Chicago Hospitals, Chicago, IL.)*

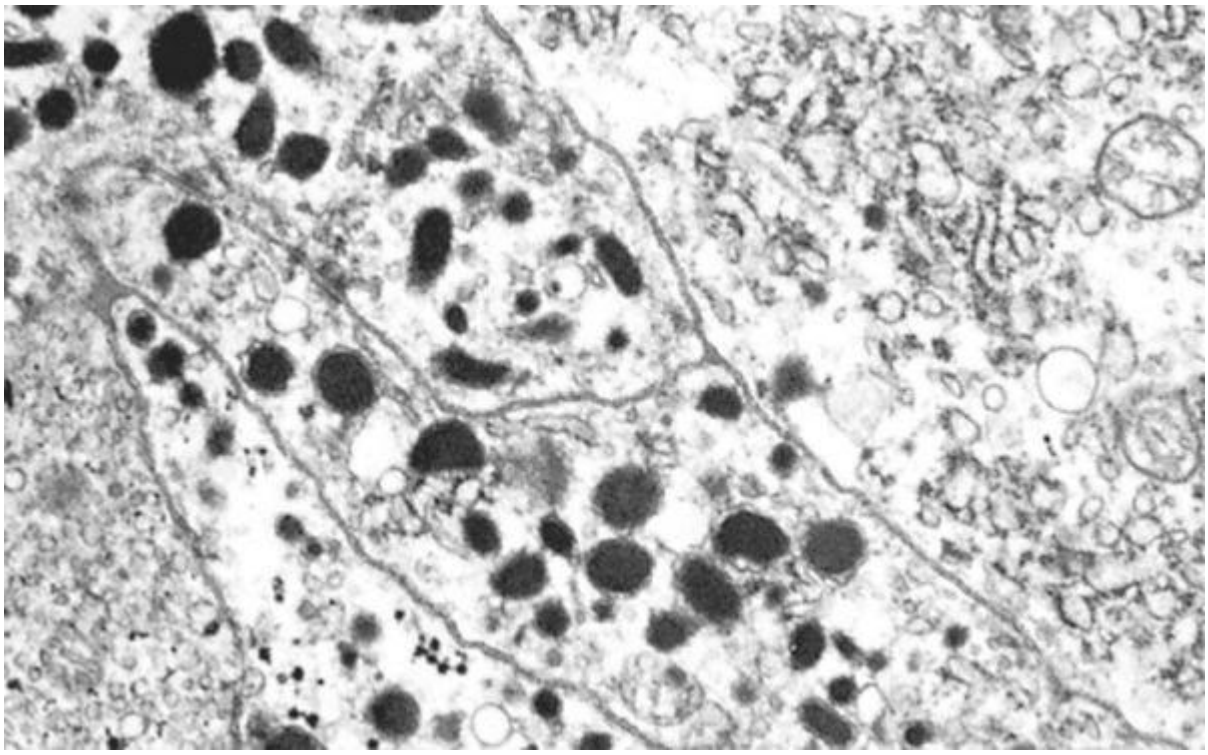

FIGURE 24-55 Electron micrograph of pheochromocytoma. This tumor contains membrane-bound secretory granules in which catecholamines are stored (30,000×).

Clinical Course.

The dominant clinical manifestation of pheochromocytoma is *hypertension*, observed in 90% of patients. Approximately two thirds of patients with hypertension demonstrate *paroxysmal episodes*, which are described as an abrupt, precipitous elevation in blood pressure, associated with tachycardia, palpitations, headache, sweating, tremor, and a sense of apprehension. These episodes may also be associated with pain in the abdomen or chest, nausea, and vomiting. *Isolated* paroxysmal episodes of hypertension occur in fewer than half of patients; more commonly, patients demonstrate chronic, sustained elevation in blood pressure punctuated by the aforementioned paroxysms. The paroxysms may be precipitated by emotional stress, exercise, changes in posture, and palpation in the region of the tumor; patients with urinary bladder paragangliomas occasionally precipitate a paroxysm during micturition. The elevations of blood pressure are induced by the sudden release of catecholamines that may acutely precipitate congestive heart failure, pulmonary edema, myocardial infarction, ventricular fibrillation, and cerebrovascular accidents. The cardiac complications have been attributed to what has been called *catecholamine cardiomyopathy*, or catecholamine-induced myocardial instability and ventricular arrhythmias. Nonspecific myocardial changes, such as focal necrosis, mononuclear infiltrates, and interstitial fibrosis, have been attributed either to ischemic damage secondary to the catecholamine-induced vasomotor constriction of the myocardial circulation or to direct catecholamine toxicity. In some cases pheochromocytomas secrete other hormones, such as ACTH and somatostatin, and may therefore be associated with clinical features related to the secretion of these or other peptide hormones. The laboratory diagnosis of pheochromocytoma is based on the demonstration of increased urinary excretion of free catecholamines and their metabolites, such as vanillylmandelic acid and metanephrines.

Isolated benign tumors are treated with surgical excision, after preoperative and intraoperative medication of patients with adrenergic-blocking agents to prevent a hypertensive crisis. Multifocal lesions require long-term medical treatment for hypertension.

3.14.6 Multiple Endocrine Neoplasia Syndromes

The MEN syndromes are a group of genetically inherited diseases resulting in proliferative lesions (hyperplasia, adenomas, and carcinomas) of multiple endocrine organs. Like other inherited cancer disorders (Chapter 7), endocrine tumors arising in the context of MEN syndromes have certain distinct features that contrast with their sporadic counterparts.

- Tumors occur at a *younger age* than sporadic tumors.
- They arise in *multiple endocrine organs*, either *synchronously* (at the same time) or *metachronously* (at different times).
- Even in one organ, the tumors are often *multifocal*.
- The tumors are usually preceded by an *asymptomatic stage of endocrine hyperplasia* involving the cell of origin. For example, individuals with MEN-2 almost universally demonstrate C-cell hyperplasia in the thyroid parenchyma adjacent to medullary thyroid carcinomas.
- These tumors are usually *more aggressive* and *recur* in a higher proportion of cases than do similar sporadic endocrine tumors.

MULTIPLE ENDOCRINE NEOPLASIA, TYPE 1

MEN-1, or *Wermer syndrome*, is a rare heritable disorder with a prevalence of about 2 per 100,000. MEN-1 is characterized by abnormalities involving the *parathyroid, pancreas*, and *pituitary glands*; thus the mnemonic device, the *3Ps*:

- *Parathyroid: Primary hyperparathyroidism* is the most common manifestation of MEN-1 (80% to 95% of patients) and is the initial manifestation of the disorder in most patients, appearing in almost all patients by age 40 to 50. Parathyroid abnormalities include both hyperplasia and adenomas. Hyperplasias arising in the context of MEN-1 are monoclonal.
- *Pancreas: Endocrine tumors of the pancreas* are a leading cause of morbidity and mortality in persons with MEN-1. These tumors are usually aggressive and often present with metastatic disease. It is not uncommon to find multiple “microadenomas” scattered throughout the pancreas in conjunction with one or two dominant lesions. Pancreatic endocrine tumors are often functional; however, since pancreatic polypeptide is the most commonly secreted product, these tumors might not be accompanied by an endocrine hypersecretion syndrome. Among symptomatic pancreatic tumors, gastrinomas associated with Zollinger-Ellison syndrome and insulinomas associated with hypoglycemia and neurologic manifestations are the most common subtypes.
- *Pituitary:* The most frequent anterior pituitary tumor encountered in MEN-1 is a *prolactinoma*; some patients develop acromegaly from somatotrophin-secreting tumors.

It is now recognized that the spectrum of this disease extends beyond the *3Ps*. The *duodenum is the most common site of gastrinomas in individuals with MEN-1* (far in excess of the frequency of pancreatic gastrinomas), and synchronous duodenal and pancreatic tumors may be present in the same individual. In addition, carcinoid tumors, thyroid and adrenocortical adenomas, and lipomas are more frequent than in the general population.

MEN-1 syndrome is caused by germline mutations in the *MEN1* tumor suppressor gene, which encodes a 610–amino acid product known as *menin*. How menin acts is poorly understood, but it is clear that it plays a part in regulating normal gene transcription.[81] Menin is a component of several different transcription factor complexes, which (depending on the other constituent proteins) may either activate or inhibit gene expression. For example, some complexes containing menin activate the expression of

cell cycle inhibitors, such as p16 and p27, whereas menin interferes with the ability of the transcription factor JunD to activate transcription.[82] As with many other ubiquitously expressed tumor suppressors and oncogenes that are preferentially associated with specific kinds of tumors, why defects in menin selectively increase the frequency of neuroendocrine tumors is unknown.

The dominant clinical manifestations of MEN-1 usually result from the peptide hormones that are overproduced and include such abnormalities as recurrent hypoglycemia due to insulinomas, intractable peptic ulcers in persons with Zollinger-Ellison syndrome, nephrolithiasis caused by PTH-induced hypercalcemia, or symptoms of prolactin excess from a pituitary tumor. As expected, malignant behavior by one or more of the endocrine tumors arising in these patients is often the proximate cause of death.

MULTIPLE ENDOCRINE NEOPLASIA, TYPE 2

MEN-2 is subclassified into three distinct syndromes: MEN-2A, MEN-2B, and familial medullary thyroid cancer.

- *MEN-2A*, or *Sipple syndrome*, is characterized by *pheochromocytoma, medullary carcinoma*, and *parathyroid hyperplasia* (see Table 24-11). Medullary carcinomas of the thyroid occur in almost 100% of patients. They are usually multifocal and are virtually always associated with foci of C-cell hyperplasia in the adjacent thyroid. The medullary carcinomas may elaborate calcitonin and other active products and are usually clinically aggressive. Among individuals with MEN-2A, 40% to 50% have pheochromocytomas, which are often bilateral and may arise in extra-adrenal sites. Parathyroid hyperplasia and evidence of hypercalcemia or renal stones occur in 10% to 20% of patients. MEN-2A is clinically and genetically distinct from MEN-1 and has been linked to germline mutations in the *RET* proto-oncogene on chromosome 10q11.2. As was noted earlier, the *RET* proto-oncogene encodes a receptor tyrosine kinase that binds *glial-derived neurotrophic factor* (GDNF) and other ligands in the GDNF family and transmits growth and differentiation signals (Chapter 7). *Loss-of-function* mutations in *RET* result in intestinal aganglionosis and Hirschsprung disease (Chapter 17). In contrast, in MEN-2A (as well as in MEN-2B), germline mutations constitutively activate the *RET* receptor, resulting in *gain of function*.
- *MEN-2B* has significant clinical overlap with MEN-2A. Patients develop medullary thyroid carcinomas, which are usually multifocal and more aggressive than in MEN-2A, and pheochromocytomas. However, unlike in MEN-2A, primary hyperparathyroidism is not present. In addition, MEN-2B is accompanied by *neuromas* or ganglioneuromas involving the skin, oral mucosa, eyes, respiratory tract, and gastrointestinal tract, and a *marfanoid habitus*, with long axial skeletal features and hyperextensible joints (see Table 24-11). A single amino acid change in *RET*, distinct from the mutations that are seen in MEN-2A, seems to be responsible for virtually all cases of MEN-2B and affects a critical region of the tyrosine kinase catalytic domain of the protein.[83] The resulting conformational change leads to autophosphorylation and constitutive activation of RET in the absence of ligand. Of note, approximately a third of sporadic medullary thyroid carcinomas harbor an identical somatic mutation, and these cases are associated with aggressive disease and an adverse prognosis.
- *Familial medullary thyroid cancer* is a variant of MEN-2A, in which there is a strong predisposition to medullary thyroid cancer but not the other clinical manifestations of MEN-2A or MEN-2B. A substantial majority of cases of medullary thyroid cancer are sporadic, but as many as 20% may be familial. Familial medullary thyroid cancers develop at an older age than those occurring in the full-blown MEN-2 syndrome and follow a more indolent course.

In contrast to MEN-1, in which the long-term benefit of early diagnosis by genetic screening is not well established, diagnosis via screening of at-risk family members in MEN-2A kindred is important because medullary thyroid carcinoma is a life-threatening disease that can be prevented by early thyroidectomy. Now, routine genetic testing identifies *RET* mutation carriers earlier and more reliably in MEN-2 kindred; *all individuals carrying germline RET mutations are advised to undergo prophylactic thyroidectomy to prevent the inevitable development of medullary carcinomas*.

3.14.7 Pineal Gland

The rarity of clinically significant lesions (virtually only tumors) justifies brevity in the consideration of the pineal gland. It is a minute, pinecone-shaped organ (hence its name), weighing 100 to 180 mg and lying between the superior colliculi at the base of the brain. It is composed of a loose, neuroglial stroma enclosing nests of epithelialappearing *pineocytes*, cells with photosensory and neuroendocrine functions (hence the designation of the pineal gland as the "third eye"). Silver impregnation stains reveal that these cells have long, slender processes reminiscent of primitive neuronal precursors intermixed with the processes of astrocytic cells. The principal secretory product of the pineal gland is melatonin, which is involved in the control of circadian rhythms, including the sleep–wake cycle; hence the popular use of melatonin for the treatment of jet lag.

All tumors involving the pineal are rare; most (50% to 70%) arise from sequestered embryonic germ cells (Chapter 28). They most commonly take the form of so-called *germinomas*, resembling testicular seminoma (Chapter 21) or ovarian dysgerminoma (Chapter 22). Other lines of germ cell differentiation include embryonal carcinomas; choriocarcinomas; mixtures of germinoma, embryonal carcinoma, and choriocarcinoma; and, uncommonly, typical teratomas (usually benign). Whether to characterize these germ cell neoplasms as pinealomas is still a subject of debate, but most "pinealophiles" favor restricting the term *pinealoma* to neoplasms arising from the pineocytes.

3.14.7.1 Pinealomas

These neoplasms are divided into two categories, pineoblastomas and pineocytomas, based on their level of differentiation, which, in turn, correlates with their aggressiveness. These tumors are rare, and are described in specialized texts.

The Skin: More Than a Mechanical Barrier

Little more than a century ago, the noted pathologist Rudolph Virchow considered the skin as a mere protective covering for more delicate and functionally sophisticated internal viscera.[1] Then, and for the century that followed, the skin was considered primarily a passive protective barrier to both fluid loss and mechanical injury. Over the last few decades, however, studies have demonstrated the skin to be a

complex organ—the largest in the body—in which precisely regulated cellular and molecular interactions govern many crucial responses to our environment.

Like other complex organs, the skin is composed of several interdependent cell types and structures that are functionally cooperative (Fig. 25-1).

- *Squamous epithelial cells (keratinocytes)*, in addition to producing protective keratin protein, are major sites for the biosynthesis of soluble molecules (cytokines) that regulate adjacent epidermal cells as well as cells in the dermis.
- *Melanocytes* within the epidermis are cells responsible for the production of melanin, a brown pigment that protects against potentially injurious ultraviolet (UV) radiation in sunlight.
- *Dendritic cells*. Skin is constantly battered with microbial and nonmicrobial antigens that are processed by intraepidermal dendritic *Langerhans cells*, which interact with the systemic immune system by migrating to regional lymph nodes. Specialized *dendrocytes* within the dermis perform similar functions there.
- *Lymphocytes*. Both the innate and adaptive immune systems respond to these signals (Fig. 25-2), including a subset of lymphocytes programmed to home to the skin through expression of cutaneous lymphocyte-associated antigen (CLA). As elsewhere in the body, cutaneous T cells are divided into helper (CD4+) and cytotoxic (CD8+) populations (Chapter 6). The local tissue response to cytokines produced by these T cells mediates the microscopic patterns and clinical expressions of cutaneous inflammatory and infectious diseases.[2]
- *Neural end organs* and *axonal processes* warn of potentially damaging physical factors in the environment and have recently been found to assist in regulation of immunocompetent cells, indicating important neuroimmune modulation.[3] Among the neural network are neuroendocrine *Merkel cells* residing within the epithelial basal cell layer. These may serve as mechanoreceptors or possibly provide neuroendocrine function in skin.[4]
- *Adnexal components. Sweat glands* guard against deleterious variations in body temperature, and *hair follicles*, in addition to manufacturing hair shafts, harbor protected niches of epithelial stem cells capable of regenerating superficial epithelial skin structures that have been disrupted by various hostile external and internal agents (Chapter 3).[5]

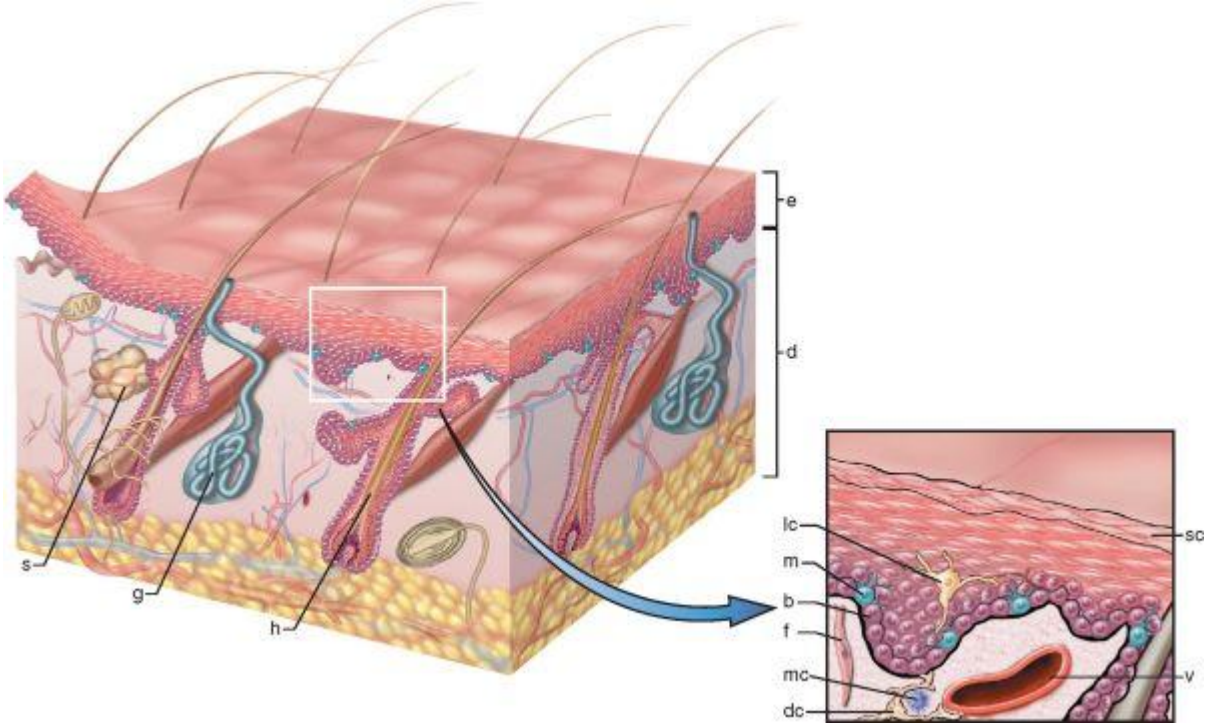

FIGURE 25-1 **A**, The skin is composed of an epidermal layer (e) from which specialized adnexa (hair follicles, h; sweat glands, g; and

sebaceous glands, s) descend into the underlying dermis (d). **B**, This projection of the epidermal layer (e) and underlying superficial dermis demonstrates the progressive upward maturation of basal cells (b) into cornified squamous epithelial cells of the stratum corneum (sc). Melanin-containing dendritic melanocytes (m) (and rare Merkel cells containing neurosecretory granules) and midepidermal dendritic Langerhans cells (lc) are also present. The underlying dermis contains small vessels (v), fibroblasts (f), perivascular mast cells (mc), and dendrocytes (dc), potentially important in dermal immunity and repair.

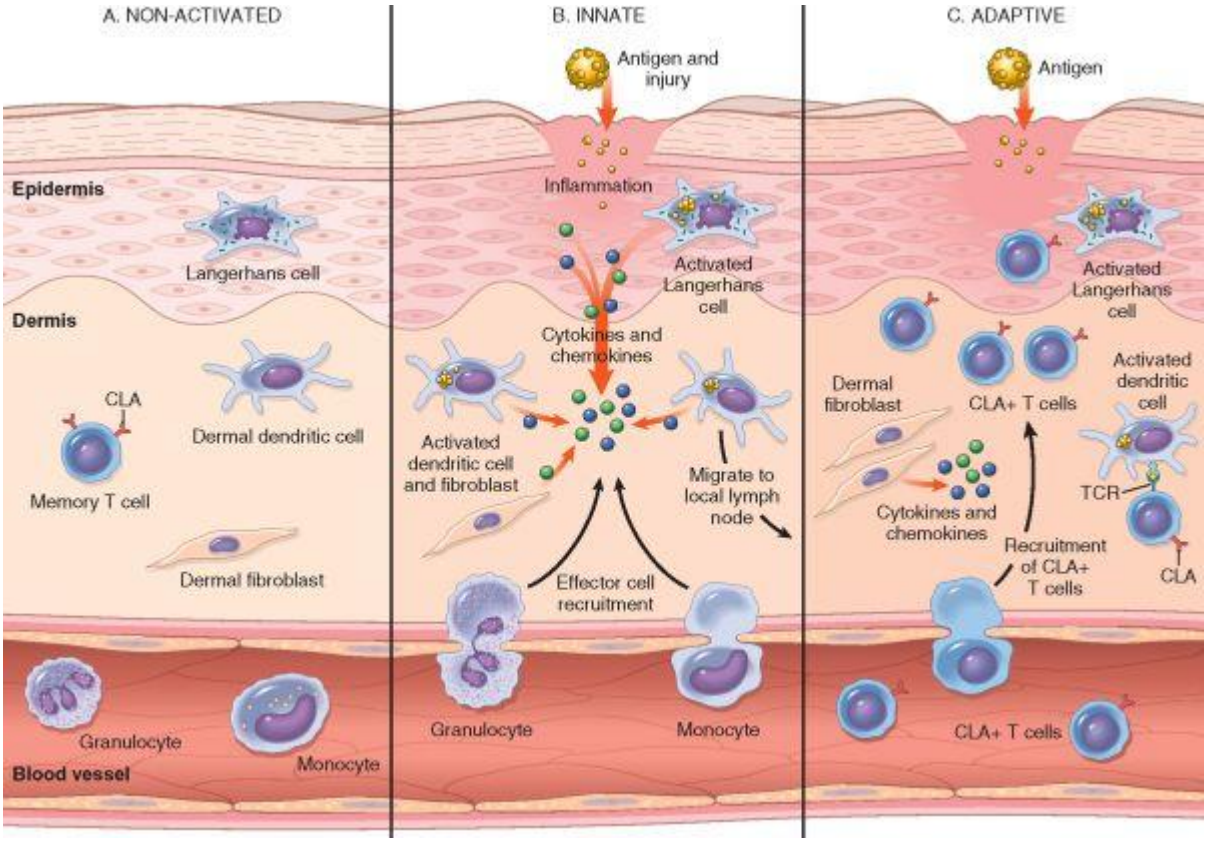

FIGURE 25-2 The cutaneous immune system. **A**, In the absence of inflammation, skin is populated by several immune cells, some stationary and others transitory, that survey the environment and are primed for response. **B**, The innate response to epithelial injury or antigen presentation activates the resident immune cells that then recruit nonspecific effector cells such as neutrophils and eosinophils. **C**, The adaptive response occurs when antigen presented in the context of the major histocompatibility complex is specifically recognized by T cells and as a result, additional antigen-specific skin-homing (CLA+) T cells are recruited. TCR, T-cell receptor.

Although the human integument may appear drab compared with the skin and pelage of certain other members of the animal kingdom, it is indeed extraordinarily vibrant with regard to the diversity and complexity of protective functions that it serves.

Imbalances in factors affecting the delicate homeostasis that exists among skin cells may result in conditions as diverse as wrinkles and hair loss, blisters and rashes, and life-threatening cancers and disorders of immune regulation. For example, chronic exposure to sunlight fosters premature cutaneous aging, blunting of immunological responses to environmental antigens, and the development of a variety of premalignant and malignant cutaneous neoplasms. Ingested agents, such as therapeutic drugs, can cause an enormous number of rashes or exanthems. Systemic disorders, such as diabetes mellitus, amyloidosis, and lupus erythematosus, may also have important manifestations in the skin.

Skin conditions are very common, affecting about one third of the United States population each year. Since skin is uniquely accessible to visual examination, for the experienced observer it can yield numerous insights into the functional state of the body, if not the soul, of a patient. Accurate description of the appearance of skin lesions is critical, since the gross appearance is often essential in formulating diagnoses and in understanding pathogenesis. To underscore the point, the appearance of skin lesions will be emphasized under each of the specific entities.

There are literally thousands of specific skin diseases. Only those that are common or that illustrate important pathologic mechanisms are described here. But first a brief primer of important clinical and histologic terms used in describing diseases of the skin is presented below.

DEFINITIONS OF MACROSCOPIC TERMS

Excoriation	Traumatic lesion breaking the epidermis and causing a raw linear area (i.e., deep scratch); often self-induced
Lichenification	Thickened and rough skin characterized by prominent skin markings (as lichen on a tree trunk); usually the result of repeated rubbing
Macule	Circumscribed lesion, 5 mm or smaller in diameter, characterized by flatness and distinguished by coloration (**patch** is greater than 5 mm)
Onycholysis	Separation of nail plate from nail bed
Papule	Elevated dome-shaped or flat-topped lesion 5 mm or less across (**nodule** is greater than 5 mm)
Plaque	Elevated flat-topped lesion, usually greater than 5 mm across (may be caused by coalescent papules)
Pustule	Discrete, pus-filled, raised lesion
Scale	Dry, horny, platelike excrescence; usually the result of imperfect cornification
Vesicle	Fluid-filled raised lesion 5 mm or less across (**Bulla** is greater than 5 mm. **Blister** is the common term for either.)
Wheal	Itchy, transient, elevated lesion with variable blanching and erythema formed as the result of dermal edema

DEFINITIONS OF MICROSCOPIC TERMS

Acantholysis	Loss of intercellular cohesion between keratinocytes
Acanthosis	Diffuse epidermal hyperplasia
Dyskeratosis	Abnormal, premature keratinization within cells below the stratum granulosum
Erosion	Discontinuity of the skin showing incomplete loss of the epidermis
Exocytosis	Infiltration of the epidermis by inflammatory cells
Hydropic swelling (ballooning)	Intracellular edema of keratinocytes, often seen in viral infections
Hypergranulosis	Hyperplasia of the stratum granulosum, often due to intense rubbing
Hyperkeratosis	Thickening of the stratum corneum, often associated with a qualitative abnormality of the keratin
Lentiginous	A linear pattern of melanocyte proliferation within the epidermal basal cell layer
Papillomatosis	Surface elevation caused by hyperplasia and enlargement of contiguous dermal papillae
Parakeratosis	Keratinization with retained nuclei in the stratum corneum. On mucous membranes, parakeratosis is normal.
Spongiosis	Intercellular edema of the epidermis

Ulceration	Discontinuity of the skin showing complete loss of the epidermis revealing dermis or subcutis
Vacuolization	Formation of vacuoles within or adjacent to cells; often refers to basal cell–basement membrane zone area

3.15.2 Disorders of Pigmentation & Melanocytes

Skin pigmentation has historically had major societal implications. Cosmetic desire for increased pigmentation (tanning) among whites and for fairness among normally dark-skinned people have both resulted in deleterious practices. Focal or widespread loss of normal protective pigmentation can render individuals targets of unwanted attention and extraordinarily vulnerable to the harmful effects of sunlight (as in albinism). Change in preexisting skin pigmentation may signify important primary events in the skin (e.g., malignant transformation of a mole) or disorders of internal viscera (e.g., in Addison disease, see Chapter 24).

FRECKLE (EPHELIS)

Freckles are the most common pigmented lesions of childhood in lightly pigmented individuals. They are generally small (1 to several mm in diameter), tan-red or light brown macules that appear after sun exposure. Once present, freckles fade and darken in a cyclic fashion during winter and summer, respectively. This is not because of changes in the number of melanocytes, but in the degree of pigmentation.

Morphology. Hyperpigmentation of freckles results from increased amounts of melanin pigment within basal keratinocytes; melanocytes may be slightly enlarged but are normal in density. It is unclear whether the freckle represents: (1) a focal abnormality in pigment production by a discrete field of melanocytes, (2) enhanced pigment donation to adjacent basal keratinocytes, or (3) both. The café au lait spots seen in neurofibromatosis (Chapter 5) are histologically indistinguishable from freckles, but the former evolve independently from sun exposure and can contain aggregated melanosomes (macromelanosomes) within the cytoplasm of melanocytes.

LENTIGO

The term *lentigo* (plural, *lentigines*) refers to a common benign localized hyperplasia of melanocytes occurring at all ages, but often initiated in infancy and childhood. There is no sex or racial predilection, and the cause and pathogenesis are unknown. These lesions may involve mucous membranes as well as the skin, and consist of small (5–10 mm across), oval, tan-brown macules or patches. Unlike freckles, lentigines do not darken when exposed to sunlight.

Morphology. The essential histologic feature of a lentigo is linear (non-nested) melanocytic hyperplasia restricted to the cell layer immediately above the basement membrane that produces a hyperpigmented basal cell layer. So characteristic is this pattern that the term **lentiginous** is used to describe similar cellular proliferations within the basal cell layer in melanocytic tumors, such as in lentiginous nevi and in certain melanomas (termed **acral lentiginous melanomas**). Elongation and thinning of the rete ridges are also commonly seen in a lentigo.

MELANOCYTIC NEVUS (PIGMENTED NEVUS, MOLE)

Most of us have at least a few moles and probably regard them as mundane and uninteresting. However, in truth moles (or nevi) are diverse, dynamic, and biologically intriguing. Strictly speaking, the term *nevus* denotes any congenital skin lesion (e.g., a birthmark). *Melanocytic nevus* refers specifically to any neoplasm of melanocytes and hence is somewhat of a misnomer, since most melanocytic nevi are acquired.

Common acquired melanocytic nevi are *tan to brown, uniformly pigmented, small (usually <6 mm across), solid regions of relatively flat (macules)* to *elevated skin (papules) with well-defined, rounded borders* (Figs. 25-3A and 25-4A). There are numerous clinical and histologic types of melanocytic nevi, with variable clinical appearance. Table 25-1 provides a comparative summary of salient features of some commonly encountered forms of melanocytic nevi. Acquired melanocytic nevi (Figs. 25-3 and 25-4) are probably the most common type and virtually universal. They may become more prominent during pregnancy, indicating a degree of hormone sensitivity.

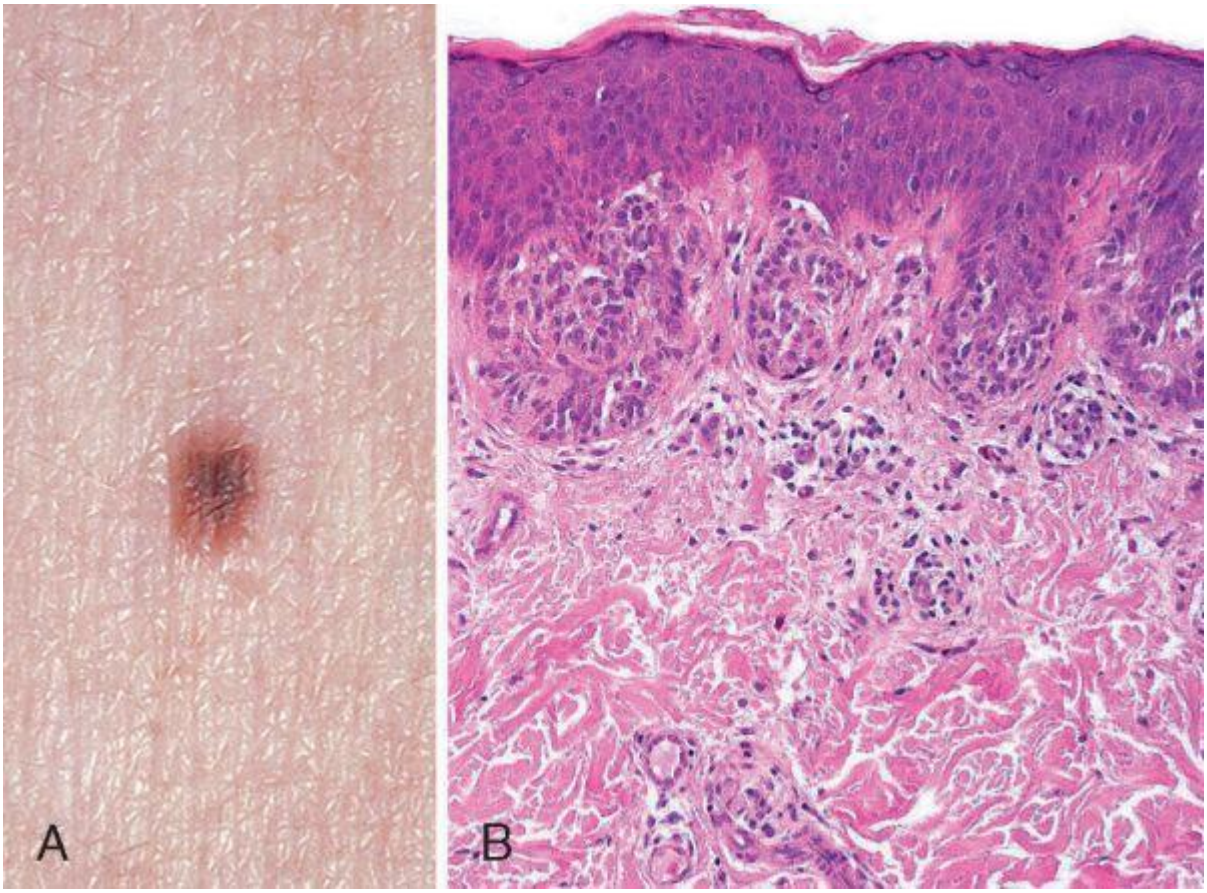

FIGURE 25-3 Melanocytic nevus, junctional type. **A**, In clinical appearance, lesions are small, relatively flat, symmetric, and uniform. **B**, On histologic examination, junctional nevi are characterized by rounded nests of nevus cells originating at the tips of rete ridges along the dermoepidermal junction.

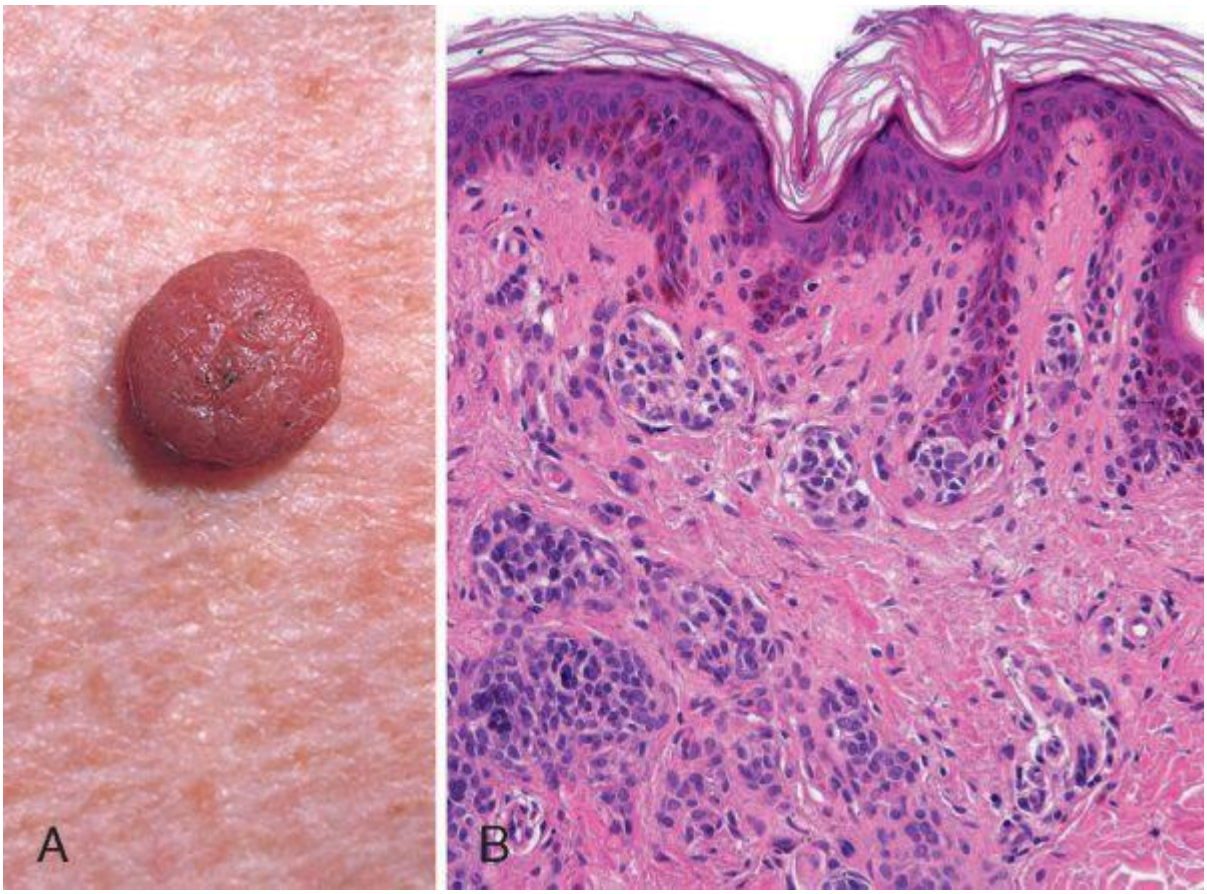

FIGURE 25-4 Melanocytic nevus, compound type. In contrast to the junctional nevus, the compound nevus (**A**) is more raised and dome-shaped. The symmetry and uniform pigment distribution suggest a benign process. Histologically (**B**), compound nevi combine the features of junctional nevi (intraepidermal nevus cell nests) with nests and cords of nevus cells in the underlying dermis.

TABLE 25-1 -- Representative Variant Forms of Melanocytic Nevi

Nevus Variant	Diagnostic Architectural Features	Cytologic Features	Clinical Significance
Congenital nevus	Deep dermal and sometimes subcutaneous growth around adnexa, neurovascular bundles, and blood vessel walls	Identical to ordinary acquired nevi	Present at birth; large variants have increased melanoma risk
Blue nevus	Non-nested dermal infiltration, often with associated fibrosis	Highly dendritic, heavily pigmented nevus cells	Black-blue nodule; often confused with melanoma clinically
Spindle and epithelioid cell nevus (Spitz nevus)	Fascicular growth	Large, plump cells with pink-blue cytoplasm; fusiform cells	Common in children; red-pink nodule; often confused with hemangioma clinically
Halo nevus	Lymphocytic infiltration surrounding nevus cells	Identical to ordinary acquired nevi	Host immune response against nevus cells and surrounding normal melanocytes
Dysplastic nevus	Coalescent intraepidermal nests	Cytologic atypia	Potential marker or precursor of melanoma

Morphology. Melanocytic nevi are thought to progress through a series of morphologic changes over time. The earliest lesions are believed to be **junctional nevi**, which consist of aggregates or nests of round cells that grow along the dermoepidermal junction (see Fig. 25-3B). Nuclei of nevus cells are uniform and rounded in contour, contain inconspicuous nucleoli, and show little or no mitotic activity. Eventually, most junctional nevi grow into the underlying dermis as nests or cords of cells to form **compound nevi** (see Fig. 25-4B). In older lesions the epidermal nests may be lost entirely to form pure **intradermal nevi**. Clinically, compound and dermal nevi are often more elevated than junctional nevi.

Progressive growth of nevus cells from the dermoepidermal junction into the underlying dermis is accompanied by a process termed **maturation** (Fig. 25-5). Whereas superficial nevus cells are larger, tend to produce melanin, and grow in nests, deeper nevus cells are smaller, produce little or no pigment, and appear as cords and single cells. The most "mature" nevus cells may be found at the deepest extent of lesions, where they often acquire fusiform contours and grow in fascicles resembling neural tissue (neurotization, see Fig. 25-5E). This striking metamorphosis correlates with enzymatic changes (progressive loss of tyrosinase activity and acquisition of cholinesterase activity in deeper, nonpigmented, nervelike nevus cells). **This sequence of maturation of individual nevus cells is of diagnostic importance in distinguishing some benign nevi from melanomas, which usually show little or no maturation**.

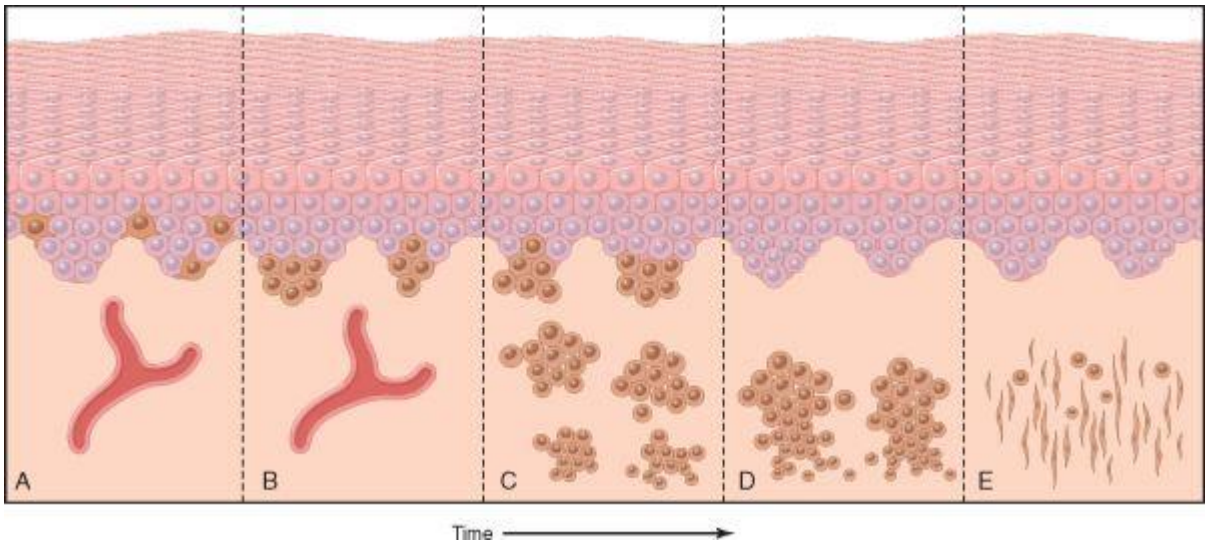

FIGURE 25-5 Maturation sequence of nondysplastic melanocytic nevi. **A**, Normal skin shows only scattered dendritic melanocytes within the epidermal basal cell layer. **B**, Junctional nevus. **C**, Compound nevus. **D**, Dermal nevus. **E**, Dermal nevus with neurotization (extreme maturation). Nevi may exist at any stage in this sequence for variable periods of time, although many are believed to progress through this sequence.

Although melanocytic nevi are common, their clinical and histologic diversity necessitates thorough knowledge of their appearance and natural evolution, lest they be confused with other skin conditions, most notably melanoma. The biologic importance of some nevi, however, resides in their possible transformation to melanoma (see below).

Pathogenesis.

Proof that nevi are neoplasms has come from studies showing that many have acquired mutations in either *BRAF* or *NRAS*. *BRAF* encodes a serine/threonine kinase that is a positive mediator of RAS signals, and the mutations in *BRAF* and *NRAS* found in nevi both cause constitutive activation of the RAS/BRAF signaling pathway (described in more detail under melanoma).[6] Given that RAS lies in a potent transforming signaling pathway, it is reasonable to ask why nevi only rarely give rise to malignant melanomas. The answer appears to lie in the phenomenon referred to as oncogene-induced senescence. Expression of either activated RAS or BRAF in normal human melanocytes causes only a limited period of proliferation that is followed by a permanent growth arrest mediated by the accumulation of p16/INK4a,[7] which you will recall is a potent inhibitor of several cyclin-dependent kinases, including CDK4 and CDK6 (Chapter 7). This protective response is disrupted in melanoma and some melanoma precursor lesions.

DYSPLASTIC NEVI

The association of melanocytic nevi with melanoma was made more than 185 years ago,[8] but a precursor of melanoma was not clearly identified until 1978 when Clark and colleagues described the lesions that are now referred to as *dysplastic nevi*.[9] Several lines of evidence support the concept that *dysplastic nevi are precursors of melanoma*. One of the most compelling pieces of evidence involves studies of families affected by *dysplastic nevus syndrome*, [10] in which a tendency to develop multiple dysplastic nevi and melanoma are co-inherited. The probability that a person with dysplastic nevus syndrome will develop melanoma is over 50% by age 60,[11] and at-risk individuals sometimes develop several melanomas at different sites. Even more directly, transformation of dysplastic nevi to melanoma has been documented histologically.

Although dysplastic nevi can give rise to melanoma, the vast majority of such lesions are clinically stable and never progress. Conversely, not all melanomas in individuals with dysplastic nevus syndrome arise from dysplastic nevi, suggesting that these lesions are best viewed as indicators or markers of increased melanoma risk. Dysplastic nevi may also occur as isolated lesions in otherwise normal individuals, in which case the risk of malignant change is very low.

Dysplastic nevi are *larger than most acquired nevi (often >5 mm across) and may number in the hundreds in those with the dysplastic nevus syndorme* (Fig. 25-6A). They are *flat macules, slightly raised plaques with a "pebbly" surface, or target-like lesions with a darker raised center and irregular flat periphery*. They can be recognized by their size, variability in pigmentation (variegation) and irregular borders, and seem to be acquired rather than congenital in most instances. Unlike ordinary moles, dysplastic nevi occur on both sun-exposed and protected body surfaces.

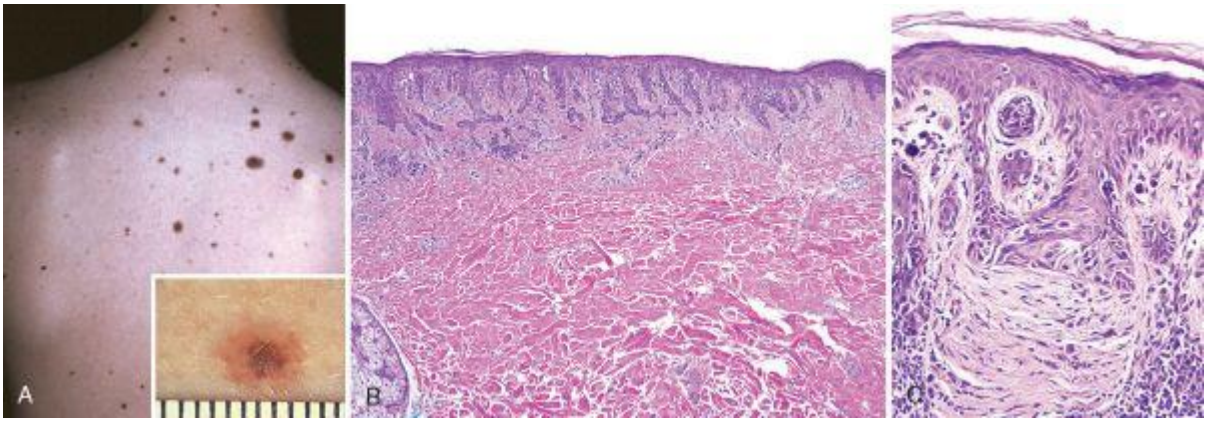

FIGURE 25-6 Dysplastic nevus. **A**, Numerous clinically atypical nevi on the back. **B**, One such lesion (*inset A*) has a compound nevus

component (*left side* of scanning field) and an asymmetric junctional nevus component (*right side* of scanning field). The former correlates grossly with the more pigmented and raised central zone and the latter with the less pigmented, flat peripheral rim. **C**, An important feature is the presence of cytologic atypia (irregularly shaped, dark-staining nuclei). The dermis underlying the atypical cells characteristically shows linear, or lamellar, fibrosis.

Morphology. Microscopically, dysplastic nevi are usually compound and exhibit both architectural and cytologic atypia (Fig. 25-6A, B). **Nevus cell nests within the epidermis may be enlarged and often fuse or coalescence with adjacent nests. As part of this process, single nevus cells begin to replace the normal basal cell layer along the dermoepidermal junction, producing lentiginous hyperplasia**. Cytologic atypia takes the form of nuclear enlargement, irregular, often angulated, nuclear contours, and hyperchromasia (Fig. 25-6C). Associated alterations in the superficial dermis include lymphocytic infiltrates (usually sparse); release of melanin from dead nevus cells into the dermis (melanin incontinence), where it is phagocytosed by dermal macrophages; and a peculiar linear fibrosis surrounding the epidermal rete ridges that are involved by the nevus. This constellation of features assists in the histologic diagnosis.

Pathogenesis.

Clark and associates have proposed stages in the development of dysplastic nevi and their eventual progression to melanoma (Fig. 25-7),[12] presumably through stepwise acquisition of mutations or epigenetic changes. Dysplastic nevus syndrome is inherited in an autosomal dominant pattern. Several mutated genes have been discovered in affected families, including *CDKN2A* on chromosome 9p21 and *CDK4* (cyclin-dependent kinase 4) on chromosome 12q14, both of which are also associated with familial forms of melanoma (discussed later). However, linkage of these mutations to the dysplastic nevus phenotype is not straightforward, as not all patients with germline *CDKN2A* and *CDK4* mutations have dysplastic nevi, and not all familial dysplastic nevi are associated with mutations in these genes. It is suspected that other genetic modifiers determine whether *CDKN2A* and *CDK4* mutations cause dysplastic nevi in a particular individual; the identities of these modifier genes, as well as the other genes that are responsible for the syndrome, are being sought. Like conventional nevi, dysplastic nevi also frequently have acquired activating mutations in *NRAS* and *BRAF*.

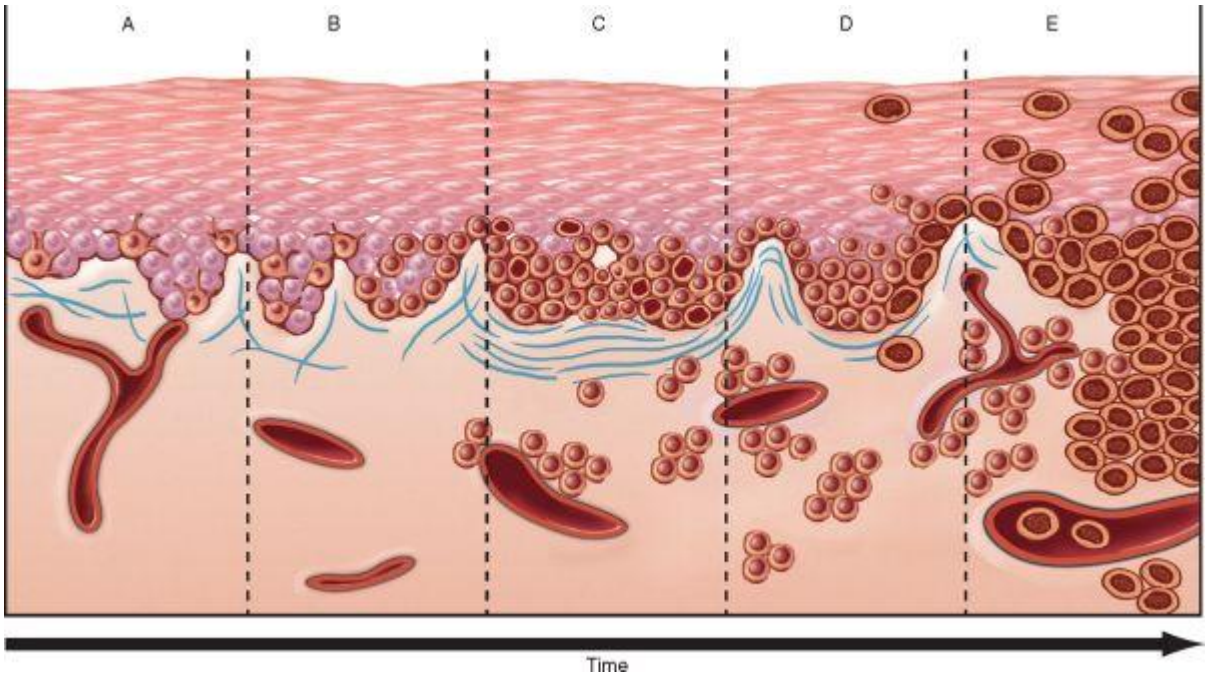

FIGURE 25-7 Potential steps of tumor progression in dysplastic nevi. **A**, Lentiginous melanocytic hyperplasia. **B**, Lentiginous junctional nevus. **C**, Lentiginous compound nevus with abnormal architectural and cytologic features (dysplastic nevus). **D**, Early melanoma, or melanoma in radial growth phase (large dark cells in epidermis). **E**, Advanced melanoma (vertical growth phase) with malignant spread into the dermis and vessels. The risk of malignant transformation of any single dysplastic nevus is extremely low but can occur.

MELANOMA

Melanoma is a relatively common neoplasm that remains deadly if not caught at its earliest stages. The great preponderance of melanomas arises in the skin; other sites of origin include the oral and anogenital mucosal surfaces, esophagus, meninges, and the eye (see Chapter 29). The following comments apply to cutaneous melanomas.

Today, as a result of increased public awareness of the signs of cutaneous melanoma, most are cured surgically.[13] Nevertheless, the reported incidence of melanoma is increasing; more than 60,000 cases and more than 8000 deaths are expected in the United States in 2008.[14]

Clinical Features.

Because melanomas evolve over time from localized skin lesions to aggressive tumors that metastasize and are resistant to therapy, early recognition and complete excision are critical. Melanoma of the skin is usually asymptomatic, although itching or pain may be early manifestations. The majority of lesions are *greater than 10 mm in diameter* at diagnosis. The most consistent clinical signs are *changes in the color, size, or shape of a pigmented lesion*. Unlike benign nevi, melanomas show striking *variations in color*, appearing in shades of black, brown, red, dark blue, and gray (Fig. 25-8A). On occasion, zones of white or flesh-colored hypopigmentation also appear, sometimes due to focal regression of the tumor. The *borders of melanomas are irregular and often notched*, not smooth, round, and uniform as in melanocytic nevi. To reiterate, *the most important warning signs, sometimes called the ABCs of melanoma, are* (1) *asymmetry*; (2) irregular *borders*; and (3) variegated *color*. Other features of pigmented lesions that should raise concern are a diameter greater than 6 mm, any change in appearance, and new onset of itching or pain.

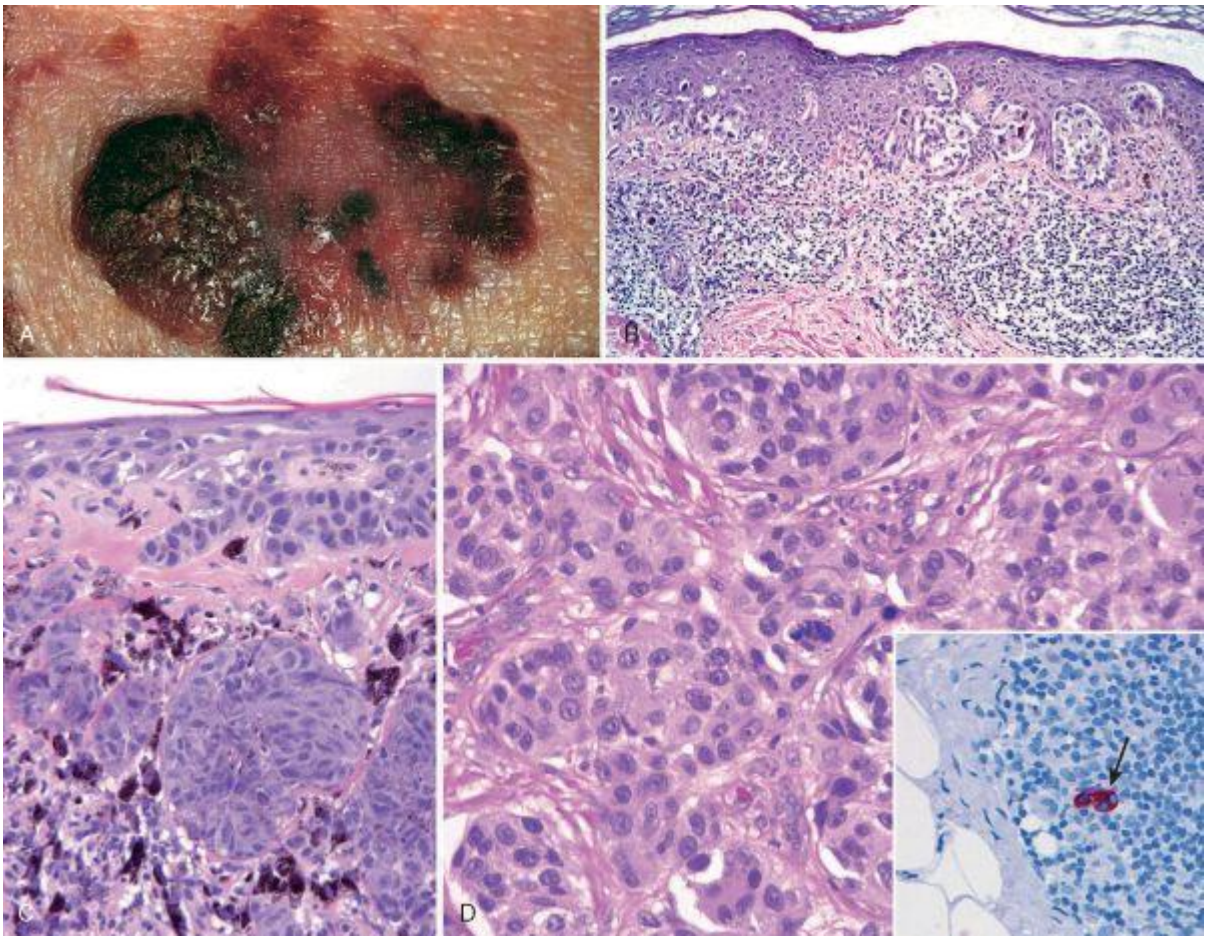

FIGURE 25-8 Melanoma. **A**, Typically, lesions are irregular in contour and pigmentation. Macular areas correlate with the radial growth phase, while raised areas usually correspond to nodular aggregates of malignant cells in the vertical phase of growth. **B**, Radial growth phase, showing irregular nested and single-cell growth of melanoma cells within the epidermis and an underlying inflammatory response within the dermis. **C**, Vertical growth phase, demonstrating nodular aggregates of infiltrating cells. **D**, High-power view of melanoma cells. The *inset* shows a sentinel lymph node with a tiny cluster of melanoma cells *(arrow)* staining for the melanocytic marker HMB-45. Even small numbers of malignant cells in a draining lymph node may confer a worse prognosis.

Morphology. Central to understanding the progression of melanoma is the concept of radial and vertical growth phases.[15] **Radial growth** describes the horizontal spread of melanoma within the epidermis and superficial dermis (Fig. 25-8B). During this initial stage the tumor cells seem to lack the capacity to metastasize. Tumors in radial growth phase fall into several clinicopathologic classes, including: **lentigo maligna**, usually presenting as an indolent lesion on the face of older men that may remain in the radial growth phase for several decades; **superficial spreading**, the most common type of melanoma, usually involving sun-exposed skin; and **acral/mucosal lentiginous** melanoma that is unrelated to sun exposure.

After a variable (and unpredictable) period of time, melanoma shifts from the radial phase to a **vertical growth phase**, during which the tumor cells invade downward into the deeper dermal layers as an expansile mass (Fig. 25-8C). **The vertical growth phase is often heralded by the appearance of a nodule and correlates with the emergence of a clone of cells with metastatic potential**. Unlike melanocytic nevi, maturation is absent from the deep invasive portion of melanoma. The probability of metastasis in such lesions correlates with the depth of invasion, which by

convention is the distance from the superficial epidermal granular cell layer to the deepest intradermal tumor cells; this measurement is known as the Breslow thickness.[16] Other histologic features that correlate with outcome include the number of mitoses and the presence of ulceration;[17,][18] these and other prognostic factors are discussed further below.

Individual melanoma cells are usually considerably larger than normal melanocytes or cells found in melanocytic nevi. They contain large nuclei with irregular contours, chromatin that is characteristically clumped at the periphery of the nuclear membrane, and prominent red (eosinophilic) nucleoli (Fig. 25-8D). The appearance of the tumor cells is similar in the radial and vertical phases of growth. While most nevi and melanomas are easily distinguished based on their appearance, a minority of "atypical" lesions occupy a histologic gray zone and have been termed **melanocytic tumors of uncertain malignant potential**;[13,][19] such lesions require complete excision and close clinical follow-up.

Prognostic Factors.

Once a melanoma is excised, a number of clinical and pathologic features are used to gauge the probability of metastatic spread and prognosis. One model predicts outcome based on the following variables:[20] (1) tumor *depth* (the Breslow thickness); (2) number of *mitoses*; (3) evidence of tumor *regression* (presumably due to the host immune response); (4) the presence and number of *tumor infiltrating lymphocytes* (TILs); (5) *gender*; and (6) *location* (central body or extremity). Determinants of a more *favorable prognosis* in this model include tumor depth of less than 1.7 mm, no or very few mitoses, a brisk TIL response, absence of regression, female gender, and location on an extremity. In a retrospective multivariate study by the American Joint Committee on Cancer (AJCC), tumor thickness and presence or absence of ulceration had prognostic significance independent of clinical stage.[21,][22] Because most melanomas initially metastasize to regional lymph nodes, additional prognostic information may be obtained by performing a sentinel lymph node biopsy; as in breast cancer (Chapter 23), this involves the identification, removal, and careful examination of the lymph node (or nodes) that is the initial site of drainage of intratumoral lymphatic vessels. Microscopic involvement of a sentinel node by even a small number of melanoma cells (micrometastases) confers a worse prognosis (Fig. 25-8D, *inset*).[23] The degree of involvement and the total number of lymph nodes involved correlate well with overall survival.

Pathogenesis.

The two most important predisposing factors are inherited genes and sun exposure. Melanomas most commonly arise on sun-exposed surfaces, particularly the upper back in men and the back and legs in women, and lightly pigmented individuals are at higher risk than are darkly pigmented individuals. However, the relationship between sun exposure and melanoma is not as straightforward as with other skin cancers (discussed later); some studies suggest that severe sunburns early in life are the most important risk factor. Since melanomas occur in dark-skinned individuals and at body sites that are not sun-exposed, sunlight is clearly not the only predisposing factor, and other environmental factors may also contribute to risk.[24]

It is estimated that 10% to 15% of melanomas are familial, and many (but not all) of those with familial melanoma also have dysplastic nevi. Several of the genes responsible for familial melanoma encode well-characterized tumor suppressors and are also mutated in sporadic tumors (discussed below). Other genetic variants linked to melanoma risk in fair-skinned populations control melanin production; these pigmentation genes have weak effects, conferring a slightly elevated risk. They include *MC1R*, which encodes the melanocortin-1 receptor; *ASIP* (agouti signaling protein), which encodes a regulator of

melanocortin receptor signaling, and *TYR*, which encodes tyrosinase, a melanocyte-specific enzyme that is required for melanin synthesis.[25]

Mutations that diminish the activity of the retinoblastoma (RB) tumor suppressor proteins are common in both familial and sporadic melanomas. The *CDKN2A* gene (discussed earlier under dysplastic nevi) is mutated in approximately 40% of pedigrees with autosomal dominant familial melanoma. *CDKN2A* is a complex locus that encodes three different tumor suppressors, p15/INK4b, p16/INK4a, and p14/ARF. Of these, loss of p16/INK4a is clearly implicated in human melanoma, and experimental evidence also strongly supports a role for loss of p14/ARF. You will recall from Chapter 7 that p16/INK4a enhances the activity of tumor suppressor proteins of the RB family by inhibiting cyclin-dependent kinase 4 (CDK4) and cyclin-dependent kinase 6 (CDK6), while p14/ARF enhances the activity of the p53 tumor suppressor by inhibiting the activity of the MDM2 oncoprotein. *CDKN2A* is mutated in approximately 10% of sporadic melanomas,[26] and these mutations uniformly abolish the production of p16/INK4a and more variably affect p14/ARF. However, it is suspected that these mutations are the tip of the "oncogenic iceberg" with respect to molecular lesions affecting the function of RB proteins. For example, as many as 30% to 70% of melanomas show loss of p16/INK4a expression though varied mechanisms,[27] and other uncommon familial and sporadic melanomas have mutations in CDK4 that prevent its inhibition by p16/INK4a. The net effect of all of these alterations is the same; increased melanocytic proliferation and escape from oncogene-induced cellular senescence.

The second common group of molecular lesions in sporadic melanoma leads to *aberrant increases in RAS and PI-3K/AKT signaling* (Fig. 25-9), which you will recall are pathways that promote cell growth and survival (Chapter 7). Activating mutations in *BRAF*, which encodes a serine/threonine kinase that is downstream of RAS, are seen in 60% to 70% of melanomas, while activating mutations in *NRAS* (which is upstream of BRAF) occur in additional 10% to 15% of tumors. For reasons that are unclear, melanomas arising in non-sun exposed sites are much more likely to have activating mutations in the c-KIT receptor tyrosine kinase,[28,][29] which sits upstream of both RAS and PI-3K/AKT, than in *NRAS* or *BRAF*. *PTEN*, a tumor suppressor that acts by downregulating PI-3K/AKT signaling, is epigenetically silenced in another 20% of melanomas.[30,][31]

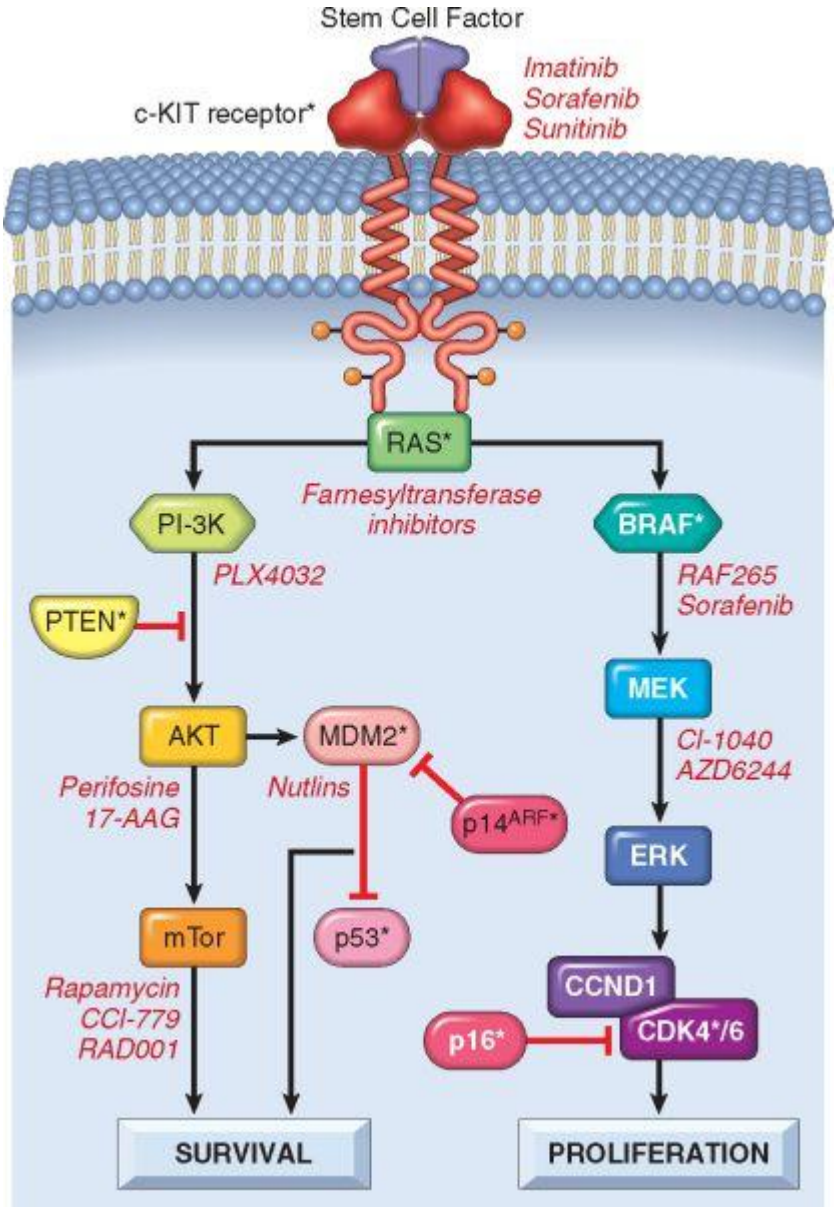

FIGURE 25-9 Pathways important in melanoma. The PI-3K/PTEN/AKT and BRAF/ERK pathways regulate cell survival and proliferation. Proteins altered in melanoma are indicated by asterisks. Inhibitors of these pathways are being studied as therapeutic agents; some specific examples are listed in red.

Molecular lesions of these two kinds are probably necessary, but not sufficient, for the development of melanoma. As discussed earlier, melanocytic nevi have the same activating mutations in *NRAS* and *BRAF* that are found in melanomas, yet become malignant very rarely, probably because unbridled RAS signaling leads to cellular senescence. p16/INK4a appears to be essential for the oncogene-induced cellular senescence,[31] and in its absence proliferation persists, placing melanocytes at risk for transformation into a melanoma. However, dysplastic nevi sometimes have lesions in both p16/INK4a and RAS or BRAF, yet transform into full-blown melanomas only somewhat more frequently than conventional nevi. Clearly, other pathways yet to be identified also contribute to the transformation process.

These molecular insights have spawned attempts to treat melanoma with new therapeutic agents that target the RAS and PI-3K/AKT pathways (Fig. 25-9). Such approaches are urgently needed, as metastatic melanoma is resistant to both conventional chemotherapy and radiation treatment. Ultimately, it is likely that these types of targeted therapies will be used in combinations tailored to the oncogenic leions found in individual tumors.[32] For example, a tumor with an activating mutation in c-KIT will require treatment with different inhibitors than a tumor with an activating mutation in RAS or BRAF. Immunotherapeutic approaches for melanoma in which host lymphocytes are "trained" to recognize and kill melanoma cells have also generated considerable interest, sparked in part by the recognition that spontaneous remissions of metastatic melanoma occur sporadically that are presumably mediated by the host immune response. Excellent responses are obtained on occasion,[33] but the general applicability of such treatments has yet to be demonstrated.

3.15.3 Benign Epithelial Tumors

Benign epithelial neoplasms are common and usually biologically inconsequential, although they may cause significant psychological discomfort for the affected individual. These tumors, derived from the keratinizing stratified squamous epithelium of the epidermis and hair follicles and the ductular epithelium of cutaneous glands, often recapitulate the structures from which they arise. They are sometimes confused clinically with malignancy, particularly when they are pigmented or inflamed, and histologic examination of a biopsy is frequently required to establish a definitive diagnosis. In rare instances they are a telltale sign of syndromes associated with potentially life-threatening visceral malignancies, such as multiple trichilemmomas in Cowden syndrome or multiple sebaceous neoplasms in Muir-Torre syndrome. Diagnosis of epithelial tumors in these instances may facilitate recognition of the underlying syndrome and implementation of appropriate clinical interventions.

SEBORRHEIC KERATOSES

These common epidermal tumors occur most frequently in middle-aged or older individuals. They arise spontaneously and are particularly numerous on the trunk, although the extremities, head, and neck may also be involved. In people of color, multiple small lesions on the face are termed *dermatosis papulosa nigra*.

Seborrheic keratoses characteristically appear as round, flat, coin-like, waxy plaques that vary in diameter from millimeters to several centimeters (Fig. 25-10, *inset*). They are uniformly tan to dark brown and usually have a velvety to granular surface. Inspection with a hand lens usually reveals small, round, porelike ostia impacted with keratin, a feature helpful in differentiating these pigmented lesions from melanomas.

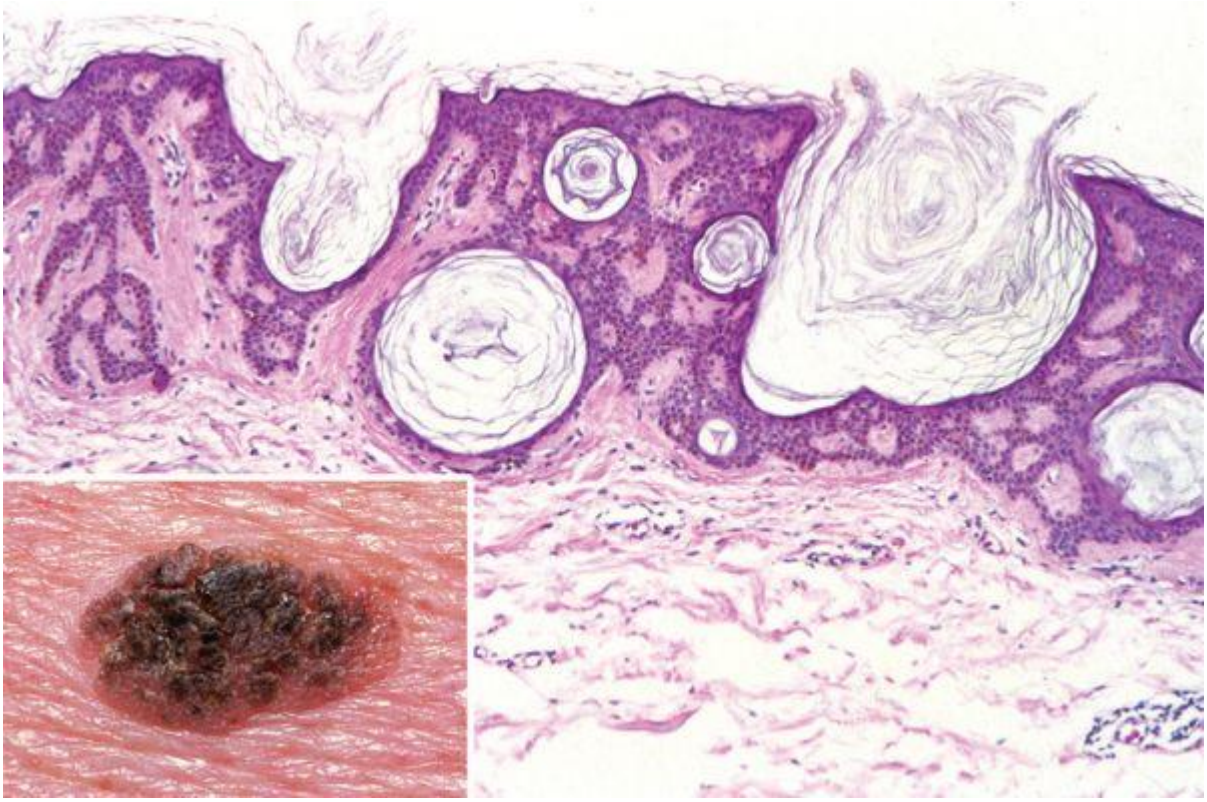

FIGURE 25-10 Seborrheic keratosis. A well-demarcated coinlike pigmented lesion containing dark keratin-filled surface plugs *(inset)* is composed histologically of benign basaloid cells associated with prominent keratin-filled "horn" cysts, some of which communicate with the surface (pseudo-horn cysts).

Morphology. On histologic examination, these neoplasms are exophytic and sharply demarcated from the adjacent epidermis. They are composed of sheets of small cells that most resemble basal cells of the normal epidermis (Fig. 25-10). Variable melanin pigmentation is present within these basaloid cells, accounting for the brown coloration. Exuberant keratin production (hyperkeratosis) occurs at the surface, and small keratin-filled cysts (horn cysts) and invaginations of keratin into the main mass (invagination cysts) are characteristic features. Interestingly, when seborrheic keratoses become irritated and inflamed, they develop whirling foci of squamous differentiation resembling eddy currents in a stream.[27]

Pathogenesis.

Activating mutations in the fibroblast growth factor receptor-3 *(FGFR3)* gene are found in many sporadic seborrheic keratoses and are thought to drive the growth of the tumor.[34,][35] Seborrheic keratoses may occur explosively in large numbers, as part of a paraneoplastic syndrome *(Leser-Trélat sign)*, possibly under the stimulation of transforming growth factor-α produced by tumor cells, most commonly carcinomas of the gastrointestinal tract.[36]

ACANTHOSIS NIGRICANS

Acanthosis nigricans is a condition marked by thickened, hyperpigmented skin with a "velvet-like" texture that most commonly appears in the flexural areas (axillae, skin folds of the neck, groin, and

anogenital regions). *It can be an important cutaneous marker of benign and malignant conditions* and, accordingly, is divided into two types.[37] The *benign type*, which constitutes about 80% of all cases, develops gradually and usually occurs in childhood or during puberty. It may occur (1) as an autosomal dominant trait with variable penetrance, (2) in association with obesity or endocrine abnormalities (particularly with pituitary or pineal tumors and diabetes), and (3) as part of several rare congenital syndromes. As with seborrheic keratoses, acanthosis nigricans sometimes occurs as a paraneoplastic process resulting from the production of growth factors by a variety of tumors. The *malignant type* refers to lesions arising in middle-aged and older individuals in association with underlying cancers, most commonly gastrointestinal adenocarcinomas.

Morphology. All forms of acanthosis nigricans have similar histologic features. The epidermis and underlying enlarged dermal papillae undulate sharply to form numerous repeating peaks and valleys. Variable hyperplasia may be seen, along with hyperkeratosis and slight basal cell layer hyperpigmentation (but no melanocytic hyperplasia).

Pathogenesis.

Because lesions of acanthosis nigricans may precede clinical symptoms and signs of the underlying disorder, recognition of this entity may lead to early detection of covert systemic disease. The familial form is associated with germline activating mutations in FGFR3; depending on the mutation, acanthosis may be an isolated finding or be seen together with skeletal deformities, including achondroplasia and thanatophoric dysplasia.[38]

FIBROEPITHELIAL POLYP

The fibroepithelial polyp has many names (acrochordon, squamous papilloma, skin tag) and is one of the most common cutaneous lesions. It is generally detected as an incidental finding in middle-aged and older individuals on the neck, trunk, face, and intertriginous areas as a soft, flesh-colored, bag-like tumor often attached to the surrounding skin by a slender stalk. Rarely, fibroepithelial polyps and tumors of perifollicular mesenchyme (specialized fibroblasts associated with the hair bulb) are seen together in Birt-Hogg-Dubé syndrome, but the vast majority of polyps are sporadic.[39]

Morphology. On histologic examination these tumors consist of fibrovascular cores covered by benign squamous epithelium. It is not uncommon for the polyps to undergo ischemic necrosis due to torsion, which may cause pain and precipitate their removal.

Fibroepithelial polyps are usually inconsequential, but can occasionally be associated with diabetes, obesity, and intestinal polyposis. Of interest, like melanocytic nevi and hemangiomas they often become more numerous or prominent during pregnancy, presumably related to hormonal stimulation.

EPITHELIAL CYST (WEN)

Epithelial cysts are common lesions formed by the invagination and cystic expansion of the epidermis or a hair follicle. The lay term, *wen*, derives from the Anglo-Saxon *wenn*, meaning a lump or tumor. These cysts are filled with keratin and lipid-containing debris derived from sebaceous secretions. Clinically, they are dermal or subcutaneous, well-circumscribed, firm, and often moveable nodules. When large, they may be subject to traumatic rupture, which can lead to inflammation and pain.

Morphology. Epithelial cysts are divided into several histologic types. The **epidermal inclusion cyst** has a wall resembling normal epidermis and is filled with laminated strands of keratin. **Pilar** or **trichilemmal cysts** have a wall that resembles follicular epithelium, without a granular cell layer and filled by a more homogeneous mixture of keratin and lipid. The **dermoid cyst** is similar to the epidermal inclusion cyst, but also contains multiple appendages (such as small hair follicles) budding outward from its wall. Finally, **steatocystoma simplex** is a cyst with a wall resembling the sebaceous gland duct, and from which numerous compressed sebaceous lobules originate. The importance of recognition of this cyst derives from the often dominantly heritable nature of the lesion **(steatocystoma multiplex)**, which can be caused by missense mutations in the gene encoding keratin 17. Interestingly, the same mutations are also associated with a syndrome called **pachyonychia congenital type 2**, which is associated with focal defects in skin, nails, and pilosebaceous cysts.[40,][41] These phenotypes are consistent with the pattern of keratin 17 expression, which is restricted to nail bed and epidermal appendages.

ADNEXAL (APPENDAGE) TUMORS

There are literally hundreds of neoplasms arising from or showing differentiation toward cutaneous appendages. Their significance varies according to type and clinical context. Some are entirely benign, but may be confused with cutaneous cancers such as basal cell carcinoma. Other appendage tumors are associated with mendelian patterns of inheritance and occur as multiple disfiguring lesions. In some instances, these lesions warn of a predisposition for internal malignancy; such is the reationship between multiple *trichilemmomas* and Cowden syndrome, a disorder caused by germline mutations in the tumor suppressor gene *PTEN* that is associated with an increased risk of breast cancer and many other tumors.[42] Selected examples are provided here to illustrate neoplasms of hair follicles and sebaceous, eccrine, and apocrine glands.

Appendage tumors are often nondescript, flesh-colored solitary or multiple papules and nodules. Some have a predisposition for occurrence on specific body surfaces. For example, the *eccrine poroma* occurs predominantly on the palms and soles. *Cylindroma*, an appendage tumor with ductal (apocrine or eccrine) differentiation, usually occurs on the forehead and scalp (Fig. 25-11A), where coalescence of nodules with time may produce a hat-like growth, hence the name *turban tumor*. These lesions may be dominantly inherited; in such cases they appear early in life and are associated with inactivating mutations in the tumor suppressor gene *CYLD*, which encodes a deubiquitinating enzyme that regulates NF-κB and the cell cycle.[43,][44] Germline mutations in this gene are associated with several related genetic syndromes including familial cylindromatosis, multiple familial trichoepithelioma (a follicular tumor), and Brooke-Spiegler syndrome (showing both tumor types).[45] *Syringomas*, lesions with eccrine differentiation, usually occur as multiple, small, tan papules in the vicinity of the lower eyelids. *Sebaceous adenomas* can be associated with internal malignancy in the Muir-Torre syndrome, a subset of the hereditary nonpolyposis colorectal carcinoma syndrome (Chapter 17) associated with germline deficits in DNA mismatch repair proteins; some of these have mutations in genes involved in WNT signaling.[46,][47] *Pilomatricomas*, showing follicular differentiation, are associated with activating mutations in *CTNNB1*, the gene encoding β-catenin.[48] Mutations in this gene are seen in numerous neoplasms but are of interest here since WNT signaling through β-catenin is critical for early hair development and regulates the hair cycle. Adnexal tumors can also show primarily apocrine differentiation; these usually arise in body areas where apocrine glands are most prevalent, such as the axilla and scalp. Some skin adnexal tumors may arise from multipotent cutaneous stem cells, which are believed to reside in a specialized niche associated with hair follicles.[49]

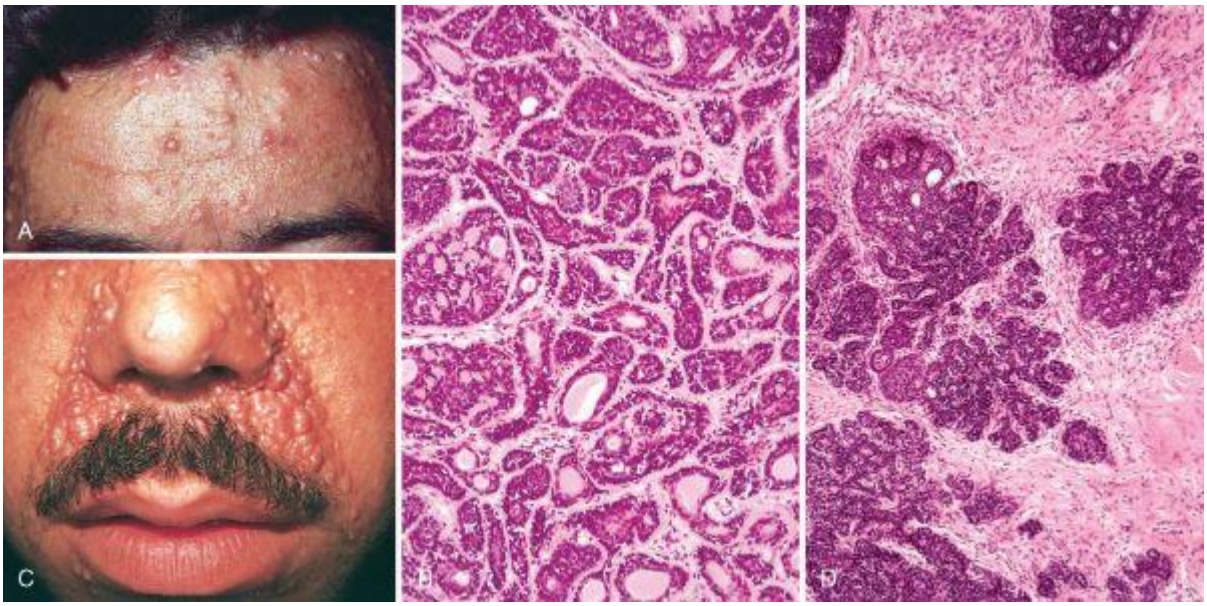

FIGURE 25-11 Adnexal tumors. **A**, Multiple cylindromas (papules) on the forehead are composed of islands of (**B**) basaloid cells containing occasional ducts that fit together like pieces of a jigsaw puzzle. **C**, Perinasal papules and small nodules of trichoepithelioma are composed of (**D**) buds of basaloid cells that resemble primitive hair follicles.

Morphology. The **cylindroma** is composed of islands of cells resembling those of the normal epidermal or adnexal basal cell layer (basaloid cells). These islands fit together like pieces of a jigsaw puzzle within a fibrous dermal matrix (Fig. 25-11B). **Trichoepithelioma** is a proliferation of basaloid cells that forms primitive structures resembling hair follicles (Fig. 25-11C, D). **Sebaceous adenoma** shows a lobular proliferation of sebocytes with increased peripheral basaloid cells and more mature sebocytes in the central portion, characterized by frothy or bubbly cytoplasm due to lipid vesicle content (Fig. 25-12A). **Pilomatrixomas** are composed of basaloid cells that show trichilemmal or hairlike differentiation similar to that seen in the germinal portion of the normal hair bulb in the anagen growth phase (Fig. 25-12B). **Apocrine carcinoma** shows ductal differentiation with prominent decapitation secretion similar to that seen in the normal apocrine gland (Fig. 25-12C). The infiltrative growth pattern is a hint of malignancy in this otherwise well-differentiated tumor.

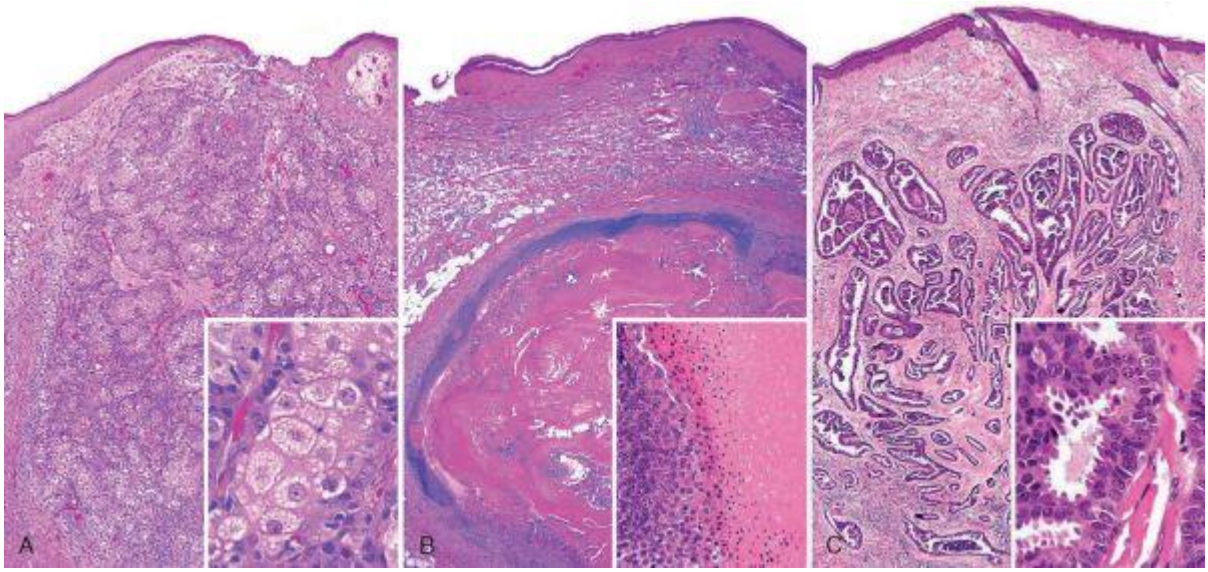

FIGURE 25-12 Adnexal tumors. **A**, Sebaceous adenoma; *inset* demonstrates sebaceous differentiation. **B**, Pilomatrixoma; *inset* shows hair matrical differentiation with characteristic maturation to anucleate "ghost cells." **C**, Apocrine carcinoma (well-differentiated); *inset* shows apocrine differentiation with characteristic luminal decapitation secretion.

Although most appendage tumors are benign, malignant variants do exist. Apocrine tumors are unusual in that malignant forms seem to be more common than benign forms. *Sebaceous carcinoma*, for example, arises from the meibomian glands of the eyelid and may follow an aggressive course replete with systemic metastases. *Eccrine* and *apocrine carcinomas* are often confused with metastatic adenocarcinomas to the skin because of their tendency for abortive gland formation.

3.15.4 Premalignant & Malignant Epidermal Tumors

ACTINIC KERATOSIS

The development of epidermal malignancy is typically preceded by a period of progressively worsening dysplastic changes, which are analogous to the precursor lesions that give rise to carcinoma of the squamous mucosa of the uterine cervix (Chapter 22). In the skin, these precursor lesions are called *actinic keratoses*; as the name implies, these usually occur in sun-damaged skin and exhibit hyperkeratosis. As would be expected, they occur with particularly high incidence in lightly pigmented individuals. Exposure to ionizing radiation, industrial hydrocarbons and arsenicals may induce similar lesions.

Actinic keratoses are usually less than 1 cm in diameter; are tan-brown, red, or skin-colored; and have a rough, sandpaper-like consistency. Some lesions may produce so much keratin that a "cutaneous horn" develops (Fig. 25-13A). Such horns may become so prominent that they actually resemble the horns of animals! Sun-exposed sites (face, arms, dorsum of hands) are most frequently affected. The lips may also develop similar lesions (termed *actinic cheilitis*).

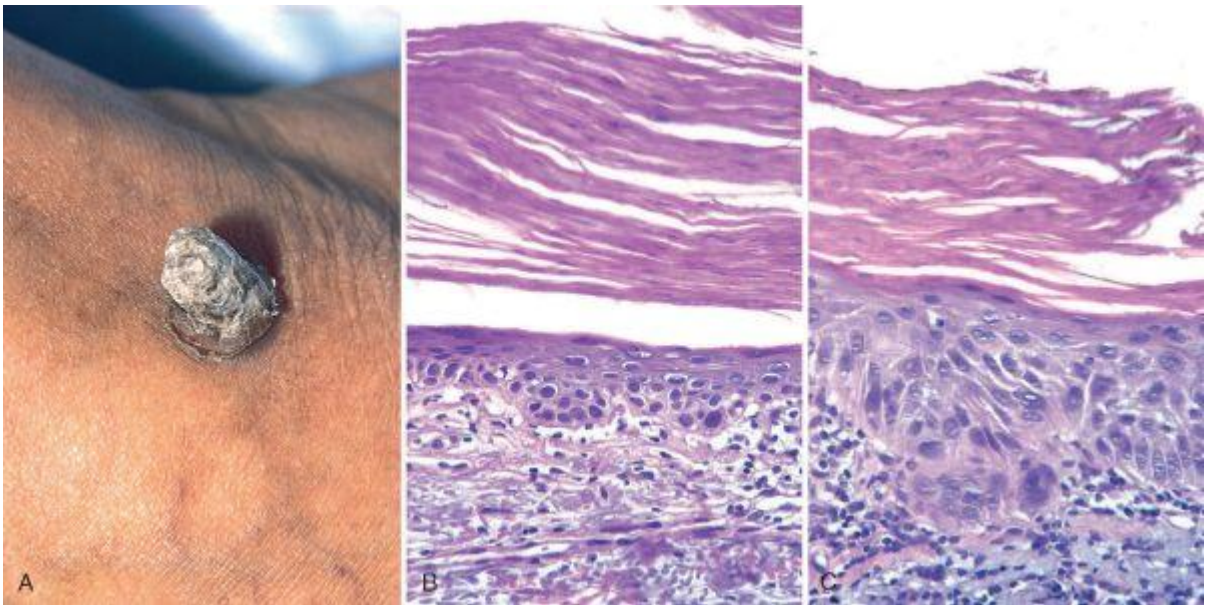

FIGURE 25-13 Actinic keratosis. **A**, Excessive scale formation in this lesion has produced a "cutaneous horn." **B**, Basal cell layer atypia (dysplasia) is associated with marked hyperkeratosis and parakeratosis. **C**, Progression to full-thickness nuclear atypia, with or without the presence of superficial epidermal maturation, heralds the development of squamous cell carcinoma in situ.

Morphology. Cytologic atypia is seen in the lowermost layers of the epidermis and may be associated with hyperplasia of basal cells (Fig. 25-13B) or, alternatively, with atrophy that results in thinning of the epidermis. The atypical basal cells usually have pink or reddish cytoplasm due to dyskeratosis. Intercellular bridges are present, in contrast to basal cell carcinoma, in which they are not visible. The superficial dermis contains thickened, blue-gray elastic fibers (elastosis), a probable result of abnormal elastic fiber synthesis by sun-damaged fibroblasts[34]. The stratum corneum is thickened, and unlike normal skin, the cells in this layer often retain their nuclei (**parakeratosis**).

Whether all actinic keratoses would inexorably lead to skin cancer (usually squamous cell carcinoma), if given enough time, is conjectural. Studies indicate that lesions may regress or remain stable during a normal life span. However, enough become malignant to warrant local eradication. This can usually be accomplished by gentle curettage, freezing, or topical application of chemotherapeutic agents. More recently, a reagent called imiquimod, which activates the innate immune system through stimulation of Toll-like receptors (TLRs), has been used to eradicate the abnormal cells that compose this tumor.[50]

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma is the second most common tumor arising on sun-exposed sites in older people, exceeded only by basal cell carcinoma. Except for lesions on the lower legs, these tumors have a higher incidence in men than in women. Invasive squamous cell carcinomas are usually discovered while they are small and resectable. Less than 5% of these tumors metastasize to regional nodes; these lesions are generally deeply invasive and involve the subcutis.

Morphology. Squamous cell carcinomas that have not invaded through the basement membrane of

the dermoepidermal junction (termed **in situ carcinoma**) appear as sharply defined, red, scaling plaques. More advanced, invasive lesions are nodular, show variable keratin production (appreciated grossly as hyperkeratotic scale), and may ulcerate (Fig. 25-14A).

Unlike actinic keratoses, in squamous cell carcinoma in situ, cells with atypical (enlarged and hyperchromatic) nuclei involve **all levels** of the epidermis (Fig. 25-13C). Invasive squamous cell carcinoma (Fig. 25-14B, C) shows variable degrees of differentiation, ranging from tumors composed of polygonal cells arranged in orderly lobules and having numerous large areas of keratinization, to neoplasms associated with geographic necrosis consisting of highly anaplastic cells that exhibit only abortive, single-cell keratinization (dyskeratosis). The latter tumors may be so poorly differentiated that immunohistochemical stains for keratins are needed to confirm the diagnosis.

Keratoacanthoma is a controversial lesion; some regard it as a variant of well-differentiated squamous cell carcinoma, while others consider it to be a distinct entity. It differs from conventional squamous cell carcinomas in that after a period of rapid growth, it usually regresses spontaneously. Grossly, it is a symmetric cup-shaped tumor with a central depression filled with keratin debris. Histologically, the tumor is composed of lobules of squamous cells with glassy cytoplasm that undergo kertinization without an intervening granular layer. Once established, keratoacanthomas elicit a brisk lymphocytic and eosinophilic host response.

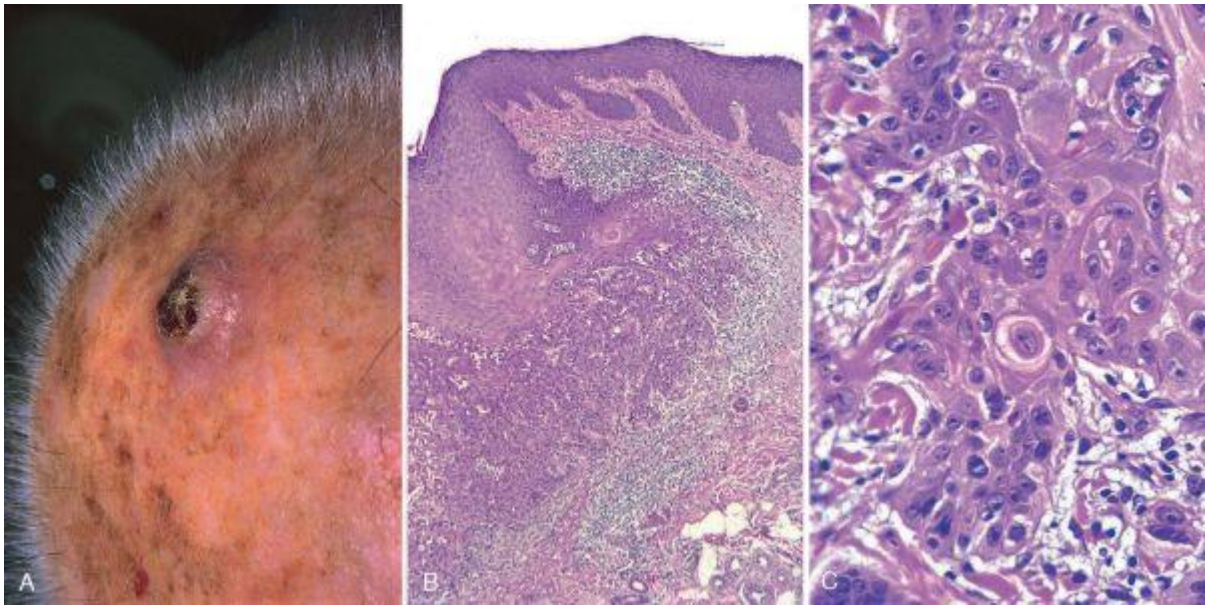

FIGURE 25-14 Invasive squamous cell carcinoma. **A**, Lesions are often nodular and ulcerated as seen in this scalp tumor. **B**, Tongues of atypical squamous epithelium have transgressed the basement membrane, invading deeply into the dermis. **C**, A magnified image reveals invasive tumor cells showing enlarged nuclei with angulated contours and prominent nucleoli.

Pathogenesis.

The most important cause of cutaneous squamous cell carcinoma is DNA damage induced by exposure to UV light. Tumor incidence is proportional to the degree of lifetime sun exposure. A second common association is with immunosuppression, most notably chronic immunosuppression as a result of chemotherapy or organ transplantation.[51] Immunosuppression may contribute to carcinogenesis by reducing host surveillance and increasing the susceptibility of keratinocytes to infection and

transformation by oncogenic viruses, particularly human papilloma virus (HPV) subtypes 5 and 8.[52] These same HPVs have been implicated in tumors arising in patients with a rare autosomal recessive condition, epidermodysplasia verruciformis, that is marked by a high susceptibility to cutaneous squamous cell carcinomas.[53] Sunlight, in addition to its damaging effect on DNA, seems to cause a defect in cutaneous immunity by dampening the immune surveillance function of epidermal Langerhans cells.[54] Other risk factors for squamous cell carcinoma include industrial carcinogens (tars and oils), chronic ulcers and draining osteomyelitis, old burn scars, ingestion of arsenicals, ionizing radiation, and (in the oral cavity) tobacco and betel nut chewing.

Most studies on the genetics of squamous cell carcinoma have focused on acquired defects in sporadic tumors and their precursors (actinic keratoses), and the relationships between these defects and sun-exposure. The incidence of *p53* mutations in actinic keratoses found in Caucasians is high, suggesting that p53 dysfunction is an early event in the development of tumors induced by sunlight. Normally, DNA damaged by UV light is sensed by checkpoint kinases such as ATM and ATR, which send out signals that upregulate the expression and stability of p53. p53 in turn arrests cells in the G_1 phase of the cell cycle and promotes either "high-fidelity" DNA repair or the elimination of cells that are damaged beyond repair by apoptosis (Chapter 7). When these protective functions of p53 are lost, DNA damage induced by UV light is more likely to be "repaired" by error-prone mechanisms, creating mutations that are passed down to daughter cells. Of note, the mutations that are seen in *p53* often occur at pyrimidine dimers, indicating that they, too, stem from damage caused by UV light. A similar story underlies the remarkable susceptibility of patients with xeroderma pigmentosum to squamous cell carcinoma. This disorder is caused by inherited mutations in genes in the nucleotide excision repair pathway, which is required for accurate repair of pyrimidine dimers; when this pathway is defective, error-prone repair pathways take over, leading to the rapid accumulation of mutations and eventual carcinogenesis.

As with all other forms of cancer, cutaneous squamous cell carcinoma stems from molecular lesions in multiple genes. In addition to defects in p53, studies of explanted human keratinocytes suggest that dysregulated RAS signaling plays an important role in the transformation process.[55]

BASAL CELL CARCINOMA

Basal cell carcinoma is the most common invasive cancer in humans, with nearly 1 million estimated cases per year in the United States.[56] These are slow-growing tumors that rarely metastasize. They have a tendency to occur at sun-exposed sites and in lightly pigmented people. As with squamous cell carcinoma, the incidence of basal cell carcinoma rises sharply with immunosuppression and in people with inherited defects in DNA repair such as xeroderma pigmentosum (Chapter 7).

These tumors present clinically as *pearly papules often containing prominent, dilated subepidermal blood vessels (telangiectasias)* (Fig. 25-15A). Some tumors contain melanin and thus appear similar to melanocytic nevi or melanomas. Advanced lesions may ulcerate, and extensive local invasion of bone or facial sinuses may occur after many years of neglect or in unusually aggressive tumors, explaining the archaic designation *rodent ulcers*. One common and important variant, the superficial basal cell carcinoma, presents as an erythematous, occasionally pigmented plaque that may resemble early forms of melanoma.

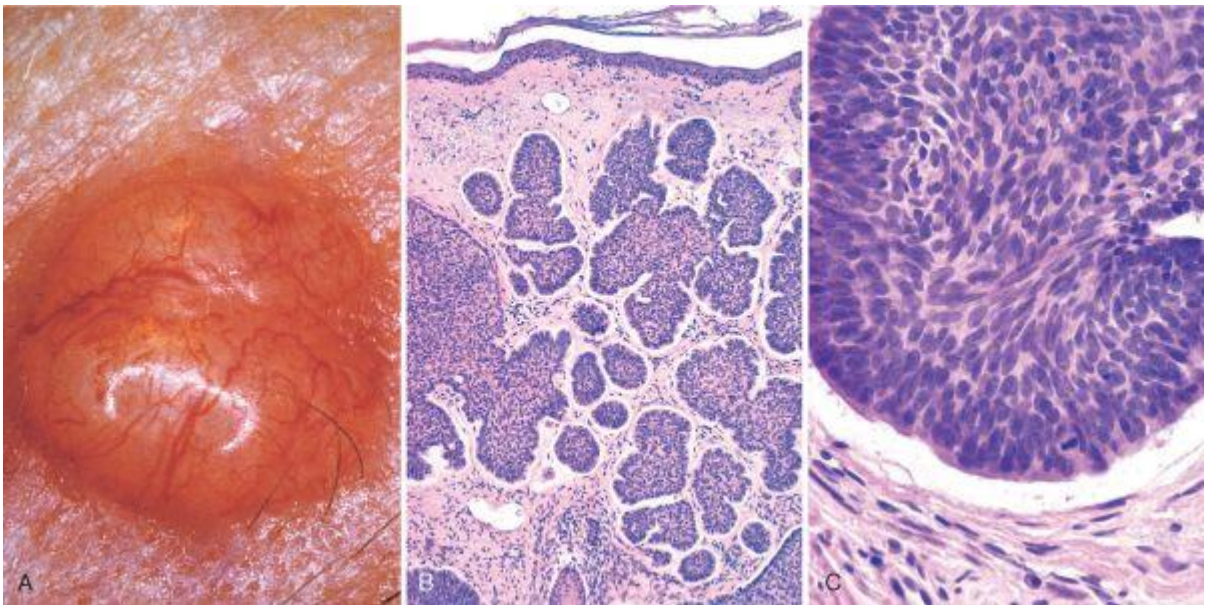

FIGURE 25-15 Basal cell carcinoma. Pearly, telangiectatic nodules (**A**) are composed of nests of uniformly atypical basaloid cells within the dermis (**B**) that are often separated from the adjacent stroma by thin clefts (**C**), an artifact of sectioning.

Morphology. Histologically, the tumor cells resemble those in the normal basal cell layer of the epidermis. They arise from the epidermis or follicular epithelium and do not occur on mucosal surfaces. Two patterns are seen: **multifocal growths** originating from the epidermis and sometimes extending over several square centimeters or more of skin surface (multifocal superficial type) and **nodular lesions** growing downward deeply into the dermis as cords and islands of variably basophilic cells with hyperchromatic nuclei, embedded in a mucinous matrix, and often surrounded by many fibroblasts and lymphocytes (Fig. 25-15B). The cells at the periphery of the tumor cell islands tend to be arranged radially with their long axes in parallel alignment **(palisading)**. In sections, the stroma retracts away from the carcinoma (Fig. 25-15C), creating clefts or separation artifacts that assist in differentiating basal cell carcinomas from certain appendage tumors that are also characterized by proliferation of basaloid cells, such as trichoepithelioma.

Pathogenesis.

Nevoid basal cell carcinoma syndrome (NBCCS; also known as *basal cell nevus* or *Gorlin syndrome*) is an autosomal dominant disorder characterized by multiple basal cell carcinomas.[57] Most of these tumors develop before age 20 and are accompanied by various other conditions including tumors (especially medulloblastomas and ovarian fibromas), odontogenic keratocysts, and pits of the palms and soles. Multiple systemic manifestations such as intracranial calcification, cleft lip and palate, abnormal segmentation of the vertebra, and rib anomalies (bifid, fused, missing, splayed ribs) may also be present.[58] Though quite rare (incidence of 1 in 56,000), this syndrome has helped to elucidate the molecular genetics of basal cell carcinoma, including the common sporadic type. Examples of other genetic syndromes associated with skin tumors are listed in Table 25-2 .

TABLE 25-2 -- Survey of Familial Cancer Syndromes with Cutaneous Manifestations

Disease	Inheritance	Chromosomal Location	Gene/Protein	Normal function/Manifestation of loss
Ataxia-telangiectasia	AR	11q22.3	*ATM*/ATM	DNA repair after radiation injury/neurologic and vascular lesions
Nevoid basal cell carcinoma syndrome	AD	9q22.3	*PTCH*/PTCH	Developmental patterning gene/multiple basal cell carcinomas; jaw cysts, etc.
Cowden syndrome	AD	10q23	*PTEN*/PTEN	Lipid phosphatase/benign follicular appendage tumors (trichilemmomas); internal adenocarcinoma (often breast)
Familial melanoma syndrome	AD	9p21	*CDKN2*/p16/INK4	Inhibits CDK phosphorylation of RB, promoting cell cycle arrest/melanoma; pancreatic carcinoma
			CDKN2/p14/ARF	Binds MDM2, promoting p53 function/melanoma; pancreatic carcinoma
Muir-Torre syndrome	AD	2p22	*MSH2*/MSH2	Involved in DNA mismatch repair/sebaceous neoplasia; internal malignancy (colon and others)
			MLH1/MLH1	
Neurofibromatosis I	AD	17q11.2	*NF1*/neurofibromin	Negatively regulates RAS signaling/neurofibromas
Neurofibromatosis II	AD	22q12.2	*NF2*/merlin	Integrates cytoskeletal signaling/neurofibromas and acoustic neuromas
Tuberous sclerosis	AD	9q34	*TSC1*/hamartin	Work together in a complex that negatively regulates mTOR/angiofibromas/mental retardation
		16p13.3	*TSC2*/tuberin	
Xeroderma pigmentosum	AR	9q22 and others	*XPA*/XPA and others	Nucleotide excision repair/melanoma and nonmelanoma skin cancers

From Tsai KY, Tsao H: The genetics of skin cancer. Am J Med Genet C Semin Med Genet 131C:82, 2004.

AD, Autosomal dominant; AR, autosomal recessive.

The gene associated with NBCCS, located on chromosome 9q22.3, is *PTCH*, the human homologue of the *Drosophila* developmental gene *patched*.[59] The pathogenesis of basal cell carcinomas in NBCCS fits the classical Knudson "two-hit" hypothesis for familial retinoblastoma (Chapter 7). Individuals with NBCCS are born with a germline mutation in one of the *PTCH* alleles; the second normal allele is inactivated in tumors by a mutation acquired by chance or due to exposure to mutagens (such as UV light).

The *PTCH* gene encodes a receptor for the protein product of the *sonic hedgehog gene (SHH)*, a member of the hedgehog *(HH)* family of genes that determine polarity during embryonic development.[60] The pathway is also involved in hair follicle formation and the hair cycle in skin.[5] The PTCH protein forms a receptor complex with another transmembrane protein, known as SMO (for "smoothened"). In the absence of its ligand, SHH, PTCH inactivates SMO and sequesters it from transducing a down-stream signal. Binding of SHH to PTCH releases the suppression of SMO, causing the up-regulation of hedgehog target genes through a signal cascade that involves the GLI1 transcription factor (Fig. 25-16). Experimental work in mice has shown that animals with defects in the *PTCH* signaling pathway, including overexpression of GLI1, develop skin tumors resembling basal cell

carcinomas.[61,][62] In NBCCS the absence of *PTCH* causes constitutive activation of SMO, leading to the development of basal cell carcinoma.

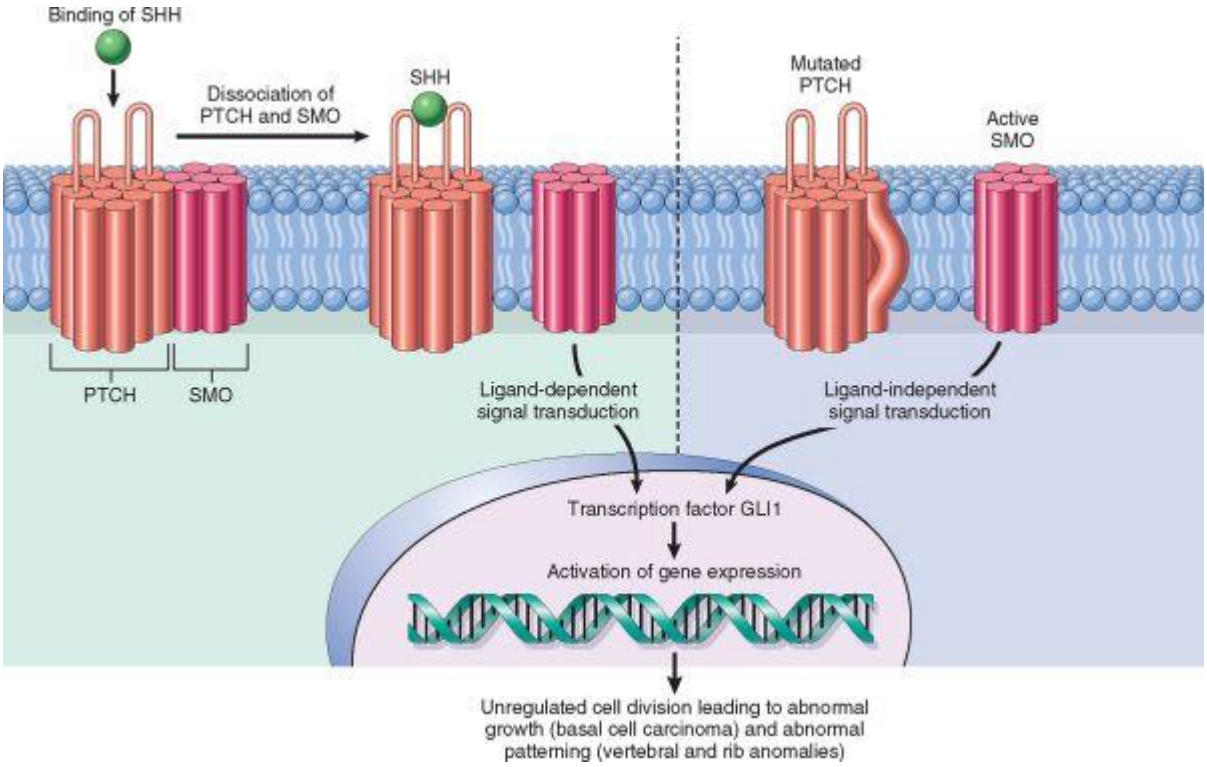

FIGURE 25-16 Normal and oncogenic hedgehog signaling. *Left*, Normally, PTCH and SMO form a receptor complex that binds sonic hedgehog (SHH). In the absence of SHH, PTCH blocks SMO activity. When SHH binds PTCH, SMO is released to trigger a signal transduction cascade that leads to activation of GLI1 and other transcription factors. *Right*, Mutations in *PTCH*, and less often in *SMO*, allow SMO to signal without ligand binding and underlie the nevoid basal cell carcinoma (Gorlin) syndrome.

Mutations of genes belonging to the *PTCH* signaling pathway are also important for the development of the common sporadic form of basal cell carcinoma, as documented by the inactivation of *PTCH* and the presence of *SMO* activating mutations in these skin neoplasms.[63] *PTCH* mutations are found in approximately 30% of sporadic basal cell carcinomas, and of these about one third have mutations (C→T transitions) that are considered hallmarks of UV damage. Mutations in *p53* occur in 40% to 60% of basal cell carcinomas, and 60% of these have "UV signature."[64] Xeroderma pigmentosum, a disorder of DNA repair, presents a striking example of the connection between sun exposure and defects in *PTCH* and *p53*.[65] In these tumors the frequency of mutations in *PTCH* and *p53* are, respectively, 90% and 40%, and the majority of these bear the UV signature.

3.15.5 Tumors of the Dermis

The dermis contains a variety of elements such as smooth muscle, pericytes, fibroblasts, neural tissue, and endothelium. Neoplasms with differentiation toward all of these tissues occur not just in the skin, but also in soft tissues and viscera. In this section we consider two representative dermal neoplasms—one benign, one malignant—that arise primarily in the skin.

BENIGN FIBROUS HISTIOCYTOMA (DERMATOFIBROMA)

Benign fibrous histiocytoma refers to a heterogeneous family of morphologically and histogenetically related benign dermal neoplasms of uncertain lineage. These tumors are usually seen in adults and often occur on the legs of young to middle-aged women. Their biologic behavior is indolent.

These neoplasms appear as firm, tan to brown papules (Fig. 25-17A). Lesions are asymptomatic or tender and may increase and decrease slightly in size over time. Most are less than 1 cm in diameter, but actively growing lesions may reach several centimeters in diameter; with time they often become flattened. The tendency for fibrous histiocytomas to dimple inward on lateral compression can be helpful in distinguishing them from nodular melanomas, which protrude when squeezed.

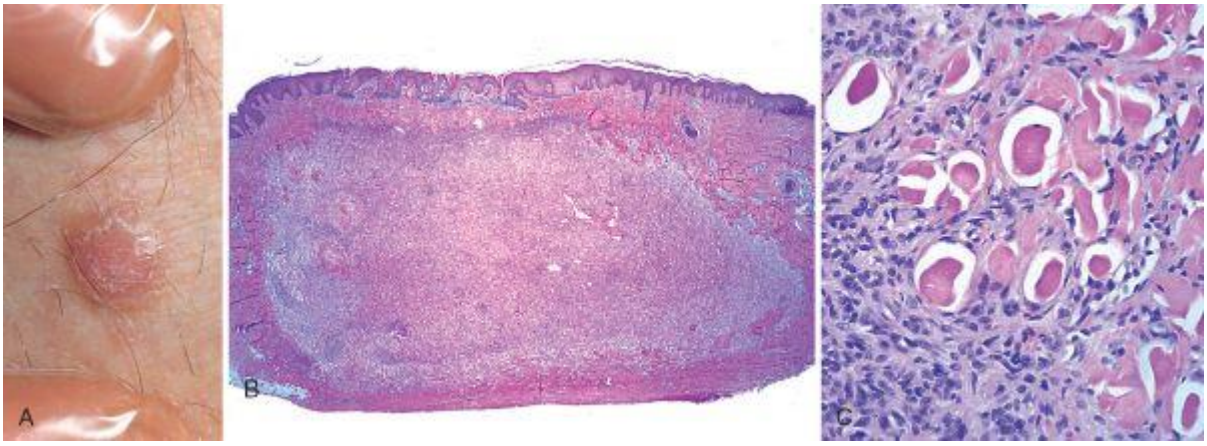

FIGURE 25-17 Benign fibrous histiocytoma (dermatofibroma). This firm, tan papule on the leg (**A**) shows a localized proliferation of benign-appearing spindle cells within the dermis (**B**). **C**, Note the characteristic overlying epidermal hyperplasia and the tendency of fibroblasts to surround individual collagen bundles.

The cause of fibrous histiocytomas remains a mystery. Many cases have a history of antecedent trauma, suggesting an abnormal response to injury and inflammation,[66] perhaps analogous to the deposition of increased amounts of altered collagen in a hypertrophic scar or keloid. These common yet curious tumors appear to be composed at least partially of factor XIIIa–positive dermal dendrocytes.

Morphology. The most common form of fibrous histiocytoma is referred to as a **dermatofibroma**. These tumors are formed by benign, spindle-shaped cells arranged in a well-defined, nonencapsulated mass within the mid-dermis (Fig. 25-17B, C). Extension of these cells into the subcutaneous fat is sometimes observed. Many cases demonstrate a peculiar form of overlying epidermal hyperplasia, characterized by downward elongation of hyperpigmented rete ridges (a pseudo-epitheliomatous pattern). Numerous histologic variants are noted, such as more cellular forms or tumors with pools of extravascular blood and hemosiderin (aneurysmal).

DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans is best regarded as a well-differentiated, primary fibrosarcoma of the skin. These tumors are slow growing, and although they are locally aggressive and can recur, they rarely metastasize. Clinically they are firm, solid nodules that arise most frequently on the trunk. They often develop as aggregated “protuberant” tumors within a firm (indurated) plaque or nodule that may sometimes ulcerate.

Morphology. On microscopic examination, these neoplasms are cellular, composed of fibroblasts arranged radially, reminiscent of blades of a pinwheel, a pattern referred to as **storiform**. Mitoses are rare. In contrast to that in dermatofibroma, the overlying epidermis is generally thinned. Deep extension from the dermis into subcutaneous fat, producing a characteristic "honeycomb" pattern, is frequently present (Fig. 25-18B, C). These tumors may extend down fibrous septae in the subcutis and thus require wider excision than would appear to be necessary to prevent local recurrence.

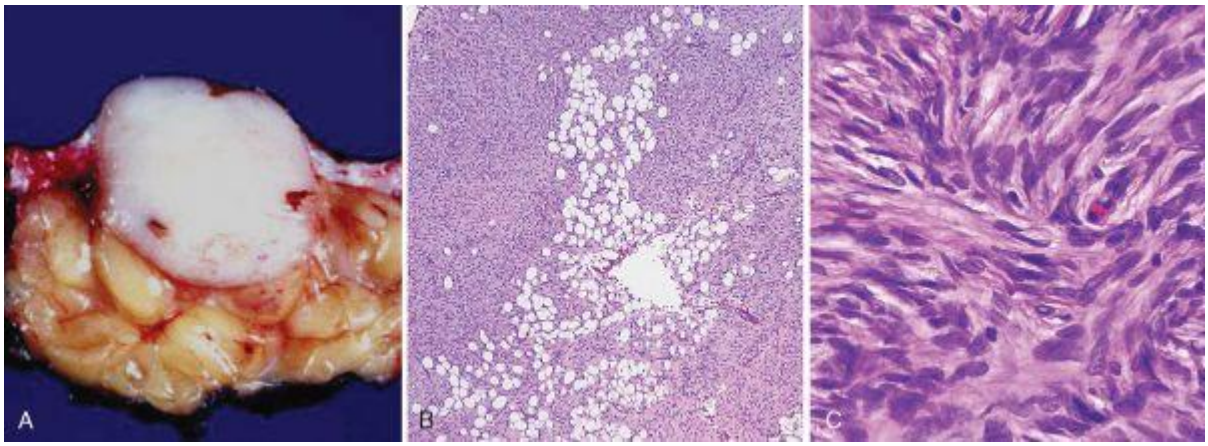

FIGURE 25-18 Dermatofibrosarcoma protuberans. **A**, The tumor usually presents as a flesh-colored to erythematous nodule, and has a fibrotic appearance on sectioning. **B, C**, Characteristic storiform cellularity is noted histologically, and the lesion often infiltrates the subcutis in a manner that resembles "Swiss cheese" to some afficianados.

Pathogenesis.

The molecular hallmark of dermatofibrosarcoma protuberans is a balanced translocation between genes encoding collagen 1A1 *(COL1A1)* and the platelet-derived growth factor-β *(PDGFB)*. It results in the juxtaposition of COL1A1 promoter sequences and the coding region of PDGFβ; this in turn leads to over-expression and secretion of PDGFβ, which drives tumor cell growth through an autocrine loop.[67,][68] Such fusion genes are increasingly being recognized in a wide spectrum of tumors, including carcinomas.[69] While the primary mode of treatment is local wide excision, in cases not amenable to this approach the targeted tyrosine kinase inhibitor imatinib mesylate is used. This inhibits PDGF-β receptor activation and has marked antitumor activity.[70] Withdrawal of the drug allows tumor regrowth even after long-term treatment, so use of this agent is lifelong.

3.15.6 Tumors of Cellular Migrants to the Skin

Aside from tumors that arise directly from epidermal and dermal cells, several proliferative disorders of the skin involve cells whose progenitors arise elsewhere and home to the cutaneous microenvironment. The two examples discussed in this section—namely, cutaneous T-cell lymphoma and mastocytosis—are primary cutaneous disorders that arise from lymphocytes and mast cells, respectively.

MYCOSIS FUNGOIDES (CUTANEOUS T-CELL LYMPHOMA)

Cutaneous T cell lymphoma (CTCL) represents a spectrum of lymphoproliferative disorders affecting the skin (see also Chapter 13).[71] Two different clinical types of malignant T-cell disorders were originally recognized: *mycosis fungoides*, a chronic proliferative process; and a more aggressive nodular

eruptive variant, *mycosis fungoides d'emblée*. It is now known that a variety of presentations of T-cell lymphoma occur in the skin, but this section will focus on mycosis fungoides.

Mycosis fungoides is a T-cell lymphoma that presents in the skin and may evolve into generalized lymphoma.[72] Most affected individuals have disease that remains localized to the skin for many years; a minority have rapid systemic dissemination. This condition may occur at any age, but most commonly it afflicts persons older than age 40.

Lesions of mycosis fungoides usually involve truncal areas and include scaly, red-brown *patches*; raised, scaling *plaques* that may even be confused with psoriasis; and fungating *nodules*. Prognosis is related to the percentage of body surface involved and progression from patch to plaque to nodular forms. Eczema-like lesions typify early stages of disease when obvious visceral or nodal spread has not occurred. Raised, indurated, irregularly outlined, erythematous plaques may then supervene. Development of multiple, large (≤10 cm or more in diameter), red-brown nodules correlates with systemic spread. Sometimes plaques and nodules ulcerate (Fig. 25-19A). Ultimately, lesions may affect numerous body surfaces, including the trunk, extremities, face, and scalp. In some individuals, seeding of the blood by malignant T cells is accompanied by diffuse erythema and scaling of the entire body surface (erythroderma), a condition known as *Sézary syndrome* (Chapter 13).

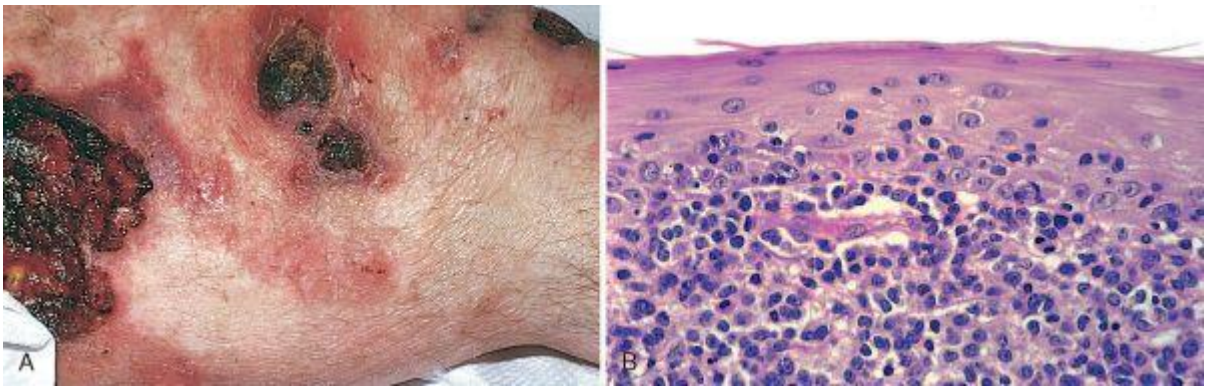

FIGURE 25-19 Cutaneous T-cell lymphoma. **A**, Several ill-defined, erythematous, often scaling, and occasionally ulcerated plaques. **B**, Microscopically, there is an infiltrate of atypical lymphocytes that show a tendency to accumulate beneath the epidermal layer and to invade the epidermis.

The proliferating cells in CTCL are clonal populations of lymphocytes of the CD4 subset.[2,][73] The neoplastic cells are targeted to the skin by expression of CLA (see Fig. 25-2) and often express aberrant cell surface antigens as well as clonal T-cell receptor gene rearrangements. Detection of these features may be of diagnostic assistance in difficult cases. Topical therapy with steroids or UV light is often used for early lesions of CTCL, whereas more aggressive systemic chemotherapy is indicated for advanced disease.

Morphology. The histologic hallmark of CTCL of the mycosis fungoides type is the presence of the **Sézary-Lutzner cells**. These are T-helper cells (CD4+) that characteristically form band-like aggregates within the superficial dermis (Fig. 25-19B) and invade the epidermis as single cells and small clusters **(Pautrier microabscesses)**. These cells have markedly infolded nuclear membranes, imparting a hyperconvoluted or cerebriform contour. Although patches and plaques show pronounced

epidermal infiltration by Sézary-Lutzner cells (epidermotropism), in more advanced nodular lesions the malignant T cells often lose this epidermotropic tendency, grow deeply into the dermis, and eventually spread systemically.

MASTOCYTOSIS

The term *mastocytosis* refers to a spectrum of rare disorders characterized by increased numbers of mast cells in the skin and, in some instances, in other organs. A localized cutaneous form of the disease that affects predominantly children and accounts for more than 50% of all cases is termed *urticaria pigmentosa*. These lesions are multiple, although solitary mastocytomas may also occur, usually shortly after birth. About 10% of individuals with mast cell disease have systemic disease, with mast cell infiltration of many organs. These individuals are often adults, and unlike localized cutaneous disease, the prognosis may be poor.

The pathologic findings in mastocytosis are highly variable. In urticaria pigmentosa, lesions are multiple and widely distributed, consisting of round to oval, red-brown, nonscaling papules and small plaques. Solitary mastocytomas present as one or several pink to tan-brown nodules that may be pruritic or show blister formation (Fig. 25-20A). In systemic mastocytosis skin lesions similar to those of urticaria pigmentosa are accompanied by mast cell infiltration of bone marrow, liver, spleen, and lymph nodes. Many of the signs and symptoms of mastocytosis are due to the effects of histamine, heparin, and other substances released as a result of mast cell degranulation. *Darier sign* refers to a localized area of dermal edema and erythema (wheal) that occurs when lesion skin is rubbed. *Dermatographism* refers to an area of dermal edema resembling a hive that occurs in normal skin as a result of localized stroking with a pointed instrument. In systemic disease, all of the following may be seen: pruritus and flushing triggered by certain foods, temperature changes, alcohol, and certain drugs (morphine, codeine, aspirin); watery nasal discharge (rhinorrhea); rarely, gastrointestinal or nasal bleeding, possibly due to the anticoagulant effects of heparin; and bone pain as a result of osteoblastic and osteoclastic involvement.

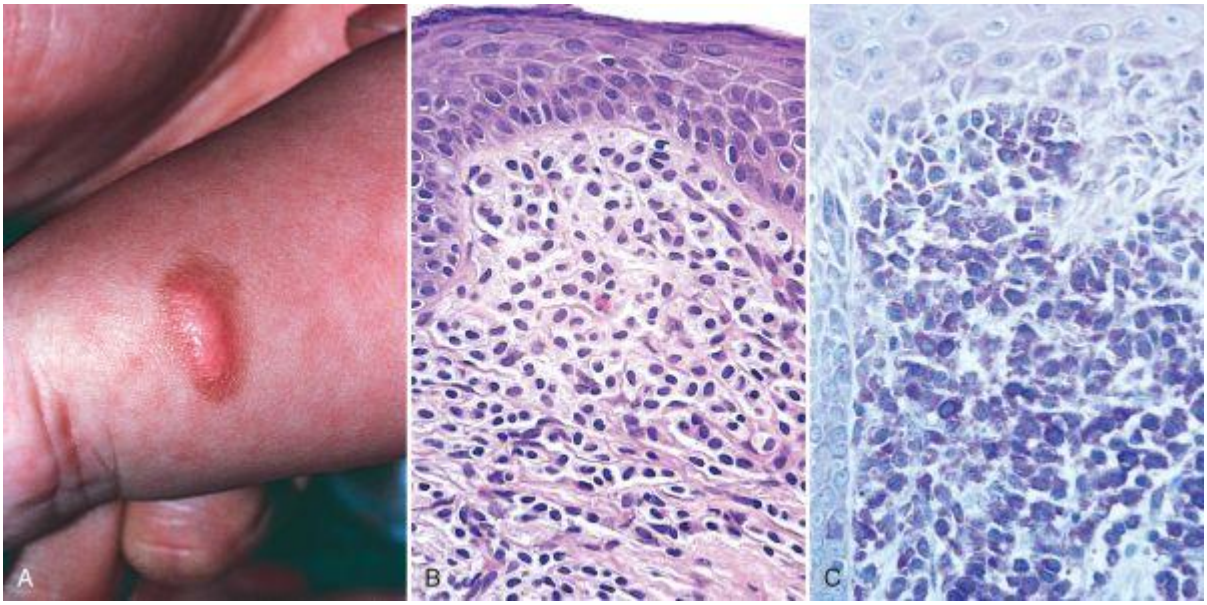

FIGURE 25-20 Mastocytosis. **A**, Solitary mastocytoma in a 1-year-old child. **B**, By routine histology, numerous ovoid cells with uniform, centrally located nuclei are observed in the dermis. **C**, Giemsa staining reveals purple, "metachromatic" granules within the cytoplasm of the cells.

Morphology. The histologic picture in urticaria pigmentosa or solitary mastocytoma varies from a subtle increase in the numbers of spindle-shaped and stellate mast cells around superficial dermal blood vessels, to large numbers of tightly packed, round to oval mast cells in the upper to mid-dermis (Fig. 25-20B). Variable fibrosis, edema, and small numbers of eosinophils may also be present. Mast cells may be difficult to differentiate from lymphocytes in routine, hematoxylin and eosin–stained sections, and special metachromatic stains (toluidine blue or Giemsa) must be used to visualize their granules (Fig. 25-20C). Even with these stains, extensive degranulation may result in failure to recognize these cells by light microscopy, but their identity can be readily confirmed with immunohistochemical stains for mast cell markers, such as mast cell tryptase.

Pathogenesis.

The pathogenesis of many cases of mastocytosis involves acquired activating point mutations in the c-KIT receptor tyrosine kinase. The resulting increase in c-KIT signaling drives mast cell growth and survival.[74,][75] Recognition of this etiology has led to attempts to treat this disorder with c-KIT inhibitors.

3.15.7 Disorders of Epidermal Maturation

ICHTHYOSIS

Of the numerous disorders that impair epidermal maturation, ichthyosis is perhaps one of the most striking. The term is derived from the Greek root *ichthy-*, meaning "fishy," and accordingly, this group of genetically inherited disorders is associated with chronic, excessive keratin buildup (hyperkeratosis) that results clinically in fish-like scales (Fig. 25-21A). Most ichthyoses become apparent either at or around the time of birth. Acquired (noninherited) variants also exist; in the acquired *ichthyosis vulgaris* in adults, there can be an association with lymphoid and visceral malignancies. The clinical types of ichthyosis vary according to the mode of inheritance, histology, and clinical features; the primary categories include *ichthyosis vulgaris* (autosomal dominant or acquired), *congenital ichthyosiform erythroderma* (autosomal recessive), *lamellar ichthyosis* (autosomal recessive), and *X-linked ichthyosis*.[76]

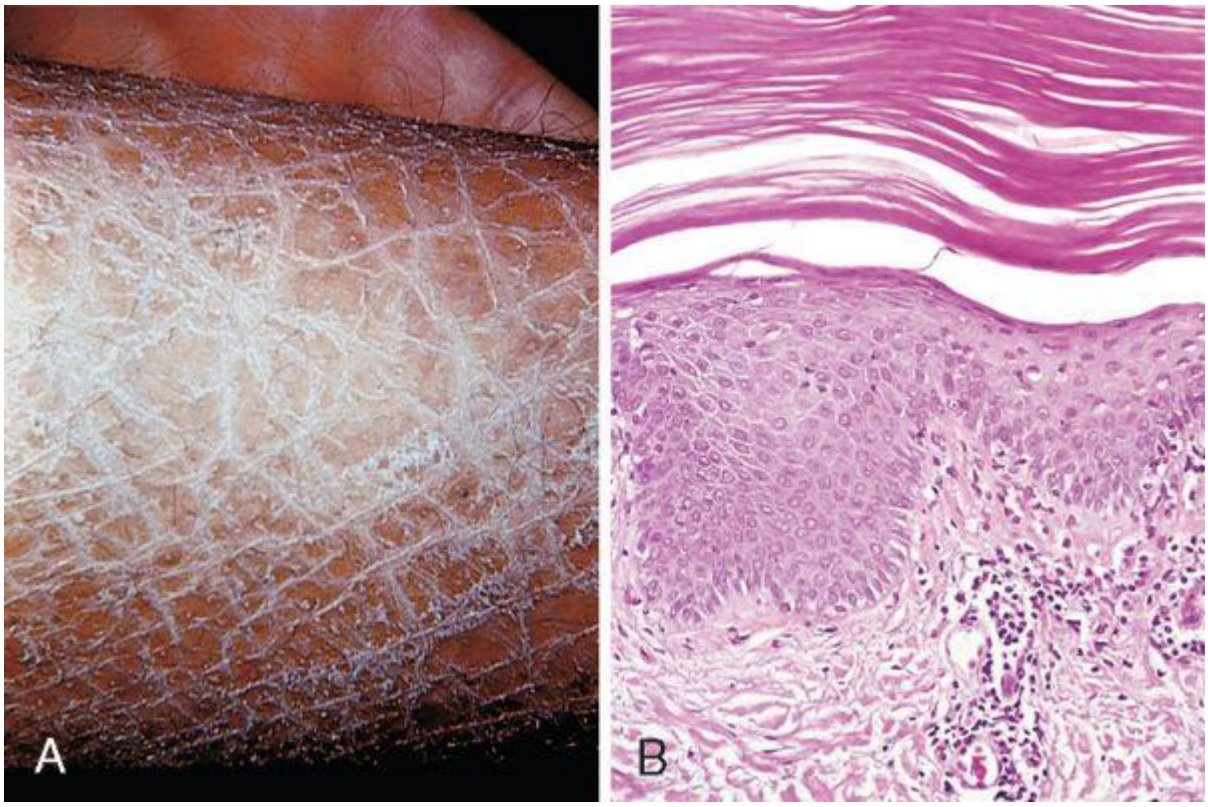

FIGURE 25-21 Ichthyosis. Note prominent fishlike scales (**A**) and compacted, thickened stratum corneum (**B**).

Morphology. All forms of ichthyosis exhibit a buildup of compacted stratum corneum that is associated with loss of the normal basket-weave pattern (Fig. 25-21B). There is generally little or no inflammation. Variations in the thickness of the epidermis and the stratum granulosum and the gross appearance and distribution of lesions are used to subclassify these disorders.

Pathogenesis.

The primary abnormality in some forms of ichthyosis is defective desquamation, leading to retention of abnormally formed scale. For example, in X-linked ichthyosis, affected individuals have a deficiency of steroid sulfatase, an enzyme important for the removal of proadhesive cholesterol sulfate secreted into the intercellular spaces. Accumulation of cholesterol sulfate results in persistent cell-to-cell adhesion within the stratum corneum, hindering the desquamation process.

3.15.8 Acute Inflammatory Dermatoses

Literally thousands of inflammatory dermatoses have been described. In general, acute lesions last from days to weeks and are characterized by inflammatory infiltrates (usually composed of lymphocytes and macrophages rather than neutrophils), edema, and variable degrees of epidermal, vascular, or subcutaneous injury. Chronic lesions, on the other hand, persist for months to years and are often associated with changes in epidermal growth (atrophy or hyperplasia) or dermal fibrosis. The lesions discussed here are selected as examples of the more commonly encountered acute dermatoses.

URTICARIA

Urticaria (hives) is a common disorder of the skin characterized by localized mast cell degranulation and resultant dermal microvascular hyperpermeability. This gives rise to pruritic edematous plaques called *wheals*. Angioedema is closely related to urticaria and is characterized by deeper edema of both the dermis and the subcutaneous fat.

Urticaria most often occurs between ages 20 and 40, although all age groups are susceptible. Individual lesions develop and fade within hours (usually <24 hours), and episodes may last for days or persist for months. Lesions vary from small, pruritic papules to large edematous plaques (Fig. 25-22A). Individual lesions may coalesce to form annular, linear, or arciform configurations. Sites of predilection for urticarial eruptions include any area exposed to pressure, such as the trunk, distal extremities, and ears. Persistent episodes of urticaria may herald an underlying disease (e.g., collagen vascular disorders, Hodgkin lymphoma), but in the majority of cases no underlying cause can be identified.

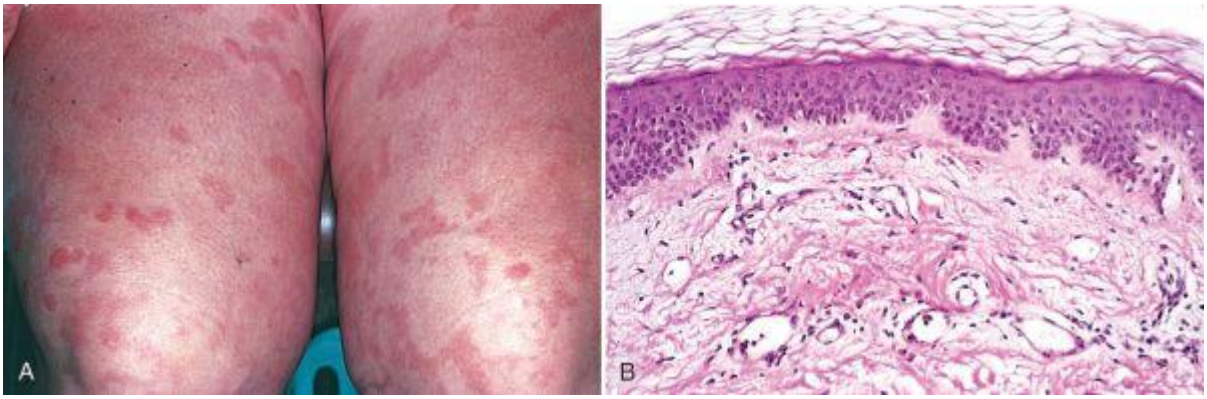

FIGURE 25-22 Urticaria. **A**, Erythematous, edematous, often circular plaques are characteristic. **B**, Histologically, there is superficial dermal edema, manifested by spaces between collagen bundles, and dilated lymphatic and blood-filled vascular spaces; the epithelium is normal.

Morphology. The histologic features of urticaria may be very subtle. There is usually a sparse superficial perivenular infiltrate consisting of mononuclear cells and rare neutrophils. Eosinophils may also be present. Collagen bundles are more widely spaced than in normal skin, a result of superficial dermal edema (Fig. 25-22B). Superficial lymphatic channels are dilated due to increased absorption of edema fluid. Epidermal changes are typically absent.

Pathogenesis.

In most cases, urticaria results from antigen-induced release of vasoactive mediators from mast cell granules through sensitization with specific IgE antibodies. This *IgE-dependent* reaction can follow exposure to many different antigens (pollens, foods, drugs, insect venom) (Chapter 6). *IgE-independent* urticaria may also result from substances that in certain individuals directly incite the degranulation of mast cells, such as opiates, certain antibiotics, curare, and radiographic contrast media. Another cause of IgE-independent urticaria is exposure to chemicals, such as aspirin, that suppress prostaglandin synthesis from arachidonic acid. *Complement-mediated urticaria* is seen in *hereditary angioneurotic edema* (Chapter 6), caused by an inherited deficiency of C1 inhibitor that results in uncontrolled activation of the early components of the complement system and production of vasoactive mediators.[77]

ACUTE ECZEMATOUS DERMATITIS

The Greek word *eczema*, meaning “to boil over,” vividly describes the appearance of acute eczematous dermatitis. All forms of eczema are characterized by red, papulovesicular, oozing, and crusted lesions that, if persistent, develop into raised, scaling plaques due to reactive acanthosis and hyperkeratosis (Fig. 25-23). Based on initiating factors, eczematous dermatitis can be subdivided into the following categories: (1) allergic contact dermatitis, (2) atopic dermatitis, (3) drug-related eczematous dermatitis, (4) photoeczematous dermatitis, and (5) primary irritant dermatitis.

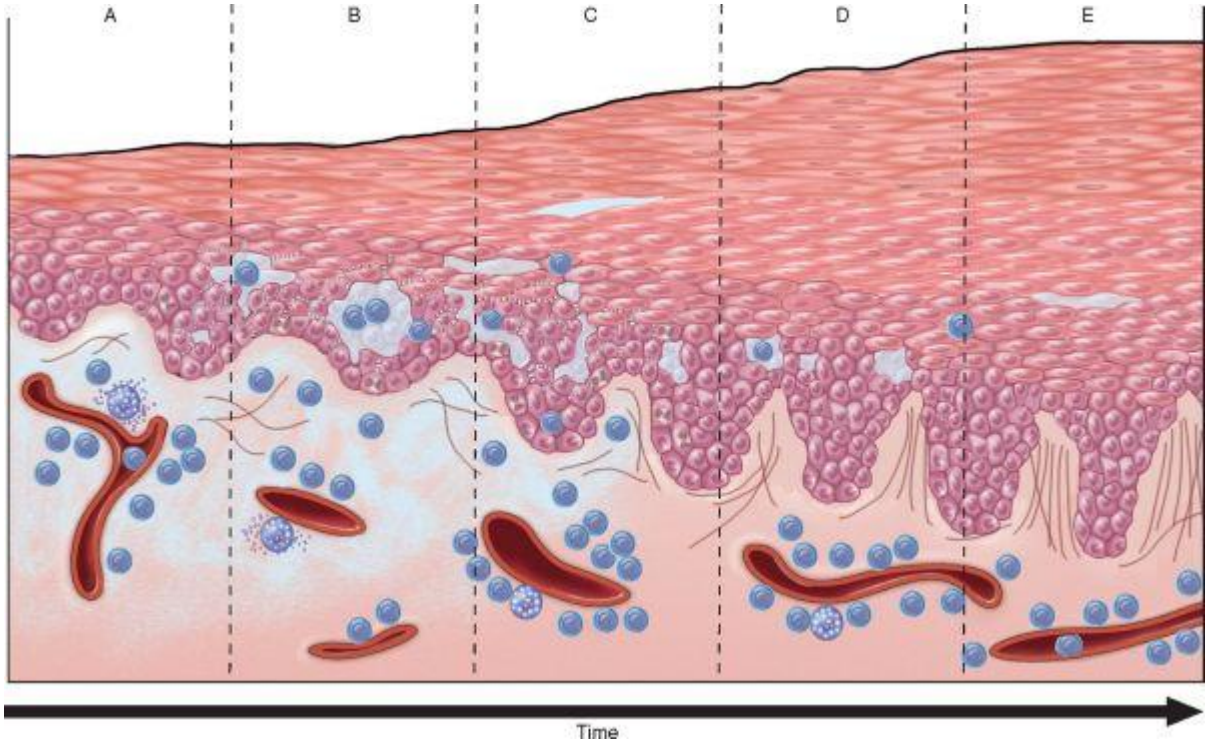

FIGURE 25-23 Stages of eczema development. **A**, Initial dermal edema and perivascular infiltration by inflammatory cells is followed within 24 to 48 hours by epidermal spongiosis and microvesicle formation (**B**). **C**, Abnormal scale, including parakeratosis, follows, along with progressive acanthosis (**D**) and hyperkeratosis (**E**) as the lesion becomes chronic.

A striking example of eczema is an acute contact reaction to topical antigens such as poison ivy/oak *(Rhus toxicodendron)*, characterized by pruritic, edematous, oozing plaques, often containing small and large blisters (vesicles and bullae) (Fig. 25-24A). Such lesions are prone to bacterial superinfection, which produces a yellow crust (impetiginization). With time, persistent lesions become less “wet” (fail to ooze or form vesicles) and become progressively scaly (hyperkeratotic) as the epidermis thickens (acanthosis). The clinical causes of eczema are sometimes broadly divided into “inside” and “outside” types: disease resulting from external application of antigen (such as poison ivy) or reaction to an internal circulating antigen (such as ingested food or drug).

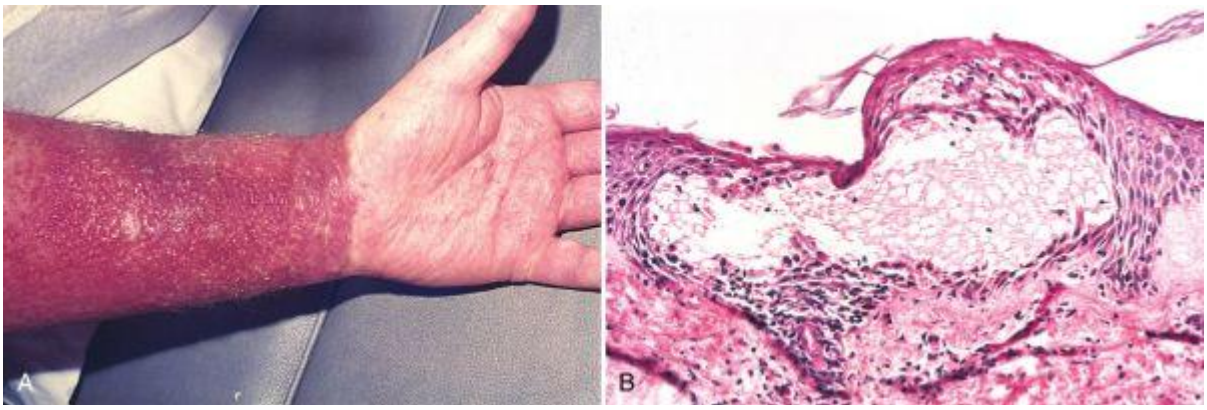

FIGURE 25-24 Eczematous dermatitis. **A**, Acute allergic contact dermatitis, with numerous vesicles on erythematous skin due to antigen exposure (in this case, laundry detergent in clothing). **B**, Histologically, intercellular edema within the epidermis creates small, fluid-filled intraepidermal vesicles.

Treatment of eczema involves a search for offending substances that can be removed from the environment. Topical steroids can also be used that nonspecifically block the inflammatory response. Such treatments are palliative and not curative, but are helpful in interrupting acute exacerbations of eczema that can become self perpetuating if unchecked.

Morphology. Spongiosis characterizes acute eczematous dermatitis, hence the histologic synonym spongiotic dermatitis. Unlike urticaria, in which edema is restricted to the superficial dermis, edema seeps into the intercellular spaces of the epidermis, splaying apart keratinocytes, particularly in the stratum spinosum. Mechanical shearing of intercellular attachment sites (desmosomes) and cell membranes by progressive accumulation of intercellular fluid may result in the formation of intraepidermal vesicles (Fig. 25-24B).

During the earliest stages of eczematous dermatitis, there is a superficial, perivascular, lymphocytic infiltrate associated with papillary dermal edema and mast cell degranulation. The pattern and composition of this infiltrate may provide clues to the underlying cause. For example, eczema resulting from certain ingested drugs is marked by a lymphocytic infiltrate, often containing eosinophils, around deep as well as superficial dermal vessels. By contrast, eczematous dermatitis resulting from contact antigens tends to produce an inflammatory reaction that preferentially affects the superficial dermal layer.

Pathogenesis.

This has been well studied in dermatitis triggered by contact antigens (e.g., poison ivy). Initially, antigens at the epidermal surface are taken up by dendritic Langerhans cells, which then migrate by way of dermal lymphatics to draining lymph nodes. Here, antigens, now processed by the Langerhans cell, are presented to naive CD4+ T cells, which are activated and develop into effector and memory cells (Chapter 6). On antigen re-exposure, these memory T cells migrate to affected skin sites of antigen localization, where they adhere to post-capillary venules, extravasate into tissues, and release cytokines and chemokines that recruit the numerous inflammatory cells characteristic of eczema. This process occurs within 24 hours and accounts for the initial erythema and pruritus that characterize cutaneous delayed hypersensitivity in the acute, spongiotic phase.[2]

Langerhans cells within the epidermis play a central role in contact dermatitis, and understandably factors that affect Langerhans cell function impact the inflammatory reaction. Chronic exposure to UV light is injurious to epidermal Langerhans cells and can prevent sensitization to contact antigens.[78] Other factors that modulate Langerhans cell function include neuropeptides released from nerve endings that terminate near the Langerhans cell body.[79]

ERYTHEMA MULTIFORME

Erythema multiforme is an uncommon, self-limited disorder that seems to be a hypersensitivity reaction to certain infections and drugs. This disorder affects individuals of any age and is associated with the following conditions: (1) infections such as herpes simplex, mycoplasmal infections, histoplasmosis, coccidioidomycosis, typhoid, and leprosy, among others; (2) administration of certain drugs (sulfonamides, penicillin, barbiturates, salicylates, hydantoins, and antimalarials); (3) malignant disease (carcinomas and lymphomas); and (4) collagen vascular diseases (lupus erythematosus, dermatomyositis, and polyarteritis nodosa).[80]

Affected individuals present with an array of "multiform" lesions, including macules, papules, vesicles, and bullae as well as the characteristic target lesion consisting of a red macule or papule with a pale, vesicular, or eroded center (Fig. 25-25A). Although lesions may be widely distributed, symmetric involvement of the extremities frequently occurs. An extensive and symptomatic febrile form of the disease, which is often but not exclusively seen in children, is called *Stevens-Johnson syndrome*. Typically, erosions and hemorrhagic crusts involve the lips and oral mucosa, although the conjunctiva, urethra, and genital and perianal areas may also be affected. Secondary infection of involved areas due to loss of skin integrity may result in life-threatening sepsis. Another variant, termed *toxic epidermal necrolysis*, results in diffuse necrosis and sloughing of cutaneous and mucosal epithelial surfaces, producing a clinical situation analogous to an extensive burn when both infection and fluid loss are clinical concerns.[81]

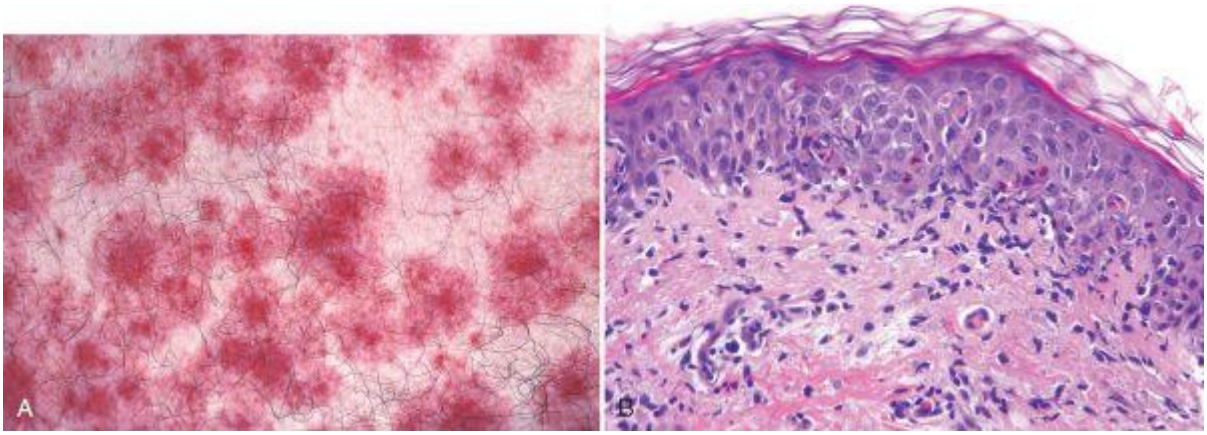

FIGURE 25-25 Erythema multiforme. **A**, The target-like clinical lesions consist of a central blister or zone of epidermal necrosis surrounded by macular erythema. **B**, Early lesions show lymphocytes collecting along the dermoepidermal junction where basal keratinocytes have begun to become vacuolated. With time, necrotic/apoptotic keratinocytes accumulate in the overlying epithelium.

Morphology. On histologic examination, early lesions show a superficial perivascular, lymphocytic infiltrate associated with dermal edema and accumulation of lymphocytes along the dermoepidermal junction, where they are intimately associated with degenerating and necrotic keratinocytes, a pattern

termed *interface dermatitis* (Fig. 25-25B). With time there is upward migration of lymphocytes into the epidermis. Discrete and confluent zones of epidermal necrosis occur with concomitant blister formation. Epidermal sloughing leads to shallow erosions. The clinical **targetoid (target-like) lesion** shows central necrosis surrounded by a rim of perivenular inflammation (see Fig. 25-25A).

Pathogenesis.

Erythema multiforme has similarities to other conditions characterized by immunologically mediated epidermal cell injury such as acute graft-versus-host disease, skin allograft rejection, and fixed drug eruptions.[82] In all these conditions epithelial cells are killed by skin-homing (CLA+) CD8+ cytotoxic T lymphocytes (CTLs). In erythema multiforme these cytotoxic cells are more prominent in the central portion of the lesions while CD4+ helper and Langerhans cells are more common in the raised, erythematous periphery. The precise target antigens within the epidermis that are recognized by CTLs in erythema multiforme remain unknown, but there is growing evidence that the basal cells that reside at the very tips of epidermal rete ridges may preferentially undergo apoptosis.[83]

3.15.9 Chronic Inflammatory Dermatoses

This category includes inflammatory skin disorders that persist for many months to years. The skin surface in some chronic inflammatory dermatoses is roughened as a result of excessive or abnormal scale formation and shedding. However, not all scaling lesions are inflammatory; witness the hereditary ichthyoses, described above, with extensive scale due to defects in desquamation.

PSORIASIS

Psoriasis is a common chronic inflammatory dermatosis affecting as many as 1% to 2% of people in the United States. Persons of all ages may develop the disease. Psoriasis is sometimes associated with arthritis, myopathy, enteropathy, spondylitic joint disease, or the acquired immunodeficiency syndrome. Psoriatic arthritis may be mild or may produce severe deformities resembling the joint changes seen in rheumatoid arthritis.

Psoriasis most frequently affects the *skin of the elbows, knees, scalp, lumbosacral areas, intergluteal cleft, and glans penis*. The typical lesion is a well-demarcated, pink to *salmon-colored plaque* covered by loosely adherent scale that is characteristically *silver-white in color* (Fig. 25-26A). Variations exist, with some lesions occurring in annular, linear, gyrate, or serpiginous configurations. Psoriasis is one cause of total body erythema and scaling known as *erythroderma. Nail changes* occur in 30% of cases of psoriasis and consist of yellow-brown discoloration (often likened to an oil slick), with pitting, dimpling, separation of the nail plate from the underlying bed (onycholysis), thickening, and crumbling. In the rare variant called *pustular psoriasis* multiple small pustules form on erythematous plaques. This type of psoriasis is either benign and localized (hands and feet) or generalized and life-threatening, with associated fever, leukocytosis, arthralgia, diffuse cutaneous and mucosal pustules, secondary infection, and electrolyte disturbances.[84]

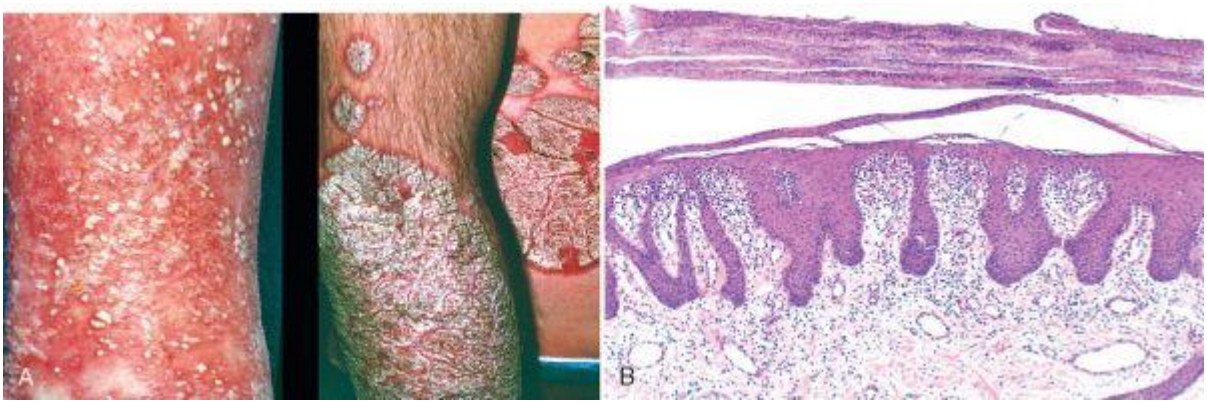

FIGURE 25-26 Clinical evolution of psoriasis. **A**, Early and eruptive lesions may be dominated by signs of inflammation, including small pustules and erythema *(left)*. Established, chronic lesions demonstrate erythema surmounted by characteristic silver-white scale *(right)*. **B**, Histologically, established lesions demonstrate marked epidermal hyperplasia, parakeratotic scale, and neutrophils within the superficial epidermal layers.

Morphology. Established lesions of psoriasis have a characteristic histologic picture. Increased epidermal cell turnover results in marked epidermal thickening (acanthosis), with regular downward elongation of the rete ridges sometimes described as appearing like test tubes in a rack (Fig. 25-26B). Mitotic figures are easily identified well above the basal cell layer, where mitotic activity is confined in normal skin. **The stratum granulosum is thinned or absent, and extensive overlying parakeratotic scale is seen**. Typical of psoriatic plaques is thinning of the portion of the epidermal cell layer that overlies the tips of dermal papillae (suprapapillary plates) and dilated, tortuous blood vessels within these papillae. This constellation of changes results in abnormal proximity of vessels within the dermal papillae to the overlying parakeratotic scale, and accounts for the characteristic clinical phenomenon of multiple, minute, bleeding points when the scale is lifted from the plaque **(Auspitz sign)**. Neutrophils form small aggregates within slightly spongiotic foci of the superficial epidermis **(spongiform pustules)** and within the parakeratotic stratum corneum **(Munro microabscesses)**. In pustular psoriasis, larger abscess-like accumulations of neutrophils are present directly beneath the stratum corneum.

Pathogenesis.

The pathogenesis of psoriasis seems to be multifactorial, with contributions from genetic and environmental factors. There is a strong association between psoriasis and HLA-C, particularly with the *HLA-Cw*0602* allele. About two thirds of affected individuals carry this allele; homozygotes for *HLA-Cw*0602* have a 2.5-fold higher risk of developing psoriasis than heterozygotes. Nevertheless, only 10% of individuals with *HLA-Cw*0602* develop psoriasis, indicating that other factors interact with this MHC molecule in causing disease susceptibility.[85] Sensitized populations of CD4+ T_H1 and T_H17 cells and activated CD8+ effector T cells enter the skin and accumulate in the epidermis. The culprit antigens remain elusive. T cell homing to the skin may create an abnormal microenvironment by inducing the secretion of cytokines and growth factors that induce keratinocyte proliferation, resulting in the characteristic lesions. The interactions between CD4+ T cells, CD8+ T cells, dendritic cells, and keratinocytes give rise to a cytokine "soup" dominated by T_H1-type and T_H17-type cytokines such as IL-12, interferon-γ, tumor necrosis factor (TNF), and IL-17.[2] The lymphocytes also produce growth factors for keratinocytes. Psoriatic lesions can be induced in susceptible individuals by local trauma, a process known as the *Koebner phenomenon*. The trauma may induce a local inflammatory response that

promotes lesion development. There is much evidence that, as with rheumatoid arthritis, TNF is a major mediator in the pathogenesis of psoriasis. Indeed, anti-TNF therapies provide benefit and are currently in use.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a chronic inflammatory dermatosis even more common than psoriasis, affecting 1% to 3% of the general population.[84] It classically involves regions with a high density of sebaceous glands, such as the scalp, forehead (especially the glabella), external auditory canal, retroauricular area, nasolabial folds, and the presternal area. However, it is important to note that seborrheic dermatitis is not a disease of the sebaceous glands. The individual lesions are macules and papules on an erythematous-yellow, often greasy base, typically in association with extensive scaling and crusting. Fissures may also be present, particularly behind the ears. Dandruff is the common clinical expression of seborrheic dermatitis of the scalp. In infants, seborrheic dermatitis presents as cradle cap but can also be part of a disorder known as *Leiner disease*, in which the condition is generalized and associated with diarrhea and failure to thrive. A severe form of seborrheic dermatitis that is difficult to treat is seen in many HIV–infected individuals with low CD4 counts.[86]

Morphology. Lesions of seborrheic dermatitis share histologic features with both spongiotic dermatitis and psoriasis, with earlier lesions being more spongiotic and later ones more acanthotic. Typically, mounds of parakeratosis containing neutrophils and serum are present at the ostia of hair follicles (so-called *follicular lipping*). A superficial perivascular inflammatory infiltrate generally consists of an admixture of lymphocytes and neutrophils. With human immunodeficiency virus infection, apoptotic keratinocytes and plasma cells may also be present.

Pathogenesis.

The etiology of seborrheic dermatitis is unknown. However, therapeutic studies with ketoconazole, an antifungal agent, suggest that the lipophilic yeast *Malassezia furfur*, which is associated with tinea versicolor, may have a role in some cases.[87] Involvement of sebum is supported by clinical observations of people with Parkinson disease, who typically show increased sebum production secondary to dopamine deficiency and have a markedly increased incidence of seborrheic dermatitis.[88] Indeed, once treated with levodopa, the oiliness of the skin decreases and the seborrheic dermatitis improves. However, because other conditions associated with increased sebaceous activity such as acne (discussed below) do not show this association, sebum production is unlikely to be the sole or primary factor in the pathogenesis of seborrheic dermatitis.

LICHEN PLANUS

“Pruritic, purple, polygonal, planar papules, and plaques” are the tongue-twisting “six p's” of this disorder of skin and mucosa. Lichen planus is usually self-limited and most commonly resolves spontaneously 1 to 2 years after onset, often leaving zones of postinflammatory hyperpigmentation. Oral lesions may persist for years. Squamous cell carcinoma has been noted to occur in chronic mucosal and paramucosal lesions of lichen planus, but a direct pathogenetic relationship has not been established.[89,][90]

Cutaneous lesions consist of itchy, violaceous, flat-topped papules that may coalesce focally to form plaques (Fig. 25-27A). These papules are often highlighted by white dots or lines called *Wickham striae*, which are created by areas of hypergranulosis. In darkly pigmented individuals, lesions may acquire a dark-brown color due to release of melanin into the dermis as the basal cell layer is destroyed. Multiple lesions are characteristic and are symmetrically distributed, particularly on the extremities,

often about the wrists and elbows, and on the glans penis. In 70% of cases, oral lesions are present as white, reticulated, or netlike areas involving the mucosa. As in psoriasis, the Koebner phenomenon may be seen in lichen planus.[91]

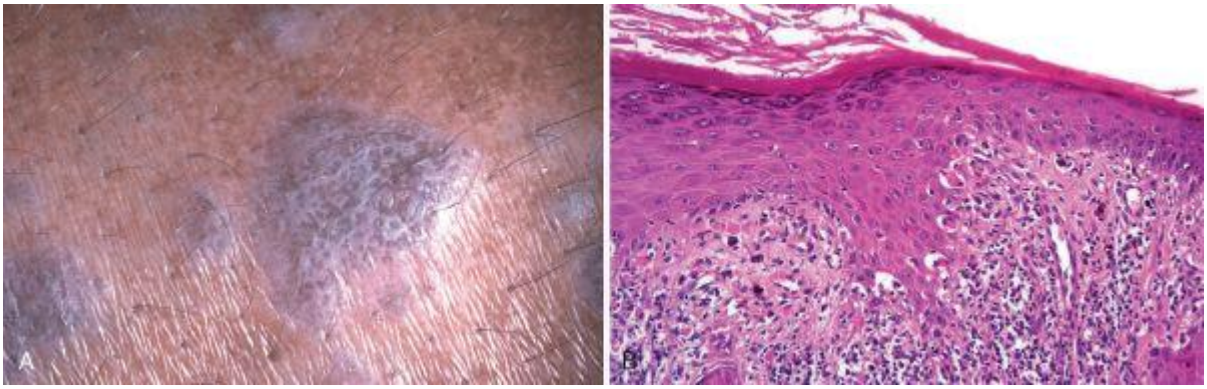

FIGURE 25-27 Lichen planus. **A**, This flat-topped pink-purple, polygonal papule has a white lacelike pattern that is referred to as Wickham stria. **B**, Biopsy specimen demonstrating a bandlike infiltrate of lymphocytes at the dermoepidermal junction, hyperkeratosis, hypergranulosis and pointed rete ridges (sawtoothing) as a result of chronic basal cell layer injury.

Morphology. Lichen planus is characterized histologically by a dense, continuous infiltrate of lymphocytes along the dermoepidermal junction, a prototypic example of *interface dermatitis* (Fig. 25-27B). The lymphocytes are intimately associated with basal keratinocytes, which show degeneration, necrosis, and a resemblance in size and contour to more mature cells of the stratum spinosum (squamatization). A consequence of this destructive infiltration of lymphocytes is a redefinition of the normal, smoothly undulating configuration of the dermoepidermal interface to a more angulated zigzag contour (sawtoothing). Anucleate, necrotic basal cells may become incorporated into the inflamed papillary dermis, where they are referred to as **colloid** or **Civatte bodies**. Though characteristic of lichen planus, these bodies may be detected in any chronic dermatitis in which basal keratinocytes are injured and destroyed. Although the lesions bear some similarities to those in erythema multiforme, lichen planus shows changes of chronicity, namely, epidermal hyperplasia (or rarely atrophy) and thickening of the granular cell layer and stratum corneum (hypergranulosis and hyperkeratosis, respectively). Lichen planus preferentially affecting the epithelium of hair follicles is referred to as **lichen planopilaris**.

Pathogenesis.

The pathogenesis of lichen planus is not known. It is plausible that expression of altered antigens at the level of the basal cell layer and the dermoepidermal junction elicit a cell-mediated cytotoxic (CD8+/CLA+ T cell) immune response. In support of this notion, T lymphocyte infiltrates and hyperplasia of Langerhans cells are characteristic features of this disorder.[92]

3.15.10 Blistering (Bullous) Diseases

Although vesicles and bullae (blisters) occur in several unrelated conditions such as herpesvirus infection, spongiotic dermatitis, erythema multiforme, and thermal burns, there exists a group of disorders in which blisters are the primary and most distinctive features. These *bullous diseases*, as they are called, produce dramatic lesions and in some instances are fatal if untreated. Blisters in the various disorders occur at different levels within the skin (Fig. 25-28); histologic assessment is essential for

accurate diagnosis and provides insight into the pathogenic mechanisms. Knowledge of the molecular structure of the intercellular and cell-to-matrix attachments that provide the skin with mechamical stability is helpful in understanding these diseases (Fig. 25-29).

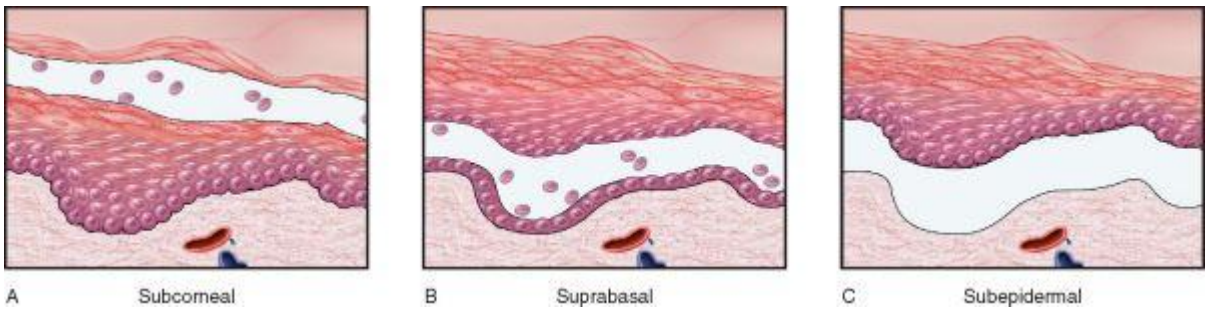

FIGURE 25-28 Schematic representation of histologic levels of blister formation. **A**, In a subcorneal blister the stratum corneum forms the roof of the bulla (as in pemphigus foliaceus). **B**, In a suprabasal blister a portion of the epidermis, including the stratum corneum, forms the roof (as in pemphigus vulgaris). **C**, In a subepidermal blister the entire epidermis separates from the dermis (as in bullous pemphigoid).

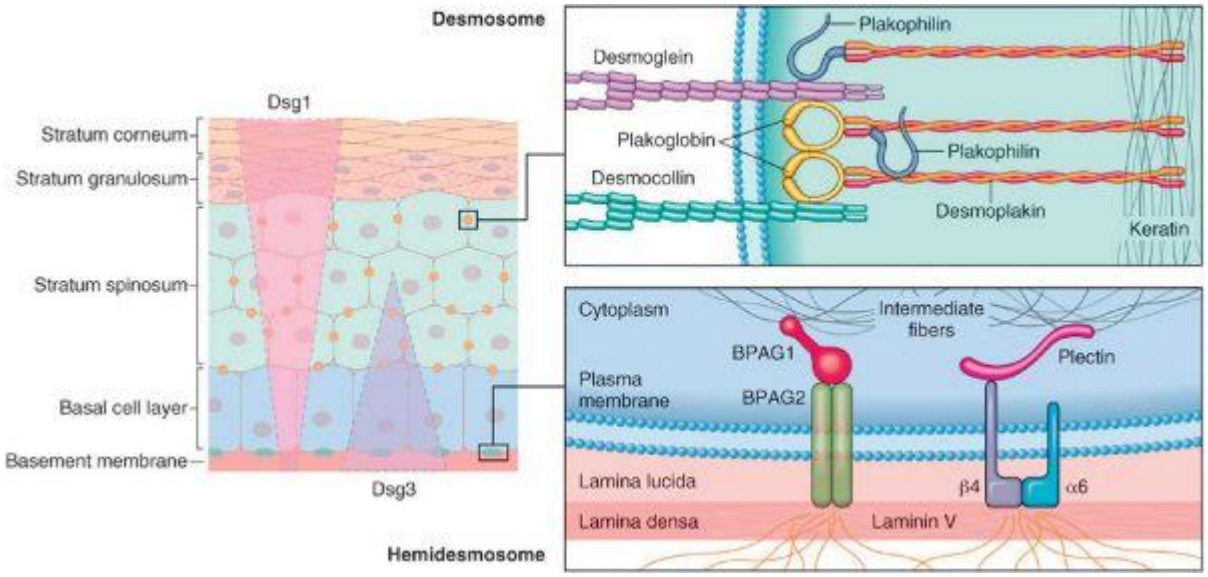

FIGURE 25-29 Squamous cell adhesion molecules. Knowledge of the proteins composing desmosomes and hemodesmosomes is key to understanding blistering disorders. Desmogleins 1 and 3 (Dsg1, Dsg3) are functionally interchangeable components of desmosomes, but have different distributions within the epidermis *(left panel)*. In pemphigus vulgaris, autoantibodies against Dsg1 and Dsg3 cause blisters in the deep suprabasal epidermis, whereas in pemphigus foliaceus, the autoantibodies are against Dsg1 alone, leading to superficial, subcorneal blisters. In bullous phemphigoid, autoantibodies bind BPAG2, a component of the hemidesomes, leading to blister formation at the level of the lamina lucida of the basement membrane. Dermatitis herpetiformis is caused by IgA autoantibodies to the fibrils that anchor hemidesmosomes to the dermis. The various forms of epidermolysis bullosa are caused by genetic defects in genes encoding proteins that either form or stabilize desmosomes or hemidesmosomes. α6/β4, α6/β4 integrin.

INFLAMMATORY BLISTERING DISORDERS

Pemphigus

Pemphigus is a blistering disorder caused by *autoantibodies that result in the dissolution of intercellular attachments within the epidermis and mucosal epithelium*. Though rare, without treatment it may be life-threatening, and its pathobiology provides important insight into the molecular mechanisms of

keratinocyte adhesion. The majority of individuals who develop pemphigus are in the fourth to sixth decades of life, and men and women are affected equally. There are multiple variants: (1) pemphigus vulgaris, (2) pemphigus vegetans, (3) pemphigus foliaceus, (4) pemphigus erythematosus, and (5) paraneoplastic pemphigus.[93]

Pemphigus vulgaris, by far the most common type (accounting for more than 80% of cases worldwide), involves the mucosa and skin, especially on the scalp, face, axilla, groin, trunk, and points of pressure. It may present as oral ulcers that may persist for months before skin involvement appears. Primary lesions are superficial vesicles and bullae that rupture easily, leaving shallow erosions covered with dried serum and crust (Fig. 25-30A). *Pemphigus vegetans* is a rare form that usually presents not with blisters but with large, moist, verrucous (wart-like), vegetating plaques studded with pustules on the groin, axillae, and flexural surfaces. *Pemphigus foliaceus* is a more benign form that is endemic in Brazil (where it is called *fogo selvagem*) and occurs sporadically in other geographic regions. Sites of predilection are the scalp, face, chest, and back, and the mucous membranes are only rarely affected. Bullae are so superficial that only zones of erythema and crusting, sites of previous blister rupture resulting in superficial erosions, are usually present on physical examination (Fig. 25-31A). *Pemphigus erythematosus* is considered to be a localized, less severe form of pemphigus foliaceus that may selectively involve the malar area of the face in a lupus erythematosus–like fashion. *Paraneoplastic pemphigus* occurs in association with various malignancies, most commonly non-Hodgkin lymphoma.

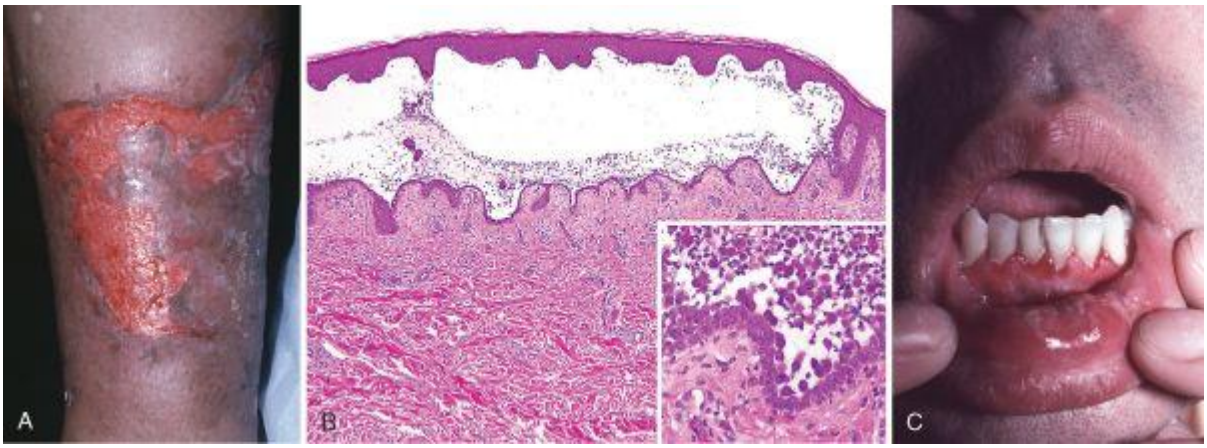

FIGURE 25-30 Pemphigus vulgaris. **A**, Eroded plaques are formed on rupture of confluent, thin-roofed bullae, here affecting axillary skin. **B**, Suprabasal acantholysis results in an intraepidermal blister in which rounded (acantholytic) epidermal cells are identified *(inset)*. **C**, Ulcerated blisters in the oral mucosa are also common as seen here on the mucosal portion of the lip.

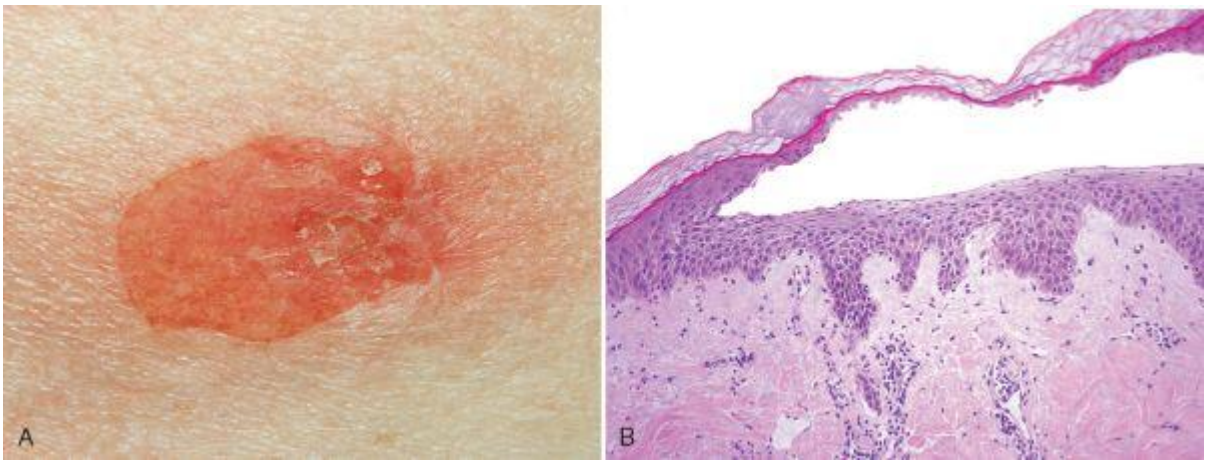

FIGURE 25-31 Pemphigus foliaceus. **A**, The delicate, superficial (subcorneal) blisters are much less erosive than seen in pemphigus vulgaris. **B**, Subcorneal separation of the epithelium is seen.

The mainstay of treatment is immunosuppressive agents, which decrease the titers of the pathogenic antibodies. In those with the most severe form of the disease, pemphigus vulgaris, this lowers but does not entirely prevent mortality.

Morphology. The common histologic denominator in all forms of pemphigus is **acantholysis**, the dissolution, or lysis, of the intercellular adhesions that connect squamous epithelial cells. Acantholytic cells dissociate from one another, lose their polyhedral shape and become rounded. In pemphigus vulgaris and pemphigus vegetans, acantholysis selectively involves the cells immediately above the basal cell layer. In the vegetans variant, there is also overlying epidermal hyperplasia. The **suprabasal acantholytic blister** that forms is characteristic of pemphigus vulgaris (see Fig. 25-30B). The single layer of intact basal cells that forms the blister base has been likened to a row of tombstones. In pemphigus foliaceus, a blister forms by similar mechanisms but, unlike the case with pemphigus vulgaris, selectively involves the superficial epidermis at the level of the stratum granulosum (Fig. 25-31B). Variable superficial dermal infiltration by lymphocytes, histiocytes, and eosinophils accompanies all forms of pemphigus.

Pathogenesis.

All forms of pemphigus are caused by IgG autoantibodies against desmogleins, and show linkage to specific HLA types.[94] By direct immunofluorescence, lesional sites show a characteristic net-like pattern of intercellular IgG deposits. IgG is usually seen at all levels of the epithelium in pemphigus vulgaris, but tends to be more superficial in pemphigus foliaceus (Fig. 25-32). The distribution of desmoglein 1 and 3 in the epidermis and the presence of autoantibodies to one or both proteins appear to explain the position and severity of the blisters (Fig. 25-29). The antibodies seem to function primarily by directly disrupting the intercellular adhesive function of the desmosomes and may activate intercellular proteases as well.[95] Paraneoplastic pemphigus most often arises in the setting of lymphoid neoplasms, and is caused by autoantibodies that may recognize desmogleins of other proteins involved in intercellular adhesion.[96]

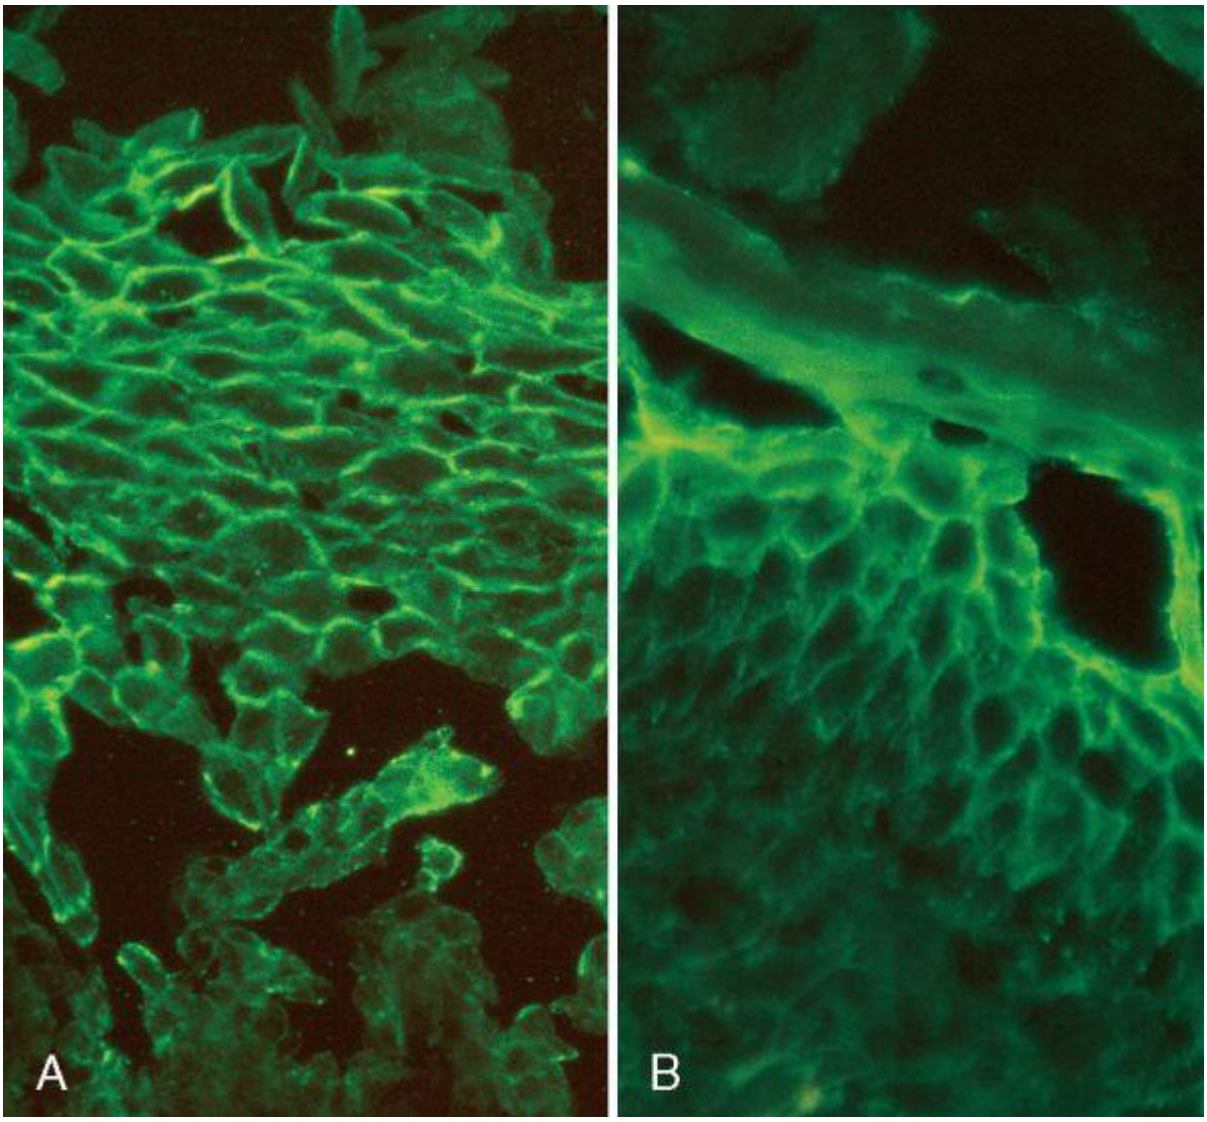

FIGURE 25-32 Direct immunofluorescence of pemphigus. **A**, In pemphigus vulgaris there is deposition of immunoglobulin along the plasma membranes of epidermal keratinocytes in a reticular or fishnet-like pattern. Also note the early suprabasal separation due to loss of cell-to-cell adhesion (acantholysis). **B**, In pemphigus foliaceus the immunoglobulin deposits are more superficial.

Bullous Pemphigoid

Generally affecting elderly individuals, bullous pemphigoid shows a wide range of clinical presentations. It may involve only the skin, either locally or generally, or the skin and mucosal surfaces. Clinically, lesions are tense bullae, filled with clear fluid, on normal or erythematous skin (Fig. 25-33A). Lesions are usually up to 2 cm in diameter but occasionally may reach 4 to 8 cm in diameter. The bullae do not rupture as easily as do the blisters seen in pemphigus and, if they are not secondarily infected, heal without scarring. Sites of involvement include the inner aspects of the thighs, flexor surfaces of the forearms, axillae, groin, and lower abdomen. Oral lesions are present in 10% to 15% of affected individuals, usually appearing after the cutaneous lesions.[97] Some patients may present with urticarial plaques, with extreme associated pruritus.

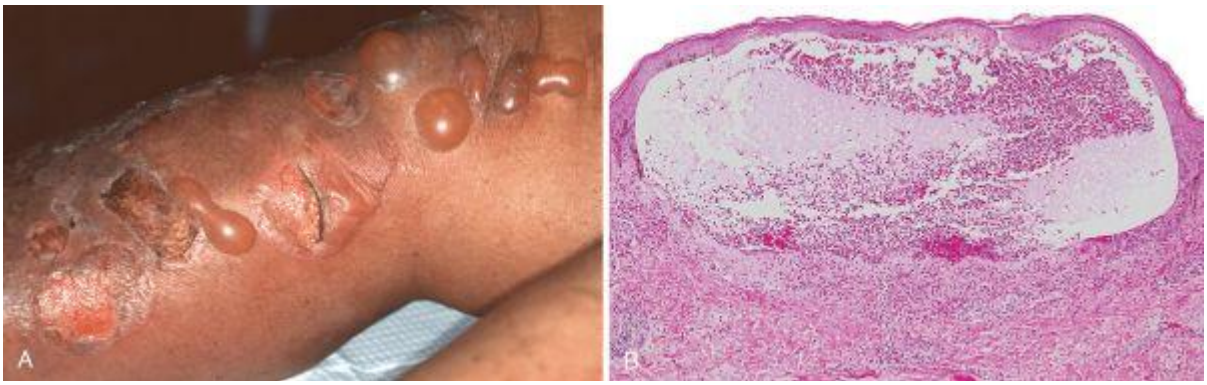

FIGURE 25-33 Bullous pemphigoid. **A**, Clinical bullae result from basal cell layer vacuolization, producing tense, intact subepidermal blisters that are difficult to rupture given the roof formed by the full thickness of the epidermis. Ulceration results upon rupture as the blisters are subepidermal. **B**, Histopathology shows an intact blister with eosinophils, as well as lymphocytes and occasional neutrophils, that may be intimately associated with basal cell layer destruction and the creation of the subepidermal cleft.

Morphology. The separation of bullous pemphigoid from pemphigus is based on the identification of **subepidermal, nonacantholytic** blisters. Early lesions show a superficial and sometimes deep perivascular infiltrate of lymphocytes and variable numbers of eosinophils, occasional neutrophils, superficial dermal edema, and associated basal cell layer vacuolization (Fig. 25-33B). Eosinophils showing degranulation are typically detected directly beneath the epidermal basal cell layer. The vacuolated basal cell layer eventually gives rise to a fluid-filled blister.

Pathogenesis.

Bullous pemphigoid features *linear* deposition of immunoglobulin and complement in the basement membrane zone (Fig. 25-34A). Reactivity also occurs in the basal cell–basement membrane attachment plaques (hemidesmosomes), where most of the bullous pemphigoid antigen (BPAG) is located. This protein is involved normally in dermoepidermal bonding. There are two forms of the antigen recognized by auto-antibodies—BPAG1, a 230-kD plakin protein, and BPAG2, a 180-kD protein also known as collagen type XVIII. Both BPAG1 and BPAG2 are recognized as normal constituents of the hemidesmosomes that bind basal cells at the dermoepidermal junction (Figs. 25-34B and 25-29). Only antibodies to BPAG2 are proven to cause blistering.[98] Generation of auto-antibodies to this hemidesmosome component results in continuous and linear deposition of IgG along the basement membrane and the fixation of complement with subsequent tissue injury by means of locally recruited neutrophils and eosinophils.

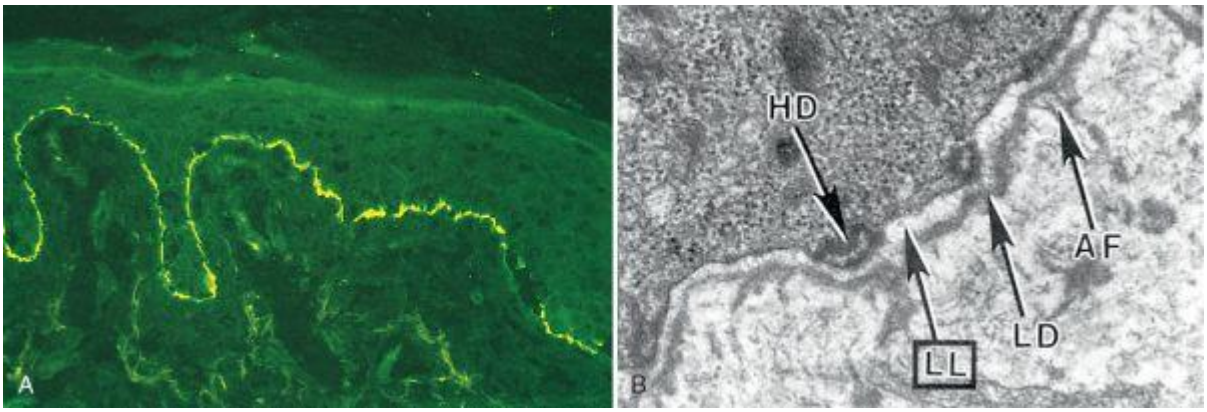

FIGURE 25-34 **A**, Linear deposition of complement along the dermoepidermal junction in bullous pemphigoid; the pattern has been likened to ribbon candy. **B**, Bullous pemphigoid antigen is located in the lowermost portion of the basal cell cytoplasm in association with hemidesmosomes (HD), with blister formation affecting the lamina lucida (LL) of the basement membrane zone. AF, anchoring fibrils; LD, lamina densa. (See also Fig. 25-31 .)

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is a rare disorder characterized by *urticaria and grouped vesicles*. The disease affects predominantly males, often in the third and fourth decades. In some cases it occurs in association with intestinal celiac disease and responds to a gluten-free diet.

Pathogenesis.

The association of dermatitis herpetiformis with celiac disease provides a clue to its pathogenesis. Genetically predisposed individuals develop lgA antibodies to dietary gluten (derived from the wheat protein gliadin). The antibodies cross-react with reticulin, a component of the anchoring fibrils that tether the epidermal basement membrane to the superficial dermis. The resultant injury and inflammation produce a subepidermal blister. Some people with dermatitis herpetiformis and gluten-sensitive enteropathy respond to a gluten-free diet.

Morphology. As an early event, fibrin and neutrophils accumulate selectively at the **tips of dermal papillae**, forming small microabscesses (Fig. 25-35A). The basal cells overlying these microabscesses show vacuolization and focal dermoepidermal separation that ultimately coalesce to form a true **subepidermal blister**. By direct immunofluorescence, dermatitis herpetiformis shows discontinuous, **granular deposits of lgA** selectively localized in the tips of dermal papillae (Fig. 25-35B).

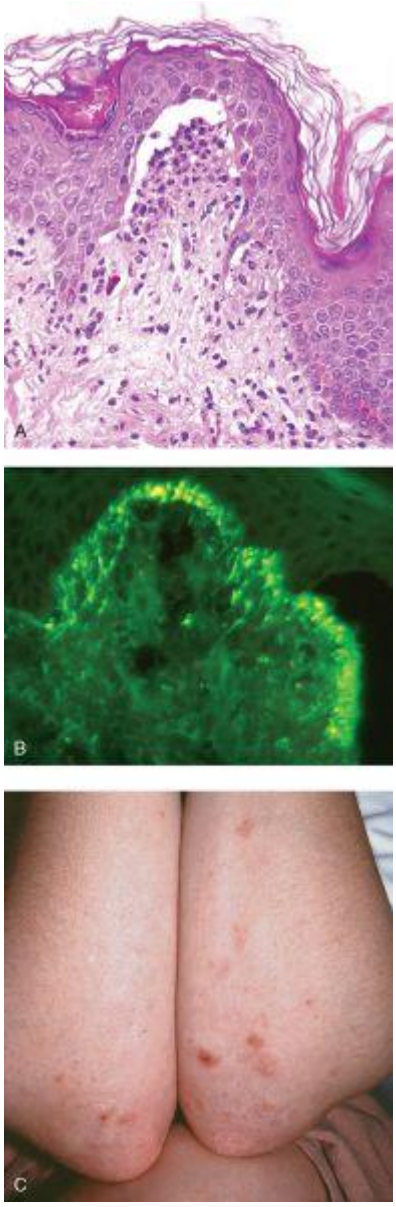

FIGURE 25-35 Dermatitis herpetiformis. **A**, The blisters are associated with basal cell layer injury initially caused by accumulation of neutrophils (microabscesses) at the tips of dermal papillae. **B**, Selective deposition of IgA autoantibody at the tips of dermal papillae is characteristic. **C**, Lesions consist of intact and eroded (usually scratched) erythematous blisters, often grouped (seen here on elbows and arms). *(**B**, Courtesy of Dr. Victor G. Prieto, Houston, Texas.)*

Clinical Features.

The urticarial plaques and vesicles of dermatitis herpetiformis are extremely *pruritic*. The lesions are bilateral, symmetric and grouped, involving preferentially the extensor surfaces, elbows, knees, upper back, and buttocks (Fig. 25-35C).

NONINFLAMMATORY BLISTERING DISORDERS

Epidermolysis Bullosa and Porphyria

Some primary disorders characterized by vesicles and bullae are mediated by non-inflammatory mechanisms. Two such diseases are *epidermolysis bullosa* and *porphyria*.

Epidermolysis bullosa constitutes a group of disorders caused by inherited defects in structural proteins that lend mechanical stability to the skin. The common feature is a proclivity to form blisters at sites of pressure, rubbing, or trauma, at or soon after birth.[99] In the *simplex type*, defects of the basal cell layer of the epidermis result from mutations in the genes encoding keratins 14 or 5. These two proteins normally pair with one another to make a functional keratin fiber, thus explaining the similar phenotype resulting from mutation of either gene. In the *junctional type*, blisters occur in otherwise histologically normal skin at precisely the level of the lamina lucida (Figs. 25-36 and 25-29). In the scarring *dystrophic types*, blisters develop beneath the lamina densa, in association with rudimentary or defective anchoring fibrils. Dystrophic epidermolysis bullosa is an inherited disease resulting from mutations in the *COL7A1* gene that encodes type VII collagen (Chapter 3). Squamous cell carcinoma can sometime arise in these chronic blisters.[100] The histologic changes are so subtle that electron microscopy may be required to differentiate among these types in clinically ambiguous settings. Overall, approximately ten genes encoding structural proteins at the dermoepidermal junction have been implicated in the various forms of this disease.[101] One form, termed *non-Herlitz junctional epidermolysis bullosa* is caused by a genetic defect (usually a point mutation) in the *LAMB3* gene that encodes laminin Vβ3. Successful gene therapy has been carried out in one individual with this disease by inserting a normal LAMB3 gene into keratinocytes.

FIGURE 25-36 Epidermolysis bullosa. **A**, Junctional epidermolysis bullosa showing typical erosions in flexural creases. **B**, A noninflammatory subepidermal blister has formed at the level of the lamina lucida.

Porphyria refers to a group of uncommon inborn or acquired disturbances of porphyrin metabolism. Porphyrins are pigments normally present in hemoglobin, myoglobin, and cytochromes. The classification of porphyrias is based on both clinical and biochemical features. The five major types are (1) congenital erythropoietic porphyria, (2) erythrohepatic protoporphyria, (3) acute intermittent porphyria, (4) porphyria cutanea tarda, and (5) mixed porphyria. Cutaneous manifestations consist of urticaria and vesicles that heal with scarring and that are exacerbated by exposure to sunlight. The primary alterations by light microscopy are a *subepidermal vesicle* (Fig. 25-37) *with associated marked thickening of the walls of superficial dermal vessels*. The pathogenesis of these alterations is not well understood, although serum proteins, including immunoglobulins, typically form glassy deposits in the walls of superficial dermal microvessels.

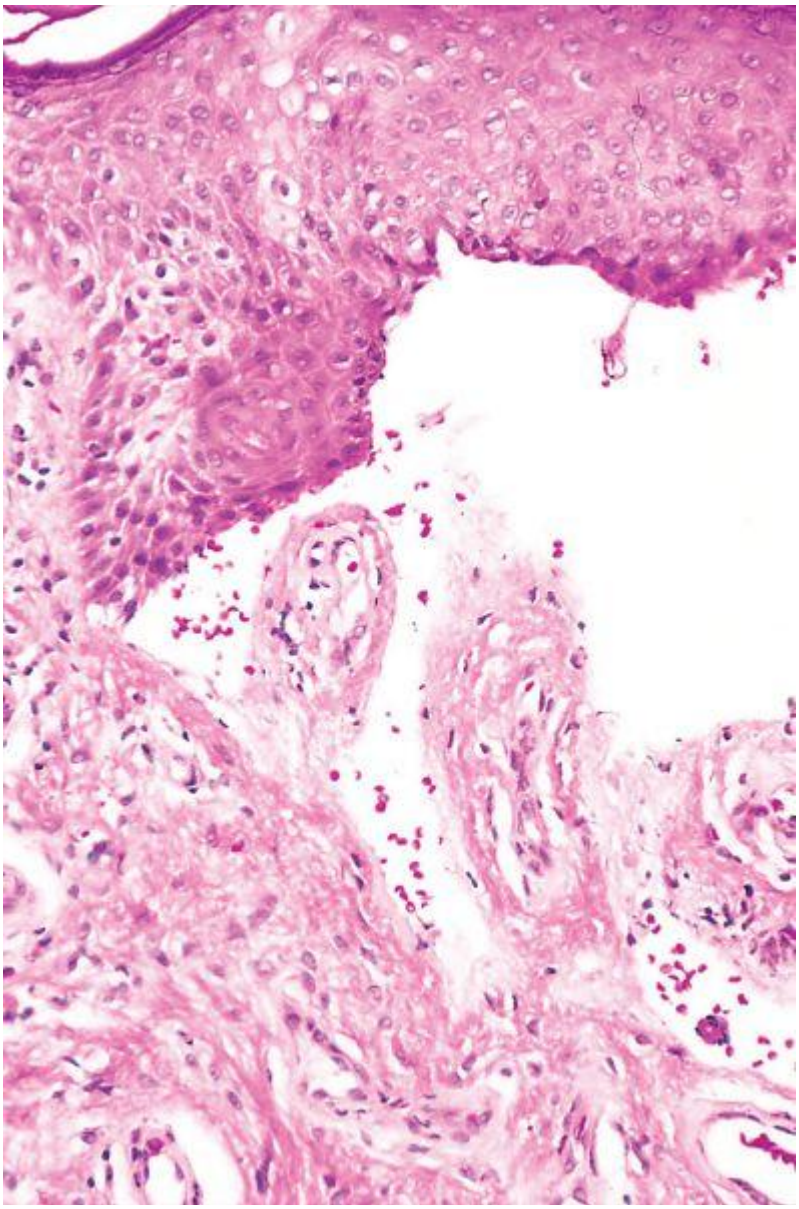

FIGURE 25-37 Porphyria. A noninflammatory blister is forming at the dermoepidermal junction; note the seemingly rigid dermal papillae at the base that contain the altered superficial vessels.

3.15.11 Disorders of Epidermal Appendages

ACNE VULGARIS

Virtually universal in the middle to late teenage years, acne vulgaris affects both males and females, although males tend to have more severe disease. Acne is seen in all races but is usually milder in people of Asian descent. Acne vulgaris in adolescents is believed to occur as a result of physiologic hormonal variations and alterations in hair follicles, particularly the sebaceous gland. The clinical features of acne may be induced or exacerbated by drugs (corticosteroids, adrenocorticotropic hormone, testosterone, gonadotropins, contraceptives, trimethadione, iodides, and bromides), occupational contactants (cutting oils, chlorinated hydrocarbons, and coal tars), and occlusive conditions such as heavy clothing, cosmetics, and tropical climates. Some families seem to be particularly affected by acne, suggesting a hereditary component.

Acne is divided into noninflammatory and inflammatory types, although the types may coexist. The former consists of open and closed comedones. *Open comedones* are small follicular papules containing a central black keratin plug. This color is the result of oxidation of melanin pigment (not dirt). *Closed comedones* are follicular papules without a visible central plug. Because the keratin plug is trapped beneath the epidermal surface, these lesions are potential sources of follicular rupture and inflammation. Inflammatory acne is characterized by erythematous papules, nodules, and pustules (Fig. 25-38A). Severe variants (e.g., acne conglobata) result in sinus tract formation and physical scarring.

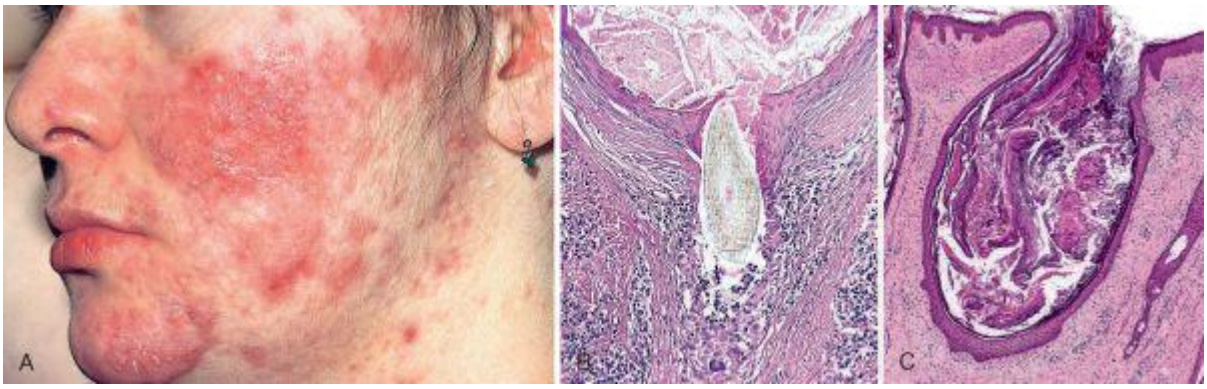

FIGURE 25-38 Acne. **A**, Inflammatory acne associated with erythematous papules and pustules. **B**, A hair shaft pierces the follicular epithelium, eliciting inflammation and fibrosis. **C**, Open comedone.

Morphology. Four key components contribute to the development of acne: (1) changes in keratinization of the lower portion of the follicular infundibulum with the development of a keratin plug blocking outflow of sebum to the skin surface; (2) hypertrophy of sebaceous glands with puberty or increased activity due to hormonal stimulation; (3) lipase-synthesizing bacteria *(Propionibacterium acnes)* colonizing the upper and midportion of the hair follicle, converting lipids within sebum to pro-inflammatory fatty acids; and (4) inflammation of the follicle associated with release of cytotoxic and chemotactic factors.[103] Depending on the stage of the disease, open or closed comedones, papules, pustules, or deep inflammatory nodules may develop. Open comedones have large, patulous orifices, whereas those of closed comedones are identifiable only microscopically (Fig. 25-38B, C). Variable lymphohistiocytic infiltrates are present in and around affected follicles, and extensive acute and chronic inflammation accompanies follicular rupture. Dermal abscesses may form in association with rupture (see Fig. 25-38C), and gradual resolution, often with scarring, ensues.

Pathogenesis.

The pathogenesis of acne is incompletely understood. Endocrine factors have been implicated (especially androgens) because, historically, young castrated males generally do not develop the condition (a questionable tradeoff). It has been postulated that bacterial lipases of *Propionibacterium acnes* break down sebaceous oils, liberating highly irritating fatty acids and resulting in the earliest inflammatory phases of acne.[104] Inhibition of lipase production is a rationale for administration of antibiotics to individuals with inflammatory acne. The synthetic vitamin A derivative 13-*cis*retinoic acid (isotretinoin) has brought about remarkable clinical improvement in some cases of severe acne through its strong anti-sebaceous action.[105,][106]

ROSACEA

Rosacea is a common disease of middle age and beyond, affecting up to 3% of the US population, with a predilection for females. Four stages are recognized: (1) flushing episodes (pre-rosacea), (2) persistent erythema and telangiectasia, (3) pustules and papules, and (4) rhinophyma—permanent thickening of the nasal skin by confluent erythemaous papules and follicular prominence.[107]

Morphology. Rosacea is characterized by a nonspecific perifollicular infiltrate composed of lymphocytes surrounded by dermal edema and telangiectasia. In the pustular phase neutrophils may colonize the follicles, and follicular rupture may cause a granulomatous dermal response. The development of rhinophyma is associated with hypertrophy of sebaceous glands and follicular plugging by keratotic debris.

Pathogenesis.

Individuals with rosacea have high cutaneous levels of the endogenous antimicrobial peptide cathelicidin, an important mediator of the innate immune response. The cathelicidin peptides present are qualitatively distinct from those seen in individuals without rosacea as a result of alternative processing by serine proteases such as stratum corneum tryptic enzyme.[108] While more study is needed, it seems that inappropriate activation of the innate immune system may play a role in this disorder.

3.15.12 Panniculitis
ERYTHEMA NODOSUM AND ERYTHEMA INDURATUM

Panniculitis is an inflammatory reaction in the subcutaneous adipose tissue that may preferentially affect (1) the connective tissue septa separating lobules of fat, or (2) the lobules of fat themselves. Panniculitis often involves the lower legs and usually has a subacute to chronic course. *Erythema nodosum* is the most common form and usually has an acute presentation. Its occurrence is often associated with infections (β-hemolytic streptococcal infection, tuberculosis and, less commonly, coccidioidomycosis, histoplasmosis, and leprosy), drug administration (sulfonamides, oral contraceptives), sarcoidosis, inflammatory bowel disease, and certain malignant neoplasms, but many times a cause cannot be identified.[109]

Erythema nodosum presents as poorly defined, exquisitely tender, erythematous plaques and nodules that may be more readily palpated than seen. Fever and malaise may accompany the cutaneous signs. Over the course of weeks, lesions usually flatten and become bruiselike, leaving no residual clinical scars, while new lesions develop. Biopsy of a deep wedge of tissue to generously sample the subcutis is usually required for histologic diagnosis.

Erythema induratum is an uncommon type of panniculitis that affects primarily adolescents and menopausal women. Although the cause is not known, most observers regard this as a primary vasculitis affecting deep vessels supplying lobules of the subcutis, with subsequent necrosis and inflammation within the fat. Erythema induratum presents as an erythematous, slightly tender nodule that usually goes on to ulcerate. Originally considered a hypersensitivity response to tuberculosis, erythema induratum today most commonly occurs without an associated underlying disease.

Morphology. The histopathology of **erythema nodosum** is distinctive. In early lesions, widening of the connective tissue septa is due to edema, fibrin exudation, and neutrophilic infiltration. Later, infiltration by lymphocytes, histiocytes, multinucleated giant cells, and occasional eosinophils is associated with septal fibrosis. Vasculitis is not present. In **erythema induratum**, on the other hand, granulomatous inflammation and zones of caseous necrosis involve the fat lobule. Early lesions show

necrotizing vasculitis affecting small- to medium-sized arteries and veins in the deep dermis and subcutis.

Erythema nodosum and erythema induratum are but two of the many types of panniculitis. *Weber-Christian disease (relapsing febrile nodular panniculitis)* is a rare form of lobular, nonvasculitic panniculitis seen in children and adults. It is marked by crops of erythematous plaques or nodules, predominantly on the lower extremities, created by deep-seated foci of inflammation with aggregates of foamy histiocytes admixed with lymphocytes, neutrophils, and giant cells. *Factitial panniculitis* is a form of secondary panniculitis caused by self-inflicted trauma or injection of foreign or toxic substances. Rarely, T cell lymphomas (panniculitic T cell lymphoma) home to fat lobules, producing fat necrosis and superimposed inflammation that mimics panniculitis. Finally, disorders such as *lupus erythematosus* may occasionally have deep inflammatory components with associated panniculitis.[110] The etiologies for all of these except the self-inflicted form and the rare T cell lymphomas are not understood.

3.15.13 Infection

The skin frequently succumbs to the attack of microorganisms, parasites, and insects. We have already discussed the possible role of bacteria in the pathogenesis of common acne, and the dermatoses resulting from viruses are too numerous to list. In the setting of the immunocompromised individual, ordinarily trivial cutaneous infections may become life-threatening. Many disorders, such as herpes simplex and herpes zoster, the viral exanthems, deep fungal infections, and immune reactions in skin provoked by infectious agents, are discussed in Chapter 8 . Here we cover a representative sampling of common infections whose primary clinical manifestations are in the skin.

VERRUCAE (WARTS)

Verrucae are common lesions of children and adolescents, although they may be encountered at any age. They are caused by human papillomaviruses. Transmission of disease usually involves direct contact between individuals or auto-inoculation. Verrucae are generally self-limited, regressing spontaneously within 6 months to 2 years.

The classification of verrucae is based largely on appearance and location.[111] *Verruca vulgaris* is the most common type of wart. The lesions of verruca vulgaris occur anywhere but most frequently on the hands, particularly on the dorsal surfaces and periungual areas, where they appear as gray-white to tan, flat to convex, 0.1- to 1-cm papules with a rough, pebble-like surface (Fig. 25-39A). *Verruca plana*, or *flat wart*, is common on the face or the dorsal surfaces of the hands. The warts are slightly elevated, flat, smooth, tan papules that are generally smaller than verruca vulgaris. *Verruca plantaris* and *verruca palmaris* occur on the soles and palms, respectively. Rough, scaly lesions may reach 1 to 2 cm in diameter, coalesce, and be confused with ordinary calluses. *Condyloma acuminatum (venereal wart)* occurs on the penis, female genitalia, urethra, perianal areas, and rectum. Venereal warts appear as soft, tan, cauliflower-like masses that occasionally reach many centimeters in diameter.

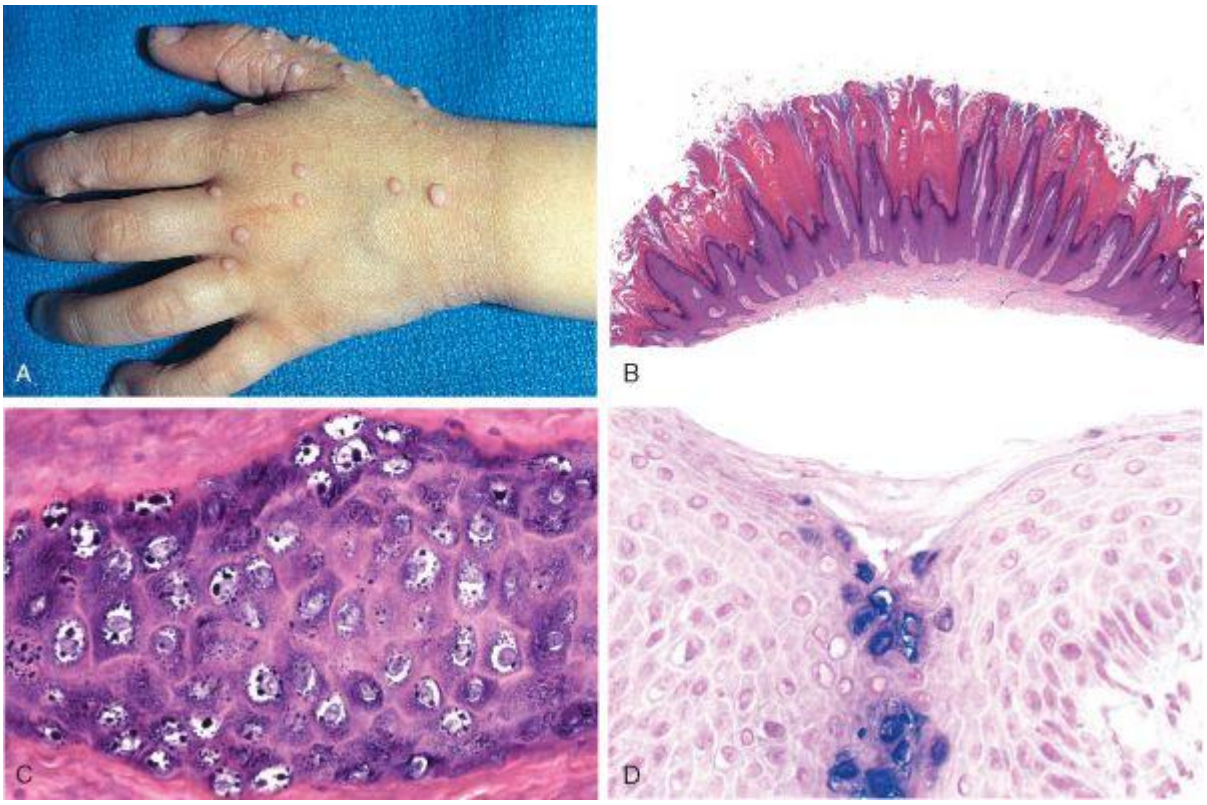

FIGURE 25-39 Verruca vulgaris. **A**, Multiple papules with rough pebble-like surfaces. **B** (low power) and **C**, (high power) histology of the lesions showing papillomatous epidermal hyperplasia and cytopathic alterations that include nuclear pallor and prominent keratohyaline granules. **D**, In situ hybridization demonstrating viral DNA within epidermal cells.

Morphology. Histologic features common to verrucae include epidermal hyperplasia that is often undulant in character, termed **verrucous or papillomatous epidermal hyperplasia** (Fig. 25-39B); and cytoplasmic vacuolization (koilocytosis) involving the more superficial epidermal layers, producing haloes of pallor surrounding infected nuclei. Electron microscopy of these zones reveals numerous viral particles within nuclei. Infected cells may also demonstrate prominent and apparently condensed keratohyaline granules and jagged eosinophilic intracytoplasmic keratin aggregates as a result of viral cytopathic effects (Fig. 25-39C). These cellular alterations are not as prominent in condylomas; hence, their diagnosis is based primarily on hyperplastic papillary architecture containing wedge-shaped zones of koilocytosis.

Pathogenesis.

More than 150 types of papillomavirus have been identified, many of them capable of producing warts in humans. The clinical variants of warts are often associated with distinct HPV subtypes. For example, anogenital warts are caused predominantly by HPV types 6 and 11. In contrast, there is a tendency for lesions induced by HPV type 16 to show some degree of dysplasia.[112] HPV type 16 has also been associated with in situ squamous cell carcinoma of the genitalia and with *bowenoid papulosis* (genital lesions of young adults with the histologic appearance of carcinoma in situ, but which usually regress spontaneously).[111] The relationship of HPV subtypes 5 and 8 to squamous cell carcinomas, particularly in individuals affected by the rare condition epidermodysplasia verruciformis, was mentioned earlier. These patients develop multiple flat warts that contain HPV genomes, some of which progress to

carcinoma. Viral typing can be accomplished by either in situ hybridization (Fig. 25-39D) or polymerase chain reaction.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a common, self-limited viral disease of the skin caused by a poxvirus. The virus is characteristically brick shaped, has a dumbbell-shaped DNA core, and measures 300 nm in maximal dimension, and thus represents the largest pathogenic poxvirus in humans and one of the largest viruses in nature. Infection is usually spread by direct contact, particularly among children and young adults.

Clinically, multiple lesions may occur on the skin and mucous membranes, with a predilection for the trunk and anogenital areas. Individual lesions are firm, often pruritic, pink to skin-colored umbilicated papules generally ranging in diameter from 0.2 to 0.4 cm. Rarely, "giant" forms occur measuring up to 2 cm in diameter. A curd-like material can be expressed from the central umbilication. Smearing this material onto a glass slide and staining with Giemsa reagent often shows diagnostic molluscum bodies.

Morphology. On microscopic examination, lesions show cuplike verrucous epidermal hyperplasia. The diagnostically specific structure is the **molluscum body**, which occurs as a large (up to 35 μm), ellipsoid, homogeneous, cytoplasmic inclusion in cells of the stratum granulosum and the stratum corneum (Fig. 25-40). In the H&E stain, these inclusions are eosinophilic in the blue-purple stratum granulosum and acquire a pale blue hue in the red stratum corneum. Numerous virions are present within molluscum bodies.

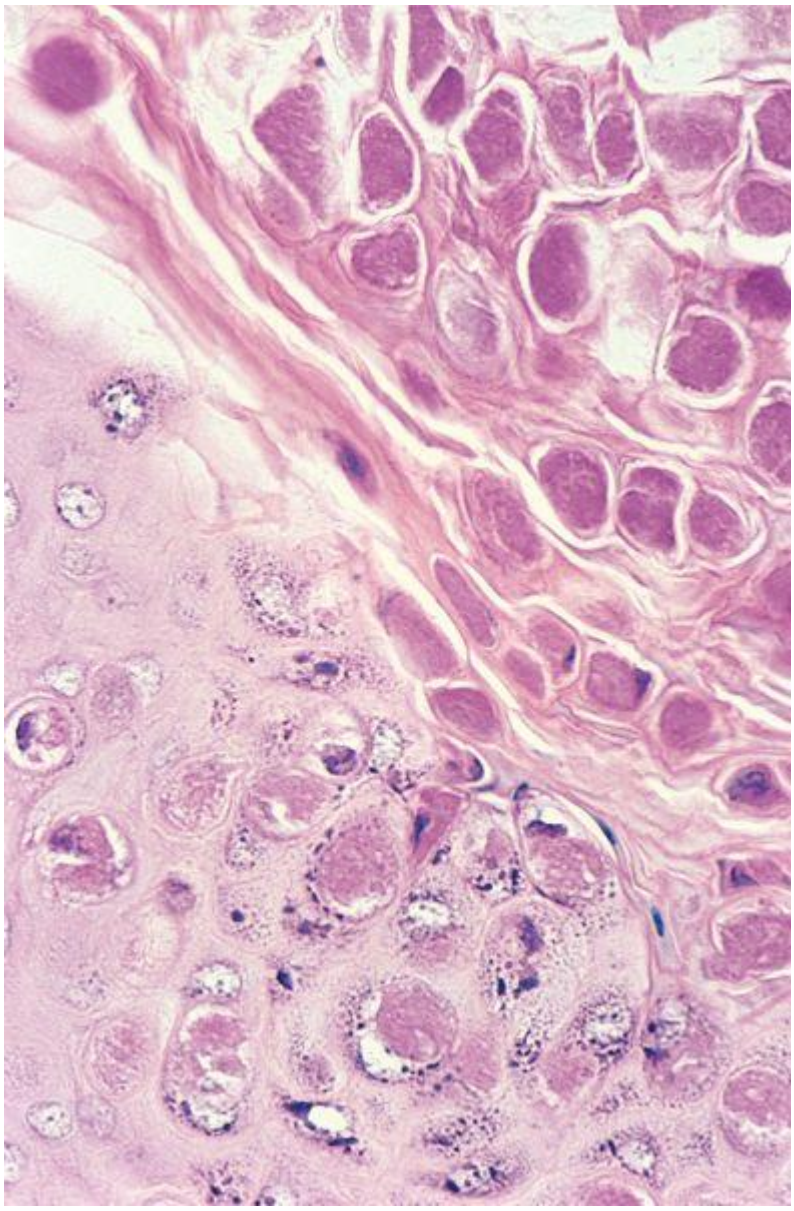

FIGURE 25-40 Molluscum contagiosum. A focus of verrucous epidermal hyperplasia contains numerous cells with ellipsoid cytoplasmic inclusions (molluscum bodies) within the stratum granulosum and stratum corneum.

IMPETIGO

Impetigo is a common superficial bacterial infection of skin. It is highly contagious and is frequently seen in otherwise healthy children as well as occasionally in adults in poor health. Two forms exist, classically referred to as *impetigo contagiosa* and *impetigo bullosa*; they differ from each other simply by the size of the pustules. Over the past decade a remarkable shift in etiology has been observed. Whereas in the past impetigo contagiosa was almost exclusively caused by group A β-hemolytic streptococci and impetigo bullosa by *Staphylococcus aureus*, both are now usually caused by *Staphylococcus aureus*.[114]

The infection usually involves exposed skin, particularly that of the face and hands. It presents as an erythematous macule, but multiple small pustules rapidly supervene. As pustules break, shallow erosions form, covered with drying serum, giving the characteristic clinical appearance of *honey-colored crust*. If the crust is not removed, new lesions form about the periphery and extensive epidermal damage may ensue. A bullous form of impetigo mainly occurs in children.

Morphology. The characteristic microscopic feature of impetigo is accumulation of neutrophils beneath the stratum corneum, often producing a subcorneal pustule. Special stains reveal the presence of bacteria in these foci. Nonspecific, reactive epidermal alterations and superficial dermal inflammation accompany these findings. Rupture of pustules results in superficial layering of serum, neutrophils, and cellular debris to form the characteristic crust. Blistering lesions may show accumulation of fluid and neutrophils beneath the stratum corneum.

Pathogenesis.

Bacterial species in the epidermis evoke an innate immune response that tends to be destructive within the epidermis leading to local serous exudate with formation of a scale crust (scab). The pathogenesis of blister formation in impetigo is related to bacterial production of a toxin that specifically cleaves desmoglein 1, the protein responsible for cell-to-cell adhesion within the uppermost epidermal layers.[115] Recall that in pemphigus foliaceus, which has a similar plane of blister formation, desmoglein 1 is compromised not by a toxin but by an autoantibody (see Fig. 25-29). Because there is virtually no involvement of the dermis, once the bacteria are eliminated the lesions heal without scarring.

SUPERFICIAL FUNGAL INFECTIONS

As opposed to deep fungal infections of the skin, where the dermis or subcutis is primarily involved, superficial fungal infections of the skin are confined to the stratum corneum, and are caused primarily by dermatophytes. These organisms grow in the soil and on animals and produce a number of diverse and characteristic clinical lesions.[116]

Tinea capitis usually occurs in children and is only rarely seen in infants and adults. It is a dermatophytosis of the scalp characterized by asymptomatic, often hairless patches of skin associated with mild erythema, crust formation, and scaling. *Tinea barbae* is a dermatophyte infection of the beard area that affects adult men; it is a relatively uncommon disorder. *Tinea corporis*, on the other hand, is a common superficial fungal infection of the body surface that affects persons of all ages, but particularly children. Predisposing factors include excessive heat and humidity, exposure to infected animals, and chronic dermatophytosis of the feet or nails. The most common type of tinea corporis is an expanding, round, slightly erythematous plaque with an elevated scaling border (Fig. 25-41A). *Tinea cruris* occurs most frequently in the inguinal areas of obese men during warm weather. Heat, friction, and maceration all predispose to its development. The infection usually first appears on the upper inner thighs, with gradual extension of moist, red patches that have raised, scaling borders. *Tinea pedis (athlete's foot)* affects 30% to 40% of the population at some time in their lives. There is diffuse erythema and scaling, often initially localized to the web spaces. Most of the inflammatory tissue reaction, however, has recently been shown to be the result of bacterial superinfection and not directly related to the primary dermatophytosis.[117] Spread to or primary infection of the nails is referred to as *onychomycosis*. This produces discoloration, thickening, and deformity of the nail plate. *Tinea versicolor* usually occurs on the upper trunk and is highly distinctive in appearance. Caused by *Malassezia furfur*, a yeast rather than a dermatophyte, the lesions consist of groups of macules of all sizes, lighter or darker than surrounding skin, with a fine peripheral scale.[87]

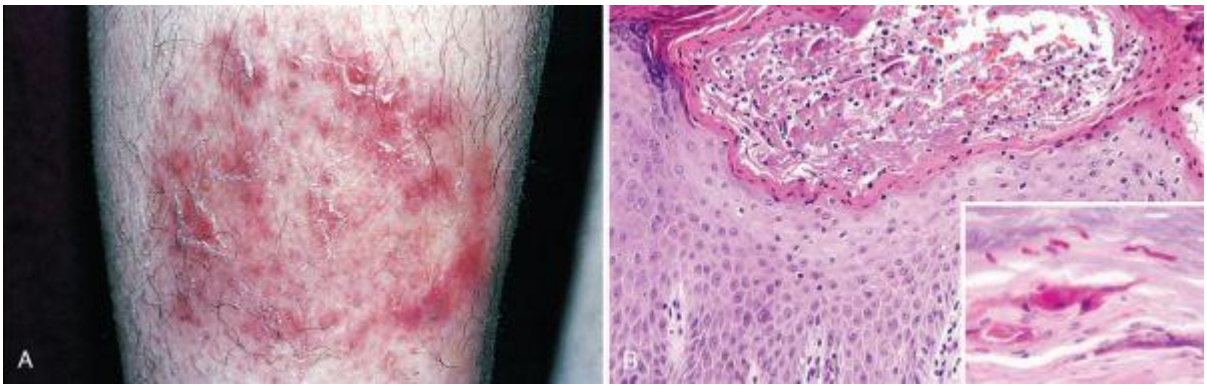

FIGURE 25-41 Tinea. **A**, Characteristic plaque of tinea corporis. Routine histology (**B**) shows a mild eczematous (spongiotic) dermatitis and focal neutrophilic abscesses. A periodic acid–Schiff stain (*inset*) reveals deep red hyphae within the stratum corneum.

Morphology. The histologic features of dermatophytoses are variable, depending on the properties of the organism, the host response, and the degree of bacterial superinfection. There may be mild eczematous dermatitis associated with intraepidermal neutrophils (Fig. 25-41B). Fungal cell walls, rich in mucopolysaccharides, stain bright pink to red with periodic acid–Schiff stain. They are present in the anucleate cornified layer of lesional skin, hair, or nails (Fig. 25-41B, *inset*). Culture of material scraped from these areas will usually permit the identification of the offending species.

3.16 26. Bones, Joints & Soft-Tissue Tumors

3.16.1 Bones

Recognized by the bard for its persistence after death (Alas, poor Yorick!), the skeletal system is vital during life. It has an essential role in mineral homeostasis, houses the hematopoietic elements, provides mechanical support for movement, protects viscera, and determines body size and shape. As is well known, bones are largely made up of an organic matrix (osteoid) and the mineral calcium hydroxyapatite, which gives the bones strength and hardness. What is not obvious is that, despite its stony hard structure, bone is a dynamic tissue that is continuously resorbed, renewed, and remodeled. These processes are carried out by several different types of bone cells that are regulated by a number of transcription factors, cytokines, and growth factors [1] [2] [3] (Fig. 26-1).

- *Osteoprogenitor* cells are pluripotent mesenchymal stem cells that are found in the vicinity of all bony surfaces. When appropriately stimulated by growth factors they produce offspring that differentiate into osteoblasts, a process that is governed by the RUNX2/CBFA1 transcription factor network and the WNT/β-catenin signaling pathway (Chapter 2).[2,][3]
- *Osteoblasts and lining cells* are located on the surface of bones. These cells synthesize, transport, and arrange the many proteins of matrix detailed later (Fig. 26-2) and initiate the process of mineralization.

Osteoblasts have receptors that bind regulatory hormones (parathyroid hormone, vitamin D, leptin, and estrogen), cytokines, growth factors, and extracellular matrix proteins, [2] [3] [4] [5] [6] and in turn express several factors that regulate the differentiation and function of osteoclasts (Fig. 26-2 , described further below). If osteoblasts become surrounded by newly deposited organic matrix, they transform into *osteocytes*; alternatively, osteoblasts remaining on the bone surface may become flattened and quiescent bone lining cells.

- *Osteocytes* communicate with each other and with cells on the bone surface via an intricate network of cytoplasmic processes that traverse tunnels in the matrix known as *canaliculi*. Osteocytes help to control calcium and phosphate levels in the microenvironment, and detect mechanical forces and translate them into biologic activity—a process called *mechanotransduction*.[5,][6]
- *Osteoclasts* are the cells responsible for bone resorption. They are derived from the same hematopoietic progenitor cells that also give rise to monocytes and macrophages. The cytokines and growth factors that regulate human osteoclast differentiation and maturation include macrophage colony-stimulating factor (M-CSF), interleukin-1 (IL-1), and tumor necrosis factor (TNF).[7,][8] Mature multinucleated osteoclasts (containing 6 to 12 nuclei) form from the fusion of circulating mononuclear precursors and have a limited life span (approximately 2 weeks). They bind to the bone surface via integrins, where they form an underlying resorption pit—a self-contained extracellular space analogous to a secondary lysosome (Fig. 26-2). The cell membrane overlying the resorption pit is thrown into numerous folds (the *ruffled border*), increasing its surface area, while the adjacent cell surface forms a tight seal with the bone that prevents leakage of digestion products. The osteoclast removes the mineral by generating an acidic environment utilizing a proton pump system and digests the organic component by releasing proteases.

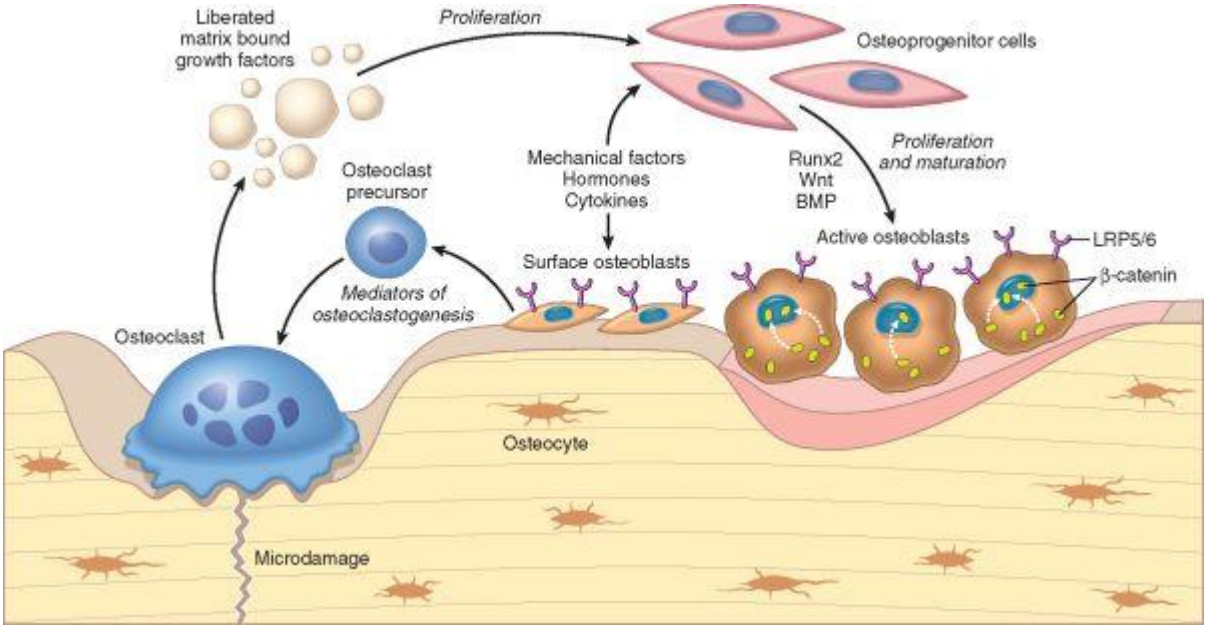

FIGURE 26-1 Bone cells and their interrelated activities. Hormones, cytokines, growth factors, and signal-transducing molecules are key in their formation and maturation, and allow communication between osteoblasts and osteoclasts. Bone resorption and formation in remodeling are coupled processes that are controlled by systemic factors and local cytokines, some of which are deposited in the bone matrix. BMP, bone morphogenic protein; LRP5/6, LDL receptor related proteins 5 and 6.

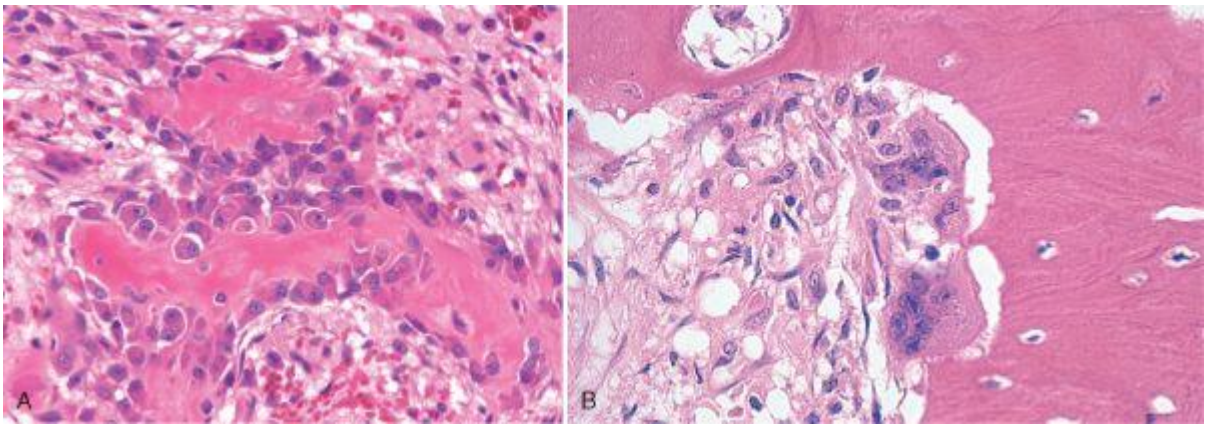

FIGURE 26-2 **A**, Active osteoblasts synthesizing bone matrix. The surrounding spindle cells represent osteoprogenitor cells. **B**, Two osteoclasts resorbing bone.

These cells and locally produced factors work together to regulate bone homeostasis. The control mechanisms are not known completely, but several signaling pathways of particular importance have emerged (Fig. 26-3). One such pathway involves three factors: (1) the transmembrane receptor RANK (receptor activator for NF-κB), which is expressed on osteoclast precursors; (2) RANK ligand, (RANKL) which is expressed on osteoblasts and marrow stromal cells; and (3) osteoprotegrin (OPG), a secreted "decoy" receptor made by osteoblasts and several other types of cells that can bind RANKL and thus short-circuit its interaction with RANK.[9] When stimulated by RANKL, RANK signaling activates the transcription factor NF-κB, which is essential for the generation and survival of osteoclasts. A second important pathway involves M-CSF produced by osteoblasts and the M-CSF receptor, which is expressed by osteoclast progenitors. Activation of the M-CSF receptor stimulates a tyrosine kinase activity that is also crucial for the generation of osteoclasts. The other notable pathway is the WNT/β-catenin pathway. WNT proteins produced by marrow stromal cells bind to the LRP5 and LRP6 receptors on osteoblasts (see Fig. 26-1) and thereby trigger the activation of β-catenin and the production of OPG. The importance of these pathways is proven by rare but informative germline mutations in the *OPG*, *RANK*, *RANKL*, and *LRP5* genes, which cause severe disturbances of bone metabolism (described later).

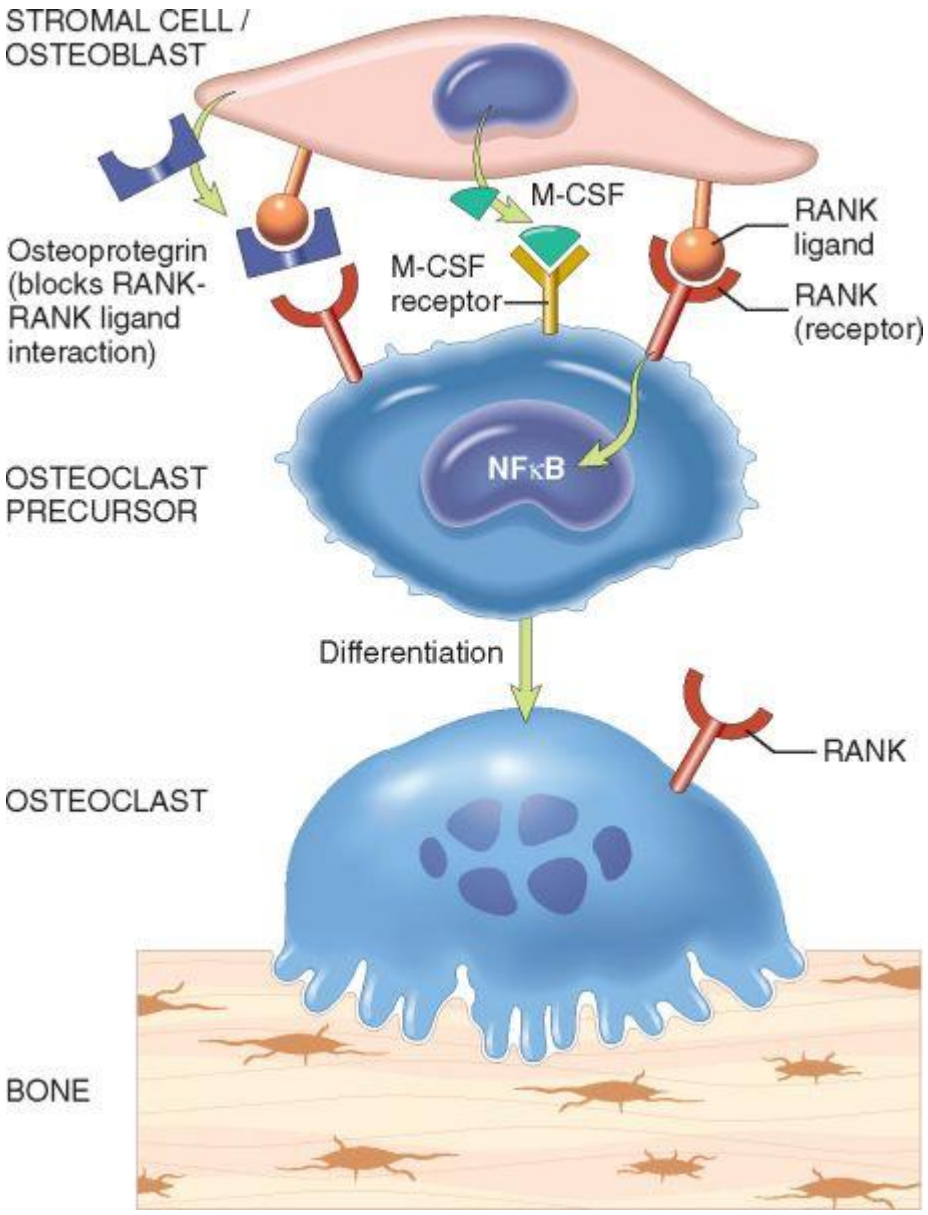

FIGURE 26-3 Paracrine molecular mechanisms that regulate osteoclast formation and function. Osteoclasts are derived from the same stem cells that produce macrophages. Osteoblast/stromal cell membrane–associated RANKL binds to its receptor RANK located on the cell surface of osteoclast precursors. This interaction in the background of macrophage colony-stimulating factor (M-CSF) causes the precursor cells to produce functional osteoclasts. Stromal cells also secrete osteoprotegrin (OPG), which acts as a decay receptor for RANKL, preventing it from binding the RANK receptor on osteoclast precursors. Consequently, OPG prevents bone resorption by inhibiting osteoclast differentiation.

Bone formation and resorption are tightly coupled and subject to fine-tuning at several levels. For example, because OPG and RANKL oppose one another, either bone resorption or bone formation can be favored by simply tipping the RANKL : OPG ratio one way or the other. Systemic factors that affect RANKL and OPG expression include hormones (parathyroid hormone, estrogen, testosterone, and glucocorticoids), vitamin D, inflammatory cytokines (e.g., IL-1), and growth factors (such as bone morphogenetic factors); each presumably acts by altering the levels of NF-κB and WNT/β-catenin signaling in osteoblasts. Another level of control involves paracrine crosstalk between osteoblasts and osteoclasts, and possibly osteocytes as well. We have seen that osteoblasts can enhance or inhibit osteoclast development and function by expressing OPG and RANKL in various proportions. As osteoclasts disassemble matrix proteins deposited by osteoblasts, growth factors, cytokines, and

enzymes (such as collagenase) bound to the matrix are liberated and activated, including some that stimulate osteoblasts. *Thus, as bone is broken down to its elemental units, substances are released into the microenvironment that initiate its renewal* (see Fig. 26-1).

The *proteins of bone* include type 1 collagen and many noncollagenous proteins derived mainly from osteoblasts. Osteoblasts deposit collagen either in a random weave known as *woven bone* or in an orderly layered manner designated *lamellar bone* (Fig. 26-4). Normally, woven bone is seen in sites of rapid bone formation such as the fetal skeleton and the base of growth plates. It is produced quickly and resists forces equally from all directions. The presence of woven bone in the adult is always abnormal; however, it is not diagnostic of a particular disease. We will see examples of this later in this chapter. *Lamellar bone, which gradually replaces woven bone during growth, is deposited much more slowly and is stronger than woven bone*.

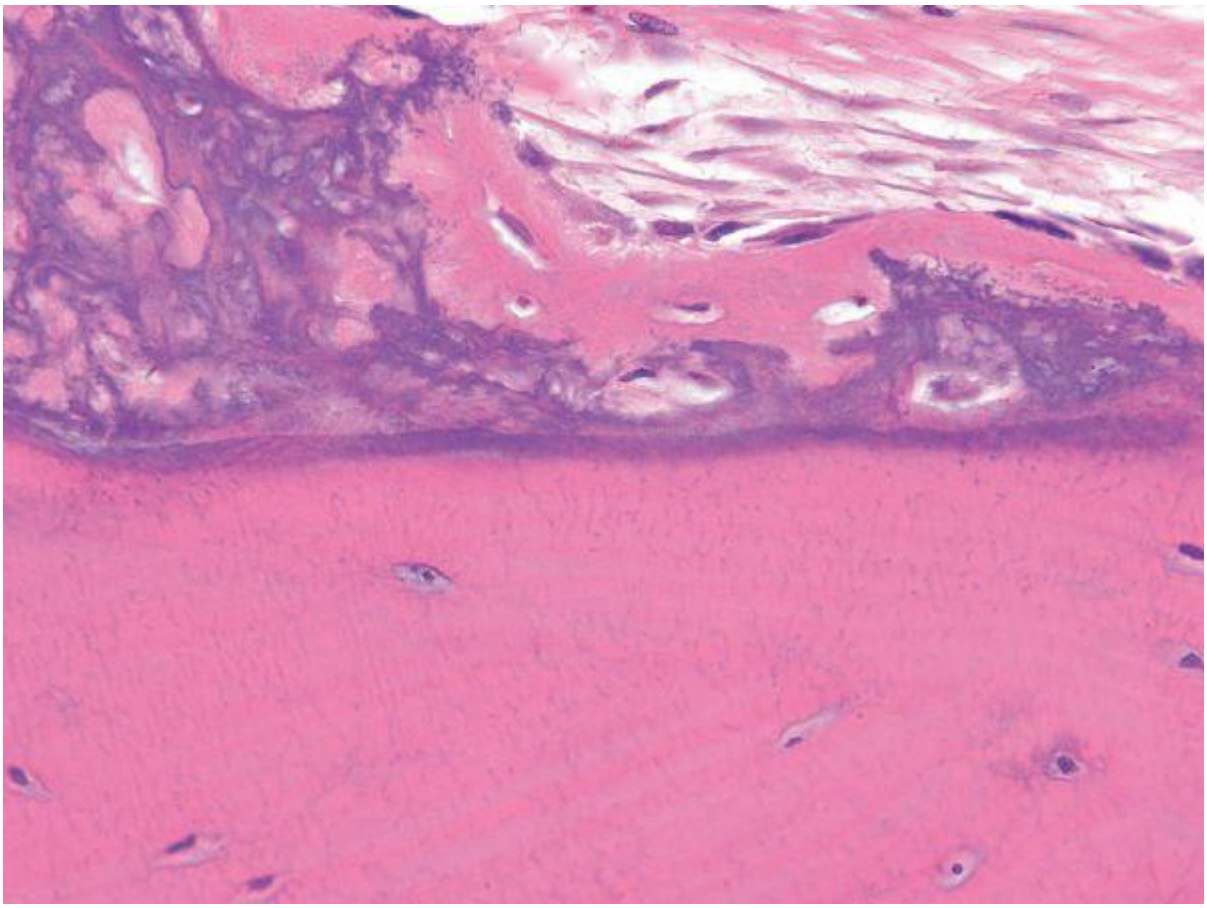

FIGURE 26-4 Woven bone *(top)* deposited on the surface of preexisting lamellar bone *(bottom)*.

The noncollagenous proteins of bone are bound to the matrix and grouped according to their function (Table 26-1).[8,][10] Of these, only osteocalcin is unique to bone. It is measurable in the serum and used as a sensitive and specific marker for osteoblast activity. Cytokines and growth factors control bone cell proliferation, maturation, and metabolism, thereby playing a crucial role translating mechanical and metabolic signals into local bone cell activity and eventual skeletal adaptation.[8,][11] In this fashion the skeleton is uniquely able to change its structure in response to new physical forces; witness the repositioning of teeth by braces.

TABLE 26-1 -- Proteins of Bone Matrix

OSTEOBLAST-DERIVED PROTEINS
Type 1 collagen
Cell adhesion proteins
Osteopontin, fibronectin, thrombospondin
Calcium-binding proteins
Osteonectin, bone sialoprotein
Proteins involved in mineralization
Osteocalcin
Enzymes
Collagenase, alkaline phosphatase
Growth factors
IGF-1, TGF-β, PDGF
Cytokines
IL-1, IL-6, RANKL
PROTEINS CONCENTRATED FROM SERUM
β_2-microglobulin
Albumin

IGF, insulin-like growth factor; TGF, transforming growth factor; PDGF, platelet-derived growth factor; IL, interleukin; RANKL, RANK ligand.

3.16.1.1 Bone Modeling, Remodeling & Peak Bone Mass

Local collections of osteocytes, osteoblasts, and osteoclasts work together to control bone formation and resorption, creating a functional unit referred to as the *basic multicellular unit* (BMU).[12,][13] Early in life, as the skeleton grows and enlarges (modeling), bone formation predominates. Once the skeleton has reached maturity, the breakdown and renewal of bone that constitutes skeletal maintenance is called *remodeling* and is probably initiated at sites experiencing fatigue and microdamage. In adults, BMUs *remodel* or replace 10% of the skeleton annually.

Peak bone mass is achieved in early adulthood after the cessation of growth, and it is determined by a variety of factors, including polymorphisms in the receptors for vitamin D and LRP5/6, nutrition, physical activity, age, and hormonal status. Beginning in the fourth decade, however, the amount of bone resorbed by the BMUs exceeds that formed, so that there is a steady decrement in skeletal mass.

3.16.1.2 Bone Growth & Development

Skeletal morphogenesis is determined by the *homeobox genes*, which encode transcription factors essential for the normal development of the skeleton.[12,][14] Most bones are first formed as a cartilage model or anlage. Subsequently, around the eighth week of gestation the process of *enchondral ossification* begins, and the cartilage is removed by osteoclast-type cells forming the medullary canal. This process progresses along the length of the bone, while concurrently the periosteum in the midshaft generates osteoblasts that deposit the beginnings of the cortex; this region is known as the *primary center of ossification*. A similar sequence of events occurs in the epiphysis, resulting in the removal of cartilage and deposition of bone in a centrifugal fashion *(secondary center of ossification)*, such that a plate of the cartilage anlage becomes entrapped between the expanding centers of ossification forming the *physis* or *growth plate* (Fig. 26-5). The chondrocytes within the growth plate are responsible for

longitudinal growth as they undergo a series of changes, including proliferation, growth, maturation, and apoptosis—controlled by a number of signaling pathways, including those involving FGF receptors and bone morphogenetic protein, hedgehog protein, and parathyroid-hormone (PTH)-related protein.[15] In the region of apoptosis the matrix mineralizes and is resorbed by osteoclasts; however, remnant struts persist and act as scaffolding for the deposition of bone on their surfaces. These structures are known as primary spongiosa and are the first bony trabeculae. A similar process occurs at the base of articular cartilage, and by this mechanism bones increase in length, and articular surfaces increase in diameter. In contrast, bones derived from *intramembranous formation*, such as the cranium and lateral portions of the clavicles, are formed by osteoblasts directly from a fibrous layer of tissue that is derived from mesenchyme. Because bone tissue is made only by osteoblasts, the enlargement of bones is achieved by the deposition of new bone on a preexisting surface. This mechanism of *appositional growth* is key to understanding bone growth and modeling.

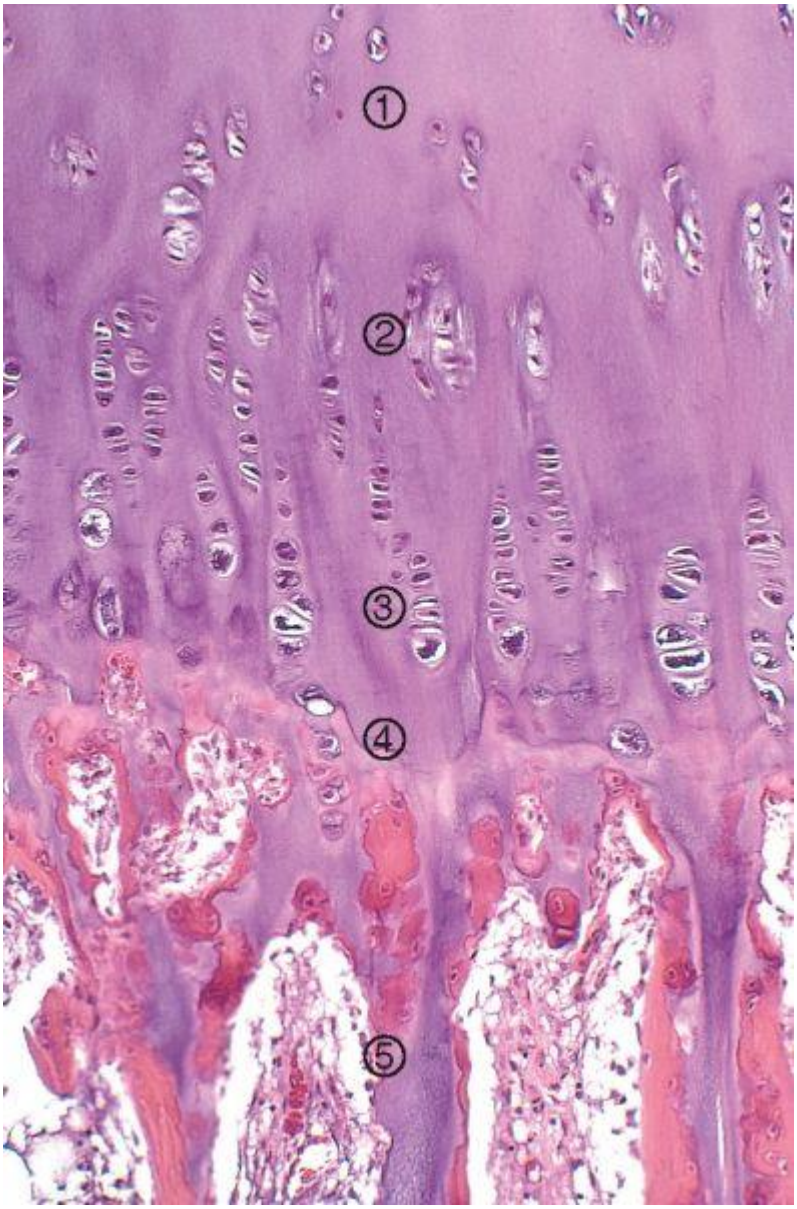

FIGURE 26-5 Active growth plate with ongoing enchondral ossification. 1, Reserve zone. 2, Zone of proliferation. 3, Zone of hypertrophy. 4, Zone of mineralization. 5, Primary spongiosa.

The complexity of the skeleton's growth, development, maintenance, and relationships with other organ systems makes it unusually vulnerable to adverse influences. Not surprisingly, then, primary and secondary diseases of bone are varied and numerous. The spectrum of bone disorders is broad and the classification system is not standardized; here we will categorize the various disorders according to their perceived pathogenesis.

3.16.1.3 Developmental Abnormalities in Bone Cells, Matrix & Structure

Developmental abnormalities of the skeleton are frequently genetically based; they first become manifest during the earliest stages of bone formation. In contrast, acquired diseases are usually detected in adulthood.[11] Developmental anomalies resulting from localized problems in the migration of the mesenchymal cells and the formation of the condensations are known as *dysostoses*. They are usually limited to defined embryologic structures and may result from mutations in certain transcription factors (e.g., *homeobox* genes). In contrast, mutations in the regulators of skeletal organogenesis, such as signaling molecules (e.g., growth factors and their receptors) and matrix components (e.g., types 1 and 2 collagen) affect cartilage and bone tissues globally; these disorders are known as *dysplasias*.[8,][11,][12,] [15] [16] [17] Table 26-2 shows a classification of developmental abnormalities of the bone based on the nature of the genetic abnormality. The classification of developmental and acquired abnormalities that follows is based on identified genetic defects and the skeletal manifestations of the disease processes. Many of the conditions can be classified in more than one category.

TABLE 26-2 -- Molecular Genetics of Diseases of the Skeleton

Human Disorder	Gene Mutation	Affected Molecule	Phenotype
DEFECTS IN TRANSCRIPTION FACTORS PRODUCING ABNORMALITIES IN MESENCHYMAL CONDENSATION AND RELATED CELL DIFFERENTIATION			
Synpolydactyly	*HOXD13*	Transcription factor	Extra digit with fusion
Waardenburg syndrome	*PAX3*	Transcription factor	Hearing loss, abnormal pigmentation, craniofacial abnormalities
Greig syndrome	*GLI13*	Transcription factor	Synpolydactyly, craniofacial abnormalities
Campomelic dysplasia	*SOX9*	Transcription factor	Sex reversal, abnormal skeletal development
Oligodontia	*PAX9*	Transcription factor	Congenital absence of teeth
Nail-patella syndrome	*LMX1B*	Transcription factor	Hypoplastic nails, hypoplastic or aplastic patellas, dislocated radial head, progressive nephropathy
Holt-Oram syndrome	*TBX5*	Transcription factor	Congenital abnormalities, forelimb anomalies
Ulnar-mammary syndrome	*TBX3*	Transcription factor	Hypoplasia or absent ulna, third to fifth digits, breast, and teeth, delayed puberty
Cleidocranial dysplasia	*CBFA1*	Transcription factor	Abnormal clavicles, wormian bones, supernumery teeth
DEFECTS IN EXTRACELLULAR STRUCTURAL PROTEINS			
Osteogenesis imperfecta types I–IV	*COL1A1, COL1A2*	Type 1 collagen	Bone fragility, hearing loss, blue sclera, dentinogenesis imperfecta
Achondrogenesis II	*COL2A1*	Type 2 collagen	Short trunk, severely shortened extremities, relatively enlarged cranium, flattened face

Human Disorder	Gene Mutation	Affected Molecule	Phenotype
Hypochondrogenesis	*COL2A1*	Type 2 collagen	Short trunk, shortened extremities, relatively enlarged, cranium, flattened face
Stickler syndrome	*COL2A1*	Type 2 collagen	Myopia, retinal detachment, hearing loss, flattened face, premature osteoarthritis
Multiple epiphyseal dysplasia	*COL9A2*	Type 9 collagen	Short or normal stature, small epiphyses, early-onset osteoarthritis
Schmid metaphyseal chondrodysplasia	*COL10A1*	Type 10 collagen	Mildly short stature, bowing of lower extremities, coxa vara, metaphyseal flaring
DEFECTS IN HORMONES AND SIGNAL TRANSDUCTION MECHANISMS PRODUCING ABNORMAL PROLIFERATION OR MATURATION OF CHONDROCYTES AND OSTEOBLASTS			
Brachdactyly type C	*CDMP1*	Signaling molecule	Shortened metacarpals and phalanges
Jansen metaphyseal chondroplasia	*PTHrp receptor*	Receptor	Short bowed limbs, clinodactyly, facial abnormalities, hypercalcemia, hypophosphatemia
Achondroplasia	*FGFR3*	Receptor	Short stature, rhizomelic shortening of limbs, frontal bossing, midface dificiency
Hypochondroplasia	*FGFR3*	Receptor	Disproportionately short stature, micromelia, relative macrocephaly
Thanatophoric dwarfism	*FGFR3*	Receptor	Severe limb shortening and bowing, frontal bossing, depressed nasal bridge
Crouzon syndrome	*FGFR2*	Receptor	Craniosynostosis
Osteoporosis-pseudoglioma syndrome	*LRP5*	Receptor	Congenital or infant-onset loss of vision, skeletal fragility

FASEB J 11:125–132, 1997; Mundlos S, Olsen BR: Heritable diseases of the skeleton. Part II: Molecular insights into skeletal development—matrix components and their homeostasis. FASEB J 11: 227–233, 1997; Superti-Furga A et al.: Molecular-pathogenetic classification of genetic disorders of the skeleton. Am J Med Genet 106:262–293, 2001.

MALFORMATIONS AND DISEASES CAUSED BY DEFECTS IN NUCLEAR PROTEINS AND TRANSCRIPTION FACTORS

Congenital malformations or dysostoses of bone are relatively uncommon. The simplest anomalies include failure of a bone to develop (e.g., congenital absence of a phalanx, rib, or clavicle); the formation of extra bones (supernumerary ribs or digits); the fusion of two adjacent digits (syndactylism); or the development of long, spider-like digits. Some of these result from defects in the formation of the mesenchymal condensations and their differentiation into the cartilage anlage. They are caused by genetic alterations that affect transcription factors, especially those encoded by the *homeobox* genes, and certain cytokines.[8,][11] One example of a defect in mesenchymal condensation is caused by a mutation in the homeobox *HOXD13* gene, which produces an extra digit between the third and fourth fingers as well as some degree of syndactyly.[12] Loss of function mutations in the *RUNX2* gene, which produces transcription factors important in osteoblastogenesis and some chondrocyte cell activity, results in *cleidocranial dysplasia*, an autosomal dominant disorder characterized by patent fontanelles, delayed closure of cranial sutures, Wormian bones, delayed eruption of secondary teeth, primitive clavicles, and short height.

DISEASES CAUSED BY DEFECTS IN HORMONES AND SIGNAL TRANSDUCTION MECHANISMS

Achondroplasia is the most common disease of the growth plate and is a major cause of dwarfism. It is caused by a mutation in the FGF receptor 3 (FGFR3).[11] Normally, FGFmediated activation of FGFR3 *inhibits* cartilage proliferation; in achondroplasia, the mutations cause constitutive activation of FGFR3 and thereby suppress growth.

Achondroplasia is an autosomal dominant disorder; curiously approximately 80% of cases stem from new mutations, almost all of which occur in the paternal allele. Affected individuals have shortened proximal extremities, a trunk of relative normal length, and an enlarged head with bulging forehead and conspicuous depression of the root of the nose. The skeletal abnormalities are usually not associated with changes in longevity, intelligence, or reproductive status.

Thanatophoric dwarfism is the most common lethal form of dwarfism, affecting about one in every 20,000 live births. It is also caused by gain-of-function mutations in FGFR3 that differ from those in achondroplasia.[11] Affected individuals have micromelic shortening of the limbs, frontal bossing, relative macrocephaly, a small chest cavity, and a bell-shaped abdomen. The underdeveloped thoracic cavity leads to respiratory insufficiency, and these individuals frequently die at birth or soon after. The histologic changes in the growth plate show diminished proliferation of chondrocytes and poor columnization in the zone of proliferation.

Increased bone mass is a manifestation of a variety of diseases. Several are caused by caused by gain-of-function mutations in the gene that encodes LPR5, a cell surface receptor that is essential for the activation of the WNT/β-catenin pathway in osteoblasts. These diseases, namely endosteal hyperostosis, Van Buchem disease, and autosomal dominant osteopetrosis type 1, are characterized by increased bone mass including cortical thickening, enlarged and elongated mandible, and increased density and enlargement of the cranial vault; some affected individuals may develop torus palatinus.

Conversely, inactivating mutations in LPR5 cause *osteoporosis pseudoglioma syndrome*. In this disorder the skeleton is severely osteoporotic, resulting in fractures due to insufficient bone formation.

DISEASES ASSOCIATED WITH DEFECTS IN EXTRACELLULAR STRUCTURAL PROTEINS

The interaction of the organic components of bone matrix is complex and a focus of intense scientific investigation. The importance of the structural bone proteins is exemplified by the diseases associated with deranged metabolism of the collagens important in bone and cartilage formation (types 1, 2, 9, 10, and 11). Their clinical manifestations are highly variable, ranging from lethal disease to premature osteoarthritis.

Type 1 Collagen Diseases (Osteogenesis Imperfecta)

Osteogenesis imperfecta, or *brittle bone disease*, is a phenotypically diverse disorder caused by deficiencies in the synthesis of type 1 collagen. It is the most common inherited disorder of connective tissue. It principally affects bone, but also impacts other tissues rich in type 1 collagen (joints, eyes, ears, skin, and teeth). Osteogenesis imperfecta usually results from autosomal dominant mutations (over 800 have been identified) in the genes that enco de theα1 and α2 chains of collagen.[19] Many of these mutations involve the substitution of glycine residues in the triple-helical domain. The genotypephenotype relationship underlying osteogenesis imperfecta is based on the location of the mutation within the protein. Mutations resulting in decreased synthesis of qualitatively normal collagen are associated with mild skeletal abnormalities. More severe or lethal phenotypes have abnormal polypeptide chains that cannot be arranged in the triple helix. Recently, mutations in the genes for cartilage-associated protein (CRTAP) and leucine proline-enriched proteoglycan 1 (LEPRE1) have been shown to be responsible for three rare variants of the disease.[20]

Clinically, osteogenesis imperfecta is separated into four major subtypes that vary widely in severity (Table 26-3). The *type II variant* is at one end of the spectrum and is uniformly fatal in utero or during the perinatal period. It is characterized by extraordinary bone fragility with multiple intrauterine fractures (Fig. 26-6). In contrast, individuals with the *type I form* have a normal life span but experience childhood fractures that decrease in frequency following puberty. Other findings include *blue sclerae* caused by decreased collagen content, making the sclera translucent and allowing partial visualization of the underlying choroid; *hearing loss* related to both a sensorineural deficit and impeded conduction due to abnormalities in the bones of the middle and inner ear; and *dental imperfections* (small, misshapen, and blue-yellow teeth) secondary to a deficiency in dentin. *The basic abnormality in all forms of osteogenesis imperfecta is too little bone*, thus constituting a type of osteoporosis with marked cortical thinning and attenuation of trabeculae.

TABLE 26-3 -- Subtypes of Osteogenesis Imperfecta

Subtype		Inheritance	Collagen Defect	Major Clinical Features
OI type I	Compatible with survival	Autosomal dominant	Decreased synthesis of pro-α1(1) chain	Postnatal fractures, blue sclera
			Abnormal pro-α1(1) or pro-α2(1) chains	Normal stature
				Skeletal fragility
				Dentinogenesis imperfecta
				Hearing impairment
				Joint laxity
				Blue sclerae
OI type II	Perinatal lethal	Most autosomal recessive	Abnormally short pro-α1(1) chain	Death in utero or within days of birth
		Some autosomal dominant	Unstable triple helix	Skeletal deformity with excessive fragility and multiple fractures
		?New mutations	Abnormal or insufficient pro-α2(1)	Blue sclera
OI type III	Progressive, deforming	Autosomal dominant (75%)	Altered structure of pro-peptides of pro-α2(1)	Compatible with survival
		Autosomal recessive (25%)	Impaired formation of triple helix	Growth retardation
				Multiple fractures
				Progressive kyphoscoliosis
				Blue sclera at birth that become white
				Hearing impairment
				Dentinogenesis imperfecta
OI type IV	Compatible with survival	Autosomal dominant	Short pro-α2(1) chain	Postnatal fractures, normal sclerae
			Unstable triple helix	Moderate skeletal fragility
				Short stature
				Sometimes dentinogenesis imperfecta

OI, osteogenesis imperfecta.

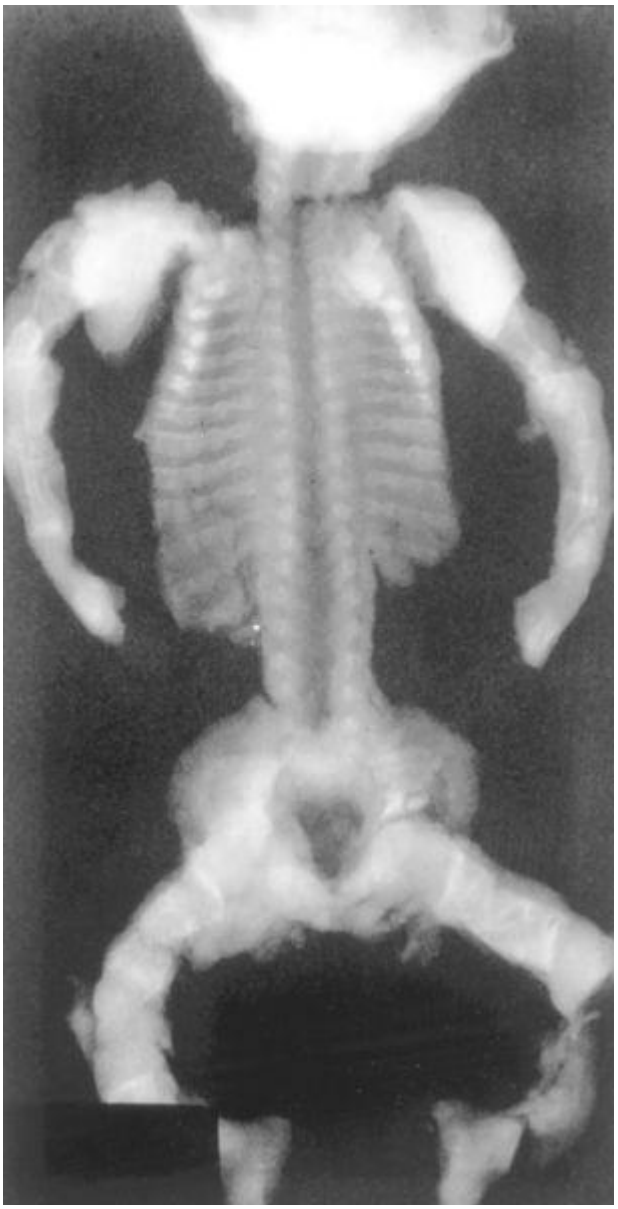

FIGURE 26-6 Skeletal radiogram of a fetus with lethal type II osteogenesis imperfecta. Note the numerous fractures of virtually all bones, resulting in accordion-like shortening of the limbs.

Diseases Associated with Mutations of Types 2, 9, 10, and 11 Collagen

Types 2, 9, 10, and 11 collagens are important structural components of hyaline cartilage. Although uncommon, mutations in the genes encoding them produce an array of disorders ranging from the fatal to those compatible with life but associated with early destruction of joints (see Table 26-2). In the severe disorders, the type 2 collagen molecules are not secreted by the chondrocytes, and insufficient bone formation occurs. In the milder disorders there is reduced synthesis of normal type 2 collagen.

DISEASES ASSOCIATED WITH DEFECTS IN FOLDING AND DEGRADATION OF MACROMOLECULES

Mucopolysaccharidoses

The mucopolysaccharidoses, as discussed earlier (Chapter 5), are a group of lysosomal storage diseases that are caused by deficiencies in the enzymes that degrade dermatan sulfate, heparan sulfate, and keratan sulfate. The affected enzymes are mainly acid hydrolases. Mesenchymal cells, especially chondrocytes, normally metabolize extracellular matrix mucopolysaccharides; hence, cartilage formation is severely affected. Consequently, many of the skeletal manifestations of the mucopolysaccharidoses result from abnormalities in hyaline cartilage, including the cartilage anlage, growth plates, costal cartilages, and articular surfaces. It is not surprising, therefore, that affected individuals are frequently of short stature and have chest wall abnormalities, and malformed bones.

DISEASES ASSOCIATED WITH DEFECTS IN METABOLIC PATHWAYS (ENZYMES, ION CHANNELS, AND TRANSPORTERS)

Osteopetrosis

Osteopetrosis, also known as *marble bone disease* and *Albers-Schönberg disease*, refers to a group of rare genetic diseases that are characterized by reduced bone resorption and diffuse symmetric skeletal sclerosis due to impaired formation or function of osteoclasts (Fig. 26-7). The term *osteopetrosis* reflects the stonelike quality of the bones; however, the bones are abnormally brittle and fracture easily, like a piece of chalk. Osteopetrosis is classified into variants based on both the mode of inheritance and the clinical findings. The two major groups include autosomal recessive and dominant forms. The autosomal recessive type is further divided into mild and severe variants. The autosomal recessive severe type and the autosomal dominant mild type are the most common variants.

FIGURE 26-7 Radiogram of the upper extremity in an individual with osteopetrosis. The bones are diffusely sclerotic, and the distal metaphyses of the ulna and radius are poorly formed *(Erlenmeyer flask deformity).*

Pathogenesis.

Most of the mutations underlying osteopetrosis interfere with the process of acidification of the osteoclast resorption pit, which is required for the dissolution of the calcium hydroxyapatite within the matrix. Examples include autosomal recessive defects in the gene *CA2*, which encodes the enzyme carbonic anhydrase II.[21] Carbonic anhydrase II is required by osteoclasts and renal tubular cells to generate protons from carbon dioxide and water. Absence of CAII prevents osteoclasts from acidifying the resorption pit and solubilizing hydroxyapatite, and also blocks the acidification of urine by the renal tubular cells. In an autosomal recessive severe form of the disease, a mutation in the chloride channel gene *CLCN7* interferes with the function of the H^+-ATPase proton pump located on the osteoclast ruffled border.[21] Another severe autosomal recessive form is caused by a mutation in the gene *TCIRG1*,

which encodes a component of the proton pump. A less severe autosomal recessive variant results from a mutation in the gene that encodes RANKL. Not surprisingly, these individuals have fewer osteoclasts than normal. In animals, osteopetrosis can also be caused by mutations in a large number of other genes, including M-CSF, RANK, and OPG, which you will recall regulate osteoclast formation and function.[21]

Morphology. The morphologic changes of osteopetrosis are explained by deficient osteoclast activity. The bones lack a medullary canal, and the ends of long bones are bulbous (Erlenmeyer flask deformity) and misshapen. The neural foramina are small and compress exiting nerves. The primary spongiosa, which is normally removed during growth, persists and fills the medullary cavity, leaving no room for the hematopoietic marrow and preventing the formation of mature trabeculae (Fig. 26-8). Deposited bone is not remodeled and tends to be woven in architecture. In the end, these intrinsic abnormalities cause the bone to be brittle and predisposed to fracture. Histologically, the number of osteoclasts may be normal, increased, or decreased depending on the underlying genetic defect.

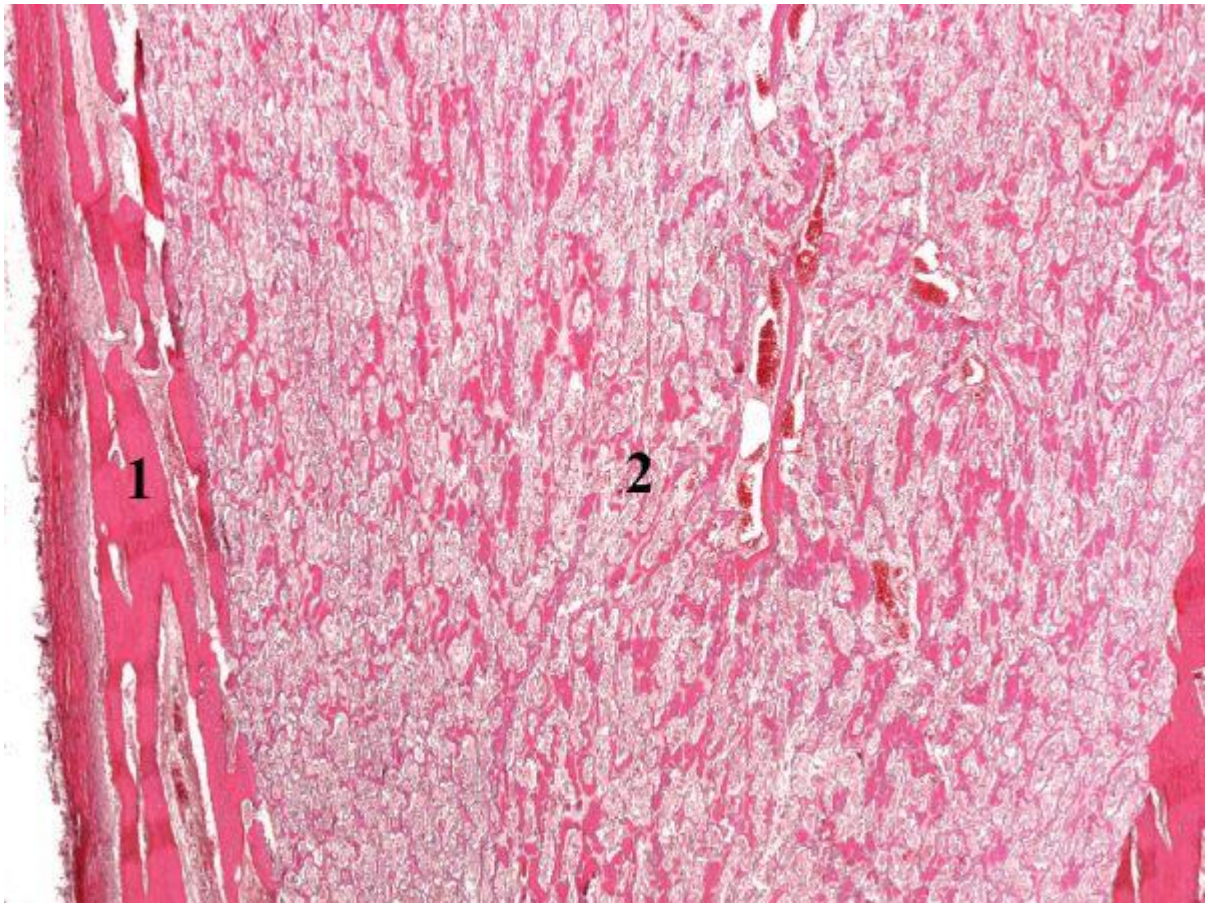

FIGURE 26-8 Section of proximal tibial diaphysis from a fetus with osteopetrosis. The cortex (1) is present, but the medullary cavity (2) is filled with primary spongiosa, which replaces the hematopoietic elements.

Clinical Features.

Severe infantile malignant osteopetrosis is autosomal recessive and usually becomes evident in utero or soon after birth. Fracture, anemia, and hydrocephaly are often seen, resulting in postpartum mortality. Affected individuals who survive into their infancy have cranial nerve defects (optic atrophy, deafness,

and facial paralysis) and repeated—often fatal—infections because of inadequacies of the marrow produced in extramedullary sites, which also causes prominent hepatosplenomegaly. The mild autosomal dominant benign form may not be detected until adolescence or adulthood, when it is discovered on x-rays performed because of repeated fractures. These individuals may also have mild cranial nerve deficits and anemia.

Osteopetrosis was the first genetic disease treated with bone marrow transplantation, since osteoclasts are derived from marrow monocyte precursors. The donor progenitor cells produce normal functioning osteoclasts, which reverse many of the skeletal abnormalities.

DISEASES ASSOCIATED WITH DECREASED BONE MASS

Osteoporosis

Osteoporosis is a disease characterized by porous bones and a reduced bone mass. The associated structural changes predispose the bone to fracture. The disorder may be localized to a certain bone or region, as in *disuse osteoporosis of a limb*, or may involve the entire skeleton, as a manifestation of a *metabolic bone disease*. Generalized osteoporosis, in turn, may be primary or secondary to a large variety of conditions (Table 26-4).

TABLE 26-4 -- Categories of Generalized Osteoporosis

PRIMARY
Postmenopausal
Senile
Idiopathic
SECONDARY
Endocrine Disorders
Hyperparathyroidism
Hyperthyroidism
Hypothyroidism
Hypogonadism
Pituitary tumors
Diabetes, type 1
Addison disease
Neoplasia
Multiple myeloma
Carcinomatosis
Gastrointestinal
Malnutrition
Malabsorption
Hepatic insufficiency
Vitamin C, D deficiencies
Drugs

Anticoagulants
Chemotherapy
Corticosteroids
Anticovulsants
Alcohol
Miscellaneous
Osteogenesis imperfecta
Immobilization
Pulmonary disease
Homocystinuria
Anemia

When the term osteoporosis is used in an unqualified manner, it usually refers to the most common forms, senile and postmenopausal osteoporosis, in which the loss of bone mass makes the skeleton vulnerable to fractures. It is estimated that one million Americans experience a fracture related to osteoporosis each year, at a cost of over 14 billion dollars. Effective treatment and prevention are imperative. The following discussion relates largely to these dominant forms of osteoporosis.

Pathogenesis.

Peak bone mass is achieved during young adulthood. Its magnitude is determined largely by hereditary factors, especially polymorphisms in the genes that influence bone metabolism (discussed later).[22] Physical activity, muscle strength, diet, and hormonal state also make important contributions. Once maximal skeletal mass is attained, a small deficit in bone formation accrues with every resorption and formation cycle of each basic multicellular unit. Accordingly, age-related bone loss, which may average 0.7% per year, is a normal and predictable biologic phenomenon. Both sexes are affected equally and whites more so than blacks. Differences in the peak skeletal mass in men versus women and in blacks versus whites may partially explain why certain populations are prone to develop this disorder.

Although much remains unknown, discoveries in the molecular biology of bone have provided intriguing new hypotheses about the pathogenesis of osteoporosis (Fig. 26-9):

- *Age-related changes* in bone cells and matrix have a strong impact on bone metabolism. Osteoblasts from elderly individuals have reduced proliferative and biosynthetic potential when compared with osteoblasts from younger individuals.[23] Also, proteins bound to the extracellular matrix (such as growth factors, which are both mitogenic to osteoprogenitor cells and stimulate osteoblastic synthetic activity) lose their biologic punch over time. The net result is a diminished capacity to make bone. This form of osteoporosis, known as *senile osteoporosis*, is categorized as a *low-turnover variant*.
- *Reduced physical activity* increases the rate of bone loss in experimental animals and humans, because mechanical forces stimulate normal bone remodeling. Bone loss in an immobilized or paralyzed extremity, the reduction of skeletal mass in astronauts in a zero gravity environment for prolonged periods, and the higher bone density in athletes exemplify the role of physical activity in preventing bone loss. The type of exercise is important, as load magnitude influences bone density more than the number of load cycles. Because muscle contraction is the dominant source of skeletal loading, resistance exercises such as weight training are more effective stimuli for increasing bone mass than repetitive endurance activities such as jogging. Certainly the decreased physical activity that is associated with aging contributes to senile osteoporosis.

- *Genetic factors are also important*, as noted previously. It is estimated that 60% to 80% of the variation in bone density is genetically determined. In genome-wide association studies (GWAS), the top associated genes include *RANKL*, *OPG*, and *RANK*,[24] which you will recall encode key regulators of osteoclasts. Also associated are the MHC locus (perhaps reflecting the effects of inflammation on calcium metabolism) and the estrogen receptor gene (discussed below). Some studies have also implicated genetic variants of the vitamin D receptor and LRP5 as risk factors.
- The body's *calcium nutritional state* is important. It has been shown that adolescent girls (but not boys) tend to have insufficient calcium intake in the diet. This calcium deficiency occurs during a period of rapid bone growth, stunting the peak bone mass ultimately achieved; thus, these individuals are at greater risk of developing osteoporosis. Calcium deficiency, increased PTH concentrations, and reduced levels of vitamin D may also have a role in the development of senile osteoporosis.
- *Hormonal influences*. In the decade after menopause, yearly reductions in bone mass may reach up to 2% of cortical bone and 9% of cancellous bone. Women may lose as much as 35% of their cortical bone and 50% of their trabecular bone within the 30 to 40 years after menopause. It is thus no surprise that post-menopausal women suffer osteoporotic fractures more commonly than men of the same age. *Postmenopausal* osteoporosis is characterized by a hormone-dependent acceleration of bone loss that occurs during the decade after menopause. *Estrogen deficiency plays the major role in this phenomenon, and estrogen replacement at menopause is protective against bone loss*. The effects of estrogen on bone mass are mediated by cytokines. Decreased estrogen levels appear to result in increased secretion of inflammatory cytokines by blood monocytes and bone marrow cells. These cytokines stimulate osteoclast recruitment and activity by increasing the levels of RANKL while diminishing the expression of OPG. Compensatory osteoblastic activity occurs, but it does not keep pace, leading to what is classified as a *high-turnover form* of osteoporosis.

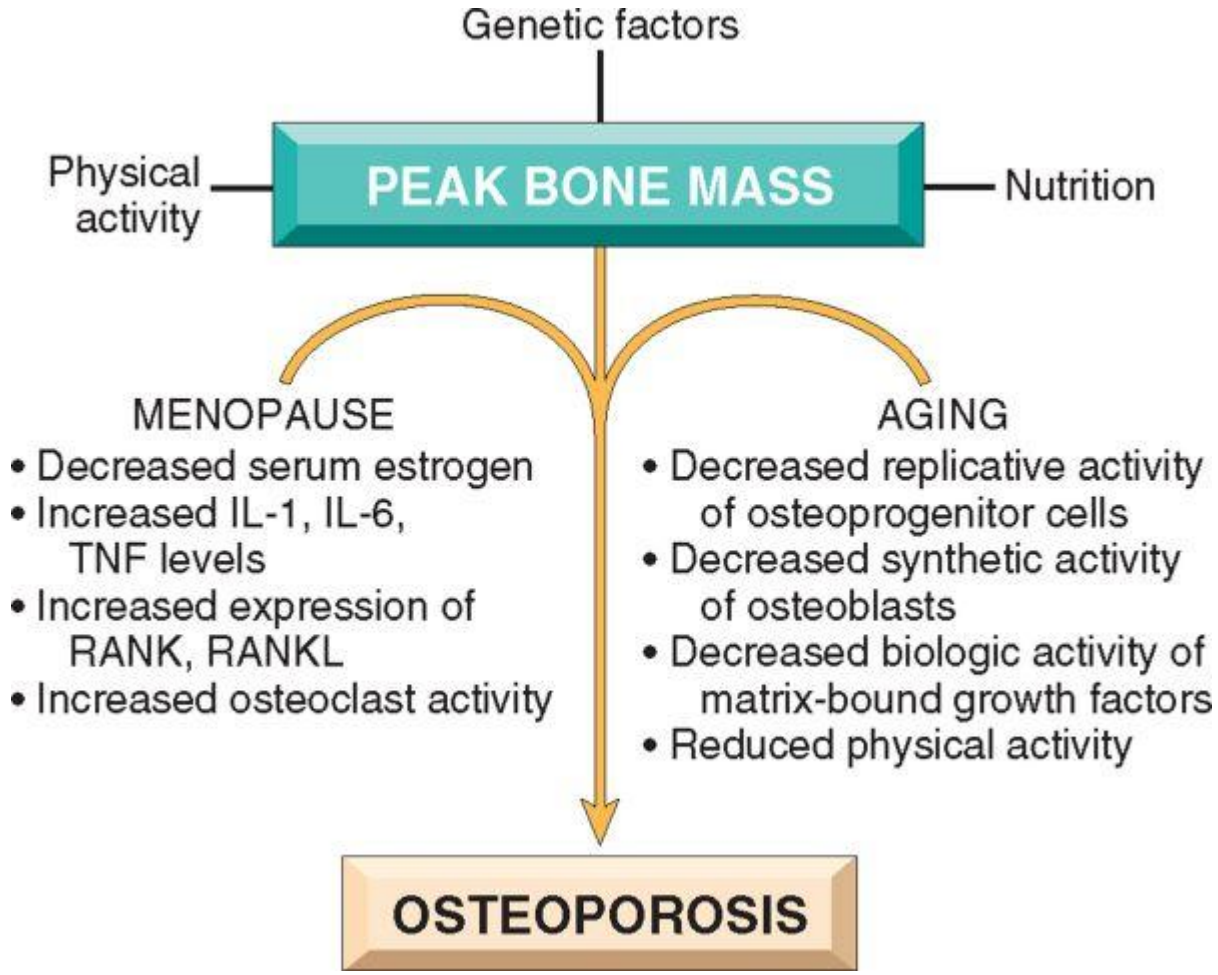

FIGURE 26-9 Pathophysiology of postmenopausal and senile osteoporosis (see text).

Morphology. The entire skeleton is affected in postmenopausal and senile osteoporosis (Fig. 26-10), but certain regions tend to be more severely involved than others. In **postmenopausal** osteoporosis the increase in osteoclast activity affects mainly bones or portions of bones that have increased surface area, such as the cancellous compartment of vertebral bodies. The trabecular plates become perforated, thinned, and lose their interconnections, leading to progressive microfractures and eventual vertebral collapse. In senile osteoporosis the cortex is thinned by subperiosteal and endosteal resorption, and the haversian systems are widened. In severe cases the haversian systems are so enlarged that the cortex mimics cancellous bone. The bone that remains is of normal composition.

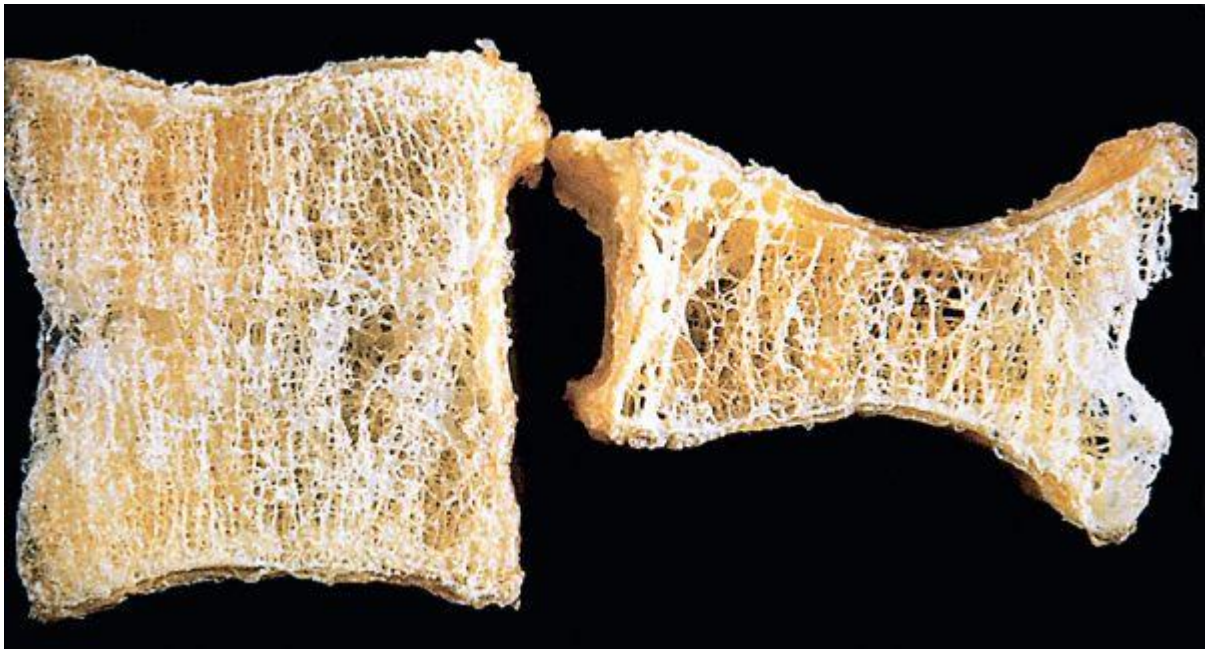

FIGURE 26-10 Osteoporotic vertebral body *(right)* shortened by compression fractures compared with a normal vertebral body. Note that the osteoporotic vertebra has a characteristic loss of horizontal trabeculae and thickened vertical trabeculae.

Clinical Course.

The clinical manifestations of osteoporosis depend on which bones are involved. Vertebral fractures that frequently occur in the thoracic and lumbar regions are painful, and when multiple can cause significant loss of height and various deformities, including lumbar lordosis and kyphoscoliosis. Complications of fractures of the femoral neck, pelvis, or spine, such as pulmonary embolism and pneumonia, are frequent and result in 40,000 to 50,000 deaths per year.

Osteoporosis cannot be reliably detected in plain radiograms until 30% to 40% of the bone mass is lost, and measurement of blood levels of calcium, phosphorus, and alkaline phosphatase are not diagnostic. Osteoporosis is thus a difficult condition to diagnose accurately, since it remains asymptomatic until skeletal fragility is well advanced. The best procedures to accurately estimate the amount of bone loss, aside from biopsy, are specialized radiographic imaging techniques, such as dual-energy X-ray absorptiometry and quantitative computed tomography, which measure bone density.

The prevention and treatment of senile and postmenopausal osteoporosis includes exercise, appropriate calcium and vitamin D intake, and pharmacologic agents, most commonly bisphosphonates, which bind to bone and inhibit osteoclasts.

DISEASES CAUSED BY OSTEOCLAST DYSFUNCTION

Paget Disease (Osteitis Deformans)

This unique skeletal disease can be divided into three phases; *(1) an initial osteolytic stage, followed by (2) a mixed osteoclastic-osteoblastic stage, which ends with a predominance of osteoblastic activity and evolves ultimately into (3) a burnt-out quiescent osteosclerotic stage* (Fig. 26-11). The net effect is a *gain in bone mass*; however, the newly formed bone is disordered and architecturally unsound.

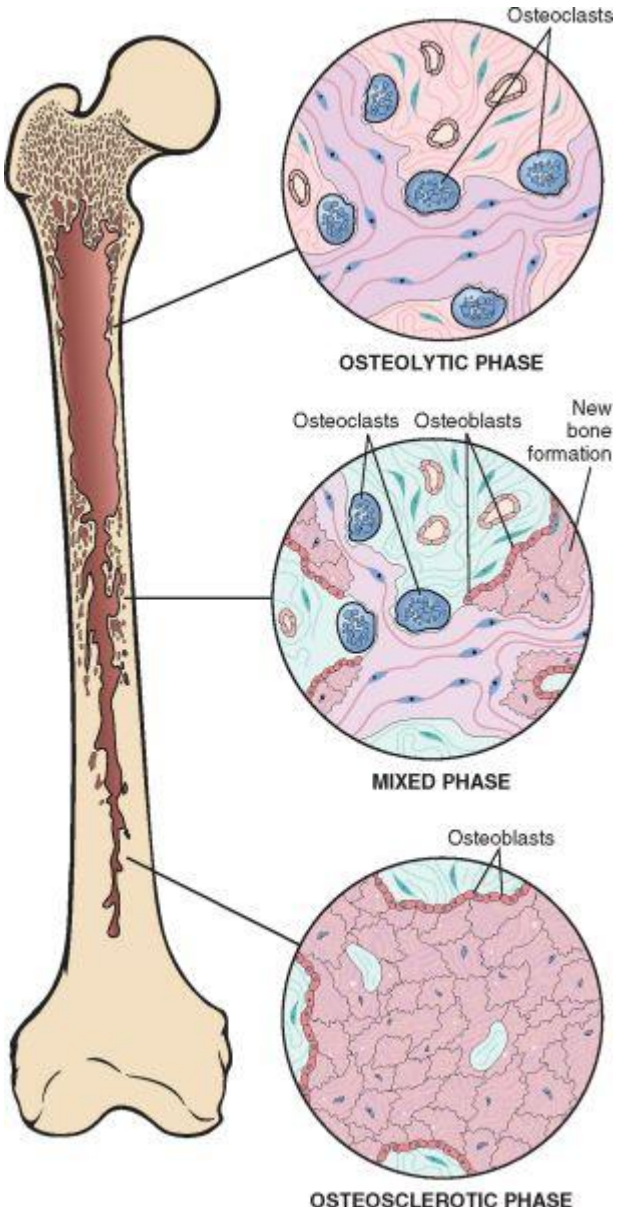

FIGURE 26-11 Diagrammatic representation of Paget disease of bone demonstrating the three phases in the evolution of the disease.

Paget disease usually begins in late adulthood (average age at diagnosis, 70 years) and becomes progressively more common thereafter. An intriguing aspect is the striking variation in its prevalence, both within certain countries and throughout the world. Paget disease is relatively common in whites in England, France, Austria, regions of Germany, Australia, New Zealand, and the United States. In contrast, Paget disease is rare in the native populations of Scandinavia, China, Japan, and Africa. The exact incidence is hard to determine because many affected individuals are asymptomatic; it is estimated that 1% of the US population over the age of 40 is affected and the prevalence rate in England is 2.5% for men and 1.6% for women 55 years or older. Recent surveys show that there has been a fall in new cases over the last 25–30 years, and a decline in its clinical severity.

Pathogenesis.

The cause of Paget disease remains uncertain, and current evidence suggests both environmental and genetic factors. The risk of developing the disorder is approximately seven times greater in first-degree relatives of affected individuals than it is in normal controls,[25] and 15% to 40% of individuals with Paget disease have a family history that shows an autosomal dominant pattern of inheritance. Mutations in the *SQSTM1* gene are present in 40% to 50% of cases of familial Paget disease, and in 5% to 10% of patients without a family history. The *SQSTM* mutations enhance NF-κB activation by RANK signaling, leading to increased osteoclast activity and an increased susceptibility to the disease. Mutations in *RANKL* and *RANK/OPG* have also been found in genetic diseases that have some phenotypic overlap with Paget disease; including familial expansile osteolysis, expansile skeletal hyperphosphatasia, early-onset Paget disease, juvenile Paget disease, and the syndrome of hereditary inclusion body myopathy, and frontotemporal dementia.

When Sir James Paget first described this condition in 1876, he attributed the skeletal changes to an inflammatory process, hence the term *osteitis deformans*. Support for this idea over the years has centered on a possible role for infection by a paramyxovirus, but this hypothesis remains unproven.

Morphology. Paget disease is a focal process that shows remarkable histologic variation over time and from site to site. The hallmark is the **mosaic pattern** of lamellar bone. This pattern, which is likened to a jigsaw puzzle, is produced by prominent cement lines that anneal haphazardly oriented units of lamellar bone (Fig. 26-12). In the initial lytic phase there are waves of osteoclastic activity and numerous resorption pits. The osteoclasts are abnormally large and have many more than the normal 10 to 12 nuclei; sometimes 100 nuclei are present. Osteoclasts persist in the mixed phase, but now many of the bone surfaces are lined by prominent osteoblasts. The marrow adjacent to the bone-forming surface is replaced by loose connective tissue that contains osteoprogenitor cells and numerous blood vessels, which transport nutrients and catabolites to and from these metabolically active sites. The newly formed bone may be woven or lamellar, but eventually all of it is remodeled into lamellar bone. As the mosaic pattern unfolds and the cell activity decreases, the periosseous fibrovascular tissue recedes and is replaced by normal marrow. In the end, the bone becomes a caricature of itself: larger than normal and composed of coarsely thickened trabeculae and cortices that are soft and porous and lack structural stability. These aspects make the bone vulnerable to deformation under stress; consequently, it fractures easily.

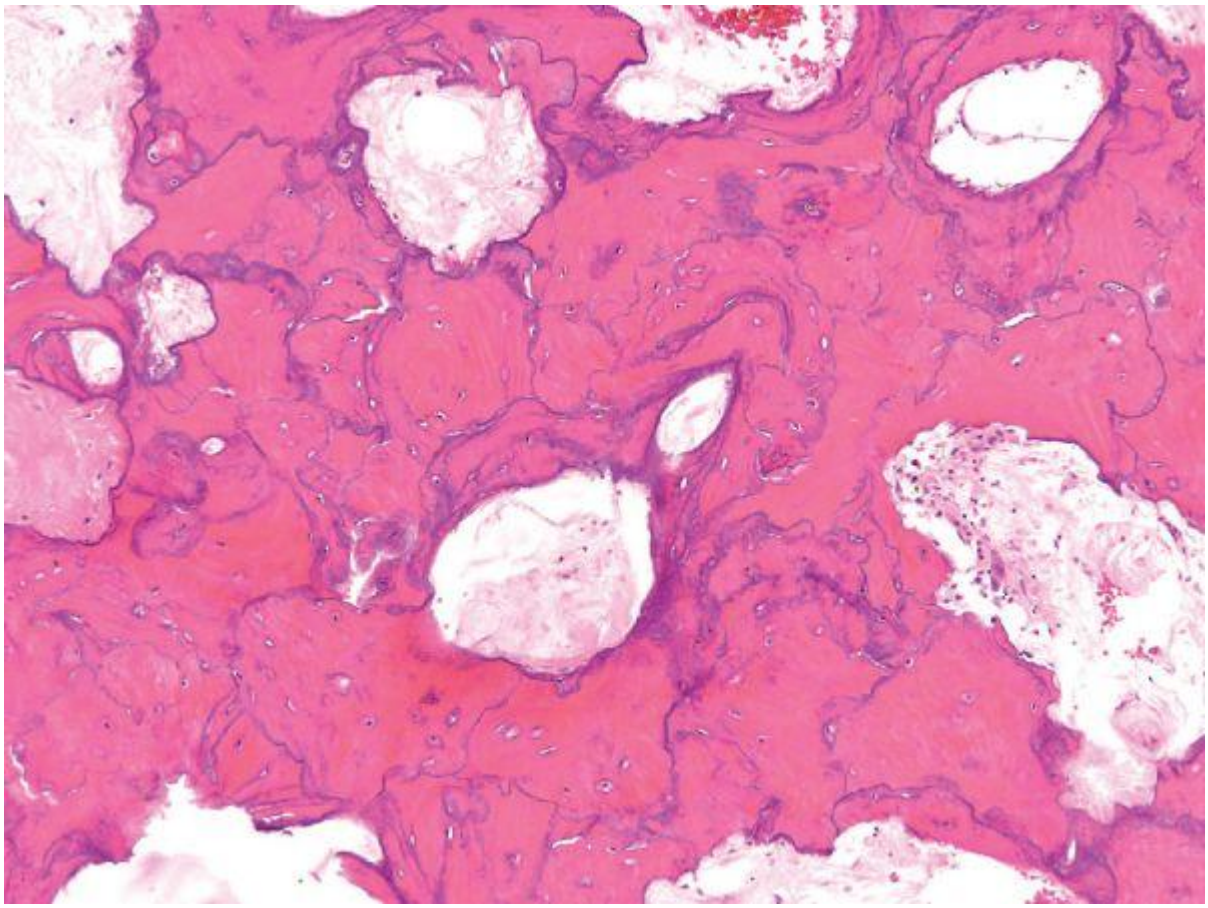

FIGURE 26-12 Mosaic pattern of lamellar bone pathognomonic of Paget disease.

Clinical Course.

Clinical findings are extremely variable and depend on the extent and site of the disease. Most cases are mild and are discovered as an incidental radiographic finding. Paget disease is monostotic in about 15% of cases and polyostotic in the remainder. The axial skeleton or proximal femur is involved in up to 80% of cases. Even though no bone is immune, involvement of the ribs, fibula, and small bones of the hands and feet is unusual.

Pain localized to the affected bone is common. It is caused by microfractures or by bone overgrowth that compresses spinal and cranial nerve roots. Enlargement of the craniofacial skeleton may produce *leontiasis ossea* and a cranium so heavy that is difficult for the person to hold the head erect. The weakened pagetic bone may lead to invagination of the skull base *(platybasia)* and compression of the posterior fossa structures. Weight bearing causes anterior bowing of the femurs and tibiae and distorts the femoral heads, resulting in the development of *severe secondary osteoarthritis*. *Chalkstick-type* fractures are another frequent complication and usually occur in the long bones of the lower extremities. Compression fractures of the spine result in spinal cord injury and the development of kyphoses. The hypervascularity of pagetic bone warms the overlying skin, and in severe polyostotic disease the increased blood flow acts like an arteriovenous shunt, leading to high-output heart failure or exacerbation of underlying cardiac disease.

A variety of tumor and tumor-like conditions develop in pagetic bone. The benign lesions include giant-cell tumor, giant-cell reparative granuloma, and extra-osseous masses of hematopoiesis. The most dreaded complication is sarcoma, which occurs in 0.7% to 0.9% of all individuals with Paget disease, and in 5% to 10% of those with severe polyostotic disease. The sarcomas are usually osteosarcoma or fibrosarcoma, and they arise in Paget lesions in the long bones, pelvis, skull, and spine.

The diagnosis can frequently be made from the radiographic findings. Pagetic bone is typically enlarged with thick, coarsened cortices and cancellous bone(Fig. 26-13). Active disease has a wedge-shaped lytic leading edge that may progress along the length of the bone at a rate of 1 cm per year.[26] Many affected individuals have elevated serum alkaline phosphatase levels and increased urinary excretion of hydroxyproline.

FIGURE 26-13 Severe Paget disease. The tibia is bowed and the affected portion is enlarged, sclerotic, and exhibits irregular thickening of both the cortical and cancellous bone.

In the absence of malignant transformation, Paget disease is usually not a serious or life-threatening disease. Most affected individuals have mild symptoms that are readily suppressed by calcitonin and bisphosphonates.

DISEASES ASSOCIATED WITH ABNORMAL MINERAL HOMEOSTASIS

Rickets and Osteomalacia

Rickets and osteomalacia are disorders characterized by a defect in matrix mineralization, most often related to a lack of vitamin D or some disturbance in its metabolism. The term *rickets* refers to the disorder in children in which deranged bone growth produces distinctive skeletal deformities. In the adult the disorder is called *osteomalacia*, because the bone that forms during the remodeling process is inadequately mineralized. This results in osteopenia and predisposition to insufficiency fractures. Both rickets and osteomalacia are discussed in Chapter 9 .

Hyperparathyroidism

Hyperparathyroidism is classified into primary and secondary types as discussed in Chapter 24 . Primary hyperparathyroidism results from autonomous hyperplasia or a tumor, usually an adenoma, of the parathyroid gland, whereas secondary hyperparathyroidism is commonly caused by prolonged states of hypocalcemia resulting in compensatory hypersecretion of PTH. Whatever the basis, the increased PTH concentrations are detected by receptors on osteoblasts, which then release factors that stimulate osteoclast activity. Thus, through a chain of signals, the skeletal manifestations of hyperparathyroidism are caused by unabated osteoclastic bone resorption. The following points should be noted:

- Similar to all metabolic bone disease, the entire skeleton is affected in hyperparathyroidism, even though some sites are more severely affected than others.
- The anatomic changes of severe hyperparathyroidism, known as *osteitis fibrosa cystica*, are now rarely encountered, because hyperparathyroidism is usually diagnosed and treated at an early asymptomatic stage detected on routine blood tests.
- Secondary hyperparathyroidism is usually not as severe or as prolonged as primary hyperparathyroidism, hence the skeletal abnormalities tend to be milder.

Morphology. For unknown reasons, the increased osteoclast activity in hyperparathyroidism affects cortical bone (subperiosteal, osteonal, and endosteal surfaces) more severely than cancellous bone. Subperiosteal resorption produces thinned cortices and the loss of the lamina dura around the teeth. X-rays reveal a pattern of radiolucency that is virtually diagnostic of hyperparathyroidism. In cancellous bone, osteoclasts tunnel into and dissect centrally along the length of the trabeculae, creating the appearance of railroad tracks and producing what is known as **dissecting osteitis** (Fig. 26-14). The correlative radiographic finding is a decrease in bone density or osteopenia. Since bone resorption and formation are coupled processes, it is not surprising that osteoblast activity is also increased in hyperparathyroidism. The marrow spaces around the affected surfaces are replaced by fibrovascular tissue.

The bone loss predisposes to microfractures and secondary hemorrhages that elicit an influx of macrophages and an ingrowth of reparative fibrous tissue, creating a mass of reactive tissue, known as a **brown tumor** (Fig. 26-15). The brown color is the result of the vascularity, hemorrhage, and hemosiderin deposition, and it is not uncommon for the lesions to undergo cystic degeneration. The combined picture of increased bone cell activity, peritrabecular fibrosis, and cystic brown tumors is the hallmark of severe hyperparathyroidism and is known as **generalized osteitis fibrosa cystica (von Recklinghausen disease of bone)**.

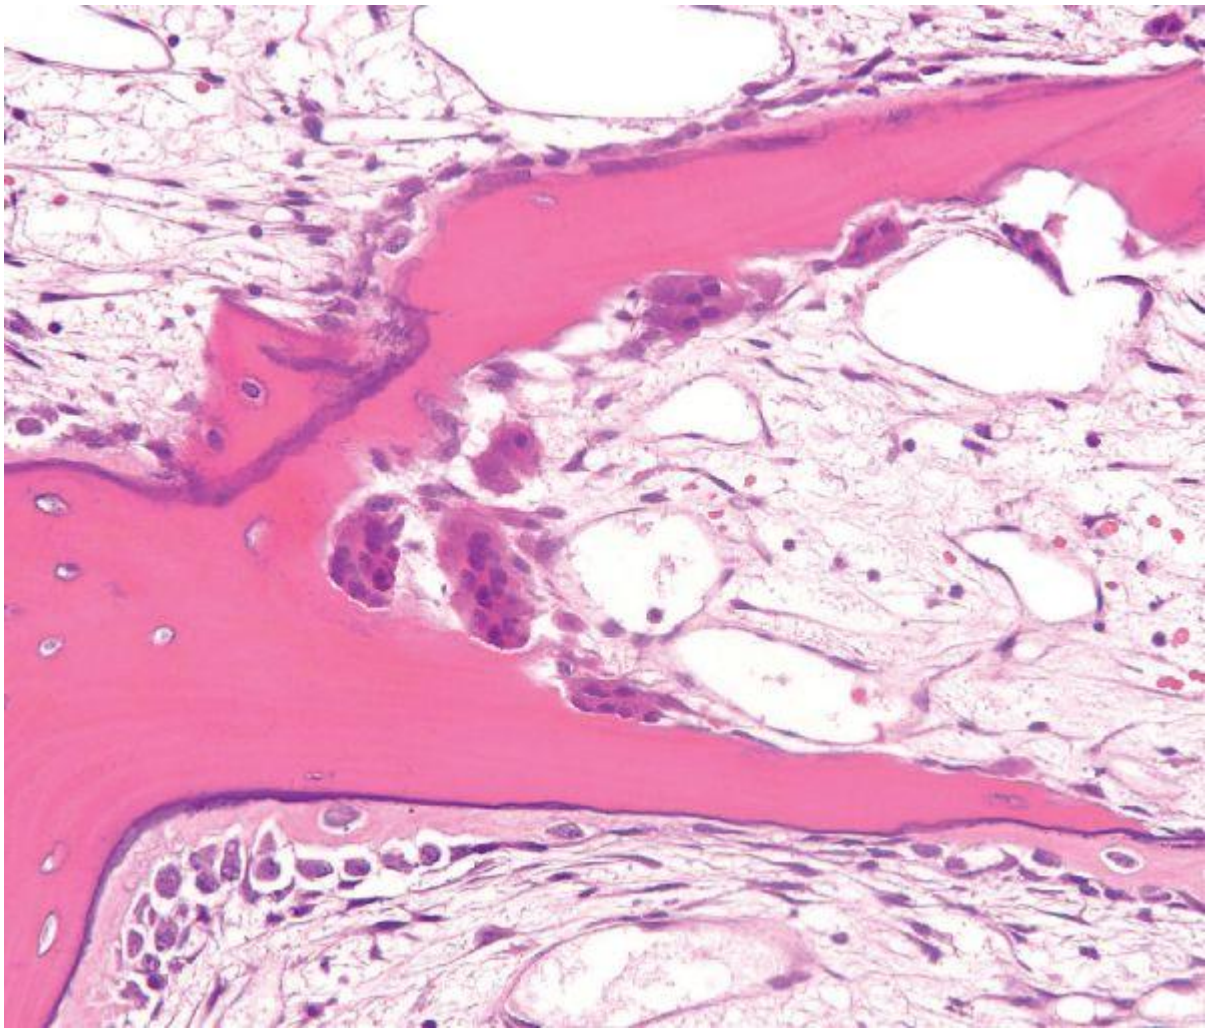

FIGURE 26-14 Hyperparathyroidism with osteoclasts boring into the center of the trabeculum (dissecting osteitis).

FIGURE 26-15 Resected rib, harboring an expansile brown tumor adjacent to the costal cartilage.

The decrease in bone mass predisposes to fractures, deformities caused by the stress of weight bearing, and joint pain and dysfunction as the lines of normal weight bearing are altered. Control of the hyperparathyroidism allows the bony changes to regress significantly or disappear completely.

Renal Osteodystrophy

The term *renal osteodystrophy* is used to describe collectively all of the skeletal changes of chronic renal disease, including (1) increased osteoclastic bone resorption mimicking osteitis fibrosa cystica, (2) delayed matrix mineralization (osteomalacia), (3) osteosclerosis, (4) growth retardation, and (5) osteoporosis. As advances in medical technology have prolonged the lives of individuals with renal disease, its impact on skeletal homeostasis has assumed greater clinical importance.

The various histologic bone changes in individuals with end-stage renal failure can be divided into three major types of disorders.[27] *High-turnover osteodystrophy* is characterized by increased bone resorption and bone formation, with the former predominating. In contrast, *low-turnover or aplastic disease* is manifested by adynamic bone (little osteoclastic and osteoblastic activity) and, less commonly, osteomalacia. Many affected individuals have the third type, which is a mixed pattern of disease.

Pathogenesis.

The pathogenesis of the various skeletal lesions can be summarized as follows:

- Chronic renal failure results in *phosphate retention* and hyperphosphatemia.
- Hyperphosphatemia, in turn, induces *secondary hyperparathyroidism*, because phosphate seems to regulate PTH secretion directly.
- Hypocalcemia develops as the levels of vitamin D (1,25-dihydroxyvitamin D_3; 1,25-$(OH)_2D_3$) fall because of

decreased conversion from the vitamin D metabolite 25-$(OH)D_3$ by damaged kidneys; inhibition of the renal hydroxylase involved in the conversion of 25-$(OH)D_3$ to the more active metabolite 1,25-$(OH)_2D_3$ by the high levels of phospate; and reduced intestinal absorption of calcium because of low levels of 1,25-$(OH)_2D_3$.

- PTH secretion markedly increases at all levels of serum calcium. 1,25-$(OH)_2D_3$ suppresses *PTH* gene expression and secretion; in renal failure there is a decrease in the binding of 1,25-$(OH)_2D_3$ to parathyroid cells; and there is decreased degradation and excretion of PTH because of compromised renal function.
- The resultant *secondary hyperparathyroidism* produces increased osteoclast activity.
- *Metabolic acidosis* associated with renal failure stimulates bone resorption and the release of calcium hydroxyapatite from the matrix.
- Other factors that are important in the genesis of adynamic renal osteodystrophy are diabetes mellitus, high dietary calcium ingestion, increasing age, and iron accumulation in bone and aluminum deposition at the site of mineralization. *Aluminum deposition*, in particular, has received a great deal of attention in the past because of its iatrogenic origin. The sources of the aluminum include dialysis solutions prepared from water with a high aluminum content and oral aluminum-containing phosphate binders. Aluminum interferes with the deposition of calcium hydroxyapatite and hence results in osteomalacia. Aluminum is not only toxic to bone but also has been implicated as the cause of dialysis encephalopathy and microcytic anemia in individuals with chronic renal failure.
- A complication that may be seen in association with hemodialysis is the deposition of *amyloid* in bone and periarticular structures. The amyloid is formed from β_2-microglobulin, which is increased in the blood of individuals who undergo long-term hemodialysis (Chapter 6).

3.16.1.4 Fractures

Traumatic and nontraumatic fractures are some of the most common pathologic conditions affecting bone. Fractures are classified as *complete* or *incomplete*; *closed (simple)* when the overlying tissue is intact; *compound* when the fracture site *communicates* with the skin surface; *comminuted* when the bone is splintered; or *displaced* when the ends of the bone at the fracture site are not aligned. If the break occurs in bone already altered by a disease process, it is described as a *pathologic fracture*. A *stress fracture* is a slowly developing fracture that follows a period of increased physical activity in which the bone is subjected to new repetitive loads—as in sports training or marching in military boot camp.

Bone is unique in its ability to repair itself; it can completely reconstitute itself by reactivating processes that normally occur during embryogenesis. This process involves regulated expression of a multitude of genes and can be separated into overlapping stages with particular molecular, biochemical, histologic, and biomechanical features, described next.

- Immediately after fracture, rupture of blood vessels results in a hematoma, which fills the fracture gap and surrounds the area of bone injury. The clotted blood provides a fibrin mesh, which helps seal off the fracture site and at the same time creates a framework for the influx of inflammatory cells and ingrowth of fibroblasts and new capillary vessels. Simultaneously, degranulated platelets and migrating inflammatory cells release PDGF, TGF-β, FGF, and interleukins, which activate the osteoprogenitor cells in the periosteum, medullary cavity, and surrounding soft tissues and stimulate osteoclastic and osteoblastic activity.[28] Thus, by the end of the first week the hematoma is organizing, the adjacent tissue is being modulated for future matrix production, and the fractured ends of the bones are being remodeled. This fusiform and predominantly uncalcified tissue—called *soft-tissue callus or procallus*—provides some anchorage between the ends of the fractured bones but offers no structural rigidity for weight bearing.
- Subsequently, the activated osteoprogenitor cells deposit subperiosteal trabeculae of woven bone that are oriented perpendicular to the cortical axis and within the medullary cavity. In some cases the activated mesenchymal cells in the soft tissues and bone surrounding the fracture line also differentiate into chondroblasts that make fibrocartilage and hyaline cartilage. In an uncomplicated fracture, the repair tissue reaches its maximal girth at the end of the second or third week, which helps stabilize the fracture site. The newly formed cartilage along the fracture line undergoes enchondral ossification, such as normally occurs at the growth plate, forming a network of bone that connects to the reactive trabeculae deposited elsewhere in the medullary cavity and beneath the periosteum. In this fashion the fractured ends are bridged by a *bony*

callus, and as it mineralizes the stiffness and strength of the callus increases to the point that controlled weight bearing can be tolerated (Fig. 26-16).

- In the early stages of callus formation an excess of fibrous tissue, cartilage, and bone is produced. If the bones are not perfectly aligned, the volume of callus is greatest in the concave portion of the fracture site. As the callus matures and is subjected to weight-bearing forces, the portions that are not physically stressed are resorbed, and in this manner the callus is reduced in size until the shape and outline of the fractured bone have been re-established. The medullary cavity is also restored, and after this has been completed it may be impossible to demonstrate the site of previous injury.

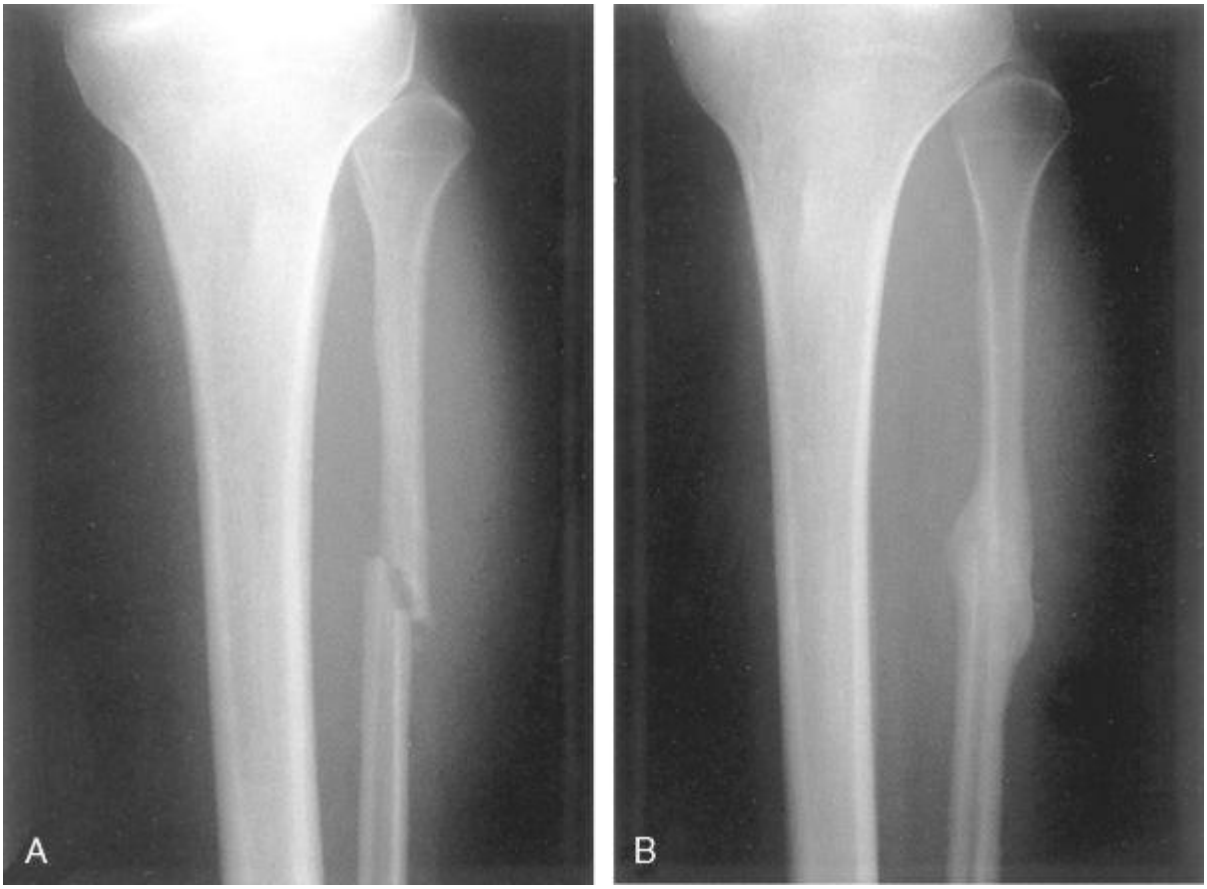

FIGURE 26-16 A, Recent fracture of the fibula. **B**, Marked callus formation 6 weeks later. *(Courtesy of Dr. Barbara Weissman, Brigham and Women's Hospital, Boston, MA.)*

The sequence of events in the healing of a fracture can be easily impeded or even blocked. For example, displaced and comminuted fractures frequently result in some deformity, and inadequate immobilization permits constant movement at the fracture site, so that the normal constituents of callus do not form, resulting in delayed union and nonunion. If a nonunion allows too much motion along the fracture gap, the central portion of the callus undergoes cystic degeneration, and the luminal surface can actually become lined by synovial-like cells, creating a false joint or *pseudoarthrosis*. A serious obstacle to healing is *infection* of the fracture site, which is a risk in comminuted and open fractures. The infection must be eradicated before bony union can be achieved.

Generally, with children and young adults, in whom most uncomplicated fractures are found, near perfect reconstitution is the norm. In older age groups in whom fractures tend to occur on a background of some other disease (e.g., osteoporosis and osteomalacia), repair is more often imperfect and may require mechanical immobilization (e.g., placement of stabilizing pins).

3.16.1.5 Osteonecrosis (Avascular Necrosis)

Infarction of bone and marrow is a relatively common event that can occur in the medullary cavity of the metaphysis or diaphysis and the subchondral region of the epiphysis. Ischemia underlies all forms of bone necrosis, which can occur in the setting of diverse predisposing conditions (Table 26-5) or as an isolated, idiopathic event. Aside from fracture, most cases of bone necrosis either are idiopathic or follow corticosteroid administration.

TABLE 26-5 -- Conditions Associated with Osteonecrosis

Trauma
Corticosteroid administration
Infection
Dysbarism (e.g., the “bends”)
Radiation therapy
Connective tissue disorders
Pregnancy
Gaucher disease
Sickle cell and other anemias
Alcohol abuse
Chronic pancreatitis
Tumors
Epiphyseal disorders

Morphology. Medullary infarcts are geographic and involve the cancellous bone and marrow. The cortex is usually not affected because of its collateral blood flow. In subchondral infarcts, a triangular or wedge-shaped segment of tissue that has the subchondral bone plate as its base undergoes necrosis. The overlying articular cartilage remains viable becauseit receives nutrition from the synovial fluid. The dead bone, recognized by its empty lacunae, is surrounded by necrotic adipocytes that frequently rupture, releasing their fatty acids, which bind calcium and form insoluble calcium soaps that may persist for life. In the healing response, osteoclasts resorb the necrotic trabeculae; however, those that remain act as scaffolding for the deposition of new bone in a process known as **creeping substitution**. In subchondral infarcts the pace of this substitution is too slow to be effective, so there is eventual collapse of the necrotic cancellous bone and distortion, fracture, and even sloughing of the articular cartilage (Fig. 26-17).

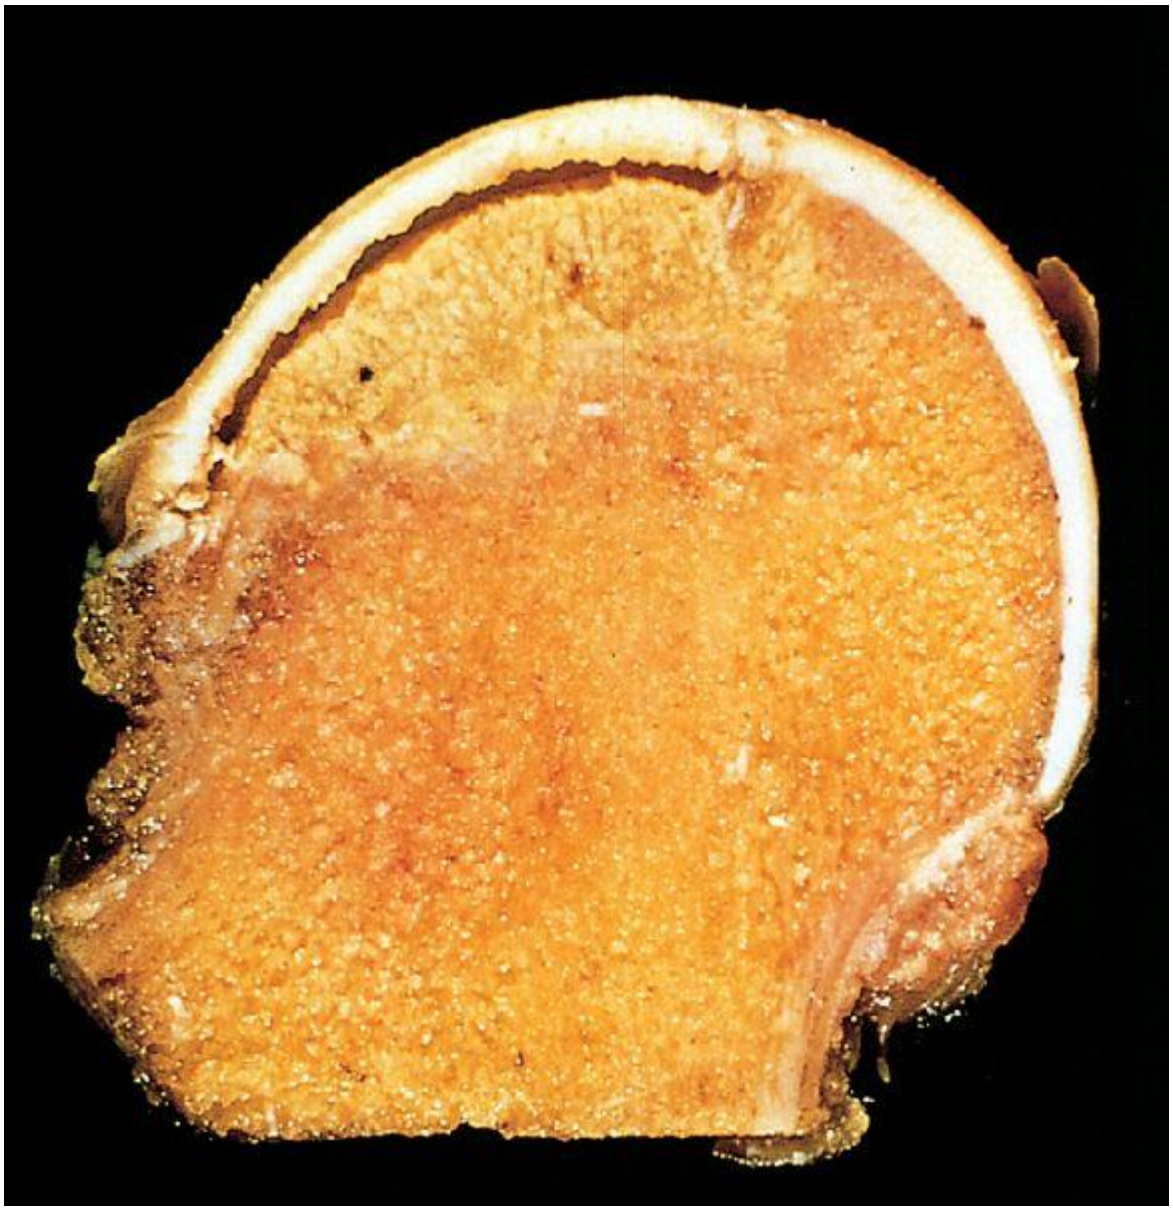

FIGURE 26-17 Femoral head with a subchondral, wedge-shaped pale yellow area of osteonecrosis. The space between the overlying articular cartilage and bone is caused by trabecular compression fractures without repair.

Clinical Course.

The symptoms depend on the location and extent of infarction. Typically, subchondral infarcts cause chronic pain that is initially associated only with activity but then becomes progressively more constant as secondary changes supervene. In contrast, medullary infarcts are clinically silent except for large ones occurring in Gaucher disease, dysbarism, and sickle cell anemia. Medullary infarcts usually remain stable over time. Subchondral infarcts, however, often collapse and may predispose to severe, secondary osteoarthritis. More than 10% of the 500,000 joint replacements performed annually in the United States are for treatment of the complications of osteonecrosis.

3.16.1.6 Infections: Osteomyelitis

Osteomyelitis denotes inflammation of bone and marrow, and the common use of the term virtually always implies infection. Osteomyelitis may be a complication of any systemic infection but frequently manifests as a primary solitary focus of disease. All types of organisms, including viruses, parasites, fungi, and bacteria, can produce osteomyelitis, but infections caused by certain pyogenic bacteria and mycobacteria are the most common. Currently in the United States, exotic infections in third world immigrants and opportunistic infections in immunosuppressed individuals have made the diagnosis and treatment of osteomyelitis quite challenging.

PYOGENIC OSTEOMYELITIS

Pyogenic osteomyelitis is almost always caused by bacteria. Organisms may reach the bone by (1) hematogenous spread, (2) extension from a contiguous site, and (3) direct implantation. In otherwise healthy children, most cases of osteomyelitis are hematogenous in origin and develop in the long bones.[30] The initiating bacteremia may stem from seemingly trivial injuries to the mucosa, such as may occur during defecation or vigorous chewing of hard foods, or minor infections of the skin. In adults, however, osteomyelitis more often occurs as a complication of open fractures, surgical procedures, and diabetic infections of the feet.[31]

Staphylococcus aureus is responsible for 80% to 90% of the cases of pyogenic osteomyelitis in which an organism is recovered. These organisms express receptors for bone matrix components such as collagen, which facilitates their adherence to bone tissue. *Escherichia coli*, *Pseudomonas*, and *Klebsiella* are more frequently isolated from individuals with genitourinary tract infections or who are intravenous drug abusers. Mixed bacterial infections are seen in the setting of direct spread or inoculation of organisms during surgery or open fractures. In the neonatal period, *Haemophilus influenzae* and group B streptococci are frequent pathogens, and individuals with sickle cell disease are predisposed to *Salmonella* infection. In almost 50% of cases, no organisms can be isolated.

The location of the infection within a bone is influenced by the osseous vascular circulation, which varies with age. In the neonate the metaphyseal vessels penetrate the growth plate, resulting in frequent infection of the metaphysis, epiphysis, or both. In children, localization of microorganisms in the metaphysis is typical. After growth plate closure, the metaphyseal vessels reunite with their epiphyseal counterparts and provide a route for the bacteria to seed the epiphyses and subchondral regions in the adult.

Morphology. The morphologic changes of osteomyelitis depend on the stage (acute, subacute, or chronic) and location of the infection. Once in bone, the bacteria proliferate and induce an acute inflammatory reaction. The entrapped bone undergoes necrosis within the first 48 hours, and the bacteria and inflammation spread within the shaft of the bone and may percolate throughout the haversian systems to reach the periosteum. In children the periosteum is loosely attached to the cortex; sizable **subperiosteal** abscesses may form that can track for long distances along the bone surface. Lifting of the periosteum further impairs the blood supply to the affected region, and both the suppurative and the ischemic injury may cause segmental bone necrosis; the dead piece of bone is known as a **sequestrum**. Rupture of the periosteum leads to a soft-tissue abscess and the eventual formation of a **draining sinus**. Sometimes the sequestrum crumbles and forms free foreign bodies that pass through the sinus tract.

In infants, but uncommonly in adults, epiphyseal infection spreads through the articular surface or along capsular and tendoligamentous insertions into a joint, producing septic or suppurative arthritis,

which can cause destruction of the articular cartilage and permanent disability. An analogous process involves the vertebrae, in which the infection destroys the hyaline cartilage end plate and intervertebral disc and spreads into adjacent vertebrae.

After the first week chronic inflammatory cells become more numerous and their release of cytokines stimulates osteoclastic bone resorption, ingrowth of fibrous tissue, and the deposition of reactive bone in the periphery. When the newly deposited bone forms a sleeve of living tissue around the segment of devitalized infected bone, it is known as an **involucrum** (Fig. 26-18). Several morphologic variants of osteomyelitis have eponyms: **Brodie abscess** is a small intraosseous abscess that frequently involves the cortex and is walled off by reactive bone; **sclerosing osteomyelitis of Garré** typically develops in the jaw and is associated with extensive new bone formation that obscures much of the underlying osseous structure.

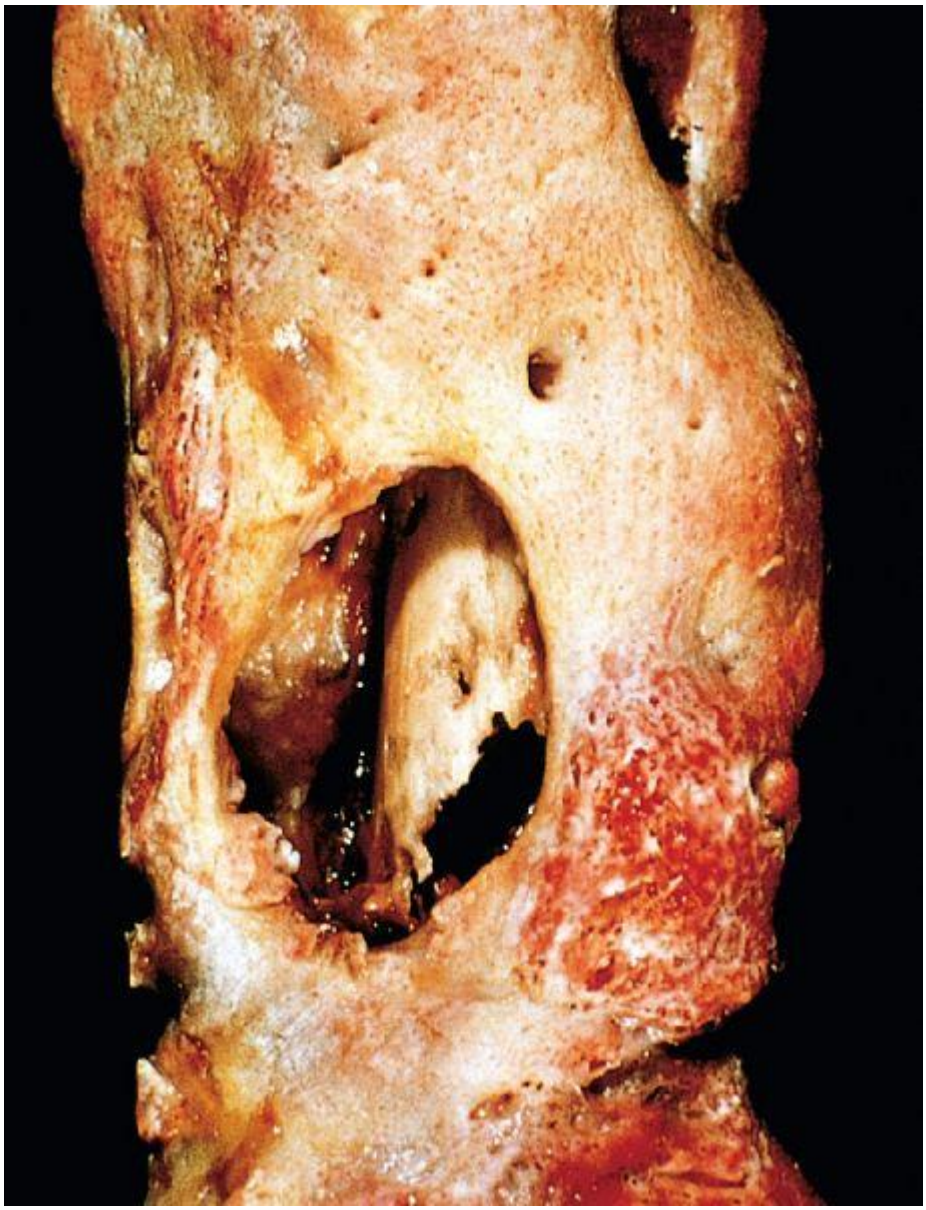

FIGURE 26-18 Resected femur in a person with draining osteomyelitis. The drainage tract in the subperiosteal shell of viable new bone *(involucrum) reveals the inner native necrotic cortex (sequestrum).*

Clinical Course.

Clinically, hematogenous osteomyelitis may manifest as an acute systemic illness with malaise, fever, chills, leukocytosis, and marked-to-intense throbbing pain over the affected region. The presentation may be subtler with only unexplained fever, particularly in infants, or only localized pain in the absence of fever in the adult. The diagnosis can be strongly suggested by the characteristic radiographic findings of a lytic focus of bone destruction surrounded by a zone of sclerosis. In many untreated cases blood cultures are positive, but biopsy and bone cultures are required to identify the pathogen in most instances. The combination of antibiotics and surgical drainage is usually curative.In 5% to 25% of cases, acute osteomyelitis fails to resolve and persists as chronic infection. Chronicity may develop when there is delay in diagnosis, extensive bone necrosis, inadequate antibiotic therapy or surgical debridement, and weakened host defenses. Acute flare-ups may mark the clinical course of chronic infection and are usually spontaneous, have no obvious cause, and may occur after years of dormancy. Other complications of chronic osteomyelitis include pathologic fracture, secondary amyloidosis, endocarditis, sepsis, development of squamous cell carcinoma in the sinus tract, and rarely sarcoma in the infected bone.

TUBERCULOUS OSTEOMYELITIS

A resurgence of tuberculous osteomyelitis is occurring in developed countries, attributed to the influx of immigrants from countries where tuberculosis is endemic, and the greater numbers of immunosuppressed people (Chapter 8). In developing countries the affected individuals are usually adolescents or young adults, whereas in the indigenous population of the United States they tend to be older, except for those who are immunosuppressed. Approximately 1% to 3% of individuals with pulmonary or extrapulmonary tuberculosis have osseous infection.

The organisms are usually blood borne and originate from a focus of active visceral disease during the initial stages of primary infection. Direct extension (e.g., from a pulmonary focus into a rib or from tracheobronchial nodes into adjacent vertebrae) or spread via draining lymphatics may also occur. The bony infection is usually solitary and in some cases may be the only manifestation of the disease that may fester for years before being recognized. Individuals with acquired immunodeficiency syndrome frequently have multifocal bone involvement.

The spine (40% of cases, especially the thoracic and lumbar vertebrae) followed by the knees and hips are the most common sites of skeletal involvement.[32] Tuberculous osteomyelitis tends to be more destructive and resistant to control than pyogenic osteomyelitis. In the spine *(Pott disease)* the infection breaks through intervertebral discs to involve multiple vertebrae and extends into the soft tissues forming abscesses. The histologic findings are typical of tuberculosis elsewhere (Chapter 8).

Typically, affected individuals present with pain on motion, localized tenderness, low-grade fevers, chills, and weight loss. Severe destruction of vertebrae frequently results in permanent compression fractures that produce severe scoliotic or kyphotic deformities and neurologic deficits secondary to spinal cord and nerve compression. Other complications of tuberculous osteomyelitis include tuberculous arthritis, sinus tract formation, psoas abscess, and amyloidosis.

SKELETAL SYPHILIS

Syphilis *(Treponema pallidum)* and yaws *(Treponema pertenue)* both can involve bone. Currently, syphilis is experiencing a resurgence; however, bone involvement remains infrequent because the disease is usually diagnosed and treated before this complication develops.

In congenital syphilis the bone lesions begin to appear about the fifth month of gestation and are fully developed at birth. The spirochetes tend to localize in areas of active enchondral ossification (osteochondritis) and in the periosteum (periostitis). In acquired syphilis bone disease may begin early in the tertiary stage, which is usually 2 to 5 years after the initial infection. The bones most frequently involved are those of the nose, palate, skull, and extremities, especially the long tubular bones such as the tibia. The syphilitic *saber shin* is produced by massive reactive periosteal bone deposition on the medial and anterior surfaces of the tibia.

Morphology. Syphilitic bone infection is characterized by edematous granulation tissue containing numerous plasma cells and necrotic bone. Typical gummas may also form in both congenital and acquired syphilis (Chapter 8). The spirochetes can be demonstrated in the inflammatory tissue with special silver stains.

3.16.1.7 Bone Tumors & Tumor-Like Lesions

Bone tumors are diverse in their gross and morphologic features, and vary in their natural history from innocuous to the rapidly fatal. It is critical to diagnose these tumors correctly, stage them accurately, and treat them appropriately, so that affected patients not only survive, but also maintain optimal function of the affected body parts.

Most bone tumors are classified according to the normal cell or tissue type they recapitulate. Lesions that do not have normal tissue counterparts are grouped according to their distinct clinicopathologic features (Table 26-6). Overall, matrix-producing and fibrous tumors are the most common, and among the benign tumors, osteochondroma and fibrous cortical defect are most frequent. Excluding malignant neoplasms of marrow origin (myeloma, lymphoma, and leukemia), osteosarcoma is the most common primary cancer of bone, followed by chondrosarcoma and Ewing sarcoma.

TABLE 26-6 -- Classification of Major Primary Tumors Involving Bones

Histologic Type	Benign	Malignant
Hematopoietic (40%)		Myeloma Malignant lymphoma
Chondrogenic (22%)	Osteochondroma Chondroma Chondroblastoma Chondromyxoid fibroma	Chondrosarcoma Dedifferentiated chondrosarcoma Mesenchymal chondrosarcoma
Osteogenic (19%)	Osteoid osteoma Osteoblastoma	Osteosarcoma
Fibrogenic	Fibrous cortical defect (fibroma) Non-ossifying fibroma	Fibrosarcoma

Histologic Type	Benign	Malignant
	Fibrous histiocytoma Desmoplastic fibroma	
Unknown origin (10%)	Giant-cell tumor Unicameral cyst Aneurysmal bone cyst	
Neuroectodermal		Ewing sarcoma
Notochordal	Benign notochordal cell tumor	Chordoma

Data on percentage of each type from Unni KK: Dahlin's Bone Tumors, 5th ed. Philadelphia, Lippincott-Raven, 1996, p 4; by permission of Mayo Foundation.

The precise incidence of specific bone tumors is not known, because many benign lesions are not biopsied. Benign tumors greatly outnumber their malignant counterparts and occur with greatest frequency within the first three decades of life, whereas in the elderly a bone tumor is likely to be malignant. In the United States about 2400 new cases of bone sarcoma are diagnosed annually, and approximately 1300 deaths from bone sarcoma occur each year.

As a group these neoplasms affect all ages and arise in virtually every bone, but most develop during the first several decades of life and have a propensity to originate in the long bones of the extremities. However, specific types of tumors target certain age groups and anatomic sites. Thus, the location of a tumor provides important diagnostic information.

Although the cause of most bone tumors is unknown, genetic alterations similar to those that occur in other tumors clearly play a role. For instance, bone sarcomas occur in the Li-Fraumeni and hereditary retinoblastoma cancer syndromes, which are linked to mutations in the genes encoding p53 and RB (Chapter 7). Bone infarcts, chronic osteomyelitis, Paget disease, radiation, and metal prostheses are also associated with a bone neoplasia. Such secondary neoplasms, however, account for only a small fraction of skeletal tumors.

Clinically, bone tumors present in various ways. The more common benign lesions are frequently asymptomatic and are detected as incidental findings. Many tumors, however, produce pain or are noticed as a slow-growing mass. In some circumstances the first hint of a tumor's presence is a sudden pathologic fracture. Radiologic imaging studies have an important role in diagnosing these lesions. In addition to providing the exact location and extent of the tumor, imaging studies can detect features that help limit diagnostic possibilities and give clues to the aggressiveness of the tumor. Ultimately, in most instances, biopsy and histologic study are necessary.

BONE-FORMING TUMORS

Common to all these neoplasms is the production of bone by the neoplastic cells. The tumor bone is usually deposited as woven trabeculae (except in osteomas) and is variably mineralized.

Osteoma

Osteomas are bosselated, round-to-oval sessile tumors that project from the subperiosteal surface of the cortex. They most often arise on or inside the skull and facial bones. They are usually solitary and are detected in middle age. Multiple osteomas are seen in the setting of *Gardner syndrome* (Chapter 17).

They consist of a composite of woven and lamellar bone that is frequently deposited in a cortical pattern with haversian-like systems. Some variants contain a component of trabecular bone in which the intertrabecular spaces are filled with hematopoietic marrow.

Osteomas are generally slow-growing tumors of little clinical significance except when they cause obstruction of a sinus cavity, impinge on the brain or eye, interfere with function of the oral cavity, or produce cosmetic problems.

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma and *osteoblastoma* are terms used to describe benign bone tumors that have identical histologic features but differ in size, sites of origin, and symptoms. *Osteoid osteomas* are by definition less than 2 cm in greatest dimension and usually occur in the teens and 20s. Seventy-five percent of affected individuals are younger than 25 years old, and men outnumber women 2 : 1. They can arise in any bone but have a predilection for the appendicular skeleton and posterior elements of the spine. In 50% of cases the femur or tibia is involved, wherein they commonly arise in the cortex and less frequently within the medullary cavity. Osteoid osteomas produce severe nocturnal pain that is relieved by aspirin.[33] The pain is probably caused by excess prostaglandin E_2 (PGE_2) production by the proliferating osteoblasts. *Osteoblastoma* is larger than 2 cm and involves the spine more frequently; the pain is dull, achy, and unresponsive to salicylates, and the tumor usually does not induce a marked bony reaction.

Morphology. Osteoid osteoma and osteoblastoma are round-to-oval masses of hemorrhagic gritty tan tissue. They are well circumscribed and composed of randomly interconnecting trabeculae of woven bone that are prominently rimmed by osteoblasts (Fig. 26-19). The stroma surrounding the neoplastic bone consists of loose connective tissue that contains many dilated and congested capillaries. The relatively small size, well-defined margins, and benign cytologic features of the neoplastic osteoblasts help distinguish these tumors from osteosarcoma. Osteoid osteomas, especially those that arise beneath the periosteum, usually elicit a tremendous amount of reactive bone formation that encircles the lesion. The actual tumor, known as the **nidus**, manifests radiographically as a small round lucency that may be centrally mineralized (Fig. 26-20).

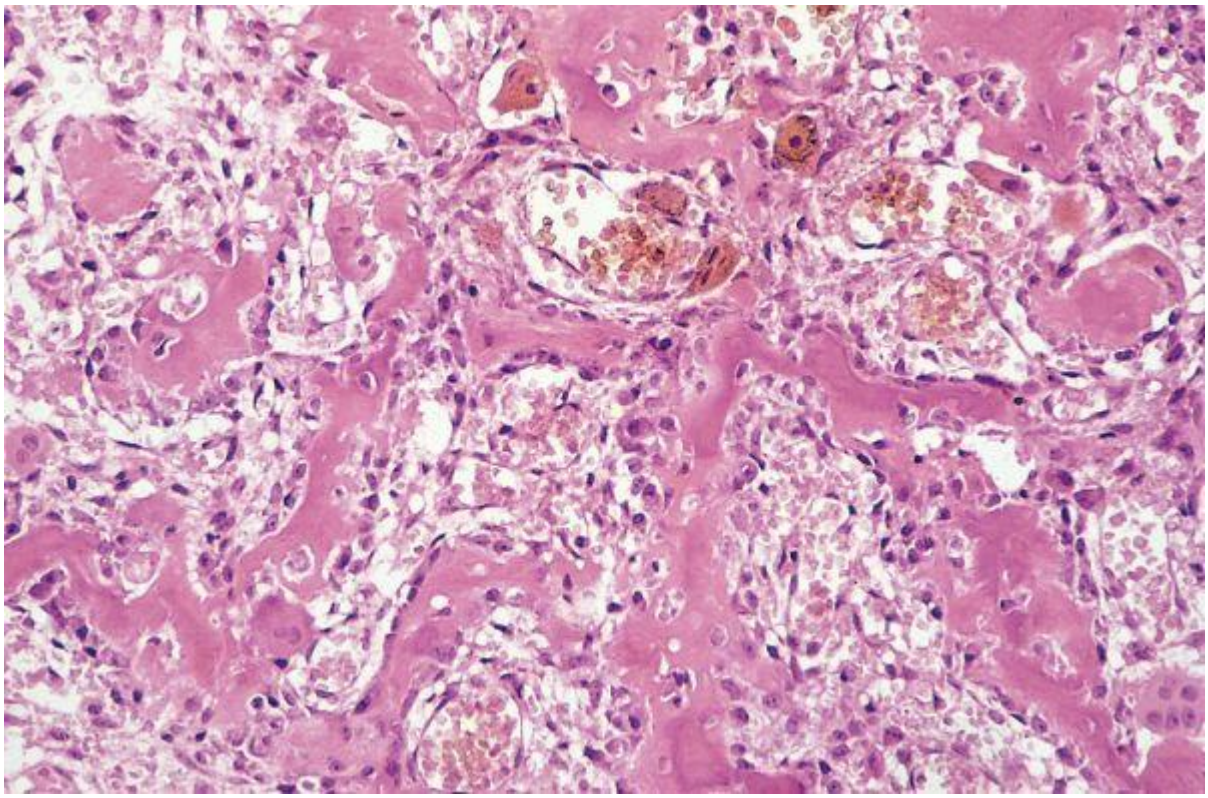

FIGURE 26-19 Osteoid osteoma composed of haphazardly interconnecting trabeculae of woven bone that are rimmed by prominent osteoblasts. The intertrabecular spaces are filled by vascularized loose connective tissue.

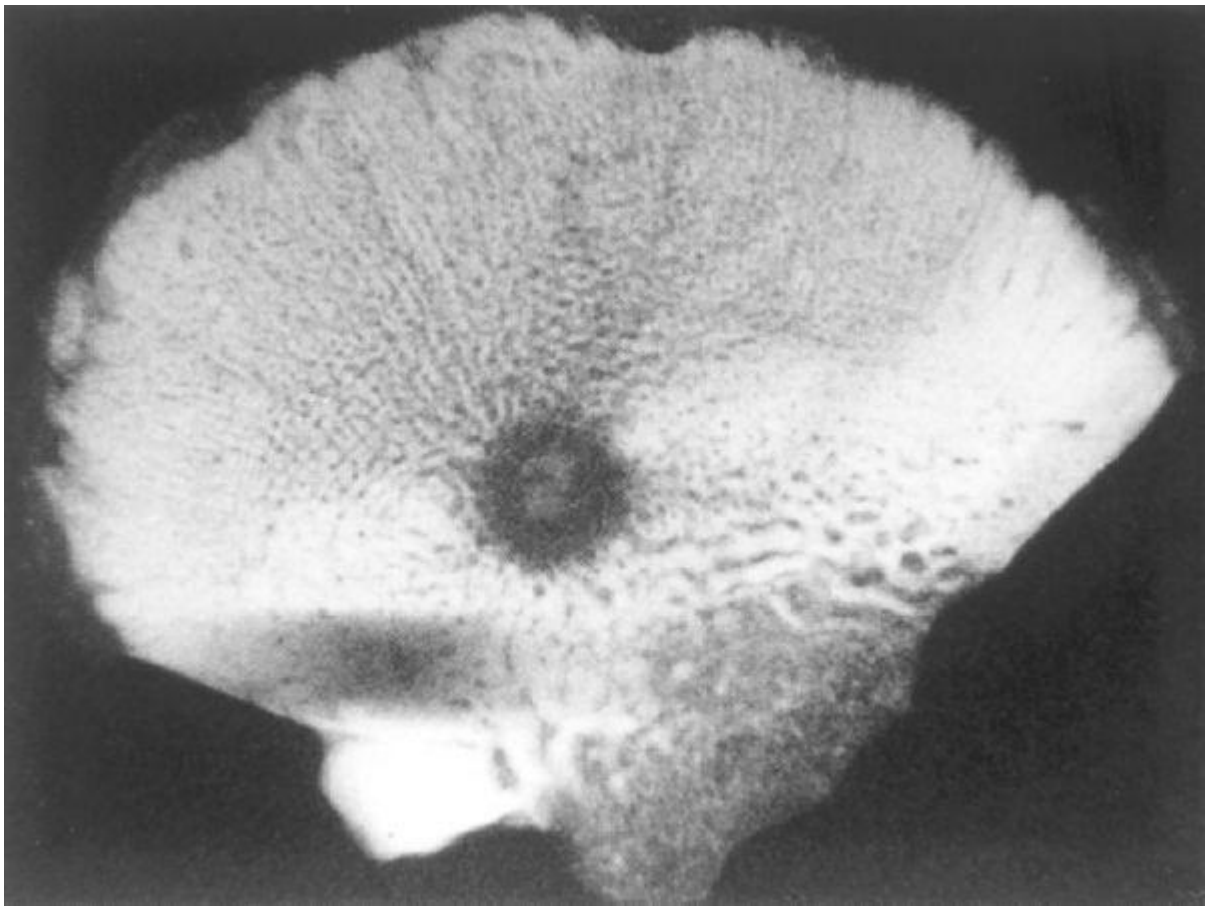

FIGURE 26-20 Specimen radiogram of intracortical osteoid osteoma. The round radiolucency with central mineralization represents the lesion and is surrounded by abundant reactive bone that has massively thickened the cortex.

Osteoid osteoma is frequently treated by radioablation. Osteoblastoma is usually curetted or excised en bloc in a conservative fashion. The possibility of malignant transformation is remote except when osteoblastoma is treated with radiation (large tumors in the base of the skull and spine), which may promote this dreaded complication.

Osteosarcoma

Osteosarcoma is a malignant mesenchymal tumor in which the cancerous cells produce bone matrix. It is the most common primary malignant tumor of bone, exclusive of myeloma and lymphoma, and accounts for approximately 20% of primary bone cancers. Osteosarcoma occurs in all age groups but has a bimodal age distribution; 75% occur in persons younger than 20 years of age.[34] The smaller second peak occurs in the elderly, who frequently suffer from conditions known to predispose to osteosarcoma—Paget disease, bone infarcts, and prior irradiation. Overall, men are more commonly affected than women (1.6 : 1). The tumors usually arise in the metaphyseal region of the long bones of the extremities, and almost 50% occur about the knee (Fig. 26-21). Any bone can be involved, however, and in persons beyond the age of 25, the incidence in flat bones and long bones is almost equal.

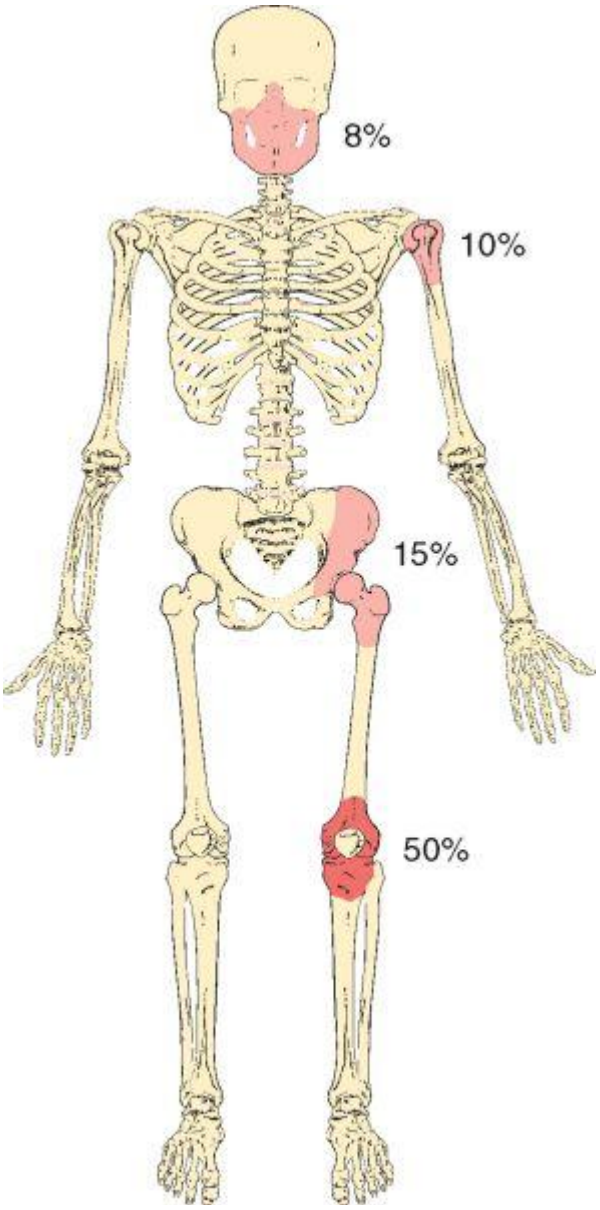

FIGURE 26-21 Major sites of origin of osteosarcomas. The numbers are approximate percentages arising at each site.

Pathogenesis.

Approximately 70% of osteosarcomas have acquired genetic abnormalities such as ploidy changes and chromosomal aberrations, none of which are specific to this tumor. More telling is the presence of very frequent mutations that interfere with function of two genes: (1) *RB*, the retinoblastoma gene, a critical cell cycle regulator; and (2) *p53*, a gene whose product regulates DNA repair and certain aspects of cellular metabolism (Chapter 7). Although the basic mechanisms that cause the development of osteosarcoma are still unknown, it is clear that defects in RB and p53 play important roles in the process. This association is emphasized by rare patients with germline mutations in *RB*, who have a roughly 1000-fold increased risk of osteosarcoma; and similarly by patients with Li-Fraumeni syndrome (germline p53 mutations), who also have a greatly elevated incidence of this tumor. Abnormalities in *INK4a*, which encodes p16 (a cell cycle regulator) and p14 (which aids and abets p53 function), also are seen in osteosarcoma. It is also noteworthy that osteosarcomas tend to occur at sites of bone growth,

presumably because proliferation makes osteoblastic cells prone to acquire mutations that could lead to transformation. The association may contribute to the high incidence of osteosarcoma in large dog breeds, such as St. Bernards and Great Danes.

Morphology. Several subtypes of osteosarcoma are recognized and are grouped according to

- Site of origin (intramedullary, intracortical, or surface)
- Degree of differentiation
- Multicentricity (synchronous, metachronous)
- Primary (underlying bone is unremarkable) or secondary to preexisting disorders such as benign tumors, Paget disease, bone infarcts, previous irradiation
- Histologic features (osteoblastic, chondroblastic, fibroblastic, telangiectatic, small cell, and giant cell).

The most common subtype arises in the metaphysis of long bones and is primary, solitary, intramedullary, and poorly differentiated.

Grossly, osteosarcomas are big bulky tumors that are gritty, gray-white, and often contain areas of hemorrhage and cystic degeneration (Fig. 26-22). The tumors frequently destroy the surrounding cortices and produce soft-tissue masses. They spread extensively in the medullary canal, infiltrating and replacing the marrow surrounding the preexisting bone trabeculae. Infrequently, they penetrate the epiphyseal plate or enter the joint. When joint invasion occurs, the tumor grows into it along tendoligamentous structures or through the attachment site of the joint capsule. The tumor cells vary in size and shape and frequently have large hyperchromatic nuclei. Bizarre tumor giant cells are common, as are mitoses. **The formation of bone by the tumor cells is characteristic** (Fig. 26-23). The neoplastic bone usually hasa coarse, lace-like architecture but also may be deposited in broad sheets or as primitive trabeculae. Other matrices, including cartilage or fibrous tissue, may be present in varying amounts. When malignant cartilage is abundant, the tumor is called **chondroblastic osteosarcoma**. Vascular invasion is usually conspicuous, and up to 50% to 60% of an individual tumor may be necrotic.

FIGURE 26-22 Osteosarcoma of the upper end of the tibia. The tan-white tumor fills most of the medullary cavity of the metaphysis and proximal diaphysis. It has infiltrated through the cortex, lifted the periosteum, and formed soft-tissue masses on both sides of the bone.

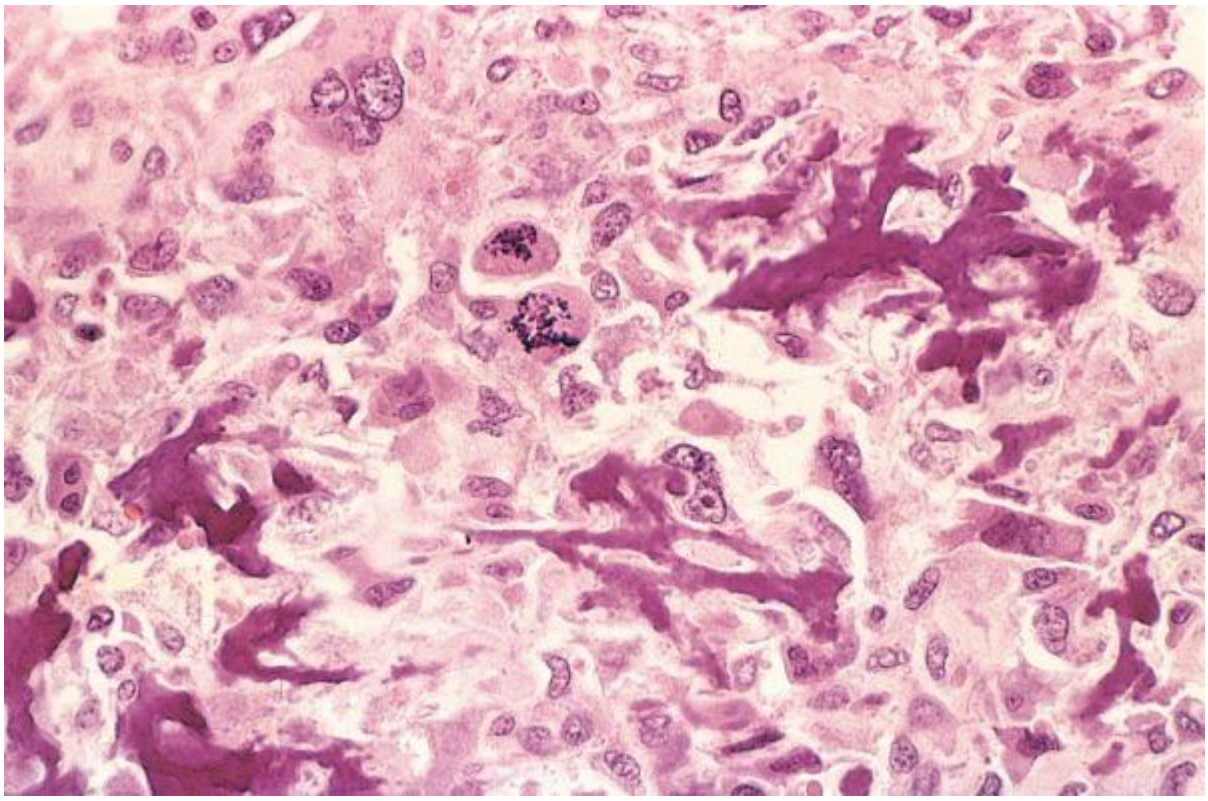

FIGURE 26-23 Coarse, lacelike pattern of neoplastic bone produced by anaplastic malignant tumor cells. Note the mitotic figures.

Clinical Course.

Osteosarcomas typically present as painful, progressively enlarging masses. Sometimes a sudden fracture of the bone is the first symptom. Radiograms of the primary tumor usually show a large destructive, mixed lytic and blastic mass with infiltrative margins (Fig. 26-24). The tumor frequently breaks through the cortex and lifts the periosteum, resulting in reactive periosteal bone formation. The triangular shadow between the cortex and raised ends of periosteum is known radiographically as *Codman triangle* and is characteristic but not diagnostic of this tumor. These aggressive neoplasms spread hematogenously, and at the time of diagnosis approximately 10% to 20% of affected individuals have demonstrable pulmonary metastases, and it is likely that many more have occult metastases. In those who die of the neoplasm, 90% have metastases to the lungs, bones, brain, and elsewhere.

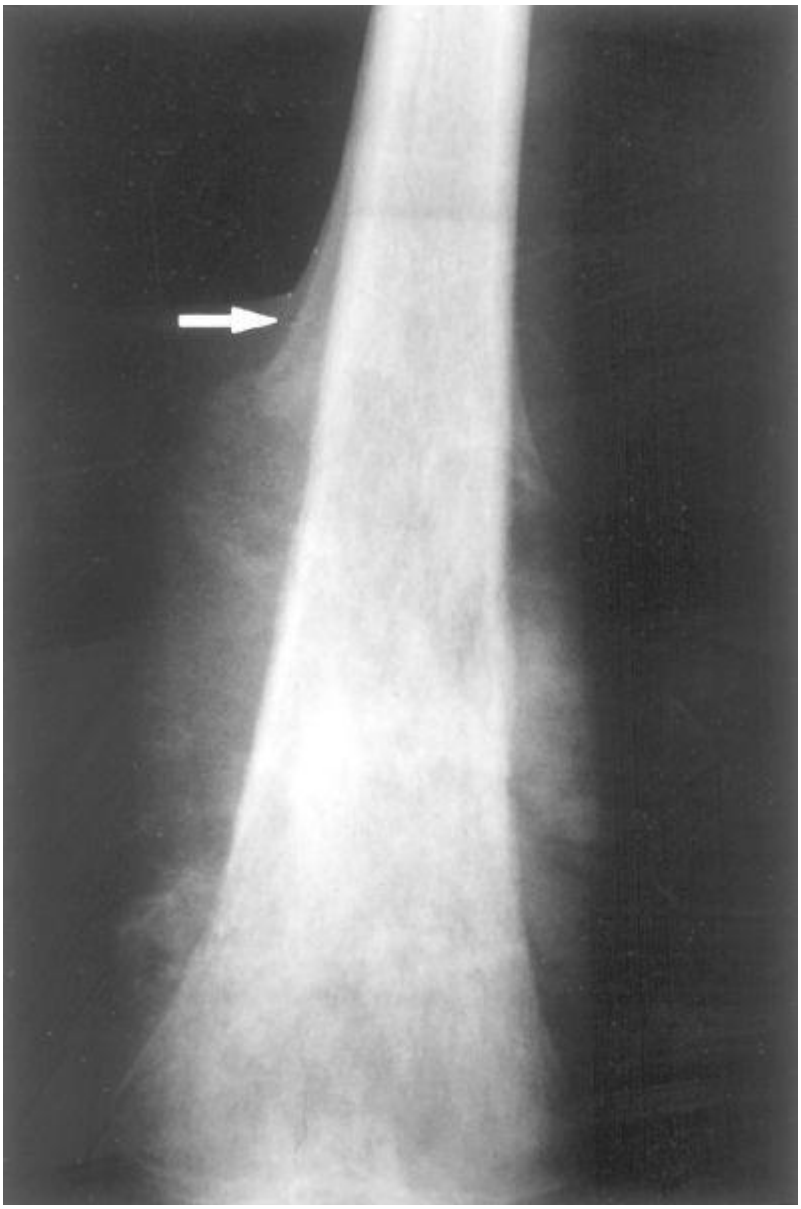

FIGURE 26-24 Distal femoral osteosarcoma with prominent bone formation extending into the soft tissues. The periosteum, which has been lifted, has laid down a proximal triangular shell of reactive bone known as a Codman triangle *(arrow)*.

Osteosarcoma is treated with a multimodality approach that includes chemotherapy, which is given under the assumption that all patients at the time of diagnosis have metastases, which are usually too small to detect by imaging. The prognosis of patients without detectable metastases has improved substantially, with 5-year survival rates reaching 60% to 70% with aggressive chemotherapy and limb salvaging surgery. Unfortunately, the outcome for patients with overt metastases or recurrent disease is still poor (approximately 20% 5-year survival rate).

CARTILAGE-FORMING TUMORS

Cartilage tumors account for the majority of primary bone tumors and are characterized by the formation of hyaline or myxoid cartilage; fibrocartilage and elastic cartilage are rare components. As in most types of bone tumors, benign cartilage tumors are much more common than malignant ones.

Osteochondroma

Osteochondroma, also known as an *exostosis*, is a benign cartilage-capped tumor that is attached to the underlying skeleton by a bony stalk. It is the most common benign bone tumor; about 85% are solitary. The remainder are seen as part of the *multiple hereditary exostosis syndrome*, which is an autosomal dominant hereditary disease. Hereditary exostoses are caused by germline loss-of-function mutations in either the *EXT1* or *EXT2* genes, whereas inactivation of only *EXT1* has been detected in sporadic tumors. These genes encode proteins that function in the biosynthesis of heparin sulfate proteoglycans (Chapter 3). Reduced expression of *EXT1* and *EXT2* results in defective endochondral ossification, which somehow sets the stage for abnormal growth. Solitary osteochondromas are usually first diagnosed in late adolescence and early adulthood, but multiple osteochondromas become apparent during childhood. Men are affected three times more often than women. Osteochondromas develop only in bones of endochondral origin and arise from the metaphysis near the growth plate of long tubular bones, especially about the knee. Occasionally, they develop from bones of the pelvis, scapula, and ribs, and in these sites they are frequently sessile and have short stalks. Rarely, they involve the short tubular bones of the hands and feet.

Morphology. Osteochondromas are sessile or mushroom shaped, and range in size from 1 to 20 cm. The cap is composed of benign hyaline cartilage varying in thickness (Fig. 26-25) and is covered peripherally by perichondrium. The cartilage has the appearance of disorganized growth plate and undergoes enchondral ossification, with the newly made bone forming the inner portion of the head and stalk. The cortex of the stalk merges with the cortex of the host bone, so that the medullary cavity of the osteochondroma and bone are in continuity.

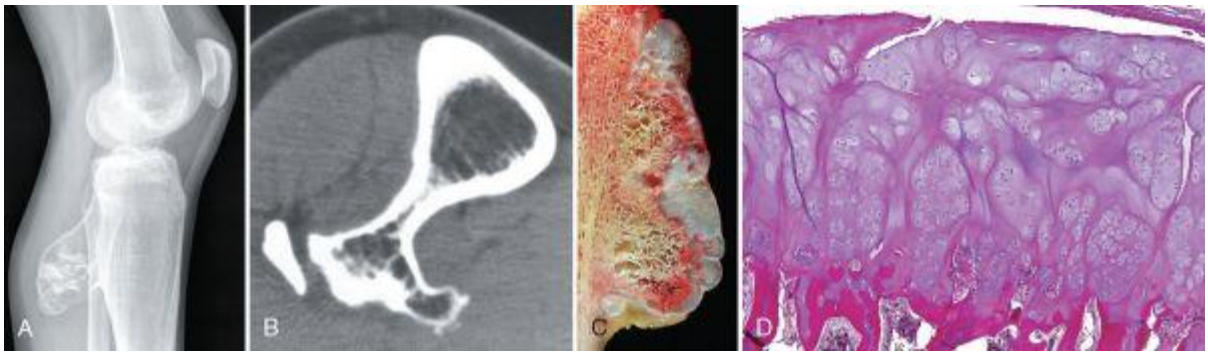

FIGURE 26-25 Osteochondroma. **A**, X-ray of an osteochondroma arising off the posterior surface of the tibia. **B**, Axial CT scan shows continuity of the cortex of the bone and the center of the osteochondroma. The fibula is adjacent to the mass. **C**, Gross specimen of sessile osteochondroma composed of a cap of hyaline cartilage undergoing enchondral ossification. **D**, The cartilage cap has the histologic appearance of disorganized growth plate-like cartilage.

Clinically, osteochondromas present as slow-growing masses, which can be painful if they impinge on a nerve or if the stalk is fractured. In many cases they are detected as an incidental finding. In multiple hereditary exostosis the underlying bones may be bowed and shortened, reflecting an associated disturbance in epiphyseal growth. Osteochondromas usually stop growing at the time of growth plate

closure. Rarely in sporadic cases, but more commonly in those with multiple hereditary exostosis, they give rise to a chondrosarcoma or some other type of sarcoma.

Chondromas

Chondromas are benign tumors of hyaline cartilage that usually occur in bones of enchondral origin. They can arise within the medullary cavity, where they are known as *enchondromas*, or on the surface of bone, where they are called *subperiosteal* or *juxtacortical chondromas*. Enchondromas are the most common of the intraosseous cartilage tumors and are usually diagnosed in individuals who are in their 20s to 40s. They are usually solitary metaphyseal lesions of tubular bones; the favored sites are the short tubular bones of the hands and feet. A syndrome of multiple enchondromas or enchondromatosis is known as *Ollier disease*. If the enchondromatosis is associated with soft-tissue hemangiomas, the disorder is called *Maffucci syndrome*.

Morphology. Enchondromas are usually smaller than 3 cm and grossly are gray-blue and translucent. They are composed of well-circumscribed nodules of cyto logically benign hyaline cartilage (Fig. 26-26). The peripheral portion of the nodules may undergo enchondral ossification, and the center can calcify and die. The chondromas in Ollier disease and Maffucci syndrome are sometimes more cellular and exhibit cytologic atypia, making it difficult to distinguish them from chondrosarcoma.

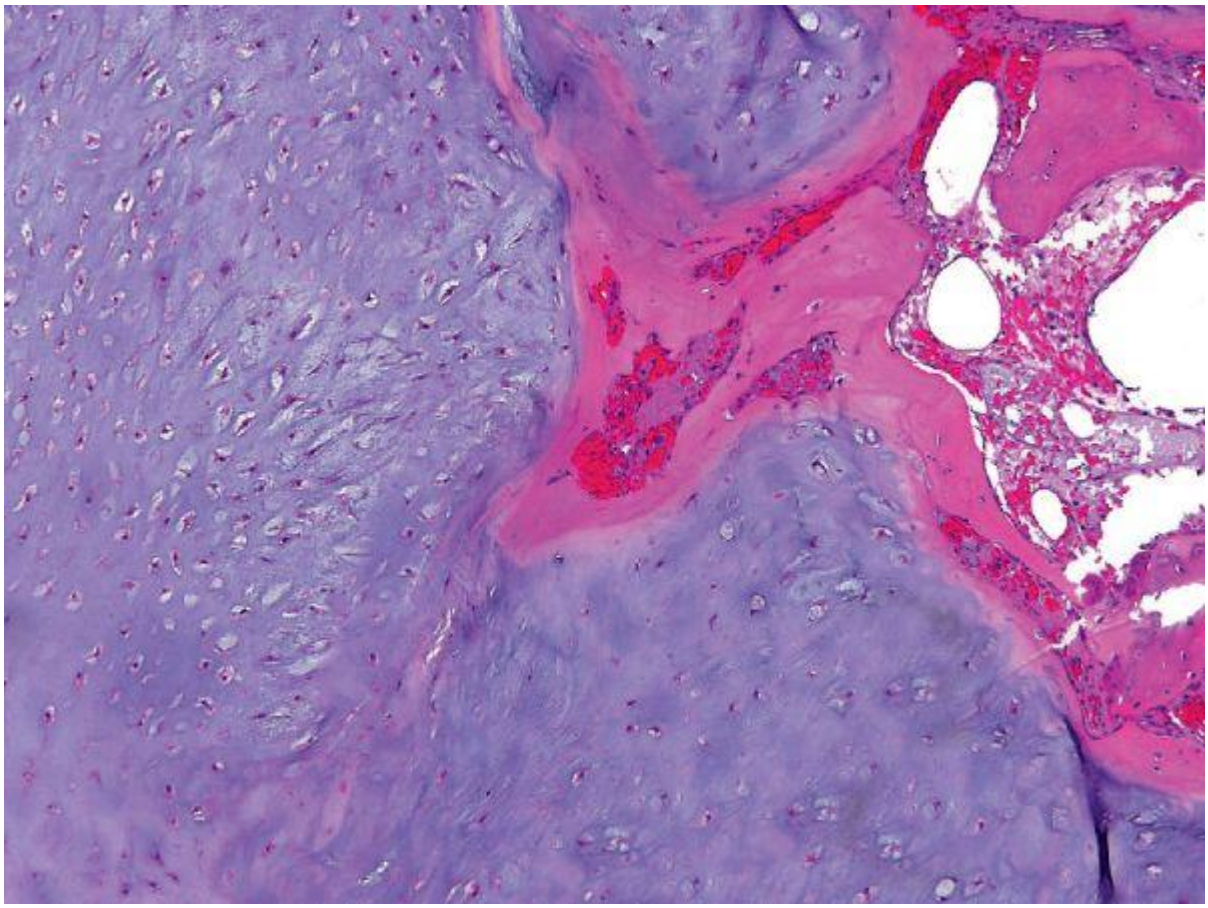

FIGURE 26-26 Enchondroma with a nodule of hyaline cartilage encased by a thin layer of reactive bone.

Clinical Features.

Most enchondromas are asymptomatic and are detected incidentally. Occasionally they are painful and cause pathologic fracture. The tumors in enchondromatosis may be numerous and large, producing severe deformities. The radiographic features are characteristic; the unmineralized nodules of cartilage produce well-circumscribed oval lucencies that are surrounded by a thin rim of radiodense bone *(C or O ring sign)*. If the matrix calcifies it is detected as irregular opacities. The nodules scallop the endosteum, but usually leave the cortex intact (Fig. 26-27). The growth potential of chondromas is limited, and most remain stable. Treatment depends on the clinical situation and is usually observation or curettage. Solitary chondromas rarely undergo sarcomatous transformation, but those associated with enchondromatoses do so more frequently. Individuals with Maffucci syndrome are also at risk of developing other types of malignancies, including ovarian carcinomas and brain gliomas.

FIGURE 26-27 Enchondroma of the phalanx with a pathologic fracture. The radiolucent nodules of hyaline cartilage scallop the endosteal surface.

Chondroblastoma

Chondroblastoma is a rare benign tumor that accounts for less than 1% of primary bone tumors. It usually occurs in young patients in their teens and has a male-to-female ratio of 2 : 1. Most arise about the knee; less common sites such as the pelvis and ribs are affected in older patients. Chondroblastoma has a striking predilection for epiphyses and apophyses (epiphyseal equivalents, i.e., iliac crest).[36]

Morphology. The tumor is composed of sheets of compact polyhedral chondroblasts that have well-defined cytoplasmic borders, moderate amounts of pink cytoplasm, and nuclei that are hyperlobulatedwith longitudinal grooves (Fig. 26-28). Mitotic activity and necrosis are frequently present. The tumor cells are surrounded by scant amounts of hyaline matrix that is deposited in a lace-like configuration; nodules of well-formed hyaline cartilage are distinctly uncommon. When the matrix calcifies it produces a characteristic chicken-wire pattern of mineralization (see Fig. 26-28). Scattered through the lesion are non-neoplastic osteoclast-type giant cells. Occasionally the tumors undergo prominent hemorrhagic cystic degeneration.

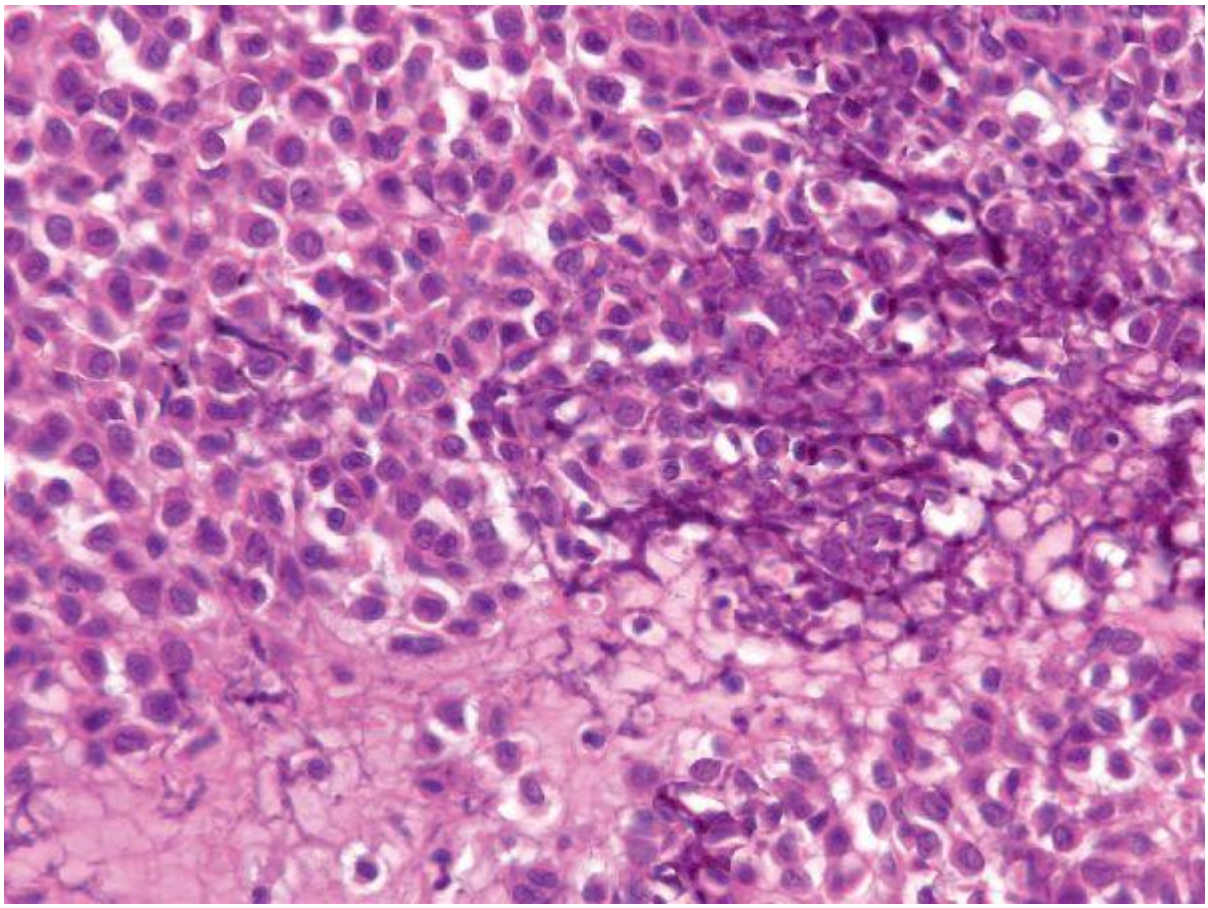

FIGURE 26-28 Chondroblastoma with scant mineralized matrix surrounding chondroblasts in a chicken wire–like fashion.

Chondroblastomas are usually painful, and because of their location near a joint they also cause effusions and restrict joint mobility. Radiographically, they produce a well-defined geographic lucency that commonly has spotty calcifications. Recurrences are not uncommon after curettage. Pulmonary metastases occur rarely in lesions that have undergone prior pathologic fracture or repeated curettage. Apparently in these circumstances the tumor cells are pushed into ruptured vessels, giving them access to the systemic circulation.

Chondromyxoid Fibroma

Chondromyxoid fibroma is the rarest of cartilage tumors and because of its varied morphology can be mistaken for sarcoma. It affects individuals in their teens and 20s and has a male preponderance. The tumors most frequently arise in the metaphysis of long tubular bones, but can involve virtually any bone of the body.

Morphology. The tumors range from 3 to 8 cm in greatest dimension and are well-circumscribed, solid, and glistening tan-gray. Microscopically, there are nodules of poorly formed hyaline cartilage and myxoid tissue delineated by fibrous septae. The cellularity varies; the areas of greatest cellularity are at the periphery of the nodules. In the cartilaginous regions the tumor cells are situated in lacunae; however, in the myxoid areas, the cells are stellate, and their delicate cell processes extend through the mucinous ground substance and approach or contact neighboring cells (Fig. 26-29). In contrast to other benign cartilage tumors, the neoplastic cells in chondromyxoid fibroma show varying degrees of cytologic atypia, including the presence of large hyperchromatic nuclei. Other findings include small foci of calcification of the cartilaginous matrix and scattered non-neoplastic, osteoclast-type giant cells.

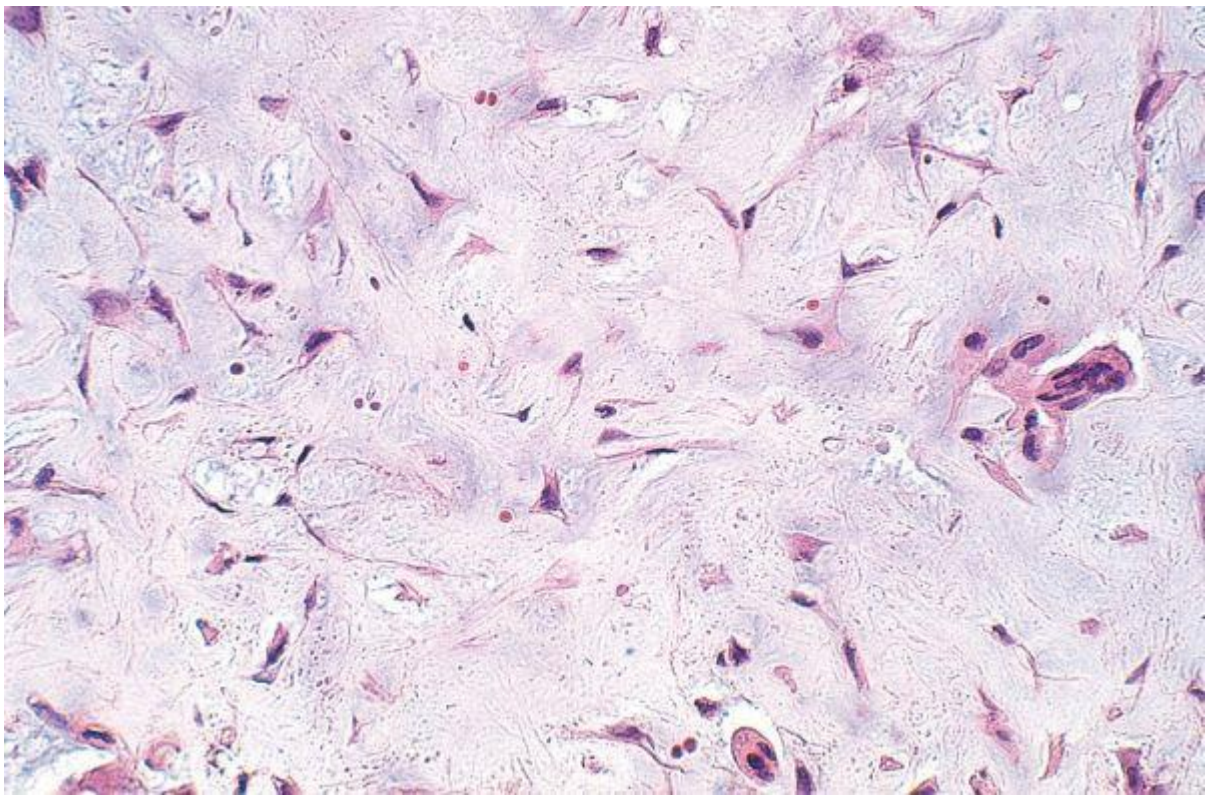

FIGURE 26-29 Chondromyxoid fibroma with prominent stellate and spindle cells surrounded by myxoid matrix. Occasional osteoclast-

type giant cells are also present.

Individuals with chondromyxoid fibroma usually complain of localized dull, achy pain. In most instances, radiograms demonstrate an eccentric geographic lucency that is well delineated from the adjacent bone by a rim of sclerosis. Occasionally the tumor expands the overlying cortex. The treatment of choice is simple curettage, and even though they may recur, they do not pose a threat for malignant transformation or metastasis.

Chondrosarcoma

Chondrosarcomas are a group of tumors that span a broad spectrum of clinical and pathologic findings. The feature common to all of them is the production of neoplastic cartilage. Chondrosarcoma is subclassified according to site as central (*intramedullary*) and peripheral (*juxtacortical* and *surface*). Histologically, they include *conventional (hyaline and/or myxoid)*, *clear cell*, *dedifferentiated*, and *mesenchymal* variants. Conventional central tumors constitute about 90% of chondrosarcomas.

Chondrosarcoma of the skeleton is about half as frequent as osteosarcoma and is the second most common malignant matrix-producing tumor of bone. Individuals with chondrosarcoma are usually in their 40s or older. The clear cell and especially the mesenchymal variants occur in younger patients, in their teens or 20s. The tumor affects men twice as frequently as women. About 15% of conventional chondrosarcomas (usually peripheral tumors) arise from a preexisting enchondroma or osteochondroma.

Morphology. Conventional chondrosarcoma is composed of malignant hyaline and myxoid cartilage. The large bulky tumors are made up of nodules of gray-white, somewhat translucent glistening tissue (Fig. 26-30). In predominantly myxoid variants, the tumors are viscous and gelatinous and the matrix oozes from the cut surface. Spotty calcifications are typically present, and central necrosis may create cystic spaces. The adjacent cortex is thickened or eroded, and the tumor grows with broad pushing fronts into the surrounding soft tissue. The malignant cartilage infiltrates the marrow space and surrounds pre-existing bony trabeculae. The tumors vary in degree of cellularity, cytologic atypia, and mitotic activity (Fig. 26-31). Low-grade or grade 1 lesions demonstrate mild hypercellularity, and the chondrocytes have plump vesicular nuclei with small nucleoli. Binucleate cells are sparse, and mitotic figures are difficult to find. Portions of the matrix frequently mineralize, and the cartilage may undergo endochondral ossification. By contrast, grade 3 chondrosarcomas are characterized by marked hypercellularity, extreme pleomorphism with bizarre tumor giant cells, and mitoses. Pure grade 3 chondrosarcomas are uncommon. Such malignant cartilage is more frequently a component of **chondroblastic osteosarcoma** (see earlier).

Approximately 10% of conventional low-grade chondrosarcomas have a second high-grade component that has the morphology of a poorly differentiated sarcoma; this combination defines **dedifferentiated chondrosarcomas**. The hallmark of **clear cell chondrosarcoma** is sheets of large malignant chondrocytes that have abundant clear cytoplasm, numerous osteoclast-type giant cells, and intralesional reactive bone formation, which often causes confusion with osteosarcoma. **Mesenchymal chondrosarcoma** is composed of islands of well-differentiated hyaline cartilage surrounded by sheets of small round cells, which can mimic Ewing sarcoma.

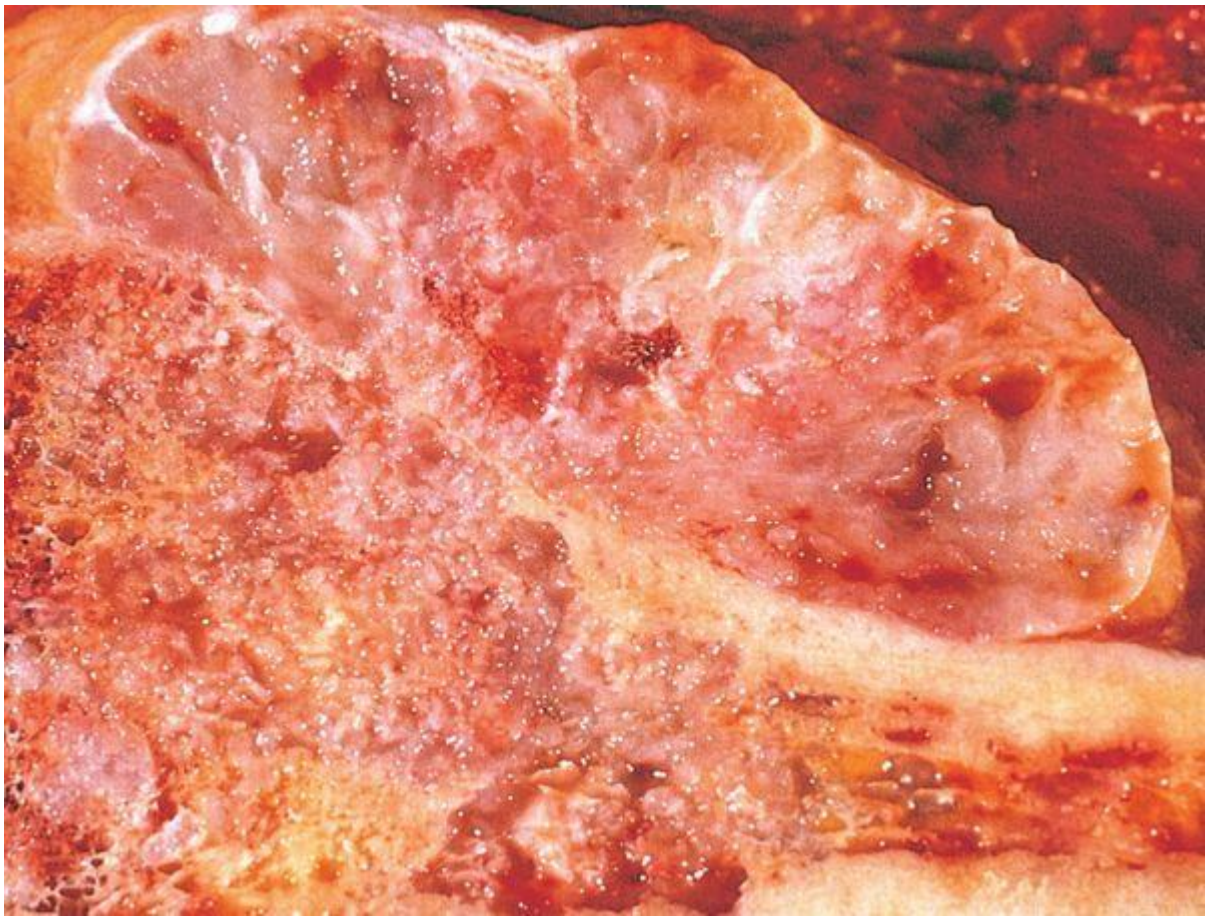

FIGURE 26-30 Chondrosarcoma with lobules of hyaline and myxoid cartilage permeating throughout the medullary cavity, growing through the cortex, and forming a relatively well-circumscribed soft-tissue mass.

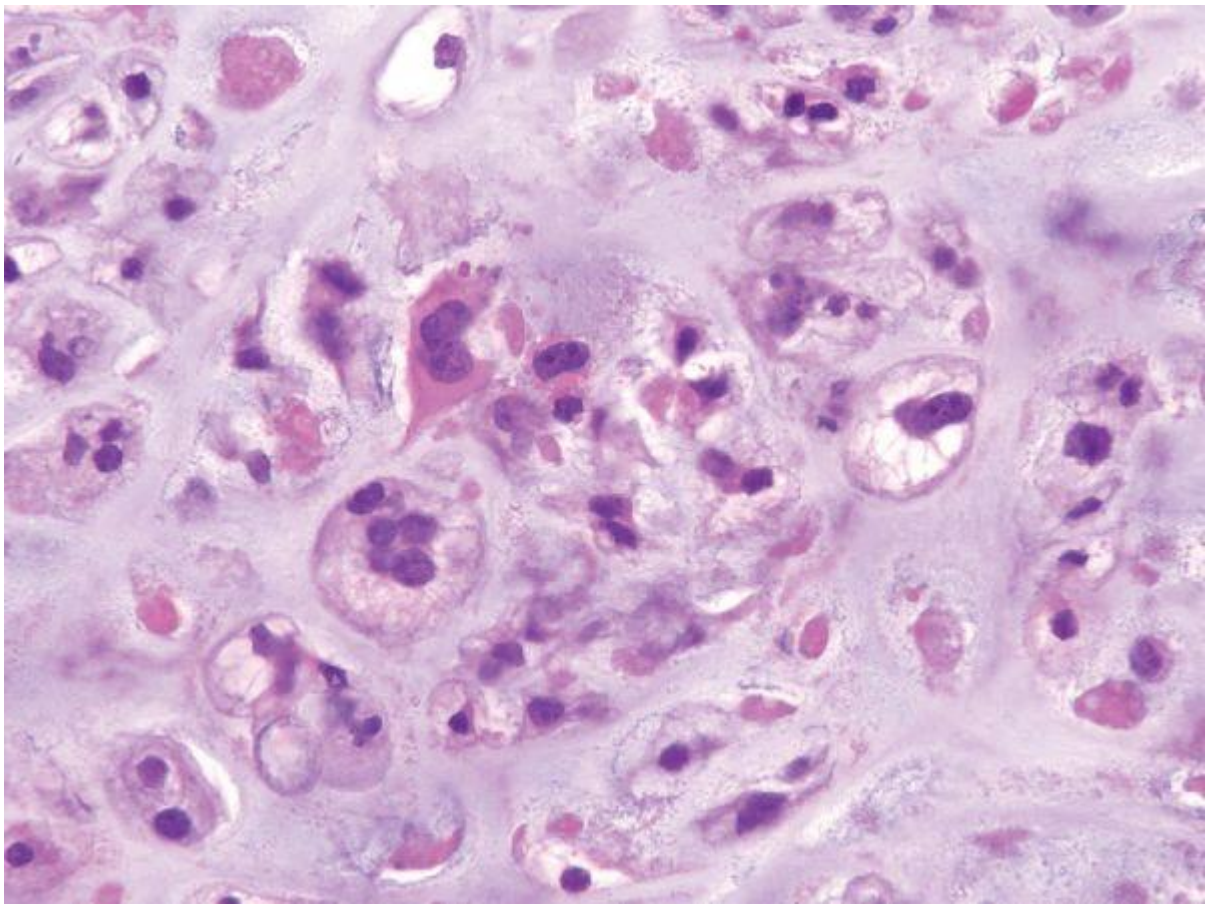

FIGURE 26-31 Anaplastic chondrocytes within a chondrosarcoma.

Chondrosarcomas commonly arise in the central portions of the skeleton, including the pelvis, shoulder, and ribs. The clear cell variant is unique in that it originates in the epiphyses of long tubular bones. *In contrast to enchondroma, chondrosarcoma rarely involves the distal extremities*. These tumors usually present as painful, progressively enlarging masses. The nodular growth pattern of the cartilage produces prominent endosteal scalloping radiographically. The calcified matrix appears as foci of flocculent densities. A slow-growing, low-grade tumor causes reactive thickening of the cortex, whereas a more aggressive high-grade neoplasm destroys the cortex and forms a soft-tissue mass. There is a direct correlation between the grade and the biologic behavior of the tumor.[37] Fortunately, most conventional chondrosarcomas are indolent and fall into the range of grade 1 and grade 2. In one analysis, the 5-year survival rates were 90%, 81%, and 43% for grades 1 through 3, respectively. None of the grade 1 tumors metastasized, whereas 70% of the grade 3 tumors disseminated. Another prognostic feature is size; tumors greater than 10 cm are more aggressive than smaller tumors. When chondrosarcomas metastasize, they spread preferentially to the lungs and skeleton. The treatment of conventional chondrosarcoma is wide surgical excision. The mesenchymal and dedifferentiated tumors are also treated with chemotherapy, because of their aggressive clinical course.

FIBROUS AND FIBRO-OSSEOUS TUMORS

Tumors composed solely or predominantly of fibrous elements are diverse and include some of the most common lesions of the skeleton.

Fibrous Cortical Defect and Non-Ossifying Fibroma

Fibrous cortical defects are extremely common, being found in 30% to 50% of children older than 2 years. They are believed to be developmental defects rather than neoplasms. The vast majority arise eccentrically in the metaphysis of the distal femur and proximal tibia, and almost half are bilateral or multiple. Often they are small, about 0.5 cm in diameter. Those that grow to 5 or 6 cm in size develop into *non-ossifying fibromas*, which are usually not detected until adolescence.

Morphology. Both fibrous cortical defects and non-ossifying fibromas produce elongated, sharply demarcated radiolucencies that are surrounded by a thin rim of sclerosis (Fig. 26-32). They consist of gray to yellow-brown cellular lesions containing fibroblasts and macrophages (histiocytes). The cytologically bland fibroblasts are frequently arranged in a storiform (pinwheel) pattern, and the histiocytes are either multinucleated giant cells or clusters of foamy macrophages (Fig. 26-33).

FIGURE 26-32 Non-ossifying fibroma of the distal tibial metaphysis producing an eccentric lobulated radiolucency surrounded by a sclerotic margin.

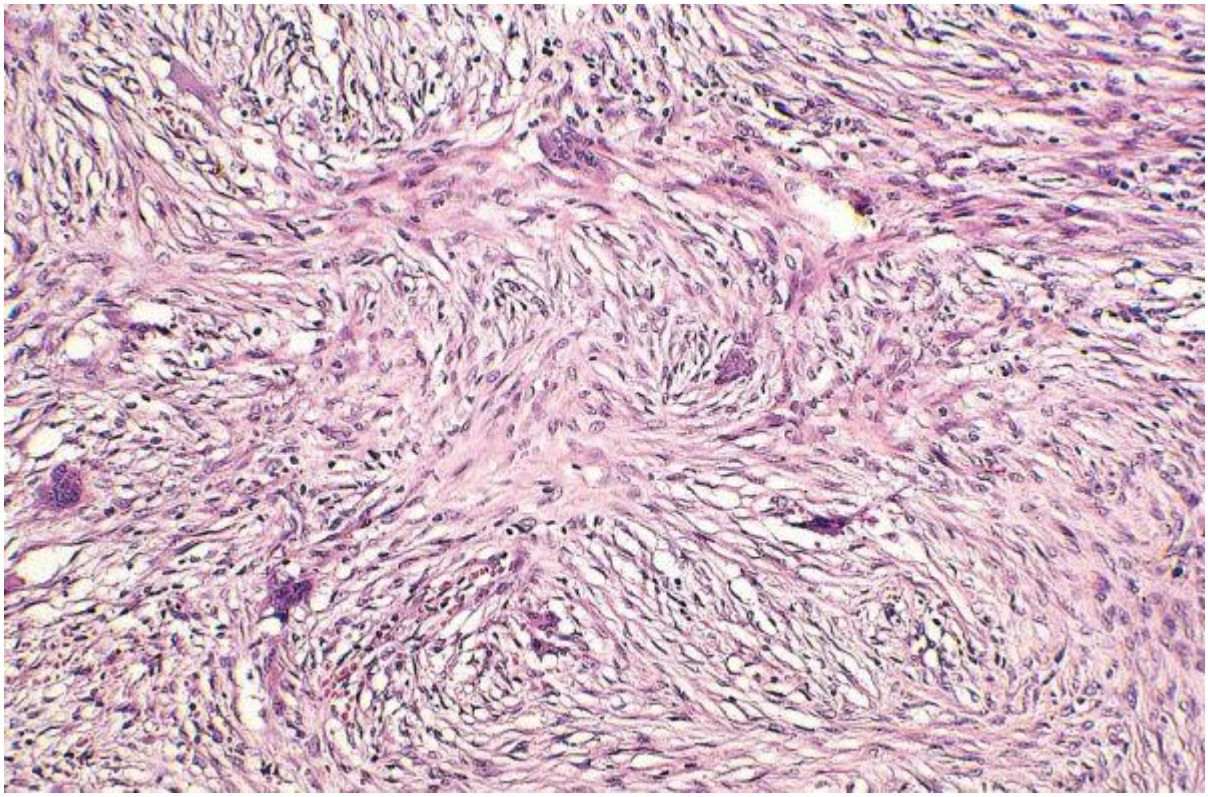

FIGURE 26-33 Storiform pattern created by benign spindle cells with scattered osteoclast-type giant cells characteristic of a fibrous cortical defect and non-ossifying fibroma.

Fibrous cortical defects are asymptomatic and are usually detected on radiography as an incidental finding. Most have limited growth potential and undergo spontaneous resolution within several years, being replaced by normal cortical bone. The few that progressively enlarge into non-ossifying fibromas may present with pathologic fracture or require biopsy and curettage to exclude other types of tumors.

Fibrous Dysplasia

Fibrous dysplasia is a benign tumor that has been likened to a localized developmental arrest; all of the components of normal bone are present, but they do not differentiate into their mature structures. The lesions arise during skeletal growth and development, and appear in three distinctive but sometimes overlapping clinical patterns: (1) involvement of a single bone (monostotic); (2) involvement of multiple bones (polyostotic); and (3) polyostotic disease, associated with café-au-lait skin pigmentations and endocrine abnormalities, especially precocious puberty. The skeletal, skin, and endocrine lesions result from a somatic gain-of-function mutation occurring during embryogenesis in the *GNAS* gene, which you will recall is also mutated in pituitary adenomas (Chapter 24). The result of the mutations in

both types of tumors is the same—the production of a hyperactive guanyl nucleotide binding protein, encoded by the *GNAS* gene, that drives abnormal growth.[38]

Monostotic fibrous dysplasia accounts for 70% of all cases. It occurs equally in boys and girls, usually in early adolescence, and often stops enlarging at the time of growth plate closure. The femur, tibia, ribs, jawbones, calvaria, and humerus are most commonly affected. The lesion is frequently asymptomatic and usually discovered incidentally but it may cause pain, fracture, and discrepancies in limb length. Fibrous dysplasia can cause marked enlargement and distortion of bone, so that if the craniofacial skeleton is involved, disfigurement, sometimes severe, can occur. Monostotic disease does not evolve into the polyostotic form.

Polyostotic fibrous dysplasia without endocrine dysfunction accounts for 27% of all cases. It manifests at a slightly earlier age than the monostotic type and may continue to cause problems into adulthood. The bones affected, in descending order of frequency, are the femur, skull, tibia, humerus, ribs, fibula, radius, ulna, mandible, and vertebrae. Craniofacial involvement is present in 50% of those who have a moderate number of bones affected and in 100% of those with extensive skeletal disease. Polyostotic disease has a propensity to involve the shoulder and pelvic girdles, resulting in severe, sometimes crippling deformities (e.g., shepherd-crook deformity of the proximal femur) and spontaneous and often recurrent fractures.

Polyostotic fibrous dysplasia associated with café-au-lait skin pigmentation and endocrinopathies is known as the *McCune-Albright syndrome* and accounts for 3% of all cases. The endocrinopathies include sexual precocity, hyperthyroidism, pituitary adenomas that secrete growth hormone, and primary adrenal hyperplasia. The severity of manifestations in McCune-Albright syndrome depends on the number and cell types that harbor the mutation in the *GNAS* gene. The most common clinical presentation is precocious sexual development, which occurs most often in girls. The bone lesions are often unilateral but can be bilateral, and the skin pigmentation is usually limited to the same side of the body. The cutaneous macules are classically large; are dark to café-au-lait; have irregular serpiginous borders (coastline of Maine); and are found primarily on the neck, chest, back, shoulder, and pelvic region.

Morphology. The lesions of fibrous dysplasia are well circumscribed, intramedullary, and vary greatly in size. Larger lesions expand and distort the bone. The lesional tissue is tan-white and gritty and is composed of curvilinear trabeculae of woven bone surrounded by a moderately cellular fibroblastic proliferation. The shapes of the trabeculae mimic Chinese letters, and the bone lacks prominent osteoblastic rimming (Fig. 26-34). Nodules of hyaline cartilage with the appearance of disorganized growth plate are also present in approximately 20% of cases. Cystic degeneration, hemorrhage, and foamy macrophages are other common findings.

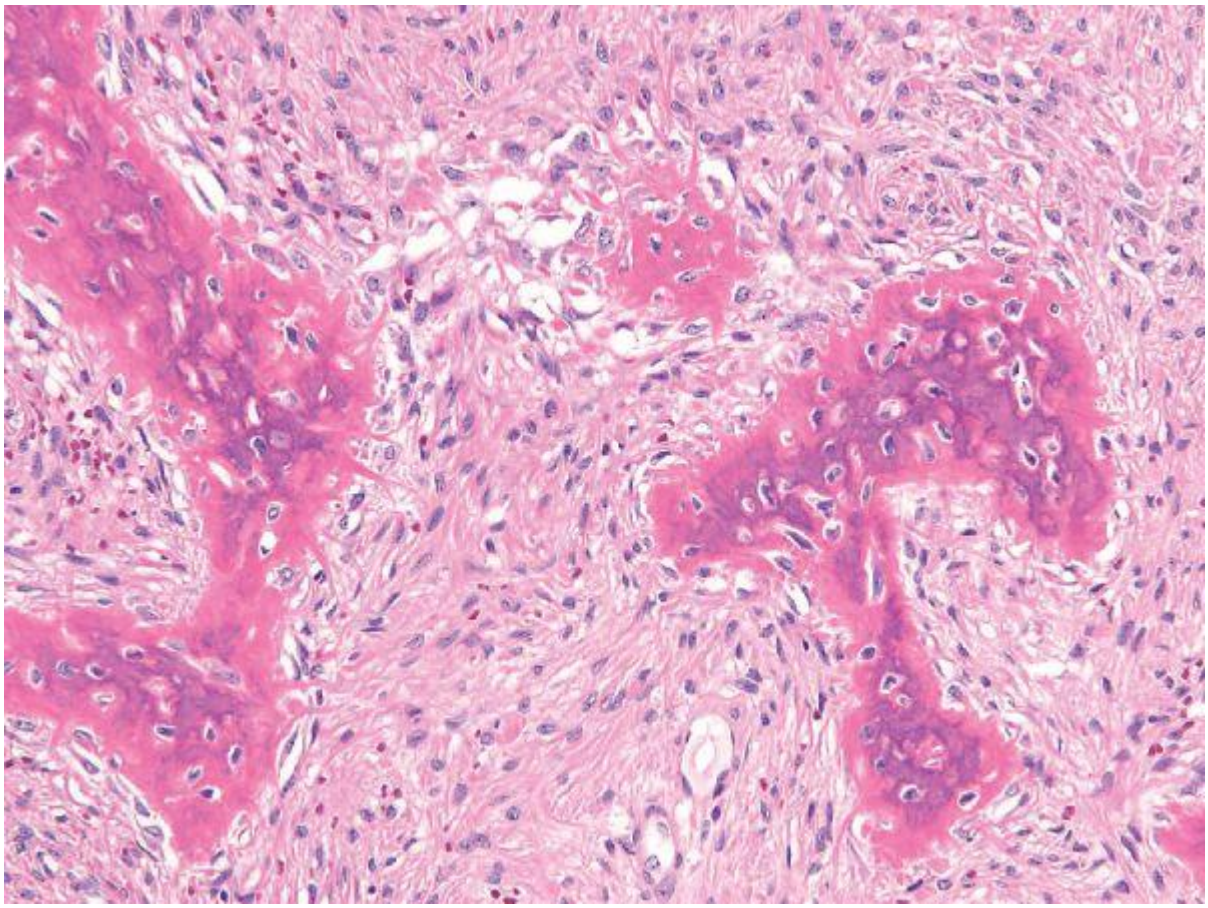

FIGURE 26-34 Fibrous dysplasia composed of curvilinear trabeculae of woven bone that lack conspicuous osteoblastic rimming and arise in a background of fibrous tissue.

Clinical Course.

The natural history of fibrous dysplasia is variable and depends on the extent of skeletal involvement. Individuals with monostotic disease usually have minimal symptoms, except if the tumor is strategically located, such as in the femoral neck. The lesion is readily diagnosed by radiology because of its typical ground-glass appearance and well-defined margination. Lesions that fracture or cause significant symptoms are cured by conservative surgery. Polyostotic involvement is frequently associated with progressive disease. Those diagnosed at an earlier age are more likely to have severe skeletal complications, such as recurring fractures, long-bone deformities and persistent pain, and involvement and distortion of the craniofacial bones. These patients may require multiple corrective orthopedic surgical procedures. Bisphosphonates can be used to reduce the severity of the bone pain. A rare complication, usually in the setting of polyostotic involvement, is malignant transformation of a lesion into a sarcoma.

Fibrosarcoma Variants

Collagen-producing sarcomas with a fibroblastic phenotype occur at any age, but most affect the middle-aged and elderly. They have a nearly equal sex distribution and usually arise de novo; however, a few develop in preexisting benign tumors, bone infarcts, pagetic bone, and previously irradiated tissue.

Morphology. Grossly these tumors are large, hemorrhagic, tan-white masses that destroy the underlying bone and frequently extend into the soft tissues. They are composed of cytologically malignant fibroblasts arranged in a herringbone storiform pattern. The level of differentiation determines the amount of collagen produced and degree of cytologic atypia. In the past, some of these tumors were called **malignant fibrous histiocytoma** because the pleomorphic cells resembled histiocytes (activated tissue macrophages).

Fibrosarcoma presents as an enlarging painful mass that usually arises in the metaphysis of long bones and pelvic flat bones. Pathologic fracture is a frequent complication. Radiographically it is permeative and lytic and often extends into the adjacent soft tissue. The prognosis depends on the size, location, stage, and grade of the tumor; large, high-grade tumors that are difficult to resect have a very poor prognosis.

3.16.1.8 Miscellaneous Tumors

EWING SARCOMA/PRIMITIVE NEUROECTODERMAL TUMOR

The Ewing sarcoma family of tumors encompasses Ewing sarcoma and primitive neuroectodermal tumor (PNET), which are primary malignant *small round-cell tumors* of bone and soft tissue (Chapter 10). Both Ewing sarcoma and PNET have a similar neural phenotype, and because they share an identical chromosome translocation they should be viewed as two variants of the same tumor that differ only in their degree of neural differentiation. Tumors that demonstrate neural differentiation are labeled PNETs, and those that are undifferentiated are diagnosed as Ewing sarcoma. This distinction has no clinical significance.

Ewing sarcoma and PNET together account for approximately 6% to 10% of primary malignant bone tumors and follow osteosarcoma as the second most common group of bone sarcomas in children. Of all bone sarcomas, Ewing sarcoma/PNET has the youngest average age at presentation, since most affected individuals are 10 to 15 years old, and approximately 80% are younger than 20 years. Boys are affected slightly more frequently than girls, and there is a striking predilection for whites; blacks are rarely afflicted. Most Ewing sarcoma/PNET have a translocation involving the *EWS* gene on chromosome 22 and a gene encoding an ETS family transcription factor; the most commonly involved *ETS* gene is *FLI1*, as part of a (11;22) (q24;q12) translocation. The fusion genes generated by these translocations produce chimeric transcription factors that alter the expression of a network of target genes, resulting in abnormal cell proliferation and survival.[39] Other recent evidence suggests that the precursor cell of Ewing sarcoma/PNET is a multipotent mesenchymal stem cell.[40]

Morphology. Arising in the medullary cavity, Ewing sarcoma and PNET usually invade the cortex, periosteum, and soft tissue. The tumor is soft, tan-white, and frequently contains areas of hemorrhage and necrosis. It is composed of sheets of uniform small, round cells that are slightly larger than lymphocytes (Fig. 26-35). They have scant cytoplasm, which may appear clear because it is rich in glycogen. The presence of **Homer-Wright rosettes** (tumor cells arranged in a circle about a central fibrillary space) is indicative of neural differentiation. Although the tumor contains fibrous septae, there is generally little stroma. Necrosis may be prominent, and there are relatively few mitotic figures in relation to the dense cellularity of the tumor.

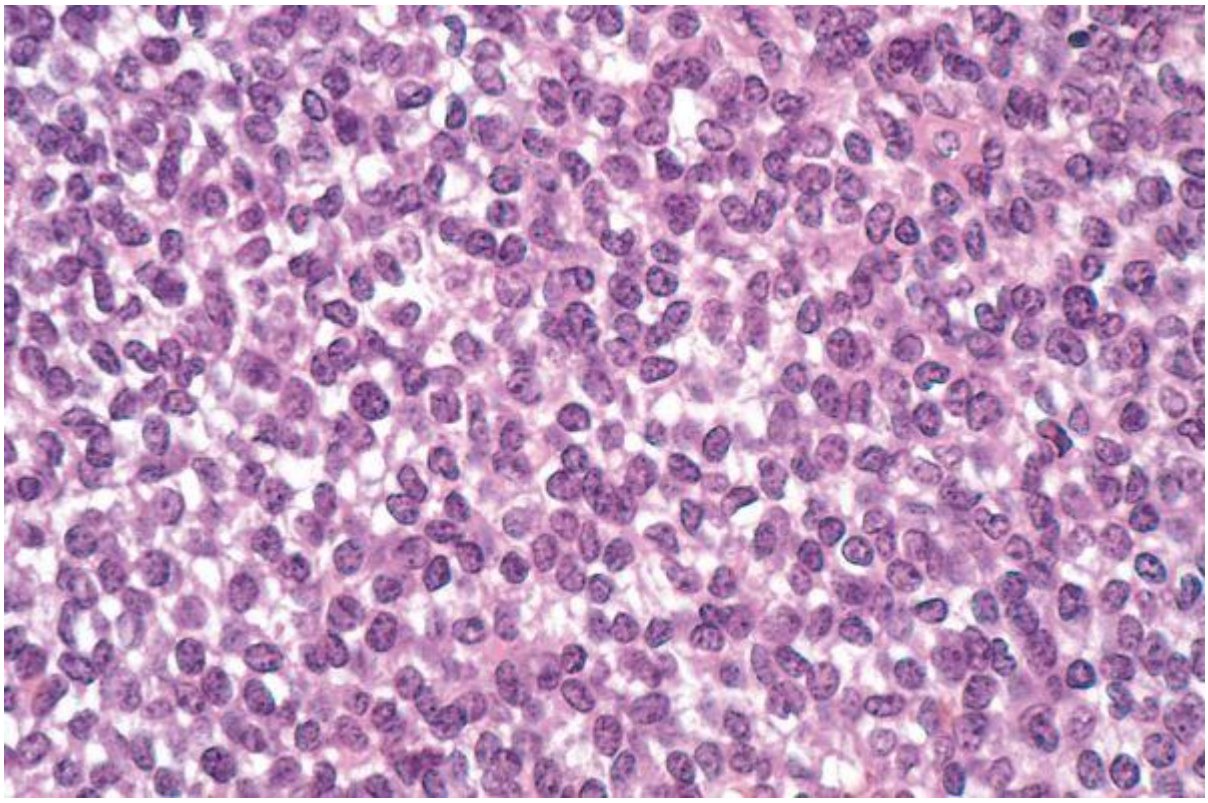

FIGURE 26-35 Ewing sarcoma composed of sheets of small round cells with small amounts of clear cytoplasm.

Clinical Features.

Ewing sarcoma and PNET usually arise in the diaphysis of long tubular bones, especially the femur and the flat bones of the pelvis. They present as painful enlarging masses, and the affected site is frequently tender, warm, and swollen. Some affected individuals have systemic findings, including fever, elevated sedimentation rate, anemia, and leukocytosis, which mimic infection. Plain radiograms show a destructive lytic tumor that has permeative margins and extension into the surrounding soft tissues. The characteristic periosteal reaction produces layers of reactive bone deposited in an *onion-skin* fashion.

Treatment includes chemotherapy and surgical excision with or without irradiation. The advent of effective chemotherapy has markedly improved the prognosis from a dismal 5% to 15% to an approximately 75% 5-year survival; at least 50% have long-term cures. The amount of chemotherapy-induced necrosis is an important prognostic finding. Gene expression arrays of tumors appear to identify individuals with the most aggressive tumors.[41]

GIANT-CELL TUMOR

Giant-cell tumor is so named because it contains a mixture of mononuclear cells and a profusion of multinucleated osteoclast-type giant cells, giving rise to the synonym *osteoclastoma*. This tumor is a relatively uncommon benign but locally aggressive neoplasm. It usually arises in individuals in their 20s to 40s. The mononuclear cells in giant-cell tumors express RANKL, and the giant osteoclast-like cells are believed to form via the RANK/RANKL signaling pathway.[42]

Morphology. These are large, red-brown tumors that frequently undergo cystic degeneration. They are mostly composed of uniform oval mononuclear cells that constitute the proliferating component of the tumor. Scattered within this background are numerous osteoclast-type giant cells having 100 or more nuclei that resemble those of the mononuclear cells (Fig. 26-36). Necrosis, hemorrhage, hemosiderin deposition, and reactive bone formation are common secondary features.

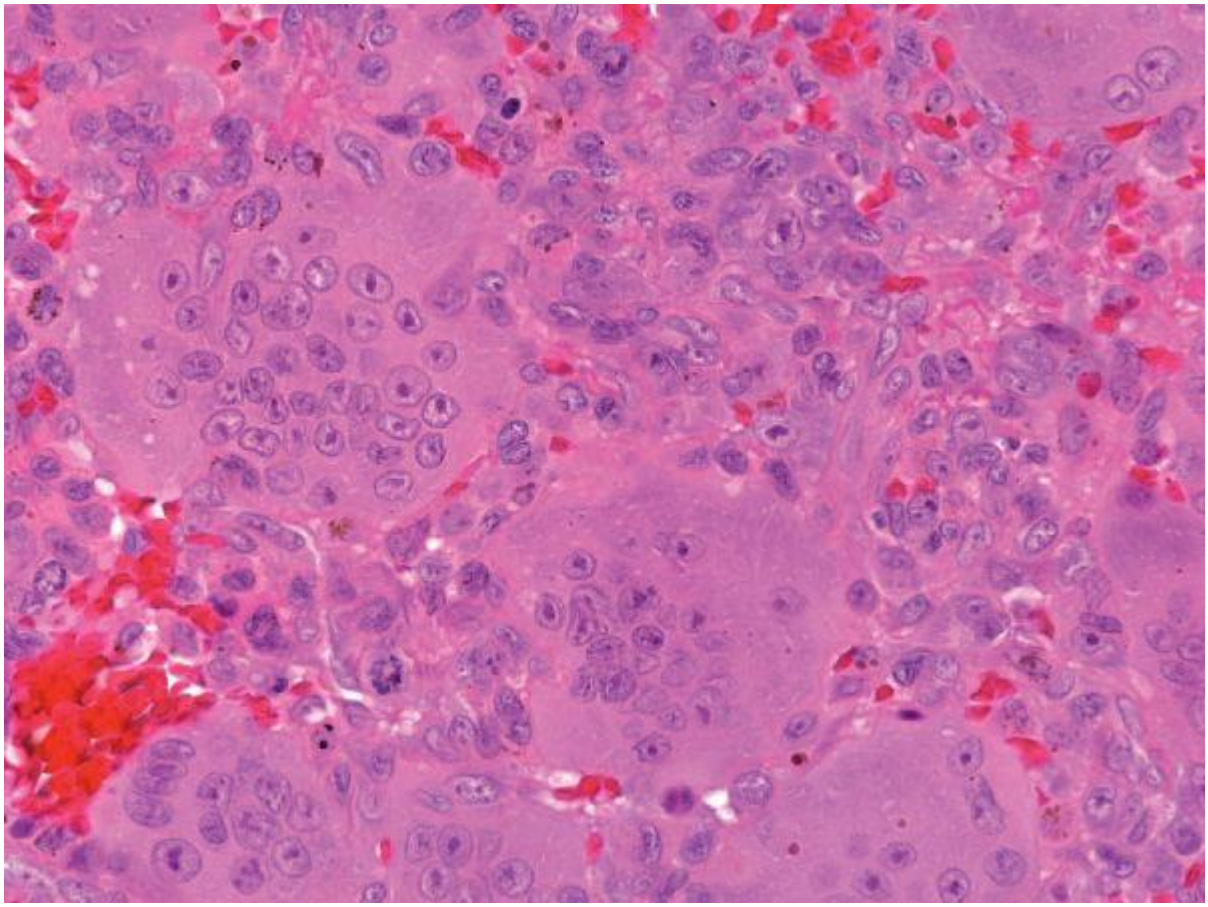

FIGURE 26-36 Benign giant-cell tumor illustrating an abundance of multinucleated giant cells with background mononuclear stromal cells.

Clinical Course.

Giant-cell tumors in adults involve both the epiphyses and the metaphyses, but in adolescents they are confined proximally by the growth plate and are limited to the metaphysis. The majority arise around the knee (distal femur and proximal tibia), but virtually any bone can be involved. The typical location of these tumors near joints frequently causes arthritis-like symptoms. Occasionally, they present with pathologic fractures. Most are solitary; however, multiple or multicentric tumors do occur, especially in the distal extremities. Giant-cell tumors often erode into the subchondral bone plate (Fig. 26-37) and destroy the overlying cortex, producing a bulging soft-tissue mass delineated by a thin shell of reactive bone. The margins with the adjacent bone are fairly circumscribed but seldom sclerotic. The biologic unpredictability of these neoplasms complicates their management. Conservative surgery such as curettage is associated with a 40% to 60% recurrence rate, and up to 4% metastasize to the lungs.

FIGURE 26-37 Magnetic resonance image of a giant-cell tumor that replaces most of the femoral condyle and extends to the subchondral bone plate.

ANEURYSMAL BONE CYST

Aneurysmal bone cyst is a benign tumor of bone characterized by multiloculated blood-filled cystic spaces that may present as a rapidly growing expansile tumor. Despite its aggressive radiographic appearance, aneurysmal bone cyst behaves in a benign fashion. This tumor is associated with distinctive 17p13 translocations that result in up-regulation of USP6, a deubiquitinating enzyme.[43]

Morphology. Grossly, aneurysmal bone cyst consists of multiple blood-filled cystic spaces separated by thin, tan-white septa (Fig. 26-38). The walls are composed of plump uniform fibroblasts (which may be mitotically active), multinucleated osteoclast-like giant cells, and reactive woven bone. The bone is lined by osteoblasts, and its deposition typically follows the contours of the fibrous septa.

Approximately one third of cases contain an unusual cartilage-like matrix, called “blue bone.” Necrosis is uncommon unless there has been a previous pathologic fracture.

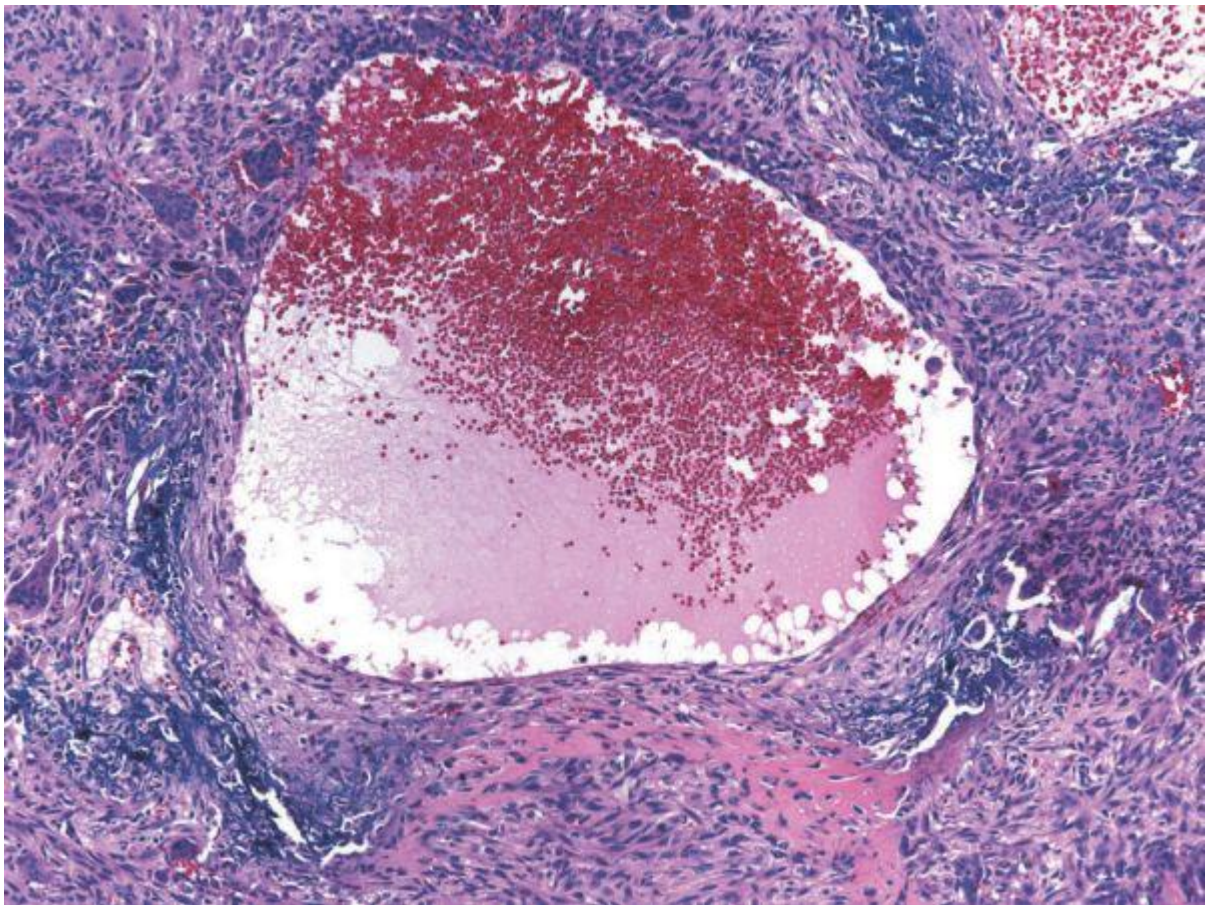

FIGURE 26-38 Aneurysmal bone cyst with blood-filled cystic space surrounded by wall containing proliferating fibroblasts, reactive woven bone, and osteoclast-type giant cells.

Clinical Course.

Aneurysmal bone cyst affects all age groups but generally occurs during the first 2 decades of life and has no sex predilection. It most frequently develops in the metaphyses of long bones and the posterior elements of vertebral bodies. The most common signs and symptoms are pain and swelling. When an aneurysmal bone cyst involves the vertebrae, it can compress nerves and cause neurologic symptoms. Rarely, pathologic fractures occur.

Radiographically, aneurysmal bone cyst is usually an eccentric, expansile lesion with well-defined margins (Fig. 26-39A). Most lesions are completely lytic and often contain a thin shell of reactive bone at the periphery. Computed tomography and magnetic resonance imaging may demonstrate internal septa and characteristic fluid-fluid levels (Fig. 26-39B).

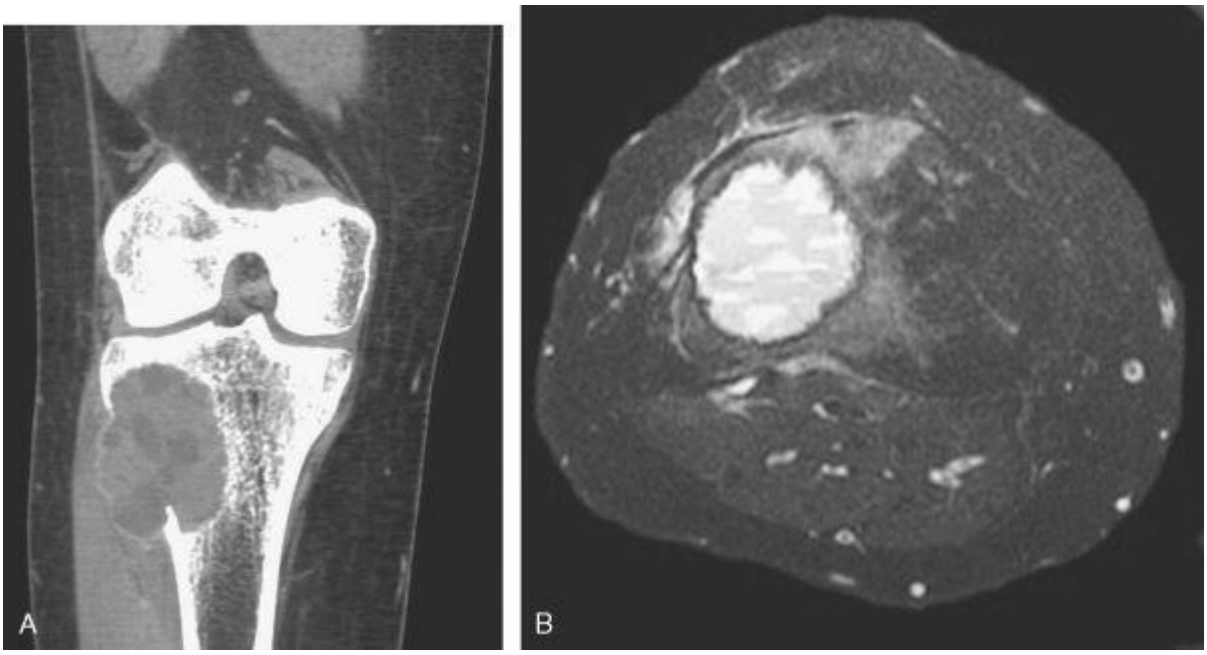

FIGURE 26-39 **A**, Coronal computed axial tomography scan showing eccentric aneurysmal bone cyst of tibia. The soft-tissue component is delineated by a thin rim of reactive subperiosteal bone. **B**, Axial magnetic resonance image demonstrating characteristic fluid-fluid levels.

The treatment of aneurysmal bone cyst is surgical, usually in the form of curettage or, in certain situations, en bloc resection. The recurrence rate is low, and spontaneous regression may occur following incomplete removal.

METASTATIC DISEASE

Metastatic tumors are the most common form of skeletal malignancy. They usually develop in later stages of tumor progression. The pathways of spread include (1) direct extension, (2) lymphatic or hematogenous dissemination, and (3) intraspinal seeding (via the Batson plexus of veins). Any cancer can spread to bone, but in adults more than 75% of skeletal metastases originate from cancers of the prostate, breast, kidney, and lung. In children, metastases to bone originate from neuroblastoma, Wilms tumor, osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma.

Skeletal metastases are typically multifocal; however, carcinomas of the kidney and thyroid are notorious for producing solitary lesions. The metastases may occur in any bone, but most involve the axial skeleton (vertebral column, pelvis, ribs, skull, sternum), proximal femur, and humerus in descending order of frequency. The red marrow in these areas, with its rich capillary network and slow blood flow, facilitates implantation and growth of the tumor cells. Metastases to the small bones of the hands and feet are uncommon and usually originate from cancers of the lung, kidney, or colon.

The radiographic manifestations of metastases may be purely lytic, purely blastic, or mixed lytic and blastic. In lytic lesions, the metastatic cells secrete substances such as prostaglandins, cytokines, and PTH-related protein that stimulate osteoclastic bone resorption; the tumor cells themselves do not directly resorb bone. Lysis of bone tissue rich in growth factors such as TGF-β, IGF-1, FGF, PDGF, and bone morphogenetic proteins, in turn helps create an environment conducive to tumor cell growth. Carcinomas of the kidney, lung, and gastrointestinal tract and malignant melanoma produce lytic bone destruction. Other metastases elicit a sclerotic response, particularly prostate adenocarcinoma, which

may do so by secreting WNT proteins that stimulate osteoblastic bone formation. Most metastases induce a mixed lytic and blastic reaction.

3.16.2 Joints

Joints are constructed to provide both movement and mechanical stability. They are classified as solid (nonsynovial) and cavitated (synovial). The solid joints, known as *synarthroses*, provide structural integrity and allow for minimal movement. They lack a joint space and are grouped according to the type of connective tissue (fibrous tissue or cartilage) that bridges the ends of the bones; fibrous synarthroses include the cranial sutures and the bonds between roots of teeth and the jawbones; cartilaginous synarthroses (synchondroses) are represented by the symphyses (manubriosternalis and pubic). *Synovial joints*, in contrast, have a joint space that allows for a wide range of motion. Situated between the ends of bones formed via enchondral ossification, they are strengthened by a dense fibrous capsule reinforced by ligaments and muscles. The boundary of the joint space consists of the synovial membrane, which is firmly anchored to the underlying capsule and does not cover the articular surface. Its contour is smooth except near the osseous insertion, where it is thrown into numerous villous folds. Synovial membranes are lined by synoviocytes, cuboidal connective cells that are arranged one to four cell layers deep. Synoviocytes synthesize hyaluronic acid and various proteins. The synovial lining lacks a basement membrane, which allows for quick exchange between blood and synovial fluid. Synovial fluid is clear and viscous, and is a filtrate of plasma containing hyaluronic acid that acts as a lubricant and provides nutrition for the articular hyaline cartilage.

Hyaline cartilage is a unique connective tissue ideally suited to serve as an elastic shock absorber and wear-resistant surface. It lacks a blood supply and does not have lymphatic drainage or innervation. Hyaline cartilage is composed of type 2 collagen, water, proteoglycans, and chondrocytes, each of which has specific functions. The collagen fibers enable the cartilage to resist tensile stresses and transmit vertical loads. The water and proteoglycans give hyaline cartilage its turgor and elasticity and have an important role in limiting friction. The chondrocytes synthesize the matrix as well as enzymatically digest it, with the half-life of the different components ranging from weeks (proteoglycans) to years (type 2 collagen). Chondrocytes secrete the degradative enzymes in an inactive form and enrich the matrix with enzyme inhibitors. Diseases that destroy articular cartilage do so by activating the catabolic enzymes and decreasing the production of inhibitors, thereby accelerating the rate of matrix breakdown. Cytokines such as IL-1 and TNF trigger the degradative process; their sources include chondrocytes, synoviocytes, fibroblasts, and inflammatory cells. Destruction of articular cartilage by indigenous cells is an important mechanism in many joint diseases.

3.16.2.1 Arthritis

OSTEOARTHRITIS

Osteoarthritis, also called *degenerative joint disease*, is the most common type of joint disease and is one of the 10 most disabling conditions in developed nations. *It is characterized by the progressive erosion of articular cartilage*. It is estimated that more than 33 billion dollars are spent annually in the United States for its treatment and for lost days of work. The term *osteoarthritis* implies an inflammatory disease; however, even though inflammatory cells may be present (usually in small numbers), osteoarthritis is considered to be an intrinsic disease of cartilage in which biochemical and metabolic alterations in individuals with genetic susceptibility result in its breakdown.

In most instances osteoarthritis appears insidiously, without apparent initiating cause, as an aging phenomenon (idiopathic or primary osteoarthritis). In these cases the disease is usually oligoarticular (affects few joints) but may be generalized. In about 5% of cases, osteoarthritis may appear in younger individuals having some predisposing condition, such as previous injuries to a joint; a congenital developmental deformity of a joint(s); or some underlying systemic disease such as diabetes, ochronosis,

hemochromatosis, or marked obesity. In these settings the disease is called *secondary osteoarthritis* and often involves one or several predisposed joints; witness the shoulder or elbow involvements in baseball players and knees in basketball players. Gender has some influence on distribution. The knees and hands are more commonly affected in women and the hips in men.

Pathogenesis.

Osteoarthritis (OA) is a multifactorial disease that has genetic and environmental components. Studies of families and twins have suggested that the risk of OA is related to the net impact of multiple genes, each with a small effect. Genome-wide association studies (GWAS) are underway and it is likely that many risk-associated genes will be identified and validated shortly; a number of candidates have been identified, including genes involved in prostaglandin metabolism and WNT signaling.[44] The major environmental factors relate to aging and biomechanical stress, which is influenced by obesity, muscle strength, and joint stability, structure, and alignment. The association with aging is strong; the prevalence of OA increases exponentially beyond the age of 50, and about 80% to 90% of individuals have evidence of the disease by age 65. Thus, OA joins heart disease and cancer as one of the unfortunate dividends of growing older. However, it is an oversimplification to consider OA an inevitable consequence of cartilage wear and tear. The mechanisms leading to OA are complex and not yet clear, but chondrocytes are at the center of the process, which can be divided into several phases: (1) chondrocyte injury, which is related to aging and genetic and biochemical factors; (2) early OA, in which chondrocytes proliferate (cloning) and secrete inflammatory mediators, collagens, proteoglycans, and proteases, which act together to remodel the cartilaginous matrix and initiate secondary inflammatory changes in the synovium and subchondral bone; and (3) late OA, in which repetitive injury and chronic inflammation lead to chondrocyte drop out, marked loss of cartilage, and extensive subchondral bone changes.[45]

Morphology. In the early stages of osteoarthritis the chondrocytes proliferate, forming clusters. Concurrently, the water content of the matrix increases and the concentration of proteoglycans decreases. Subsequently, vertical and horizontal fibrillation and cracking of the matrix occur as the superficial layers of the cartilage and type 2 collagen molecules are degraded. Grossly this manifests as a granular soft articular surface. Eventually, chondrocytes die and full-thickness portions of the cartilage are sloughed. The dislodged pieces of cartilage and subchondral bone tumble into the joint, forming loose bodies (**joint mice**). The exposed subchondral bone plate becomes the new articular surface, and friction with the opposing degenerated articular surface smooths and burnishes the exposed bone, giving it the appearance of polished ivory (**bone eburnation**) (Fig. 26-40). Concurrently there is rebuttressing and sclerosis of the underlying cancellous bone. Small fractures through the articulating bone are common, and the fracture gaps allow synovial fluid to be forced into the subchondral regions in a one-way, ball valve–like mechanism. The loculated fluid collection increases in size, forming fibrous-walled cysts. Mushroom-shaped osteophytes (bony outgrowths) develop at the margins of the articular surface and are capped by fibrocartilage and hyaline cartilage that gradually ossify. The synovium is usually only mildly congested and fibrotic, and may have scattered chronic inflammatory cells.

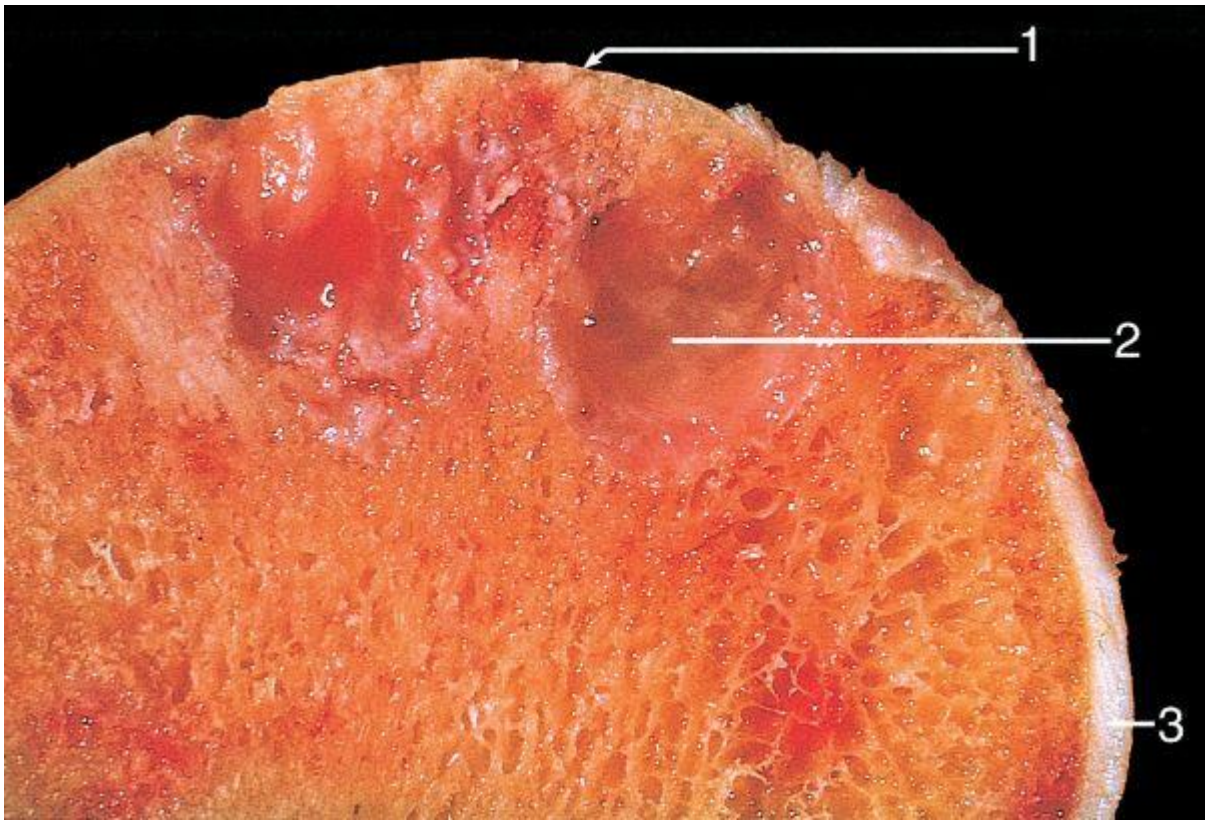

FIGURE 26-40 Severe osteoarthritis with small islands of residual articular cartilage next to exposed subchondral bone. 1, Eburnated articular surface. 2, Subchondral cyst. 3, Residual articular cartilage.

Clinical Course.

Osteoarthritis is an insidious disease. Patients with primary disease are usually asymptomatic until they are in their 50s. If a young person has significant manifestations of osteoarthritis, a search for some underlying cause should be made. Characteristic symptoms include deep, achy pain that worsens with use, morning stiffness, crepitus, and limitation of range of movement. Impingement on spinal foramina by osteophytes results in cervical and lumbar nerve root compression and radicular pain, muscle spasms, muscle atrophy, and neurologic deficits. Typically, only one or a few joints are involved except in the uncommon generalized variant. The joints commonly involved include the hips, knees, lower lumbar and cervical vertebrae, proximal and distal interphalangeal joints of the fingers, first carpometacarpal joints, and first tarsometatarsal joints of the feet (Fig. 26-41). *Heberden nodes*, prominent osteophytes at the distal interphalangeal joints, are common in women (but not men). The wrists, elbows, and shoulders are usually spared. There are still no satisfactory means of preventing primary osteoarthritis, and there are no effective methods of halting its progression. The disease may stabilize for years but more often is slowly progressive, and it is second only to cardiovascular diseases in causing long-term disability.

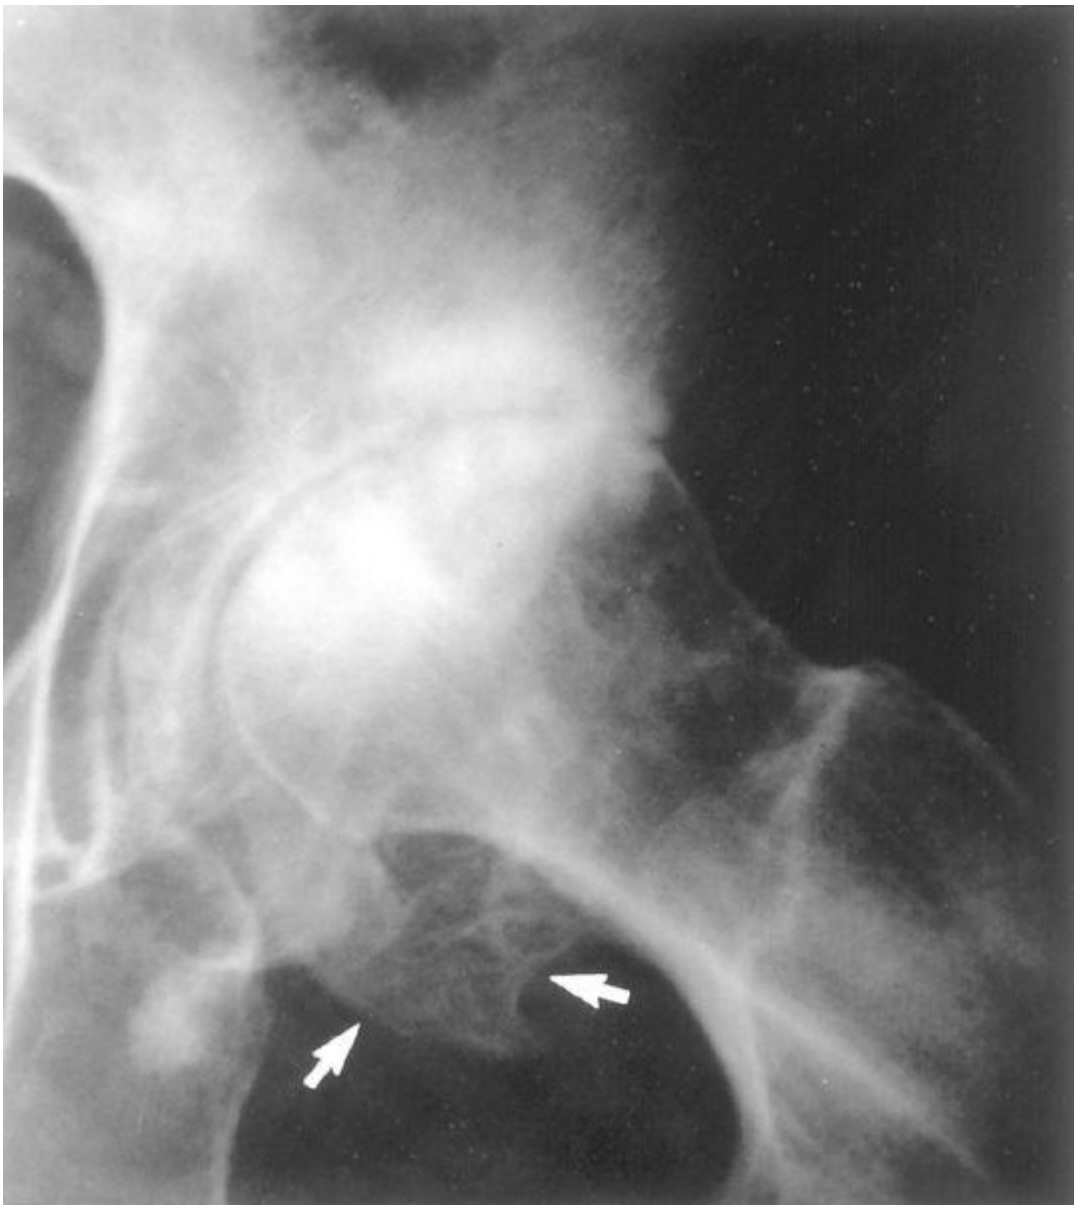

FIGURE 26-41 Severe osteoarthritis of the hip. The joint space is narrowed, and there is subchondral sclerosis with scattered oval radiolucent cysts and peripheral osteophyte lipping *(arrows)*.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic systemic inflammatory disorder that may affect many tissues and organs—skin, blood vessels, heart, lungs, and muscles—but principally attacks the joints, producing a nonsuppurative proliferative and inflammatory synovitis that often progresses to destruction of the articular cartilage and ankylosis of the joints. Although the cause of rheumatoid arthritis remains unknown, genetic predisposition, environment, and autoimmunity have pivotal roles in the development, progression, and chronicity of the disease.

About 1% of the world's population is afflicted by rheumatoid arthritis, women three to five times more often than men. It is most common in those 40 to 70 years old, but no age is immune. We first consider the morphology as a background to discuss pathogenesis.

Morphology.

Joints. Rheumatoid arthritis causes a broad spectrum of morphologic alterations; the most severe are manifested in the joints. Initially the synovium becomes grossly edematous, thickened, and hyperplastic, transforming its smooth contour to one covered by delicate and bulbous fronds (Fig. 26-42). The characteristic histologic features include (1) infiltration of synovial stroma by a dense perivascular inflammatory infiltrate composed of lymphoid aggregates (mostly CD4+ helper T cells), B cells, plasma cells, dendritic cells, and macrophages (Fig. 26-42C); (2) increased vascularity due to vasodilation and angiogenesis, with superficial hemosiderin deposits; (3) aggregation of organizing fibrin covering portions of the synovium and floating in the joint space as rice bodies; (4) accumulation of neutrophils in the synovial fluid and along the surface of synovium but usually not deep in the synovial stroma; (5) osteoclastic activity in underlying bone, allowing the synovium to penetrate into the bone and cause juxta-articular erosions, subchondral cysts, and osteoporosis; and (6) **pannus** formation. The pannus is a mass of synovium and synovial stroma consisting of inflammatory cells, granulation tissue, and synovial fibroblasts, which grows over the articular cartilage and causes its erosion. In time, after the cartilage has been destroyed, the pannus bridges the apposing bones to form a **fibrous ankylosis**, which eventually ossifies and results in bony ankylosis. Inflammation in the tendons, ligaments, and occasionally the adjacent skeletal muscle frequently accompanies the arthritis.

Skin. **Rheumatoid nodules** are the most common cutaneous lesion. They occur in approximately 25% of affected individuals, usually those with severe disease, and arise in regions of the skin that are subjected to pressure, including the ulnar aspect of the forearm, elbows, occiput, and lumbosacral area. Less commonly they form in the lungs, spleen, pericardium, myocardium, heart valves, aorta, and other viscera. Rheumatoid nodules are firm, nontender, and round to oval, and in the skin arise in the subcutaneous tissue. Microscopically they have a central zone of fibrinoid necrosis surrounded by a prominent rim of epithelioid histiocytes (activated macrophages) and numerous lymphocytes and plasma cells (Fig. 26-43).

Blood Vessels. Affected individuals with severe erosive disease, rheumatoid nodules, and high titers of rheumatoid factor are at risk of developing vasculitic syndromes (Chapter 11). Rheumatoid vasculitis is a potentially catastrophic complication of rheumatoid arthritis, particularly when it affects vital organs. The involvement of medium- to small-size arteries is similar to that occurring in polyarteritis nodosa, except that in rheumatoid arthritis the kidneys are not involved. Frequently, segments of small arteries such as **vasa nervorum** and **digital arteries** are obstructed by an obliterating endarteritis resulting in peripheral neuropathy, ulcers, and gangrene. Leukocytoclastic venulitis produces purpura, cutaneous ulcers, and nail bed infarction.

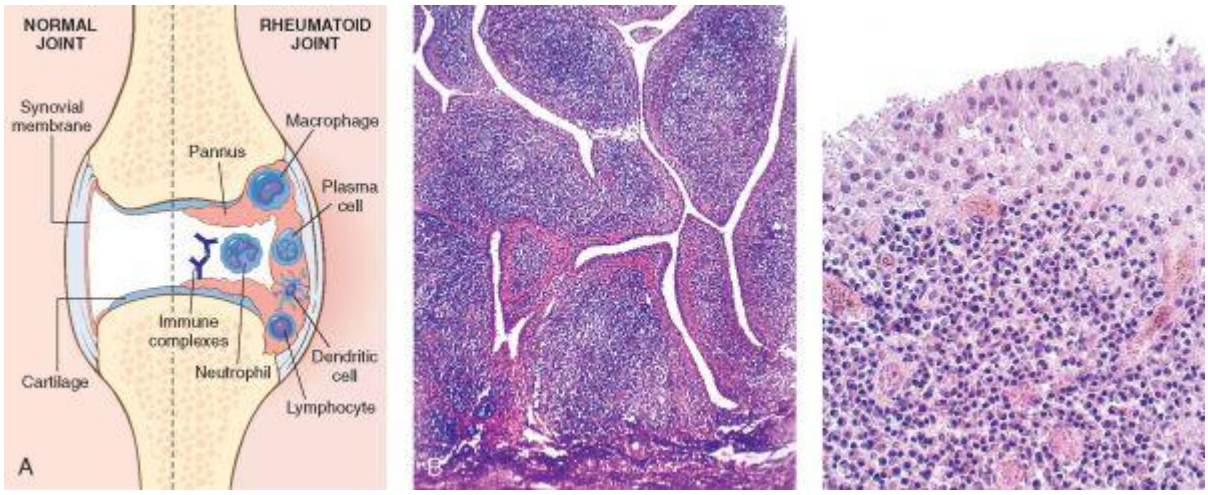

FIGURE 26-42 Rheumatoid arthritis. **A**, Schematic view of the joint lesion. **B**, Low magnification reveals marked synovial hypertrophy with formation of villi. **C**, At higher magnification, subsynovial tissue containing a dense lymphoidaggregate is seen. *(Modified from Feldmann M: Development of anti-TNF therapy for rheumatoid arthritis. Nat Rev Immunol 2:364, 2002.)*

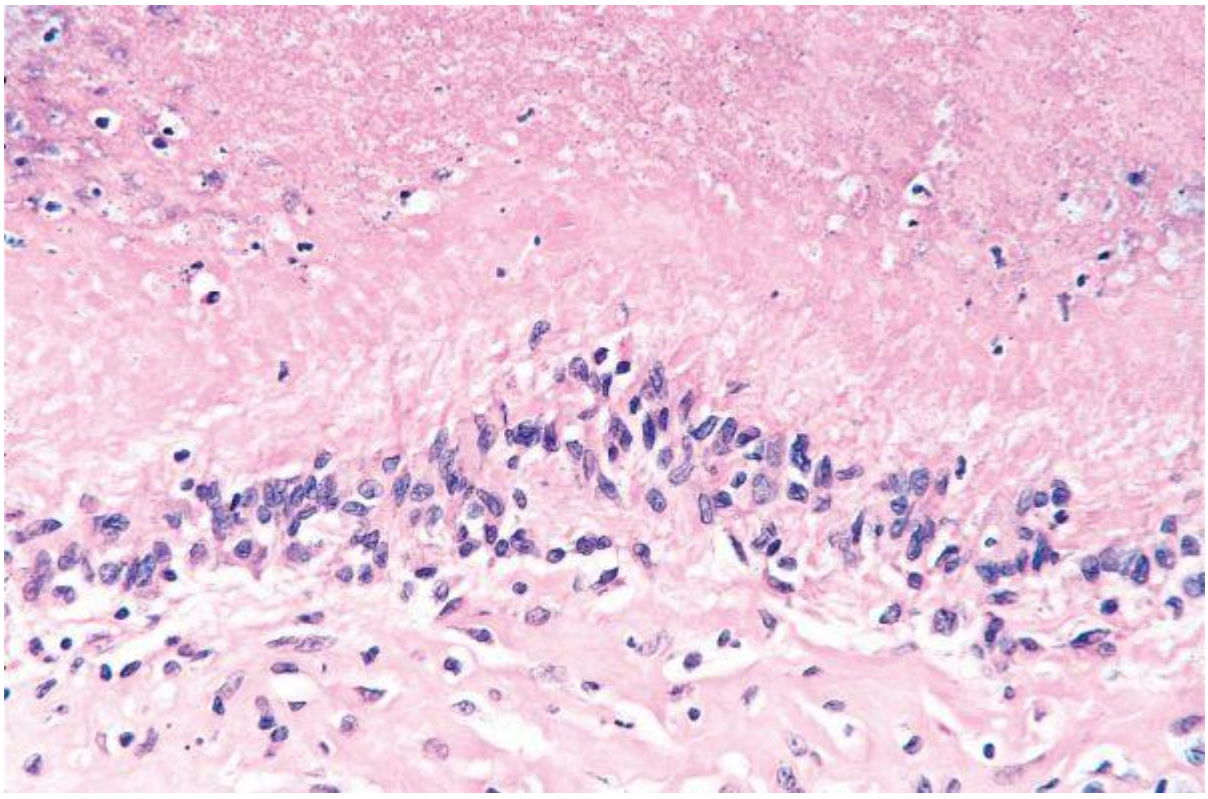

FIGURE 26-43 Subcutaneous rheumatoid nodule with an area of necrosis *(top)* surrounded by a palisade of macrophages and scattered chronic inflammatory cells.

Pathogenesis.

Although much remains uncertain, it is currently believed that *rheumatoid arthritis is triggered by exposure of a genetically susceptible host to an arthritogenic antigen* resulting in a breakdown of immunological self-tolerance and a chronic inflammatory reaction. In this manner, an acute arthritis is initiated, but it is the continuing *autoimmune reaction*, the activation of CD4+ helper T cells, and the local release of inflammatory mediators and cytokines that ultimately destroys the joint (Fig. 26-44).

- *Genetic susceptibility* is clearly a major contributor to the pathogenesis of rheumatoid arthritis. Specific *HLA-DRB1* alleles have been shown to be associated with rheumatoid arthritis, and these alleles share a common sequence of amino acids in the third hypervariable region of the β chain, which is designated the shared epitope. The shared epitope is located in the antigen-binding cleft of the DR molecule. This location is presumably the specific binding site of the arthritogen(s) that initiates the inflammatory synovitis. Another gene associated with rheumatoid arthritis is *PTPN22*; it encodes a protein tyrosine phosphatase, which participates in activation and control of inflammatory cells, including T cells.
- *Environmental arthritogen*: The environmental arthritogen thought to be the *initiator of the disease* remains uncertain. Microbial agents including Epstein-Barr virus, retroviruses, parvoviruses, mycobacteria, *Borrelia*, *Proteus mirabilis*, and *Mycoplasma* have all been implicated but none has been proved to be significant. Recently, *citrullinated proteins* (proteins modified by the enzymatic conversion of arginine to citrulline, many of which are fibrins) formed in the body (especially in the lungs of smokers) have been implicated in the pathogenesis of rheumatoid arthritis. The robust immune reaction to these autoantigens suggests that they are an important potential arthritogenic agent.[46]
- *Autoimmunity*: Once an inflammatory synovitis has been initiated, an *autoimmune reaction*—in which T cells have the pivotal role—is responsible for the chronic destructive nature of rheumatoid arthritis. The antigen inducing this reaction has not been identified with certainty; type 2 collagen and glycosaminoglycans have been implicated in animal models but may not be relevant in human disease. Regardless, activated CD4+ effector and memory T cells appear within affected joints early. T_H17 cells are important in the inflammatory reaction because they recruit neutrophils and monocytes. Interferon-γ-producing T_H1 cells may also contribute to the inflammatory reaction. *About 80% of individuals with rheumatoid arthritis have autoantibodies to the Fc portion of autologous IgG (rheumatoid factors)*. These are mostly IgM antibodies but may be of other classes and they self-associate (RA-IgG) to form immune complexes in the sera, synovial fluid, and synovial membranes. Though not a causative factor of the disease, the circulating immune complexes are markers of disease activity. Rheumatoid factor, however, is not present in some individuals with the disease (seronegative), and is sometimes found in other disease states and even in otherwise healthy people. *Antibodies to citrulline-modified peptides* (anti-cyclic citrullinated peptide [CCP] antibodies) have been recently shown to be present in many people with rheumatoid arthritis and rarely in people with other inflammatory diseases or healthy individuals. These antibodies are produced at sites of inflammation and are recognized as being relatively specific for rheumatoid arthritis. Evidence suggests that the raised levels of anti-CCP antibodies in combination with a T-cell response to the citrullinated proteins contribute to the disease becoming chronic.[47,][48]

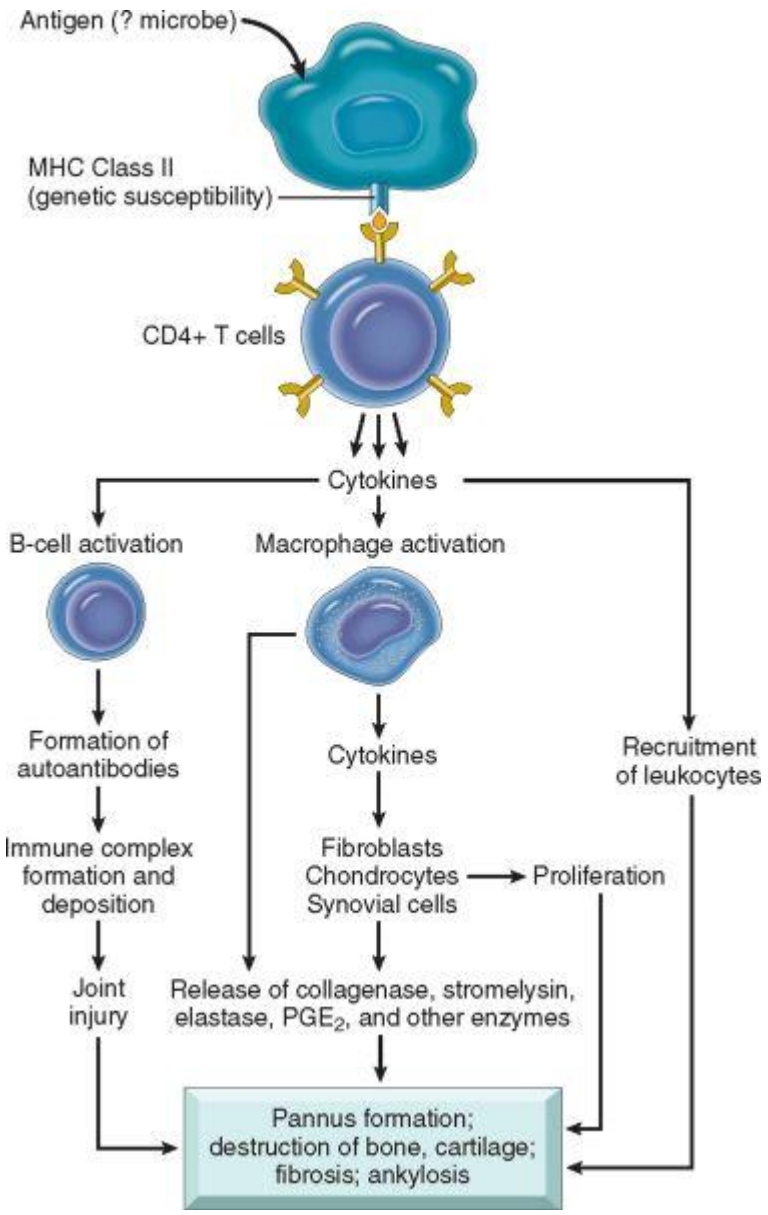

FIGURE 26-44 Immunopathogenesis of rheumatoid arthritis.

What mediators then bring about the destructive proliferative synovitis? These represent the "usual suspects." The cytokines secreted by the T cells, such as interferon-γ and IL-17, act upon and stimulate synoviocytes and macrophages, which produce pro-inflammatory molecules such as IL-1, IL-6, IL-23, TNF, PGE_2, nitric oxide, and the growth factors granulocyte-macrophage colony-stimulating factor and TGF-β. The inflammatory mediators activate endothelial cells in the synovium and thus facilitate leukocyte binding and transmigration. They also cause an *increased production of cartilage matrix metalloproteinases*, which along with antigen-antibody complexes, are important in the destruction of the articular cartilage. Additionally, they are potent stimulators of osteoclastogenesis and osteoclast activity by up-regulating the production of RANKL. RANKL is also expressed by the T cells and activated synoviocytes. Consequently the edematous, hyperplastic, and sticky (synoviocytes up-regulate vascular cell adhesion molecule) synovium rich in inflammatory cells becomes adherent to and grows

over the articular surface, forming a pannus, and stimulates resorption of the adjacent bone. *In the end, the pannus produces sustained, irreversible cartilage destruction and erosion of subchondral bone*.

From this alphabet soup of mediators and cytokines, only one has been firmly implicated in the pathogenesis of rheumatoid arthritis—TNF. Happily, proof of its involvement has come from trials of specific TNF antagonists, which relieve swelling and pain, and appear to arrest disease progression (see below).

Clinical Course.

The clinical course of rheumatoid arthritis is extremely variable. The disease begins slowly and insidiously in more than half of affected individuals. Initially there is malaise, fatigue, and generalized musculoskeletal pain, and only after several weeks to months do the joints become involved. The pattern of joint involvement varies, but it is generally *symmetrical and the small joints are affected before the larger ones*. Symptoms usually develop in the hands (metacarpophalangeal and proximal interphalangeal joints) and feet, followed by the wrists, ankles, elbows, and knees. Uncommonly the upper spine is involved, but the lumbosacral region and hips are usually spared.

Involved *joints are swollen, warm, painful, and particularly stiff on arising or following inactivity*. Approximately 10% of affected individuals have an acute onset over several days with severe symptoms and polyarticular involvement. The typical patient has progressive joint involvement over a period of months to years, with initial minimal limitation of motion that steadily becomes more severe. The disease course may be slow or rapid, and fluctuates over the years, with the greatest damage occurring in the first 4 or 5 years. Approximately 20% of affected individuals enjoy periods of partial or complete remission, but the symptoms inevitably return and involve previously unaffected joints.

The *radiographic hallmarks are joint effusions and juxta-articular osteopenia with erosions and narrowing of the joint space with loss of articular cartilage* (Fig. 26-45). Destruction of tendons, ligaments, and joint capsules produces characteristic deformities, including radial deviation of the wrist, ulnar deviation of the fingers, and flexion-hyperextension abnormalities of the fingers (swan neck, boutonnière). The end result is deformed joints that have no stability and minimal or no range of motion. Large synovial cysts, like the Baker cyst in the posterior knee, may develop as the increased intra-articular pressure causes outpunching of the synovium.

FIGURE 26-45 Rheumatoid arthritis of the hand. There is diffuse osteopenia, marked loss of the joint spaces of the carpal, metacarpal, phalangeal, and interphalangeal joints, periarticular bony erosions, and ulnar drift of the fingers.

The presence of rheumatoid factor and anti-CCP antibody are laboratory indicators that together are sensitive and fairly specific for rheumatoid arthritis. As pointed out, rheumatoid factor may not be present and also appears in many other conditions. Analysis of synovial fluid confirms an inflammatory arthritis with neutrophils, high protein content, and low mucin content, but is nonspecific. The diagnosis is based primarily on the clinical features and includes the presence of four of the following criteria: (1) morning stiffness, (2) arthritis in three or more joint areas, (3) arthritis of hand joints, (4) symmetric arthritis, (5) rheumatoid nodules, (6) serum rheumatoid factor, and (7) typical radiographic changes.

The treatment of rheumatoid arthritis is aimed at relieving the pain and inflammation, and slowing or arresting the relentless joint destruction. Therapies include corticosteroids, and synthetic and biologic disease-modifying drugs such as methotrexate and, most notably, antagonists of TNF. As mentioned

earlier, these are remarkably effective and now constitute the mainstay of treatment. Most importantly, they prevent or slow joint destruction, which is the greatest source of disability, and have altered the natural history of the disease for the better. However, anti-TNF agents are not curative, and patients must be maintained on TNF antagonists or other immunosuppressive drugs to avoid disease flares. Also, inhibiting the activity of a key inflammatory mediator comes with a price; patients treated with anti-TNF agents are susceptible to certain infections, particularly *M. tuberculosis*.

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA), previously known as juvenile rheumatoid arthritis, encompasses all forms of arthritis that develop before 16 years of age and that persist for a minimum of 6 weeks. JIA is one of the more common connective tissue diseases; it affects 30,000 to 50,000 children in the United States and is an important cause of functional disability. The etiology of JIA is unknown. It is classified into seven discrete clinical subsets that may correspond to separate diseases and genetic backgrounds; (1) systemic arthritis, (2) oligoarthritis, (3) rheumatoid factor–positive polyarthritis, (4) rheumatoid factor–negative polyarthritis, (5) enthesitis (inflammation of a point of attachment of skeletal muscle to bone)-associated arthritis, (6) psoriatic arthritis, and (7) undifferentiated arthritis.

JIA differs from rheumatoid arthritis in adults in the following ways: (1) oligoarthritis is more common, (2) systemic disease is more frequent, (3) large joints are affected more often than small joints, (4) rheumatoid nodules and rheumatoid factor are usually absent, and (5) antinuclear antibody (ANA) seropositivity is common. As in rheumatoid arthritis, risk is associated with genetic susceptibility (with particular HLA alleles) and environmental factors; the heterogeneity of the disease indicates that different factors may be at play in different individuals. The inflammatory synovitis and morphologic changes are similar to those in rheumatoid arthritis. There is evidence of abnormal immunoregulation and a prevalence of activated CD4+ memory T cells within involved joints; cytokine production is prominent and helps drive the process.

Systemic arthritis may have a rather abrupt onset, is associated with remitting, high spiking fevers, migratory and transient skin rash, hepatosplenomegaly, and serositis. Long-term follow-up shows that affected individuals may experience recurrent flares or persistent disease that may be associated with significant morbidity and serious complications.

Arthritis affecting four or fewer joints during the first 6 months of disease in the absence of psoriasis and an HLA-B27 genotype defines the *oligoarthritis variant*. The arthritis is asymmetric, develops at an early age (younger than 6 years), and is commonly associated with iridocylitis and a positive ANA.

Rheumatoid factor–positive polyarthritis is similar to the adult form of the disease and is mainly seen in teenage girls. Rheumatoid factor–negative polyarthritis involves more than five joints within the first 6 months and consists of several subtypes that have features that overlap with oligoarthritis and rheumatoid factor–negative arthritis in adults, and a subset that shows stiffness and contractions, but little swelling.

Enthesitis-related arthritis mainly affects male children younger than 6 years, and most affected individuals are HLA-B27 positive. The enthesitis and arthritis affects tendoligamentous insertion sites and joints of the lower extremities.

Undifferentiated arthritis encompasses patients who do not fulfill inclusion criteria of the other groups or have overlapping features.

Long-term prognosis of JIA is very variable. Although many affected individuals may have sustained disease activity, only about 10% develop serious functional disability.

SERONEGATIVE SPONDYLOARTHROPATHIES

The seronegative spondyloarthropathies are a group of diseases that develop in genetically predisposed individuals and are initiated by ubiquitous environmental factors, especially infectious agents. The manifestations are immune mediated and are triggered by a T-cell response presumably directed against an undefined antigen that may cross-react with native molecules of the musculoskeletal system. Clinically, the diseases produce inflammatory peripheral or axial oligoarthritis and enthesopathies. The seronegative spondyloarthropathies include *ankylosing spondylitis, reactive arthritis (Reiter syndrome and enteritis-associated arthritis), psoriatic arthritis, and arthritis associated with inflammatory bowel disease* (ulcerative colitis, Crohn disease). Many are associated with the HLA-B27 allele and a triggering infection but without specific autoantibodies (hence the term "*seronegative*"). They all have inflammation of synovial joints and share overlapping clinical features, with extra-articular involvement of the eyes, skin, and cardiovascular system being relatively commonplace.

Ankylosing Spondyloarthritis

Also known as *rheumatoid spondylitis* and *Marie-Strümpell disease*, ankylosing spondyloarthritis is a chronic synovitis that causes destruction of articular cartilage and resultant bony ankylosis, especially of the sacroiliac and apophyseal joints (between tuberosities and processes). Inflammation of tendinoligamentous insertion sites eventuates in their ossification, producing squaring and fusion of the vertebral bodies, and bony outgrowths, which together result in severe spinal immobility. It usually becomes symptomatic in the second and third decades of life, and men are affected two to three times more frequently than women. Affected individuals characteristically present with low back pain, which frequently follows a chronic progressive course. Involvement of peripheral joints, such as the hips, knees, and shoulders, occurs in at least one third of affected individuals. Fracture of the spine, uveitis, aortitis, and amyloidosis are other recognized complications. Approximately 90% of the risk of developing the disease and the severity of the clinical manifestations is determined genetically. Although 90% of affected individuals are HLA-B27 positive, it has been suspected the other genes also contribute. Recent genome-wide association studies have shown associations with *ARTS1*, a gene that encodes a peptidase that trims antigens being processed for presentation by class I HLA molecules; and *IL23R*, the gene for the IL-23 receptor, suggesting that IL-23 (which promotes T_H17 responses) may have a role in this disease.[49]

Reiter Syndrome

Reiter syndrome is a form of reactive arthritis and is defined by a triad of arthritis, nongonococcal urethritis or cervicitis, and conjunctivitis. Most affected individuals are men in their 20s or 30s, and more than 80% are HLA-B27 positive. This form of arthritis also affects individuals infected with the human immunodeficiency virus (HIV). The disease is probably caused by an autoimmune reaction initiated by prior infection of the gastrointestinal tract (*Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*) and the genitourinary system (*Chlamydia*). Arthritic symptoms usually develop within several weeks of the inciting bout of urethritis or diarrhea. Joint stiffness and low back pain are common early symptoms. The ankles, knees, and feet are affected most often, frequently in an asymmetric pattern. Synovitis of a digital tendon sheath produces the sausage finger or toe, and ossification of tendoligamentous insertion sites leads to calcaneal spurs and bony outgrowths. Patients with severe chronic disease have involvement of the spine that is indistinguishable from ankylosing spondylitis. Extra-articular involvement manifests as inflammatory balanitis, conjunctivitis, cardiac conduction abnormalities, and aortic regurgitation. The natural behavior of Reiter syndrome is extremely variable. The episodes of arthritis usually wax and wane over a period of several weeks to 6 months. Almost 50% of affected individuals have recurrent arthritis, tendinitis, fasciitis, and lumbosacral pain that can cause significant functional disability.

Enteritis-Associated Arthritis

Enteritis-associated arthritis is caused by gastrointestinal infection by *Yersinia*, *Salmonella*, *Shigella*, and *Campylobacter*, among others. The outer cell membranes of these organisms have lipopolysaccharides as a major component, and they stimulate a host of immunological responses. The arthritis appears abruptly and tends to involve the knees and ankles but sometimes also the wrists, fingers, and toes. It lasts for about a year, then generally clears and only rarely is accompanied by ankylosing spondylitis.

Psoriatic Arthritis

Psoriatic arthritis is a chronic inflammatory arthropathy that affects peripheral and axial joints and entheses and is associated with psoriasis. Susceptibility to the disease is genetically determined and related to HLA-B27 and HLA-Cw6 alleles. It develops in more than 10% of the psoriatic population and has assorted phenotypic subtypes. Symptoms manifest between the ages of 30 and 50, and those involving the joints usually develop slowly but are acute in onset in one third of affected individuals. The patterns of joint involvement are diverse. The distal interphalangeal joints of the hands and feet are first affected in an asymmetric distribution in more than 50% of patients and may be associated with a sausage-like finger. The large joints such as the ankles, knees, hips, and wrists may be involved as well.[50] Sacroiliac and spinal disease occurs in 20% to 40% of affected individuals. Aside from conjunctivitis and iritis, extra-articular manifestations are uncommon. Histologically, psoriatic arthritis is similar to rheumatoid arthritis. Psoriatic arthritis, however, is usually not as severe, remissions are more frequent, and joint destruction is less frequent.

INFECTIOUS ARTHRITIS

Microorganisms of all types can seed joints during hematogenous dissemination. Articular structures can also become infected by direct inoculation or from contiguous spread from a soft-tissue abscess or focus of osteomyelitis. Infectious arthritis is potentially serious, because it can cause rapid destruction of the joint and produce permanent deformities.

Bacterial Arthritis

Bacterial infections almost always cause an acute suppurative arthritis. The bacteria usually seed the joint during an episode of bacteremia; however, in neonates there is an increased incidence of contiguous spread from underlying epiphyseal osteomyelitis. The most common organisms are gonococcus, *Staphylococcus*, *Streptococcus*, *Haemophilus influenzae*, and gram-negative bacilli (*E. coli*, *Salmonella*, *Pseudomonas*, and others). *H. influenzae* arthritis predominates in children under 2 years of age, *S. aureus* is the main causative agent in older children and adults, and gonococcus is prevalent during late adolescence and young adulthood. Individuals with sickle cell disease are prone to infection with *Salmonella* at any age. These joint infections affect the sexes equally except for gonococcal arthritis, which is seen mainly in sexually active women. Predisposing conditions include immune deficiencies (congenital and acquired), debilitating illness, joint trauma, chronic arthritis of any cause, and intravenous drug abuse.

The classic presentation is the sudden development of an acutely painful and swollen infected joint that has a restricted range of motion. Systemic findings of fever, leukocytosis, and elevated sedimentation rate are common. In disseminated gonococcal infection the symptoms are more subacute. In 90% of nongonococcal cases, the infection involves only a single joint, usually the knee, followed in frequency by the hip, shoulder, elbow, wrist, and sternoclavicular joints. Axial articulations are more commonly involved in drug addicts. Prompt recognition and effective therapy prevent rapid joint destruction.

Tuberculous Arthritis

Tuberculous arthritis (Chapter 8) is a chronic progressive monoarticular disease that occurs in all age groups, especially adults. It usually develops as a complication of adjoining osteomyelitis or after hematogenous dissemination from a visceral (usually pulmonary) site of infection. Onset is insidious and causes gradual progressive pain. Systemic symptoms may or may not be present. Mycobacterial seeding of the joint induces the formation of confluent granulomas with central caseous necrosis. The affected synovium may grow as a pannus over the articular cartilage and erode the bone along the joint margins. Chronic disease results in severe destruction with fibrous ankylosis and obliteration of the joint space. The weight-bearing joints are usually affected, especially the hips, knees, and ankles in descending order of frequency.

Lyme Arthritis

As previously discussed (Chapter 8), Lyme arthritis is caused by infection with the spirochete *Borrelia burgdorferi*, which is transmitted by the ticks of the *Ixodes ricinus* complex. The initial infection of the skin is followed within several days or weeks by dissemination of the organism to other sites, especially the joints.

Approximately 60% to 80% of untreated individuals with Lyme disease develop joint symptoms within a few weeks to 2 years after the onset of the disease. The arthritis is the dominant feature of late disease; it tends to be remitting and migratory, and primarily involves large joints, especially the knees, shoulders, elbows, and ankles in descending order of frequency. Usually one or two joints are affected at a time, and the attacks last for a few weeks to months. Infected synovium exhibits a chronic papillary synovitis with synoviocyte hyperplasia, fibrin deposition, mononuclear cell infiltrates (especially CD4+ T cells), and onion-skin thickening of arterial walls. The morphology in severe cases can closely resemble that of rheumatoid arthritis. Silver stains may reveal small numbers of organisms in the vicinity of blood vessels in approximately 25% of cases. Chronic arthritis that is antibiotic refractory develops in approximately 10% of affected individuals and results from infection-induced autoimmunity. It is hypothesized that specific HLA-DR molecules bind an epitope of *B. burgdorferi* outer surface protein A, which initiates a T-cell reaction to this epitope. The T-cells may cross-react with an unknown self-antigen (an example of "molecular mimicry"). The joints in these patients have synovial pannus, which causes articular cartilage destruction and permanent deformities.[51]

Viral Arthritis

Arthritis can occur in the setting of a variety of viral infections, including alphavirus, parvovirus B19, rubella, Epstein-Barr virus, and hepatitis B and C virus. The clinical manifestations of the arthritis are variable and range from acute to subacute symptoms. It is unclear whether the joint symptoms are caused by direct infection of the joint by the virus, as seen in rubella and some alphavirus infections, or whether the viral infection generates an autoimmune reaction as seen in other forms of reactive or post-infectious arthritides.[52] A variety of different rheumatic conditions, including reactive arthritis, psoriatic arthritis, and septic arthritis, have developed in individuals infected with HIV. The pathogenesis of some of these forms of HIV-associated chronic arthritis is probably autoimmune. The new effective antiretroviral therapies for HIV have ameliorated their severity.

CRYSTAL-INDUCED ARTHRITIS

Articular crystal deposits are associated with a variety of acute and chronic joint disorders. Endogenous crystals shown to be pathogenic include monosodium urate (gout), calcium pyrophosphate dihydrate, and basic calcium phosphate (hydroxyapatite). Exogenous crystals, such as corticosteroid ester crystals and talcum, and the biomaterials polyethylene and methyl methacrylate, may also induce joint disease.

Silicone, polyethylene, and methyl methacrylate are used in prosthetic joints, and their debris that accumulates with long use and wear may result in local arthritis and failure of the prosthesis. Endogenous and exogenous crystals produce disease by triggering the cascade that results in cytokine-mediated cartilage destruction. Here we discuss the two most important crystal arthropathies: gout, caused by urates, and pseudo-gout, caused by calcium pyrophosphate.

Gout and Gouty Arthritis

Man is the only mammal to spontaneously develop hyperuricemia and gout, as only humans lack uricase, the enzyme responsible for the degradation of uric acid in other mammals. This, in combination with a high reabsorption rate of filtered urate, predisposes humans to hyperuricemia and gout, which is the common end point of a group of disorders that produce hyperuricemia.

Gout is marked by transient attacks of *acute arthritis* initiated by crystallization of urates within and about joints, leading eventually to *chronic gouty arthritis* and the appearance of *tophi*. Tophi represent large aggregates of urate crystals and the surrounding inflammatory reaction (see later). Most, but not all, individuals with chronic gout also develop urate nephropathy. Hyperuricemia (plasma urate level above 6.8 mg/dL) is necessary but not sufficient for the development of gout. More than 10% of the population of the Western hemisphere has hyperuricemia, and the prevalence is increasing; however, gout develops in fewer than 0.5% of these individuals. The various conditions producing hyperuricemia and gout (Table 26-7) are divided into those that produce primary gout (accounting for most idiopathic cases) and secondary gout (the cause of the hyperuricemia is known, and gout is not the main clinical expression of the disease). The role of hyperuricemia in the development of a variety of diseases, such as hypertension, chronic renal disease, cardiovascular disease, and the metabolic syndrome of hypertriglyceridemia, obesity, and insulin resistance, is controversial and remains a focus of investigation.

TABLE 26-7 -- Classification of Gout

PRIMARY GOUT (90% OF CASES)
Overproduction of uric acid
Diet
Unknown enzyme defects (80% to 90%)
Known enzyme defects (e.g., partial HGPRT deficiency, rare)
Reduced excretion of uric acid with normal production
SECONDARY GOUT (10% OF CASES)
Overproduction of uric acid with increased urinary excretion
Increased nucleic acid turnover (e.g., leukemias and other aggressive neoplasms)
Inborn errors of metabolism (e.g., complete HGPRT deficiency)
Reduced excretion of uric acid with normal production
Chronic renal disease

Pathogenesis.

Uric acid is the end product of purine metabolism. Clinically, hyperuricemia develops from overproduction of urate in approximately 10% of cases (increased cell turnover—as in cancer, psoriasis, and during tumor lysis induced by chemotherapy) and reduced excretion in the remainder.

Plasma levels of uric acid are governed by a four-part renal transport system that involves glomerular filtration, reabsorption, secretion, and postsecretory reabsorption. Approximately 90% of the filtered urate is reabsorbed, and the urate transporter 1 gene *(URAT1)* has an important role in the reabsorption process. Decreased filtration and underexcretion of uric acid underlies most cases of primary gout. Two pathways are involved in purine synthesis: (1) a de novo pathway in which purines are synthesized from non-purine precursors and (2) a salvage pathway in which free purine bases derived from the breakdown of nucleic acids of endogenous or exogenous origin are recaptured (salvaged) (Fig. 26-46). The enzyme hypoxanthine guanine phosphoribosyl transferase (HGPRT) is involved in the salvage pathway. A deficiency of this enzyme leads to increased synthesis of purine nucleotides through the de novo pathway and hence increased production of uric acid. A complete lack of HGPRT occurs in the uncommon X-linked *Lesch-Nyhan syndrome*, seen only in males and characterized by hyperuricemia, severe neurologic deficits with mental retardation, self-mutilation, and in some cases gouty arthritis. Less severe deficiencies of the enzyme may also induce hyperuricemia and gouty arthritis with only mild neurologic deficits, but together these causes of gout are uncommon.

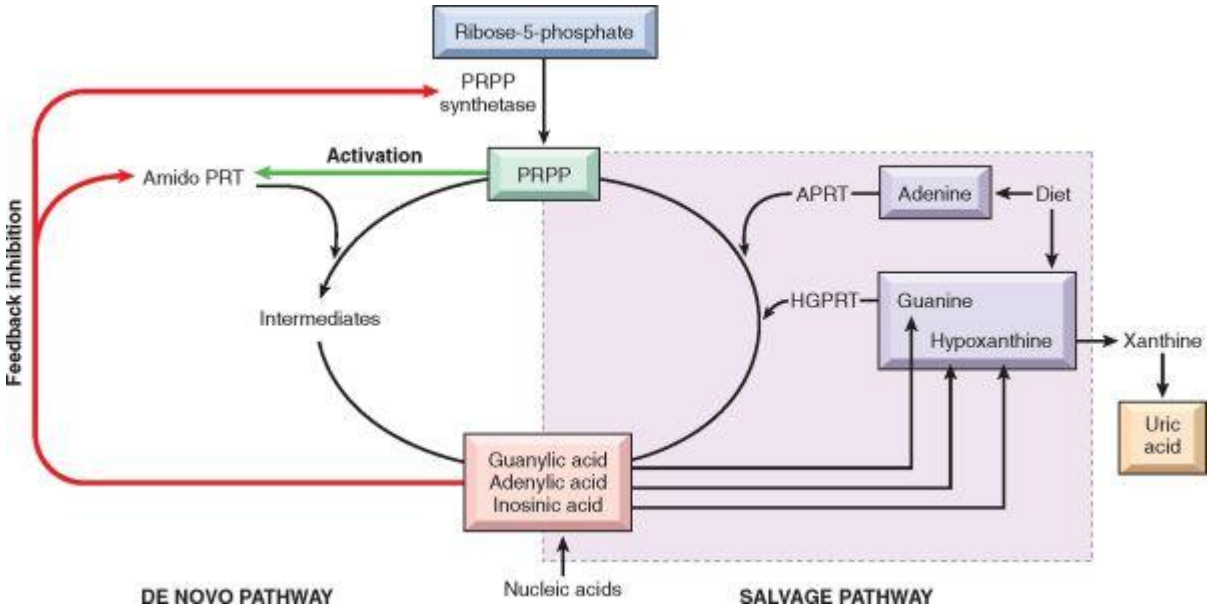

FIGURE 26-46 Purine metabolism. The conversion of PRPP to purine nucleotides is catalyzed by amido-PRT in the de novo pathway and by APRT and HGPRT in the salvage pathway. APRT, adenosine phosphoribosyltransferase; HGPRT, hypoxanthine-guanine phosporibosyltransferase; PRPP, phosphoribosyl pyrophosphate; PRT, phosphoribosyltransferase.

As stated earlier, hyperuricemia does not necessarily lead to gouty arthritis. Many factors contribute to the conversion of asymptomatic hyperuricemia into primary gout, including the following:

- *Age* of the individual and *duration of the hyperuricemia*. Gout rarely appears before 20 to 30 years of hyperuricemia.
- *Genetic predisposition*. In addition to the well-defined X-linked abnormalities of HGPRT, primary gout follows multifactorial inheritance and runs in families.
- Heavy *alcohol* consumption predisposes to attacks of gouty arthritis.
- *Obesity* increases the risk of asymptomatic gout.
- Certain *drugs* (e.g., thiazides) reduce excretion of urate and predispose to the development of gout.

- *Lead toxicity* increases the tendency to develop saturnine gout (Chapter 9).

Central to the pathogenesis of the arthritis is precipitation of monosodium urate (MSU) crystals into the joints (Fig. 26-47). The solubility of MSU in a joint is modulated by temperature (the lower the less soluble) and by the intra-articular concentration of urate and cations. Crystallization is dependent on the presence of nucleating agents such as insoluble collagen fibers, chondroitin sulfate, proteoglycans, cartilage fragments, and other crystals. Since synovial fluid is a poorer solvent for monosodium urate than plasma, urates in the joint fluid become supersaturated more easily, particularly in the peripheral joints (ankles and toes), where temperatures are as low as 20°C. With prolonged hyperuricemia, crystals and microtophi of urates develop in the synovium and in the joint cartilage. Some unknown event, possibly trauma, causes the release of crystals into the synovial fluid, which begins a cascade of events that initiates, intensifies, and sustains a powerful inflammatory response that is the hallmark of the acute attack. MSU crystals are phagocytosed by macrophages and through an incompletely understood mechanism activate the NALP3 inflammasome, a multiprotein complex that includes the protease caspase 1. The inflammasome-activated caspase 1, in turn, cleaves and activates several cytokines, most notably IL-1β and IL-18. IL-1β induces the expression of adhesion molecules and the synthesis of the neurophil chemokine CXCL8, which is essential for the localization of neutrophils at the site of acute inflammation. The neutrophils pour fuel on the fire by releasing toxic free radicals, leukotrienes (leukotriene B4), and lysosomal enzymes. Thus comes about an acute arthritis, which typically remits spontaneously in days to weeks.[53] A scheme of these events is shown in Figure 26-47 .

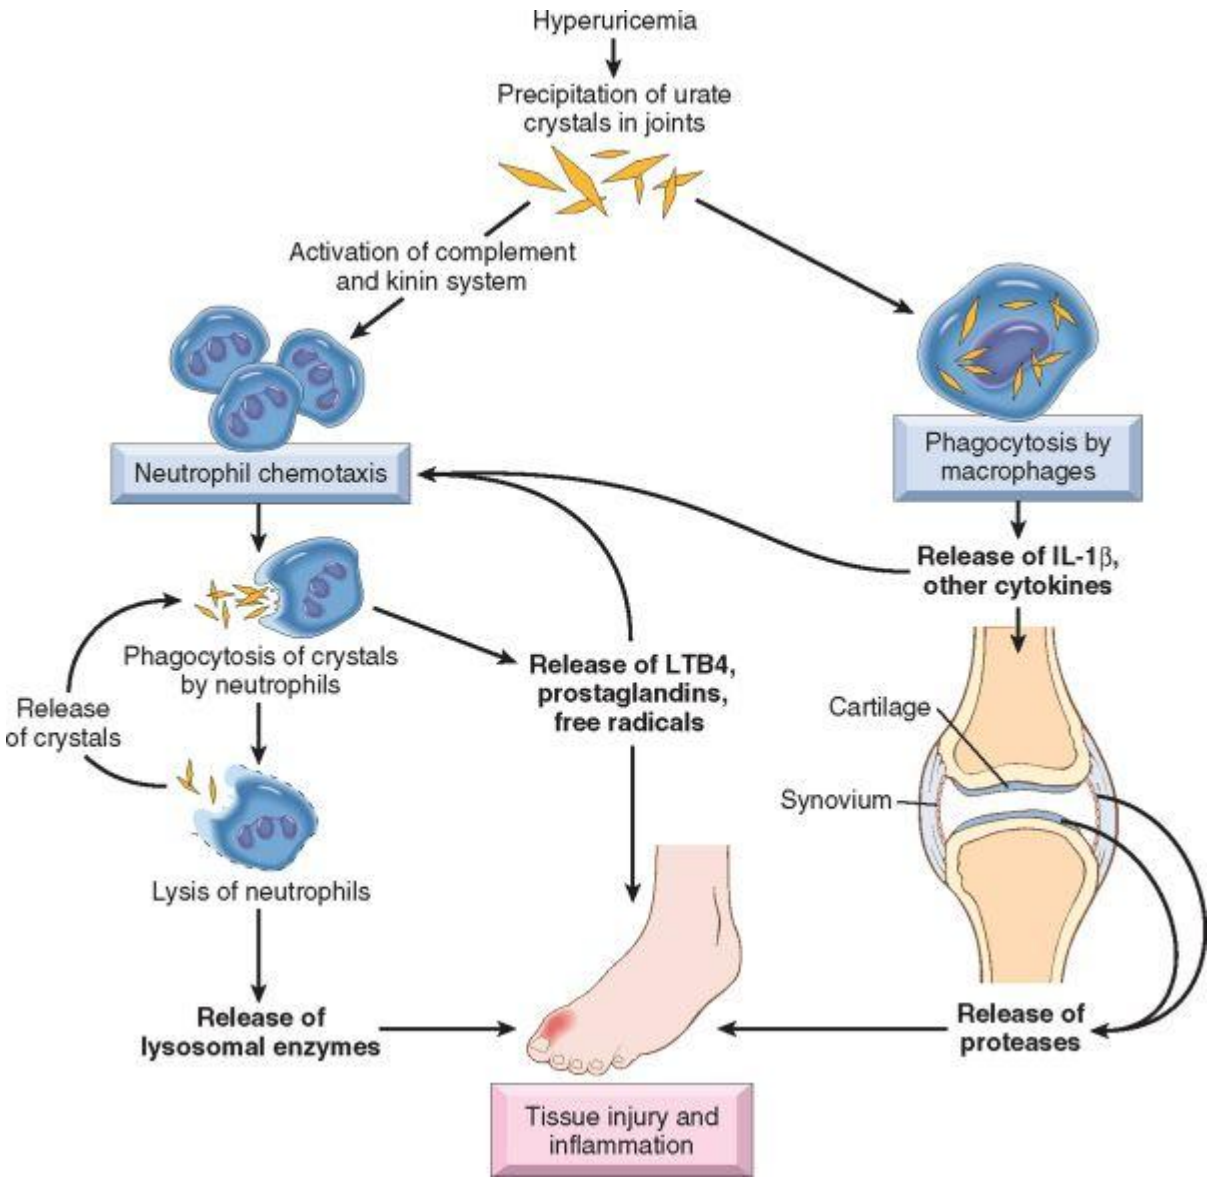

FIGURE 26-47 Pathogenesis of acute gouty arthritis. LTB4, leukotriene B4.

Repeated attacks of acute arthritis lead eventually to chronic arthritis and the formation of tophi in the inflamed synovial membranes and periarticular tissue, as well as elsewhere. In time, severe damage to the cartilage develops and the function of the joints is compromised. It is not known why the chronic arthritis is asymptomatic for intervals of days to months, even though crystals are undoubtedly present in abundance in the joints.

Morphology. The distinctive morphologic changes in gout are (1) acute arthritis, (2) chronic tophaceous arthritis, (3) tophi in various sites, and sometimes (4) gouty nephropathy. **Acute arthritis** is characterized by a dense neutrophilic infiltrate that permeates the synovium and synovial fluid. The MSU crystals are frequently found in the cytoplasm of the neutrophils and are arranged in small clusters in the synovium. They are long, slender, and needle shaped, and are negatively birefringent.

The synovium is edematous and congested, and also contains scattered lymphocytes, plasma cells, and macrophages. When the episode of crystallization abates and the crystals are resolubilized, the acute attack remits.

Chronic tophaceous arthritis evolves from the repetitive precipitation of urate crystals during acute attacks. The urates may heavily encrust the articular surfaces and form visible deposits in the synovium (Fig. 26-48). The synovium becomes hyperplastic, fibrotic, and thickened by inflammatory cells and forms a pannus that destroys the underlying cartilage leading to juxta-articular bone erosions. In severe cases, fibrous or bony ankylosis ensues, resulting in partial to complete loss of joint function.

Tophi are the pathognomonic hallmark of gout. They are formed by large aggregations of urate crystals surrounded by an intense inflammatory reaction of macrophages, lymphocytes, and large foreign body giant cells, which may have completely or partially engulfed masses of crystals (Fig. 26-49). Tophi may appear in the articular cartilage of joints and in the periarticular ligaments, tendons, and soft tissues, including the olecranon and patellar bursae, Achilles tendons, and earlobes. Less frequently they may occur in the kidneys, nasal cartilages, skin of the fingertips, palms, soles, or elsewhere. Superficial tophi can ulcerate through the overlying skin.

Gouty nephropathy (Chapter 20) is associated with the deposition of MSU crystals in the renal medullary interstitium, sometimes forming tophi, intratubular precipitations, or free uric acid crystals, and the production of uric acid renal stones. Secondary complications, such as pyelonephritis, may ensue, particularly when the urates induce some urinary obstruction.

FIGURE 26-48 Amputated great toe with white tophi involving the joint and soft tissues.

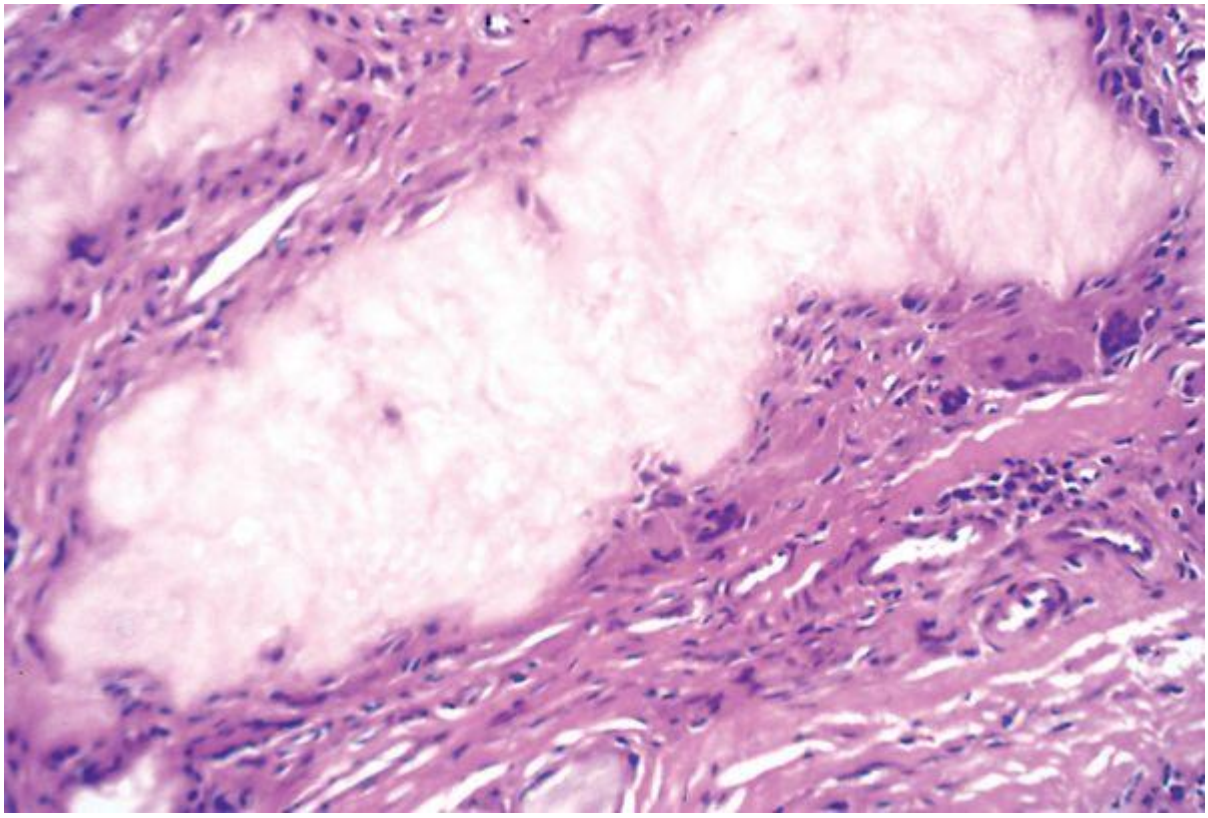

FIGURE 26-49 Photomicrograph of a gouty tophus. An aggregate of dissolved urate crystals is surrounded by reactive fibroblasts, mononuclear inflammatory cells, and giant cells.

Clinical Course.

The natural history of gout is said to have four stages: (1) asymptomatic hyperuricemia, (2) acute gouty arthritis, (3) intercritical gout, and (4) chronic tophaceous gout. *Asymptomatic hyperuricemia* appears around puberty in males and after menopause in females. After many years *acute arthritis* appears in the form of the sudden onset of excruciating joint pain associated with localized hyperemia, warmth, and exquisite tenderness. Yet constitutional symptoms are uncommon except possibly mild fever. Most first attacks are monoarticular; 50% occur in the first metatarsophalangeal joint. Eventually, about 90% of affected individuals experience acute attacks in the following locations (in descending order of frequency): insteps, ankles, heels, knees, wrists, fingers, and elbows. Untreated, acute gouty arthritis may last for hours to weeks, but gradually there is complete resolution and the patient enters an *asymptomatic intercritical period*. Although some patients never have another attack, most experience a second acute episode within months to a few years. In the absence of appropriate therapy, the attacks recur at shorter intervals and frequently become polyarticular. Eventually, over the span of years, disabling *chronic tophaceous gout* develops. On average about 12 years pass between the initial acute attack and the appearance of chronic tophaceous arthritis. At this stage, radiograms show characteristic juxta-articular bone erosion caused by osteoclastic bone resorption and loss of the joint space. Progression leads to severe crippling disease.

Cardiovascular disease including atherosclerosis and hypertension is common in individuals with gout. Renal manifestations sometimes appear in the form of renal colic associated with the passage of gravel

and stones and may proceed to chronic gouty nephropathy. About 20% of those with chronic gout die of renal failure. The diagnosis of gout should not be delayed, because numerous drugs are available to abort or prevent acute attacks of arthritis and mobilize tophaceous deposits. Their use is important, because many aspects of the disease are related to the duration and severity of the hyperuricemia. Generally, gout does not materially shorten the life span, but it may impair the quality of life.

Calcium Pyrophosphate Crystal Deposition Disease (Pseudo-Gout)

Calcium pyrophosphate crystal deposition disease (CPPD), also known as *pseudo-gout* and *chondrocalcinosis*, is one of the more common disorders associated with intra-articular crystal formation. It usually occurs in individuals over 50 years of age and becomes more common with increasing age, rising to a prevalence of 30% to 60% in those 85 years or older. The sexes and races are equally affected. CPPD is divided into sporadic (idiopathic), hereditary, and secondary types. In the hereditary variant the crystals develop relatively early in life and are associated with severe osteoarthritis. The autosomal dominant form of the disease is caused by germline mutations in the *ANKH* gene, which encodes a transmembrane pyrophosphate transport channel.[54] The secondary form is associated with various disorders, including previous joint damage, hyperparathyroidism, hemochromatosis, hypomagnesemia, hypothyroidism, ochronosis, and diabetes. The basis for crystal formation is not known; altered activity of the matrix enzymes that produce and degrade pyrophosphate is suspected.

Morphology. The crystals first develop in the articular matrix, menisci, and intervertebral discs, and as the deposits enlarge they may rupture and seed the joint. Here, they are phagocytosed by macrophages, in which they activate the NALP3 inflammasome, eliciting a series of pro-inflammatory events similar or identical to those induced by urate crystals (Fig. 26-47). Neutrophils recruited by inflammatory mediators are thought to produce damage through the release of reactive oxygen species, catabolic enzymes, and cytokines, calling forth the more chronic reactions associated with macrophages and fibrosis. The crystals form chalky white friable deposits, which are seen histologically in stained preparations as oval blue-purple aggregates. Individual crystals are generally 0.5 to 5 μm in greatest dimension, are weakly birefringent, and have geometric shapes (Fig. 26-50). Rarely the crystals are deposited in masslike aggregates simulating tophi.

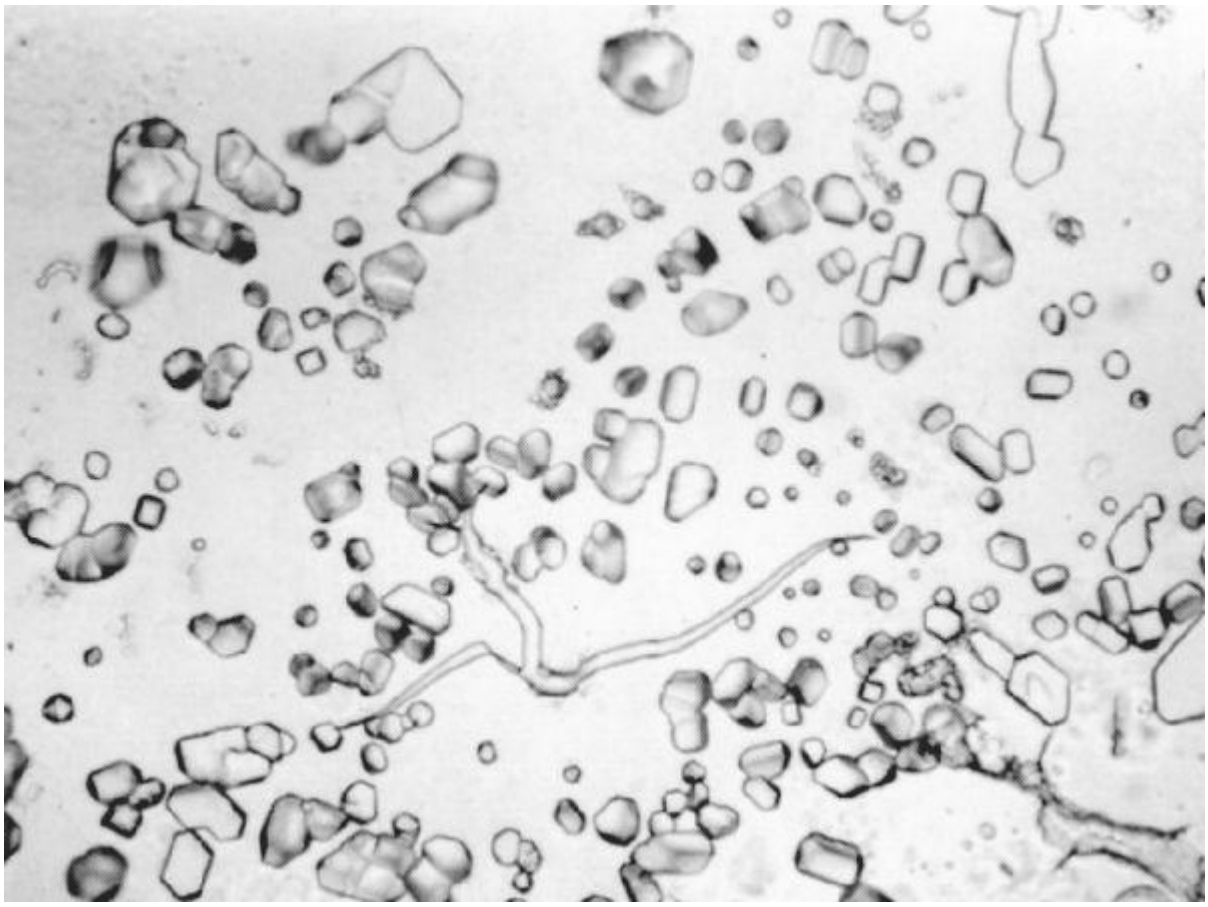

FIGURE 26-50 Smear preparation of calcium pyrophosphate crystals.

CPPD is frequently asymptomatic; however, it also can produce acute, subacute, or chronic arthritis that can be confused with osteoarthritis or rheumatoid arthritis. The joint involvement may last from several days to weeks and may be monoarticular or polyarticular; the knees, followed by the wrists, elbows, shoulders, and ankles, are most commonly affected. Ultimately, approximately 50% of affected individuals experience significant joint damage. Therapy is supportive. There is no known treatment that prevents or retards crystal formation.

3.16.2.2 Tumors & Tumor-Like Lesions

Reactive tumor-like lesions, such as ganglions, synovial cysts, and osteochondral loose bodies, commonly involve joints and tendon sheaths. They usually result from trauma or degenerative processes and are much more common than neoplasms. Primary neoplasms are unusual and tend to recapitulate the cells and tissue types (synovial membrane, fat, blood vessels, fibrous tissue, and cartilage) native to joints and related structures. Benign tumors are much more frequent than their malignant counterparts, which are rare and discussed with the soft-tissue tumors.

GANGLION AND SYNOVIAL CYST

A *ganglion* is a small (1–1.5 cm) cyst that is almost always located near a joint capsule or tendon sheath. A common location is around the joints of the wrist, where it appears as a firm, fluctuant, pea-sized

translucent nodule. It arises as a result of cystic or myxoid degeneration of connective tissue; hence the cyst wall lacks a true cell lining. The lesion may be multilocular and enlarges through coalescence of adjacent areas of myxoid change. The fluid that fills the cyst is similar to synovial fluid; however, there is no communication with the joint space.

Herniation of synovium through a joint capsule or massive enlargement of a bursa may produce a *synovial cyst*. A well-recognized example is the synovial cyst that forms in the popliteal space in the setting of rheumatoid arthritis (Baker cyst). The synovial lining may be hyperplastic and contain inflammatory cells and fibrin but is otherwise unremarkable.

TENOSYNOVIAL GIANT-CELL TUMOR (LOCALIZED AND DIFFUSE)

Tenosynovial giant-cell tumor is the term for several closely related benign neoplasms that develop in the synovial lining of joints, tendon sheaths, and bursae. They harbor a consistent chromosomal translocation, t(1;2)(p13;q37), which fuses colony-stimulating factor 1 (CSF1) coding sequences to the promoter of the collagen type VI alpha-3 gene.[55] As a result, the tumor cells overexpress CSF1, a chemoattractant for macrophages, which infiltrate the tumor in large numbers. Variants of tenosynovial giant-cell tumor include the diffuse type (previously known as pigmented villonodular synovitis), and the localized type (also known as *giant-cell tumor of tendon sheath*). Whereas the diffuse form tends to involve one or more joints, the localized kind usually occurs as a discrete nodule attached to a tendon sheath, commonly of the hand. Both variants usually are diagnosed in the 20s to 40s and affect the sexes equally.

Morphology. Grossly, tenosynovial giant-cell tumors are red-brown to mottled orange-yellow. In diffuse tumors the normally smooth joint synovium is converted into a tangled mat by red-brown folds, finger-like projections, and nodules (Fig. 26-51). In contrast, localized tumors are well circumscribed and resemble a small walnut. The neoplastic cells, which account for only 2% to 16% of the cells in the mass, are polyhedral, moderately sized, and resemble synoviocytes (Fig. 26-52). In the diffuse variant they spread along the surface and infiltrate the subsynovial issue. In nodular tumors the cells grow in a solid aggregate that may be attached to the synovium by a pedicle. Both variants are heavily infiltrated by macrophages, which may contain hemosiderin and lipid-filled vacuoles, or coalesce into multinucleated giant cells.

FIGURE 26-51 Excised synovium with fronds and nodules typical of pigmented villonodular synovitis *(arrow)*.

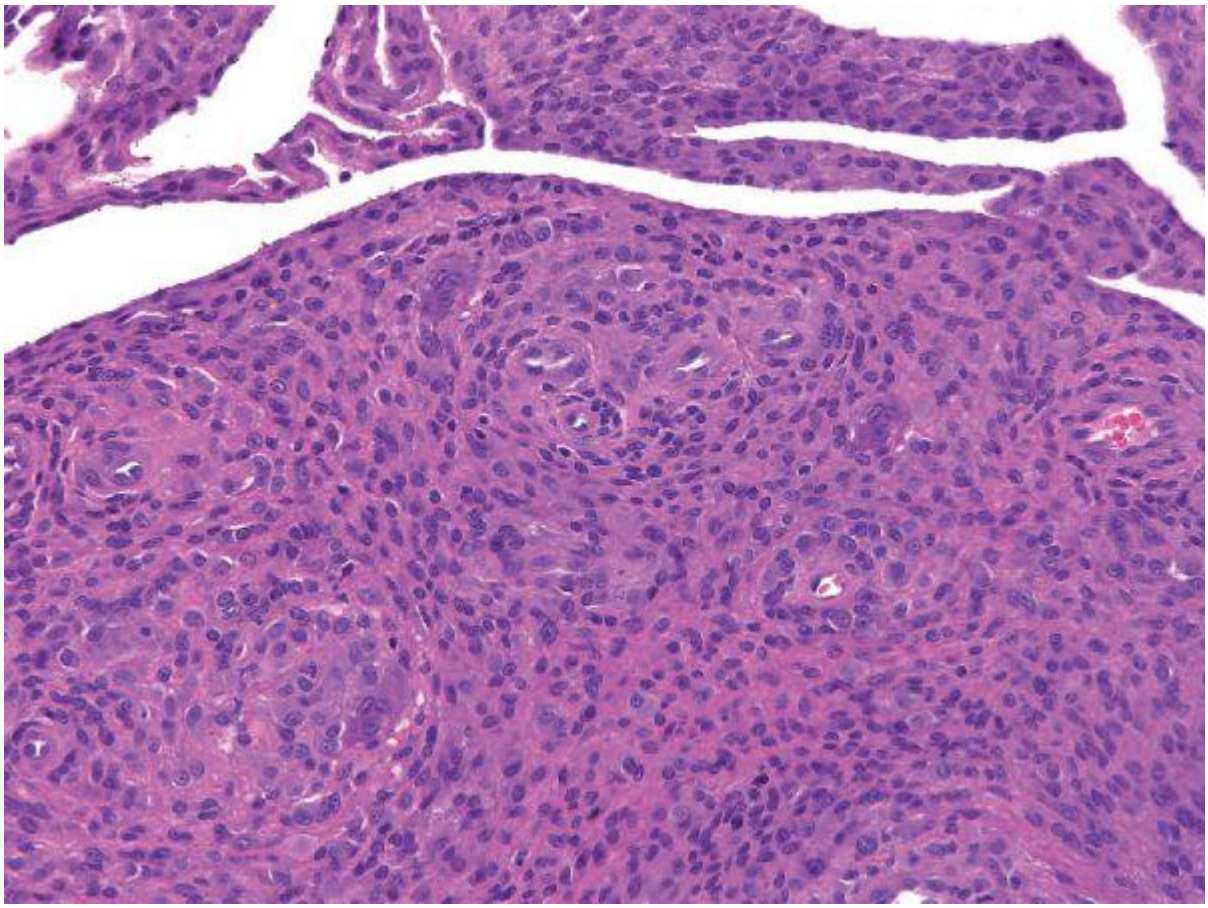

FIGURE 26-52 Sheets of proliferating cells in tenosynovial giant cell tumor bulging the synovial lining.

Diffuse tenosynovial giant-cell tumor usually presents in the knee in 80% of cases, followed in frequency by the hip, ankle, and calcaneocuboid joints. Affected individuals typically complain of pain, locking, and recurrent swelling. Tumor progression limits the range of movement of the joint and causes it to become stiff and firm. Sometimes a palpable mass is appreciated. Aggressive tumors erode into adjacent bones and soft tissues, causing confusion with other types of neoplasms. In contrast, the localized variant manifests as a solitary, slow-growing, painless mass that frequently involves the tendon sheaths along the wrists and fingers; it is the most common mesenchymal neoplasm of the hand. Cortical erosion of adjacent bone occurs in approximately 15% of cases. Surgery is the recommended treatment for both lesions; the diffuse tumors have a significant recurrence rate, because they are difficult to excise.

3.16.3 Soft-Tissue Tumors & Tumor-Like Lesions

Traditionally, soft-tissue tumors are defined as mesenchymal proliferations that occur in the extraskeletal, nonepithelial tissues of the body, excluding the viscera, coverings of the brain, and lymphoreticular system. They are classified according to the tissue they *recapitulate* (muscle, fat, fibrous tissue, vessels, and nerves) (Table 26-8), although there is little evidence that they actually arise from the normal differentiated counterpart. Some soft-tissue tumors have no normal tissue counterpart but have constant clinicopathologic features warranting their designation as distinct entities.

The true frequency of soft-tissue tumors is difficult to estimate, because most benign lesions are not removed. A conservative estimate is that benign tumors outnumber their malignant counterparts (sarcomas) by a ratio of at least 100 : 1. In the United States, little more than 8000 sarcomas are diagnosed annually (0.8% of invasive malignancies), yet they are responsible for 2% of all cancer deaths, reflecting their lethal nature. In contrast to carcinomas, sarcomas usually metastasize via hematogenous routes, making the lung and skeleton common sites of dissemination.

3.16.3.1 Pathogenesis & General Features

The cause of most soft-tissue tumors is unknown. There are documented associations, however, with radiation therapy, and rare instances in which chemical burns, thermal burns, or trauma were associated with subsequent development of a sarcoma. Exposure to phenoxyherbicides and chlorophenols has also

been implicated in some cases. Kaposi sarcoma is causally associated with the human herpesvirus 8; however, viruses are probably not important in the pathogenesis of most human sarcomas. The majority of soft-tissue tumors occur sporadically, but a small minority are associated with genetic syndromes, the most notable of which are neurofibromatosis type 1 (neurofibroma, malignant peripheral nerve sheath tumor), Gardner syndrome (fibromatosis), Li-Fraumeni syndrome (soft-tissue sarcoma), and Osler-Weber-Rendu syndrome (telangiectasia). Current evidence suggests that soft-tissue tumors develop due to mutations in mesenchymal stem cells that are widely distributed in the body. Some of the abnormalities, such as specific chromosomal translocations, produce fusion genes that encode chimeric transcription factors. How these abnormal transcription factors drive neoplastic transformation is not clear. These genetic events can be specific enough to serve as diagnostic markers in some tumors[56] (Table 26-9).

TABLE 26-9 -- Chromosomal and Genetic Abnormalities in Soft-Tissue Sarcomas

Tumor	Cytogenetic Abnormality	Genetic Abnormality
Ewing sarcoma/Primitive neuroectodermal tumor	t(11;22)(q24;q12)	*FLI1-EWS* fusion gene

Clear-cell sarcoma	t(12;22)(q13;q12)	*EWS-ATF1* fusion gene
Dermatofibrosarcoma protuberans	t(17;22)(q22;q15)	*COLA1-PDGFB* fusion gene
Alveolar soft-part sarcoma	t(X;17)(p11.2;q25)	*TFE3-ASPL* fusion gene
Congenital fibrosarcoma	t(12;15)(p13;q23)	*ETV6-NTRK3* fusion gene

Soft-tissue tumors may arise in any location; approximately 40% occur in the lower extremity, especially the thigh, 20% in the upper extremities, 10% in the head and neck, and 30% in the trunk and retroperitoneum. Regarding sarcomas, males are affected more frequently than females (1.4 : 1), and the incidence generally increases with age. Fifteen percent arise in children, and they constitute the fourth most common malignancy in this age group, following brain tumors, hematopoietic cancers, and Wilms tumor in frequency. Specific sarcomas tend to appear in certain age groups (e.g., rhabdomyosarcoma in children, synovial sarcoma in young adulthood, and liposarcoma and fibrosarcoma in middle to late adult life).

Several features of soft-tissue tumors influence their prognosis:

- Accurate histologic classification is important in establishing the prognosis of a sarcoma. The cytologic appearance and the pattern of growth of tumor cells are helpful morphologic features (Tables 26-10 and 26-11), but these features are often not sufficient to arrive at a specific diagnosis. In such cases other tests, particularly immunohistochemical stains and cytogenetic evaluation, are essential diagnostic aids.
- For many types of soft-tissue sarcomas the histologic grade is important. Grading, usually I to III, is based on the degree of differentiation, the average number of mitoses per high-power field, cellularity, pleomorphism, and an estimate of the extent of necrosis (presumably a reflection of rate of growth).[57]
- Staging helps determine the prognosis and chance of successful excision of a tumor. In the United States the American Joint Committee on Cancer (AJCC) staging system for soft-tissue sarcoma is utilized for treatment

and is largely based on tumor size, location, depth, grade, and presence or absence of metastases.

- In general, tumors arising in superficial locations (e.g., skin and subcutis) have a better prognosis than deep-seated lesions. In patients with deep-seated, high-grade sarcomas, metastatic disease develops in 80% of those with a tumor larger than 20 cm and 30% of those with a tumor larger than 5 cm. The overall 10-year survival rate for sarcomas is approximately 40%.

TABLE 26-10 -- Morphology of Cells in Soft Tissue Tumors

Cell Type	Features	Tumor Type
Spindle cell	Rod-shaped, long axis twice as great as short axis	Fibrous, fibrohistiocytic, smooth muscle, Schwann cell
Small round cell	Size of a lymphocyte with little cytoplasm	Rhabdomyosarcoma, primitive neuroectodermal tumor
Epithelioid	Polyhedral with abundant cytoplasm, nucleus is centrally located	Smooth muscle, Schwann cell endothelial, epithelioid sarcoma

TABLE 26-11 -- Architectural Patterns in Soft-Tissue Tumors

Pattern	Tumor Type
Fascicles of eosinophilic spindle cells intersecting at right angles	Smooth muscle
Short fascicles of spindle cells radiating from a central point like spokes on a wheel—storiform	Fibrohistiocytic
Nuclei arranged in columns—palisading	Schwann cell
Herringbone	Fibrosarcoma
Mixture of fascicles of spindle cells and groups of epithelioid cells—biphasic	Synovial sarcoma

With this brief background, we now turn to the individual tumors and tumor-like lesions. Some of the soft-tissuetumors are presented elsewhere: tumors of peripheral nerve (Chapter 28); tumors of vascular origin, including Kaposi sarcoma (Chapter 11); and uterine tumors of smooth muscle origin (Chapter 22).

3.16.3.2 Fatty Tumors

LIPOMAS

Benign tumors of fat, known as lipomas, are the most common soft-tissue tumor of adulthood. They are subclassified according to particular morphologic features as conventional lipoma, fibrolipoma, angiolipoma, spindle cell lipoma, myelolipoma, and pleomorphic lipoma. Some of the variants have characteristic chromosomal abnormalities; for example, conventional lipomas often show rearrangements of 12q14–q15, 6p, and 13q, and spindle cell and pleomorphic lipomas have rearrangements of 16q and 13q.

Morphology. The conventional lipoma, the most common subtype, is a well-encapsulated mass of mature adipocytes that varies considerably in size. It arises in the subcutis of the proximal extremities and trunk, most frequently during middle adulthood. Infrequently, lipomas are large, intramuscular, and poorly circumscribed.

Lipomas are soft, mobile, and painless (except angiolipoma) and are usually cured by simple excision.

LIPOSARCOMA

Liposarcomas are one of the most common sarcomas of adulthood and appear in the 40s to 60s; they are rare in children. They usually arise in the deep soft tissues of the proximal extremities and retroperitoneum, and are notorious for developing into large tumors.

Morphology. Liposarcomas are histologically divided into well-differentiated, myxoid/round cell, and pleomorphic variants. The cells in well-differentiated liposarcomas are readily recognized as lipocytes, and the tumor cells frequently contain supernumerary rings and giant rod chromosomes due to amplification of the 12q14–q15 region containing the *MDM2* oncogene. This, you may recall, inhibits p53 (Chapter 7). In the other variants, most of the tumor cells are not obviously adipogenic, but some cells indicative of fatty differentiation are almost always present. These cells are known as **lipoblasts**; they mimic fetal fat cells and contain round clear cytoplasmic vacuoles of lipid that scallop the nucleus (Fig. 26-53). The myxoid/round cell variant of liposarcoma has a t(12;16)(q13;p11) chromosomal abnormality in most cases.

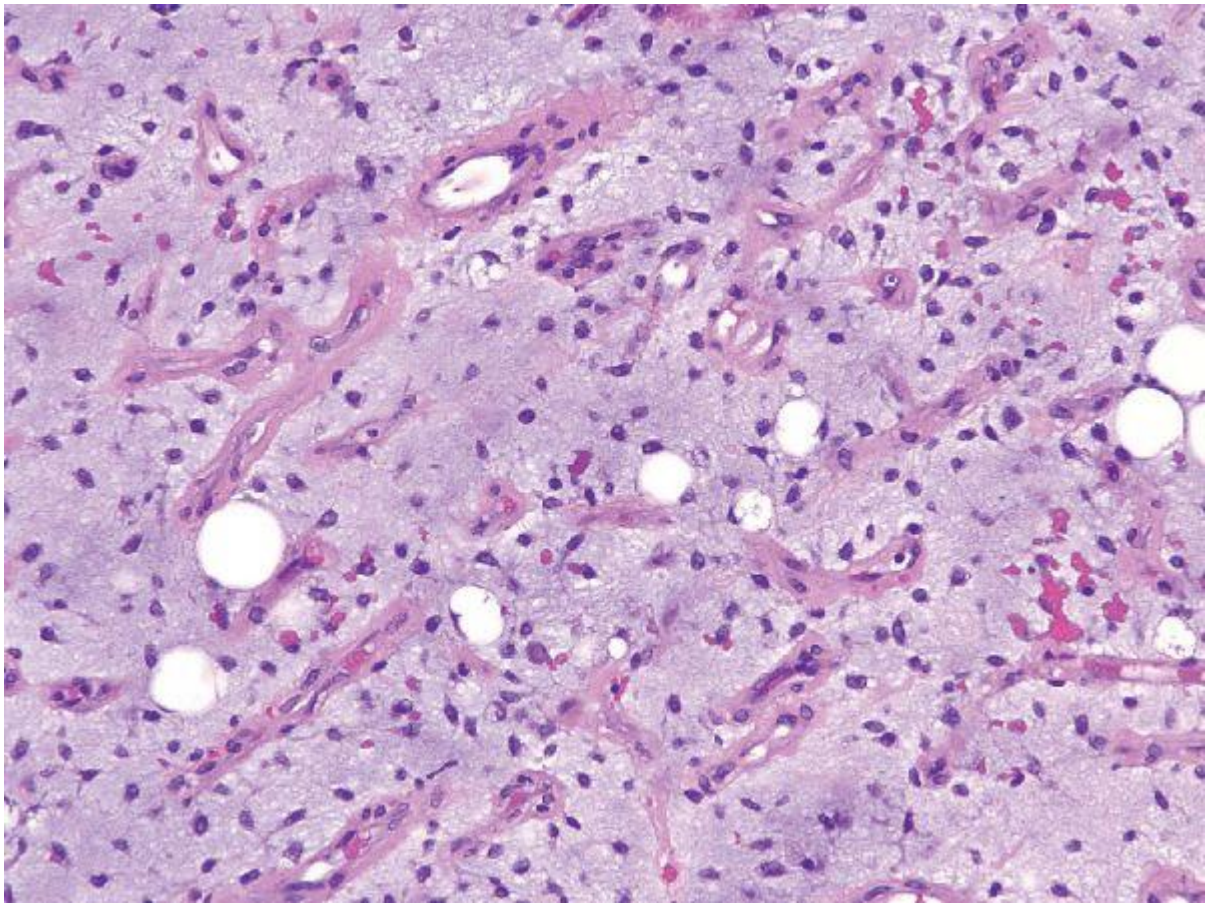

FIGURE 26-53 Myxoid liposarcoma with abundant ground substance in which are scattered adult-appearing fat cells and more primitive cells, some containing small lipid vacuoles (lipoblasts).

The well-differentiated variant is relatively indolent, the myxoid/round cell type is intermediate in its malignant behavior, and the pleomorphic variant usually is aggressive and frequently metastasizes. All types of liposarcoma recur locally and often repeatedly unless adequately excised.

REACTIVE PSEUDOSARCOMATOUS PROLIFERATIONS

Reactive pseudosarcomatous proliferations are nonneoplastic lesions that either develop in response to some form of local trauma (physical or ischemic) or are idiopathic. They are composed of plump reactive fibroblasts and related mesenchymal cells. Clinically they are alarming, because they develop suddenly and grow rapidly. Histologically they cause concern, because their hypercellularity, mitotic activity, and primitive appearance mimic sarcoma. Representative of this family of lesions are *nodular fasciitis* and *myositis ossificans*.

Nodular Fasciitis

Nodular fasciitis, also known as *infiltrative* or *pseudosarcomatous fasciitis*, is the most common of the reactive pseudosarcomas. It most often occurs in adults on the volar aspect of the forearm, followed in order of frequency by the chest and back. Affected individuals typically present with a several-week history of a solitary, rapidly growing, and sometimes painful mass. Preceding trauma is reported in only 10% to 15% of cases.

Morphology. Nodular fasciitis arises in the deep dermis, subcutis, or muscle. Grossly the lesion is several centimeters in greatest dimension, is nodular in configuration, and has poorly defined margins. The lesion is richly cellular and contains plump, immature-appearing fibroblasts and myofibroblasts arranged randomly or in short intersecting fascicles (Fig. 26-54). The cells vary in size and shape (spindle to stellate) and have conspicuous nucleoli; mitotic figures are abundant. Frequently the stroma is myxoid and contains lymphocytes and extravasated red blood cells. The histologic differential is extensive, but important lesions that must be excluded are fibromatosis and spindle cell sarcomas. Nodular fasciitis rarely recurs after excision.

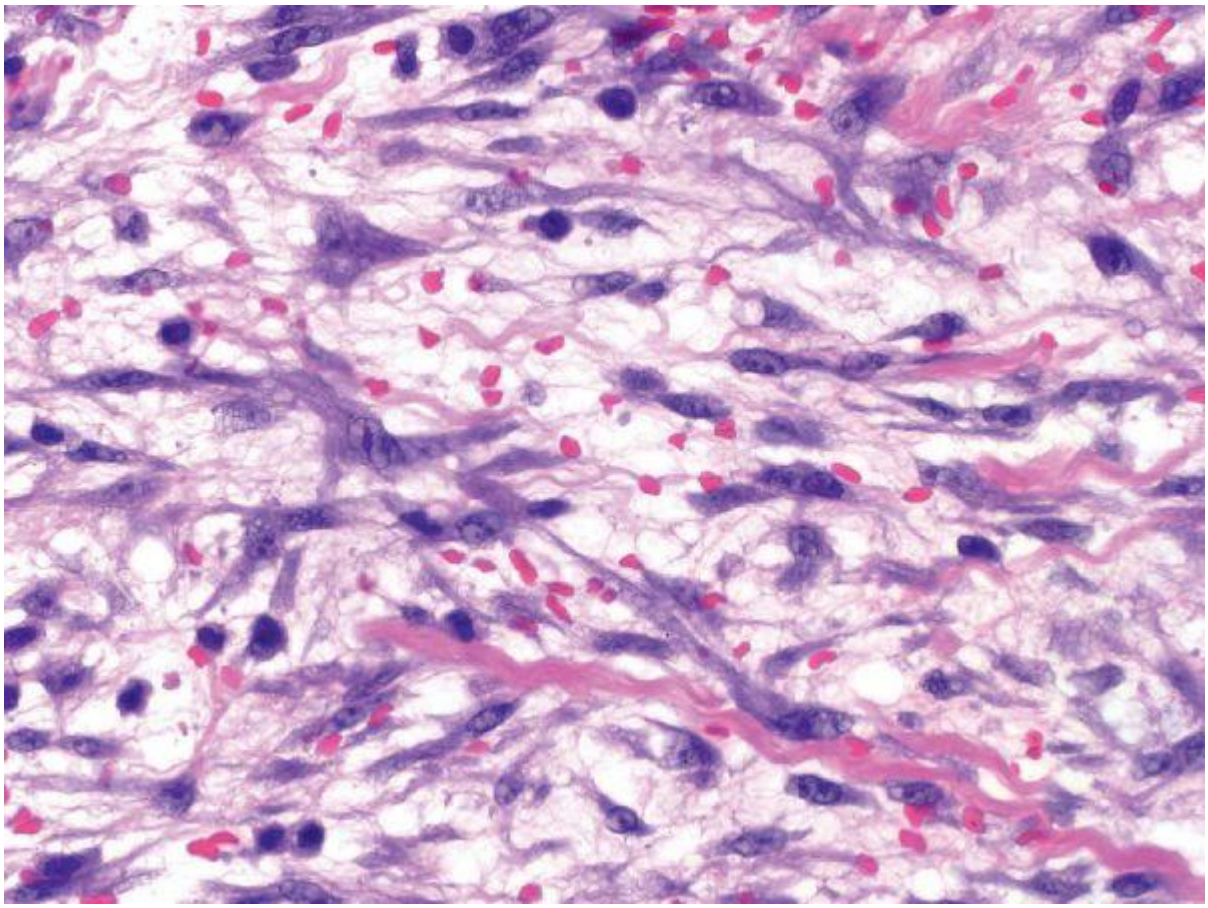

FIGURE 26-54 Nodular fasciitis with plump, randomly oriented spindle cells surrounded by myxoid stroma. Note the mitotic activity and extravasated red blood cells.

Myositis Ossificans

Myositis ossificans is distinguished from the other reactive fibroblastic proliferations by the presence of *metaplastic bone*. It usually develops in athletic adolescents and young adults and follows an episode of trauma in more than 50% of cases. The lesion typically arises in the musculature of the proximal extremities. The clinical findings are related to its stage of development; in the early phase the involved area is swollen and painful, and during the subsequent several weeks it becomes more circumscribed and firm. Eventually, it evolves into a painless, hard, well-demarcated mass.

Morphology. Grossly the usual lesion is 3 to 6 cm in greatest dimension and well-demarcated. Initially, the lesion is cellular and consists of plump, elongated fibroblast and myofibroblast-like cells simulating nodular fasciitis (see earlier). In due course these cells are surrounded by an intermediate zone that contains osteoblasts, which deposit ill-defined trabeculae of woven bone. The most peripheral zone contains well-formed, mineralized trabeculae that closely resemble cancellous bone. Eventually the entire lesion ossifies, and the intertrabecular spaces become filled with bone marrow. The mature lesion is completely ossified.

The radiographic findings parallel the morphologic progression. Initially, X-rays may show only soft-tissue fullness, but at about 3 weeks patchy flocculent radiodensities form in the periphery. The radiodensities become more extensive with time and slowly encroach on the radiolucent center (Fig. 26-55). Myositis ossificans must be distinguished from extraskeletal osteosarcoma. The latter usually occurs in elderly patients, the proliferating cells are cytologically malignant, and the tumor lacks the zonation of myositis ossificans. Simple excision of myositis ossificans is usually curative.

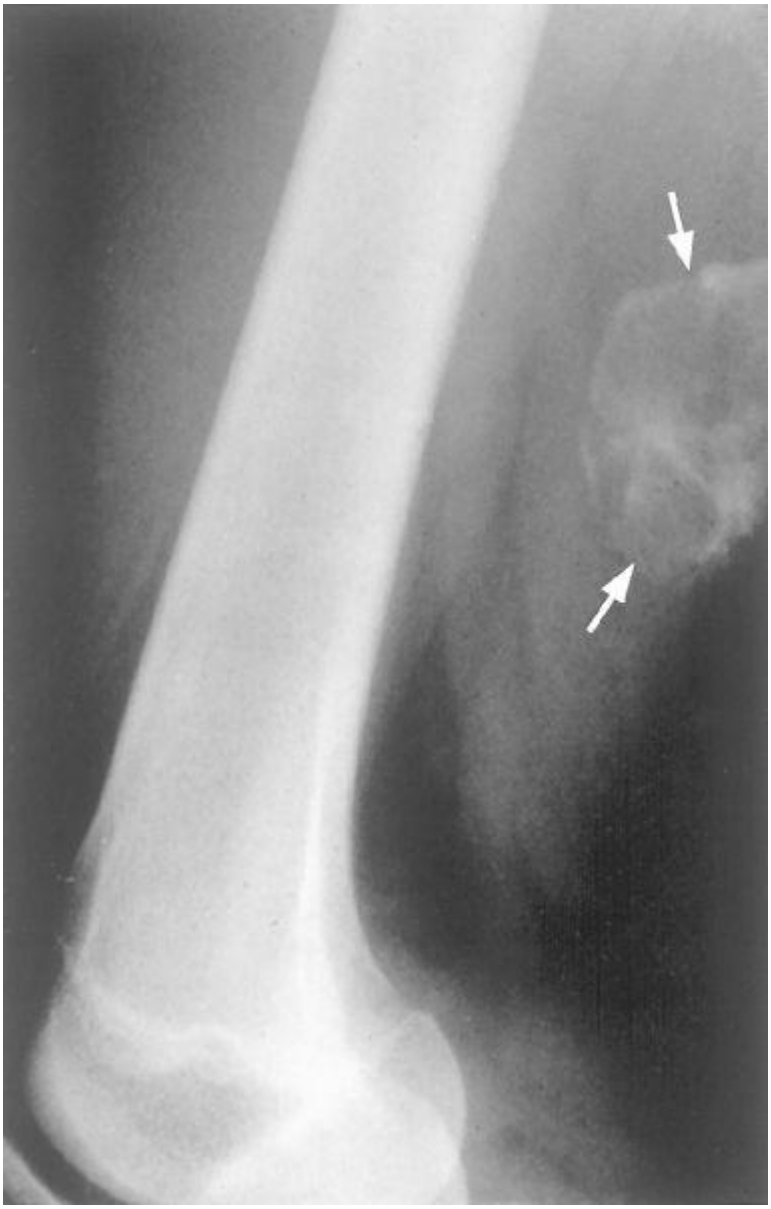

FIGURE 26-55 Peripherally mineralized myositis ossificans *(arrows)* involving the posterior thigh.

FIBROMATOSES

Superficial Fibromatosis (Palmar, Plantar, and Penile Fibromatoses)

Palmar, plantar, and penile fibromatoses, lesions that are more bothersome than serious, constitute a small group of superficial fibromatoses. They are characterized by nodular or poorly defined broad fascicles of fibroblasts and myofibroblasts surrounded by abundant dense collagen. The molecular

mechanisms underlying superficial fibromatoses are unknown, but they are different from their deep-seated counterparts.

In the palmar variant *(Dupuytren contracture)* there is irregular or nodular thickening of the palmar fascia either unilaterally or bilaterally (50%). Over a span of years, attachment tothe overlying skin causes puckering and dimpling. At the same time a slowly progressive flexion contracture develops that mainly affects the fourth and fifth fingers of the hand. Essentially similar changes are seen with *plantar fibromatosis* except that flexion contractures are uncommon and bilateral involvement is infrequent. In *penile fibromatosis (Peyronie disease)* a palpable induration or mass appears, usually on the dorsolateral aspect of the penis. Eventually, it may cause abnormal curvature of the shaft, constriction of the urethra, or both.

All forms of superficial fibromatosis affect males more frequently than females. In about 20% to 25% of cases, the palmar and plantar fibromatoses stabilize and do not progress, in some instances resolving spontaneously. Some recur after excision, particularly the plantar variant.

Deep-Seated Fibromatosis (Desmoid Tumors)

Deep-seated fibromatoses lie in a gray zone between benign fibrous tumors and low-grade fibrosarcomas. On the one hand, they often present as large, infiltrative masses that frequently recur after incomplete excision; on the other, they are composed of banal well-differentiated fibroblasts that do not metastasize. They may occur at any age but are most frequent in the teens to 30s. Deep-seated fibromatosis is divided into *extra-abdominal, abdominal,* and *intra-abdominal* types, but all have similar gross and microscopic features. Extra-abdominal fibromatosis occurs in men and women with equal frequency and arises principally in the musculature of the shoulder, chest wall, back, and thigh. Abdominal fibromatosis generally arises in the musculoaponeurotic structures of the anterior abdominal wall in women during or after pregnancy. Intra-abdominal fibromatosis tends to occur in the mesentery or pelvic walls, often in individuals having familial adenomatous polyposis (Gardner syndrome) (Chapter 17). Mutations in the *APC* or β-catenin genes are present in the majority of these tumors (whether or not the affected individuals have underlying Gardner syndrome) and have an important role in their genesis.

Morphology. These tumors occur as gray-white, firm, poorly demarcated masses varying from 1 to 15 cm in greatest diameter. They are rubbery and tough, and infiltrate surrounding structures. Histologically deep-seated fibromatosis is composed of plump banal fibroblasts arranged in broad sweeping fascicles that infiltrate the adjacent tissue (Fig. 26-56). Mitoses may be frequent. Regenerative muscle cells when trapped within these lesions may take on the appearance of multinucleated giant cells.

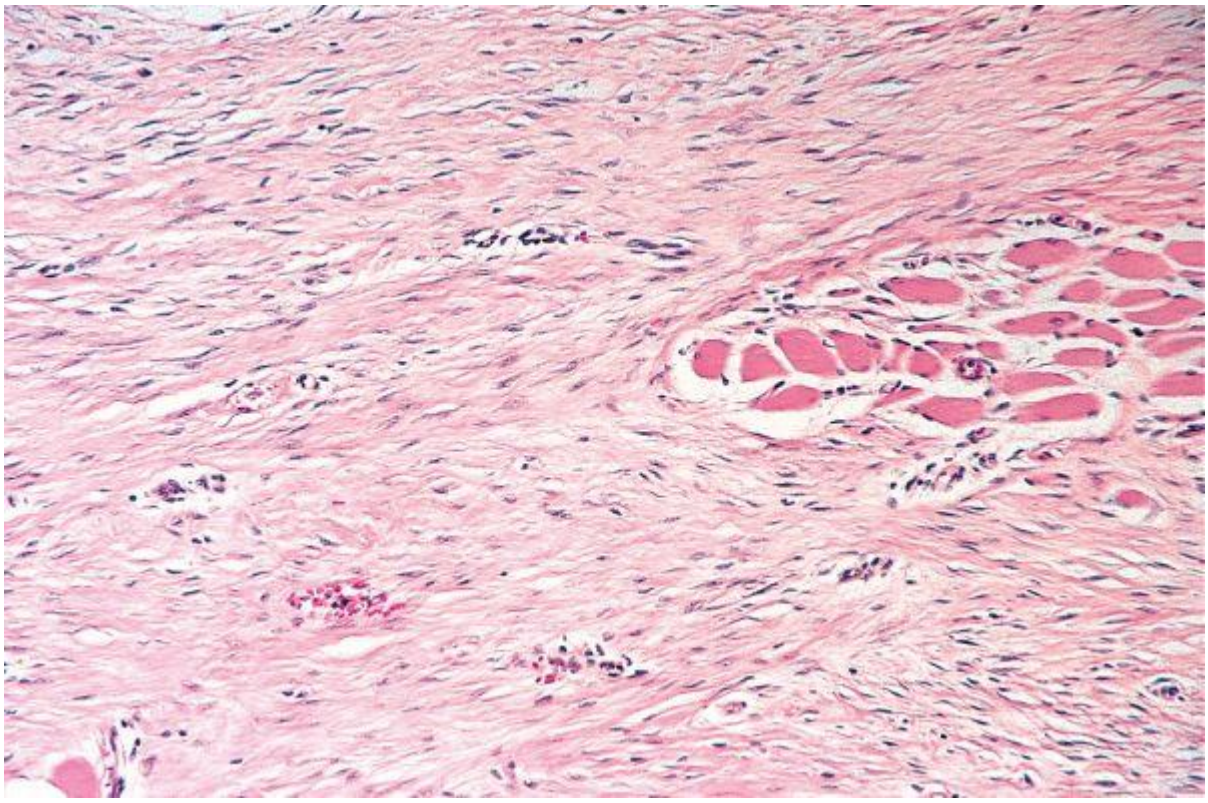

FIGURE 26-56 Fibromatosis infiltrating between skeletal muscle cells.

In addition to possibly being disfiguring or disabling, deep-seated fibromatosis is occasionally painful. Although curable by adequate excision, these lesions frequently recur locally and persistently when incompletely removed. Some tumors have responded to treatment with tamoxifen, and in other cases chemotherapy or irradiation has been effective. The rare reports of metastasis of fibromatosis must be interpreted as misdiagnosis of fibrosarcoma.

FIBROSARCOMA

Fibrosarcomas occur anywhere in the body, but are most common in the deep soft tissues of the extremities. Many tumors previously considered fibrosarcoma have been reclassified based on immunohistochemistry or cytogenetic findings as fibromatosis (desmoid), malignant peripheral nerve sheath tumors, or monophasic synovial sarcomas.

Morphology. Typically these neoplasms are unencapsulated, infiltrative, soft, fish-flesh masses often having areas of hemorrhage and necrosis. Better differentiated lesions may appear deceptivelyencapsulated. Histologic examination discloses all degrees of differentiation, from slowly growing tumors that closely resemble cellular fibromatosis and sometimes having spindled cells growing in a herringbone fashion (Fig. 26-57), to highly cellular neoplasms dominated by architectural disarray, pleomorphism, frequent mitoses, and areas of necrosis (Fig. 26-58).

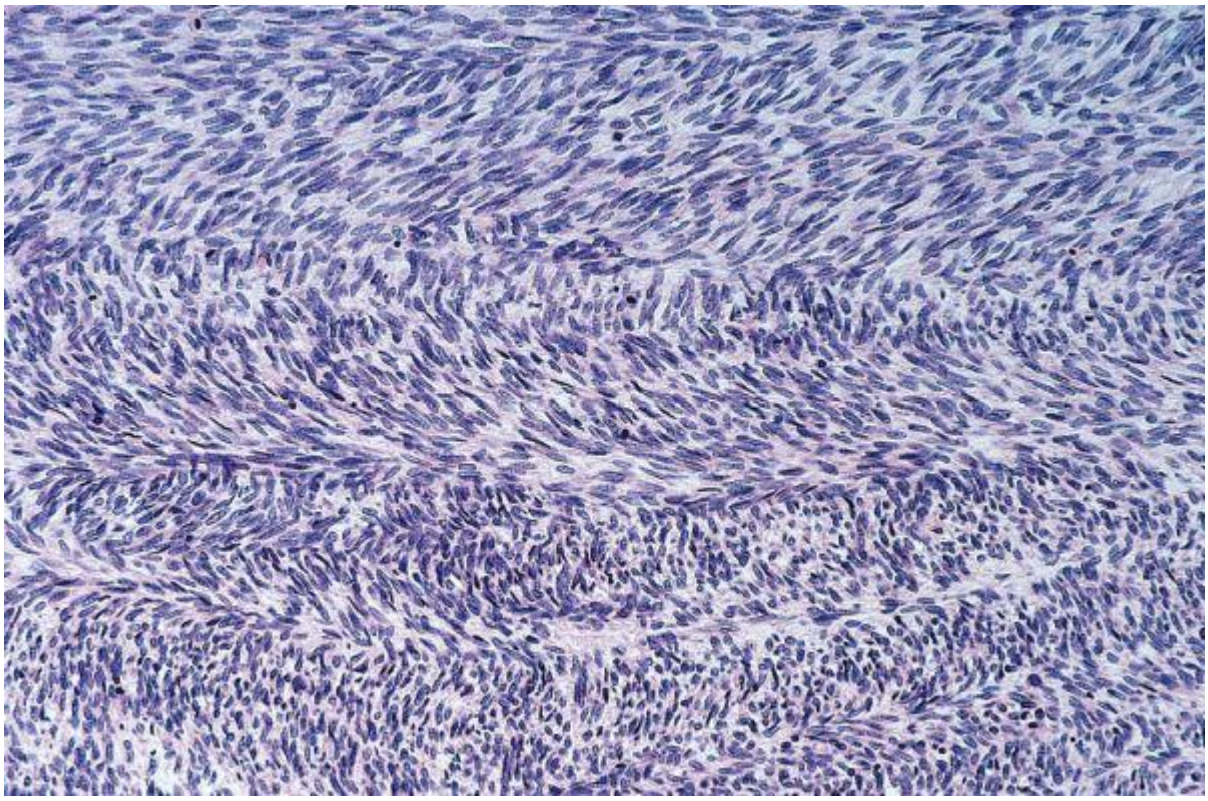

FIGURE 26-57 Fibrosarcoma composed of malignant spindle cells arranged in a herringbone pattern.

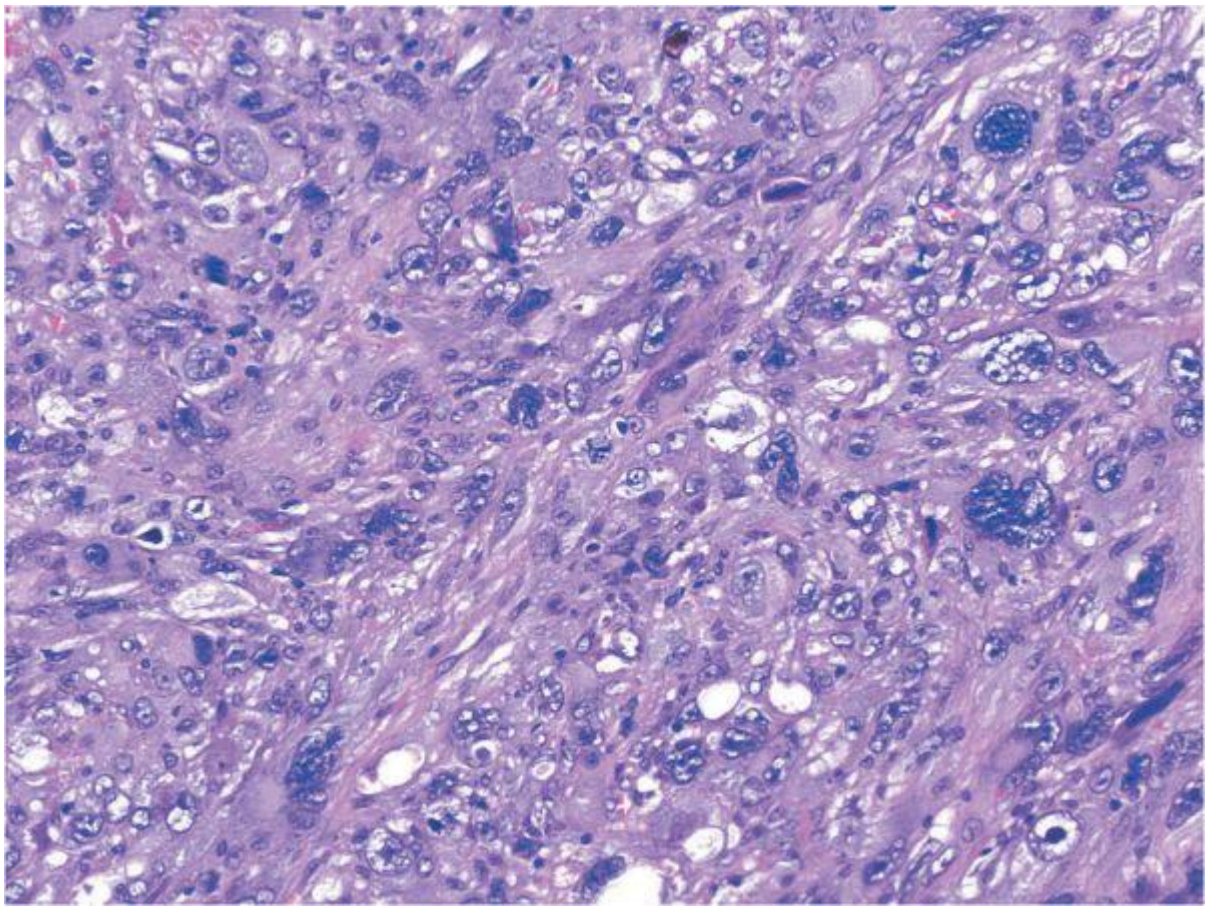

FIGURE 26-58 Pleomorphic fibrosarcoma revealing fascicles of plump spindled cells in a swirling (storiform) pattern, typical but not pathognomonic of this neoplasm.

Fibrosarcomas are aggressive tumors, recurring in more than 50% of cases and metastasizing in more than 25%.

3.16.3.4 Fibrohistiocytic Tumors

Fibrohistiocytic tumors contain cellular elements that resemble both fibroblasts and histiocytes (macrophages). The phenotype of the neoplastic cells most closely resembles fibroblasts, and the term *fibrohistiocytic* should be viewed as descriptive in nature and not one that connotes the cell of origin.

BENIGN FIBROUS HISTIOCYTOMA (DERMATOFIBROMA)

Benign fibrous histiocytoma is a relatively common lesion that usually occurs in the dermis and subcutis. It is painless and slow growing, and most often presents in mid-adult life as a firm, small (≤1 cm) mobile nodule. Its morphologic features are described in Chapter 25 .

MALIGNANT FIBROUS HISTIOCYTOMA

Once considered the most common sarcoma of adults, *malignant fibrous histiocytoma* referred to a group of soft-tissue tumors characterized by considerable cytologic pleomorphism, the presence of

bizarre multinucleate cells, and storiform architecture. The phenotype of the neoplastic cell is now recognized to be fibroblastic and as a result malignant fibrous histiocytoma is being dropped as a diagnostic entity. Tumors previously diagnosed as malignant fibrous histiocytoma are currently classified as variants of fibrosarcoma (myxofibrosarcoma, pleomorphic fibrosarcoma, etc.) and other tumor types.

3.16.3.5 Tumors of Skeletal Muscle

Skeletal muscle neoplasms, in contrast to other groups of tumors, are almost all malignant. The benign variant, rhabdomyoma, is distinctly rare. The so-called cardiac rhabdomyoma is frequently seen in individuals with tuberous sclerosis and is discussed in Chapter 12 .

RHABDOMYOSARCOMA

Rhabdomyosarcoma, the most common soft-tissue sarcoma of childhood and adolescence, usually appears before age 20. It may arise in any anatomic location, but most occur in the head and neck or genitourinary tract, where there is little if any skeletal muscle as a normal constituent. Only in the extremities do they appear in relation to skeletal muscle.

Morphology. Rhabdomyosarcoma is histologically subclassified into **embryonal**, **alveolar**, and **pleomorphic** variants. The rhabdomyoblast—the diagnostic cell in all types—contains eccentric eosinophilic granular cytoplasm rich in thick and thin filaments. Rhabdomyoblasts may be round or elongate; the latter are known as tadpole or strap cells, and may contain cross-striations visible by light microscopy (Fig. 26-59). Ultrastructurally, rhabdomyoblasts contain sarcomeres, and immunohistochemically they stain with antibodies to the myogenic markers desmin, MYOD1, and myogenin.

Embryonal rhabdomyosarcoma is the most common type, accounting for 60% of rhabdomyosarcomas. It includes the **sarcoma botryoides**, described in Chapter 22 , as well as spindle cell and anaplastic variants. The tumor occurs in children younger than 10 years of age and typically arises in the nasal cavity, orbit, middle ear, prostate, and paratesticular region. This variant of rhabdomyosarcoma commonly has parental isodisomy of chromosome 11p15.5, which leads to overexpression of the imprinted *IGFII* gene.[58] The sarcoma botryoides subtype develops in the walls of hollow, mucosal-lined structures, such as the nasopharynx, common bile duct, bladder, and vagina. Where the tumors abut the mucosa of an organ, they form a submucosal zone of hypercellularity called the **cambium layer**.

Most embryonal rhabdomyosarcomas present as a soft gray infiltrative mass. The tumor cells mimic skeletal muscle at various stages of embryogenesis and consist of sheets of both round and spindled cells in a myxoid stroma. Rhabdomyoblasts with visible cross-striations may be present.

Alveolar rhabdomyosarcoma tends to develop in early to middle adolescence, commonly arises in the deep musculature of the extremities, and represents approximately 20% of rhabdomyosarcomas. Histologically the tumor is traversed by a network of fibrous septae that divide the cells into clusters or aggregates that creates a crude resemblance to pulmonary alveolae (Fig. 26-60). The tumor cells are moderate in size, and many have little cytoplasm. Those in the center of the aggregates are dyscohesive, while those at the periphery adhere to the septae. Cells with cross-striations are identified in about 25% of cases. Cytogenetic studies have shown that this variant of rhabdomyosarcoma has a chromosomal translocation that either fuses the *PAX3* to the *FOXO1a* gene, t(2,13)(q35;q14) or the *PAX7* to the *FOXO1a* gene, t(1;13)(p36;q14).[58] Tumors with the *PAX3-FOXO1a* fusion gene are more aggressive and associated with a worse prognosis.

Pleomorphic rhabdomyosarcoma is characterized by numerous large, sometimes multinucleated, bizarre eosinophilic tumor cells. This variant is rare, has a tendency to arise in the deep soft tissue of adults, and can resemble other pleomorphic sarcomas histologically.

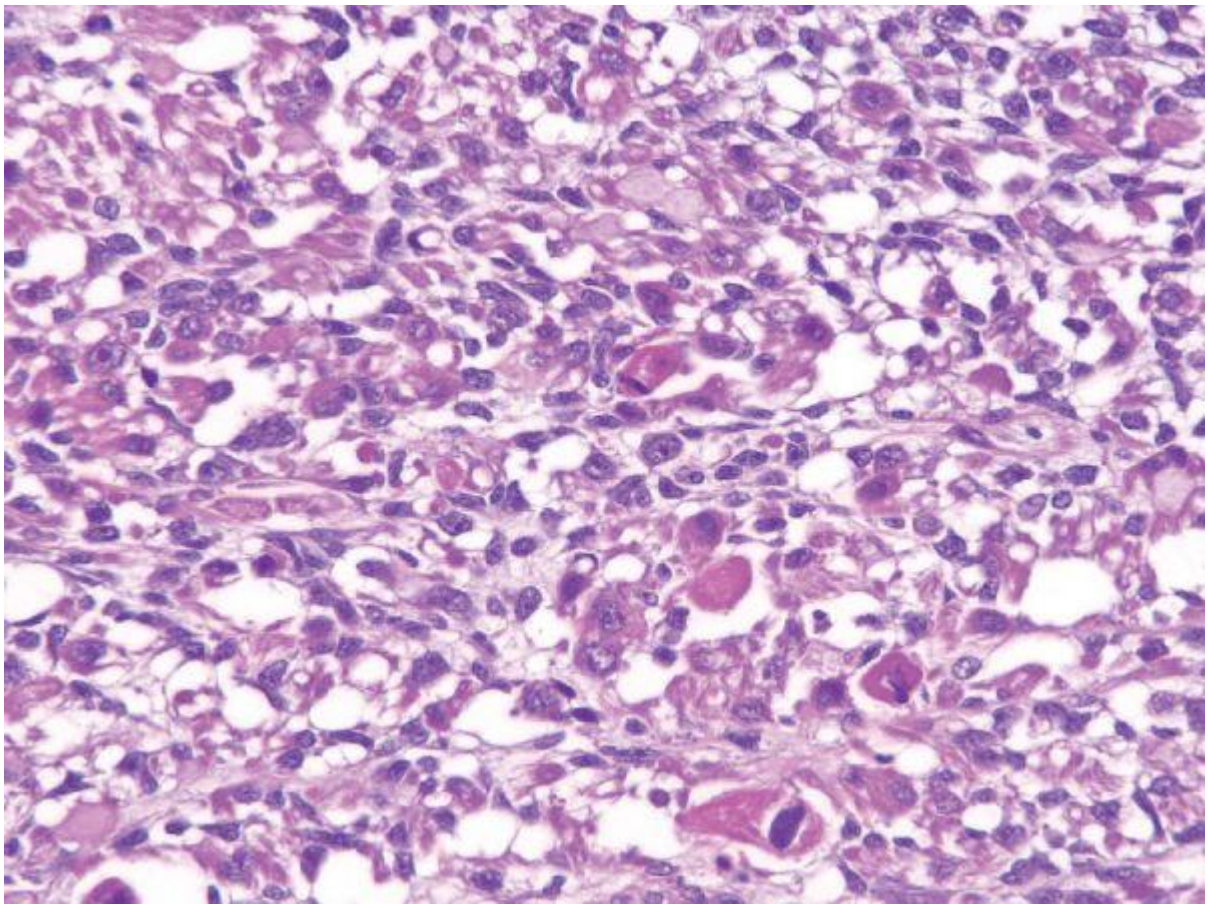

FIGURE 26-59 Rhabdomyosarcoma composed of malignant small round cells. The rhabdomyoblasts are large and round, and have abundant eosinophilic cytoplasm; no cross-striations are evident.

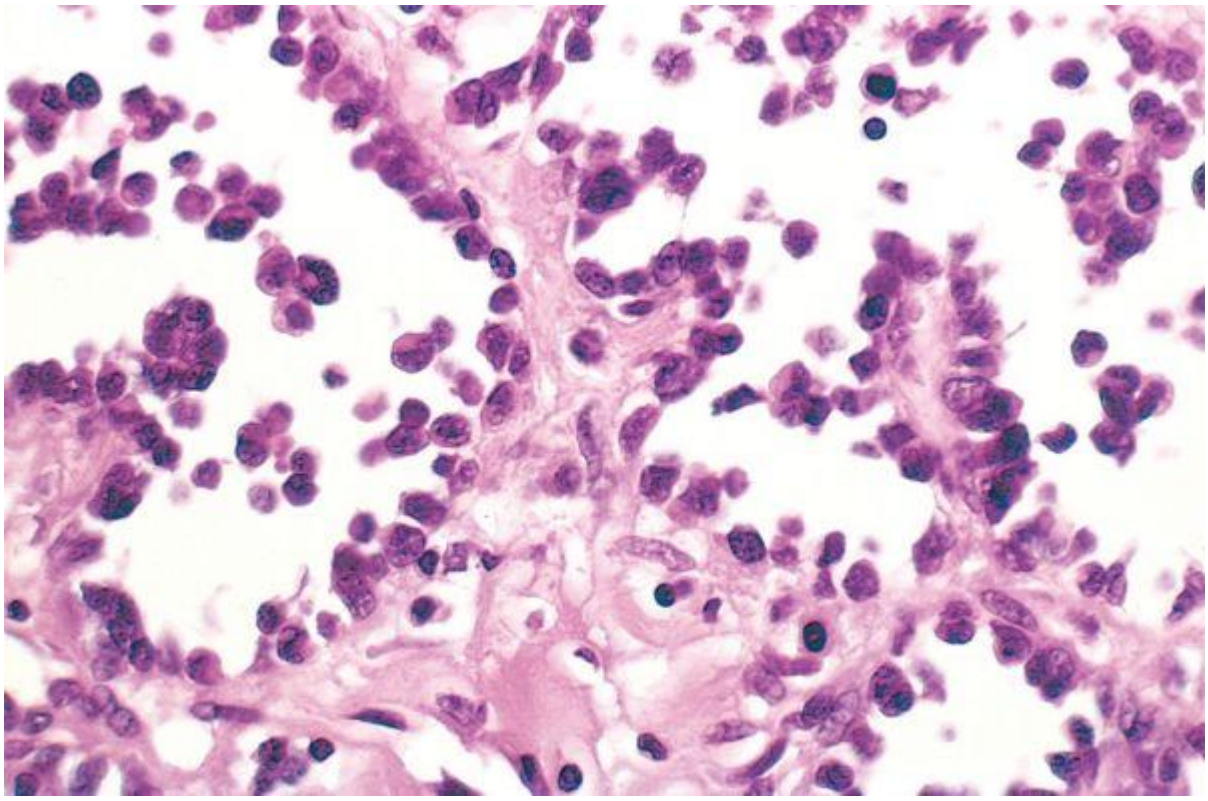

FIGURE 26-60 Alveolar rhabdomyosarcoma with numerous spaces lined by tumor cells.

Rhabdomyosarcomas are aggressive neoplasms that are usually treated with surgery and chemotherapy with or without radiation therapy. The histologic type and location of the tumor influence survival. The botryoid subtype has the best prognosis, while the anaplastic embryonal, pleomorphic, and alveolar variants are often fatal.

3.16.3.6 Tumors of Smooth Muscle

LEIOMYOMAS

Leiomyomas, the benign smooth muscle tumors, often arise in the uterus; in fact, uterine leiomyomas are the most common neoplasm in women (Chapter 22). They develop in 77% of women and, depending on their number, size, and location, may cause a variety of symptoms including infertility. Leiomyomas may also arise from the arrector pili muscles found in the skin, nipples, scrotum, and labia and less frequently develop in the deep soft tissues and the wall of the gut. Those arising in the arrector muscles *(pilar leiomyomas)* may be multiple and painful. The phenotype of multiple cutaneous leiomyomas, in some individuals, is transmitted as an autosomal dominant trait and is associated with uterine leiomyomas and a predisposition to develop renal cell carcinoma—hereditary leiomyomatosis and renal cell cancer syndrome. This disorder is associated with a germline loss-of-function mutation in the fumarate hydratase gene located on chromosome 1q42.3.

Leiomyomas are usually not larger than 1 to 2 cm in greatest dimension and are composed of fascicles of spindle cells that tend to intersect each other at right angles. The tumor cells have blunt-ended, elongated nuclei and show minimal atypia and few mitotic figures. Solitary lesions are easily cured; however, multiple tumors may be so numerous that complete surgical removal is impractical.

LEIOMYOSARCOMA

Leiomyosarcomas account for 10% to 20% of soft-tissue sarcomas. They occur in adults and afflict women more frequently than men. Most develop in the skin and deep soft tissues of the extremities and retroperitoneum.

Morphology. Leiomyosarcomas present as painless firm masses. Retroperitoneal tumors may be large and bulky and cause abdominal symptoms. Histologically they consist of malignant spindle cells with cigar-shaped nuclei arranged in interweaving fascicles. Ultrastructurally, malignant smooth muscle cells contain bundles of thin filaments with dense bodies and pinocytic vesicles, and individual cells are surrounded by basal lamina. Immunohistochemically, they stain with antibodies to smooth muscle actin and desmin.

Treatment depends on the size, location, and grade. Superficial or cutaneous leiomyosarcomas are usually small and have a good prognosis, whereas those of the retroperitoneum are large, cannot be entirely excised, and cause death by both local extension and metastatic spread.

3.16.3.7 Synovial Sarcoma

Synovial sarcoma is so named because it was once believed to recapitulate synovium, but the cell of origin is still unclear. In addition, although the term *synovial sarcoma* implies an origin from the joint linings, less than 10% are intra-articular. Synovial sarcomas account for approximately 10% of all soft-tissue sarcomas and rank as the fourth most common sarcoma. Most occur in the 20s to 40s. The majority develop in the deep soft tissue and about 60% to 70% involve the lower extremity, especially around the knee and thigh. Patients usually present with a deep-seated mass that has been noted for several years. Uncommonly, these tumors occur in the head and neck or in viscera.

Morphology. Synovial sarcomas are morphologically biphasic or monophasic. The histologic hallmark of biphasic synovial sarcoma is dual lines of differentiation (i.e., epithelial-like and mesenchymal-like). The epithelial cells are cuboidal to columnar and form glands or grow in solid cords or aggregates. The spindle cells are arranged in densely cellular fascicles that surround the epithelial cells (Fig. 26-61). Many synovial sarcomas are *monophasic*, being composed of only spindled cells or, very rarely, epithelial cells. Lesions composed solely of spindled cells are easily mistaken for fibrosarcomas or malignant peripheral nerve sheath tumors. A characteristic feature when present is calcified concretions that can sometimes be detected radiographically. Immunohistochemistry is helpful in identifying these tumors, since the tumor cells yield positive reactions for keratin and epithelial membrane antigen, differentiating them from most other sarcomas. In addition, most synovial sarcomas show a characteristic chromosomal translocation t(x;18)(p11;q11) producing *SS18-SSX1*, *SSX2*, or *SSX4* fusion genes that encode chimeric transcription factors.[59] The specific type of translocation in synovial sarcoma has not been shown to be related to prognosis.

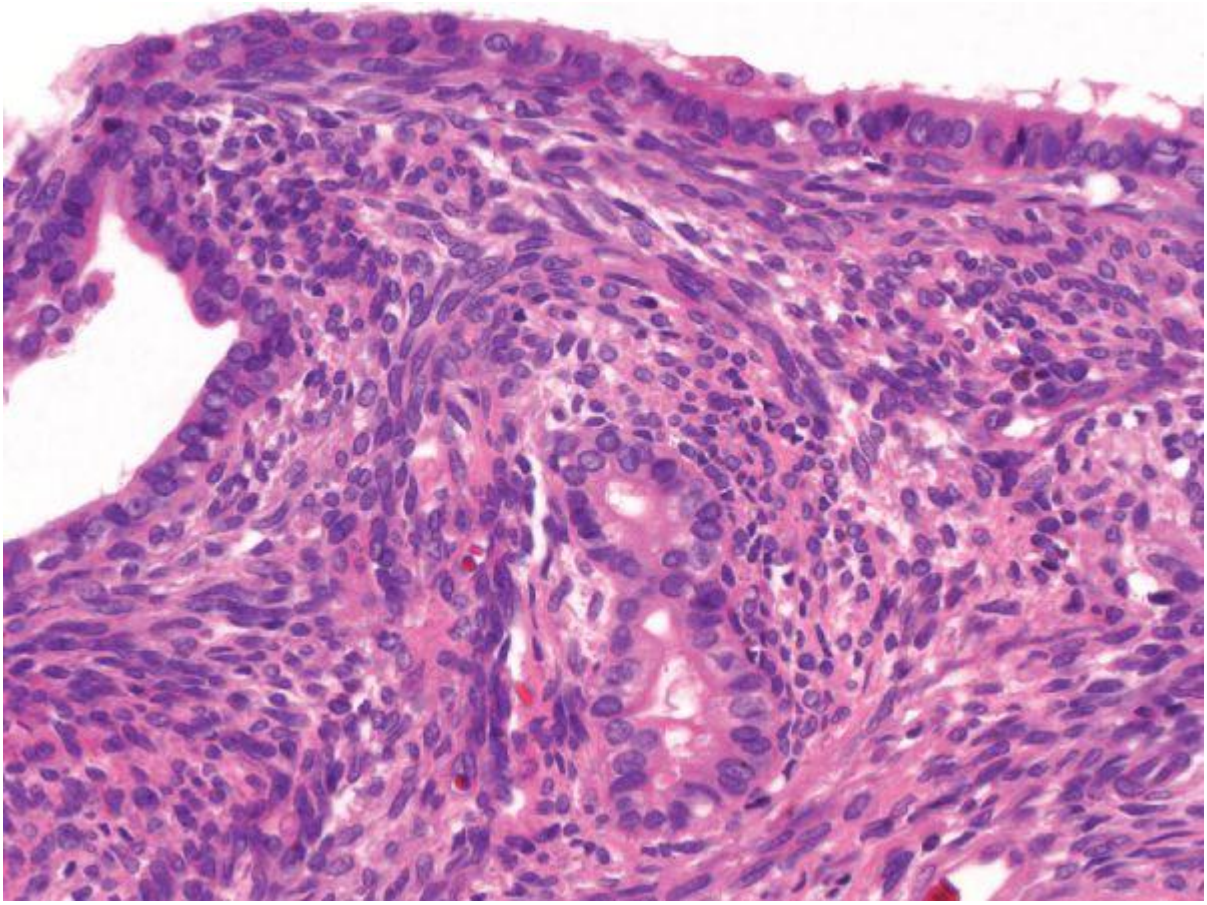

FIGURE 26-61 Synovial sarcoma revealing the classic biphasic spindle cell and glandular-like histologic appearance.

Synovial sarcomas are treated aggressively with limb-sparing therapy and frequently chemotherapy. The 5-year survival varies from 25% to 62%, and only 11% to 30% live for 10 years or longer. Common sites of metastases are the lung, skeleton, and occasionally the regional lymph nodes.

3.17 27. Peripheral Nerve & Skeletal Muscle

3.17.1 General Reactions of the Motor Unit

DOUGLAS C. ANTHONY,
MATTHEW P. FROSCH,
UMBERTO DE GIROLAMI

The functions of the neuromuscular system depend on the *motor units* (Fig. 27-1), each consisting of (1) a *lower motor neuron* in the anterior horn of the spinal cord or cranial nerve motor nucleus in the brain stem, (2) the *axon* of that neuron, and (3) the multiple *muscle fibers* it innervates. The principal structural component of peripheral nerve is the *nerve fiber* (an axon with its Schwann cells and myelin sheath). A nerve consists of numerous fibers that are grouped into fascicles by connective tissue sheaths. *Myelinated* and *unmyelinated* nerve fibers are intermingled within the fascicle. Peripheral nervous system axons are myelinated in segments (*internodes*) separated by *nodes of Ranvier*. A single Schwann cell supplies the myelin sheath for each internode. Unmyelinated axons are far more numerous than myelinated axons, and the cytoplasm of one Schwann cell envelops a variable number of unmyelinated fibers (5 to 20 axons in humans). The three major connective tissue components of peripheral nerve are the *epineurium*, which encloses the entire nerve; the *perineurium*, a multilayered concentric connective tissue sheath that encloses each fascicle; and the *endoneurium*, which surrounds individual nerve fibers. The motor and sensory fibers, which are separated within anterior and posterior roots, intermingle within the mixed sensorimotor nerve that exits the spinal canal.

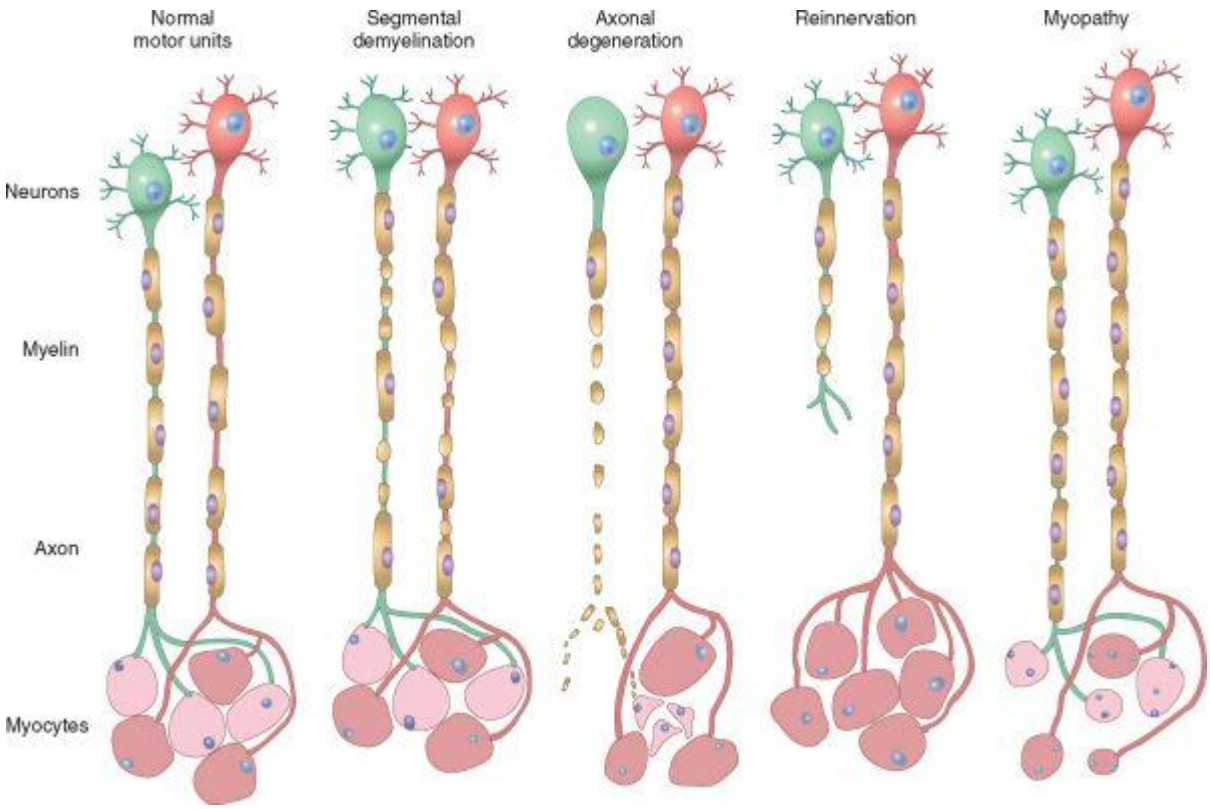

FIGURE 27-1 Normal and abnormal motor units. *Normal motor units*: Two adjacent motor units are shown (*red* and *green* neurons, *red* and

pale-pink myocytes). *Segmental demyelination*: Random internodes of myelin are injured and are remyelinated by multiple Schwann cells, while the axon and myocytes remain intact. *Axonal degeneration*: The axon and its myelin sheath undergo anterograde degeneration (shown for the *green* neuron), with resulting denervation atrophy of the myocytes within its motor unit (*pale-pink* myocytes). *Reinnervation of muscle*: Sprouting of adjacent *(red)* uninjured motor axons leads to fiber type grouping of myocytes, while the injured axon attempts axonal sprouting. *Myopathy*: Scattered myocytes of adjacent motor units are small (degenerated or regenerated), whereas the neurons and nerve fibers are normal.

General Reactions of the Motor Unit

Neuromuscular diseases are accompanied by weakness and are often due to disorders of the motor unit—either the motor neuron and axon, or the muscle fibers. The two main responses of peripheral nerve to injury are determined by the target of the injury: either the Schwann cell or the axon. Diseases that affect primarily the Schwann cell lead to a loss of myelin, referred to as *segmental demyelination*. In contrast, primary involvement of the neuron and its axon leads to *axonal degeneration*. In some diseases axonal degeneration may be followed by *axonal regeneration* and *reinnervation* of muscle.[1] The two principal pathologic processes seen in skeletal muscle are *denervation atrophy*, which follows loss of axons, and those due to a primary abnormality of the muscle fiber itself, referred to as *myopathy*.

SEGMENTAL DEMYELINATION

Segmental demyelination occurs when there is dysfunction of the Schwann cell (as in hereditary motor and sensory neuropathy) *or damage to the myelin sheath* (e.g., in Guillain-Barré syndrome); there is no primary abnormality of the axon. The process may affect some Schwann cells and their corresponding internodes while sparing others (see Fig. 27-1). The disintegrating myelin is engulfed initially by Schwann cells and later by macrophages. The denuded axon provides a stimulus for remyelination. A population of precursor cells within the endoneurium has the capacity to replace injured Schwann cells. These cells proliferate and encircle the axon and, in time, remyelinate the denuded portion.[2] Newly formed myelinated internodes are shorter than normal, however, and several are required to bridge the demyelinated region (see Fig. 27-1). The new myelin sheath is also thin in proportion to the diameter of the axon.

With sequential episodes of demyelination and remyelination, there is an accumulation of tiers of Schwann cell processes that, on transverse section, appear as concentric layers of Schwann cell cytoplasm and redundant basement membrane surrounding a thinly myelinated axon *(called onion bulbs)* (Fig. 27-2). In time, many chronic demyelinating neuropathies give way to axonal injury. The specific conditions giving rise to demyelination are described later.

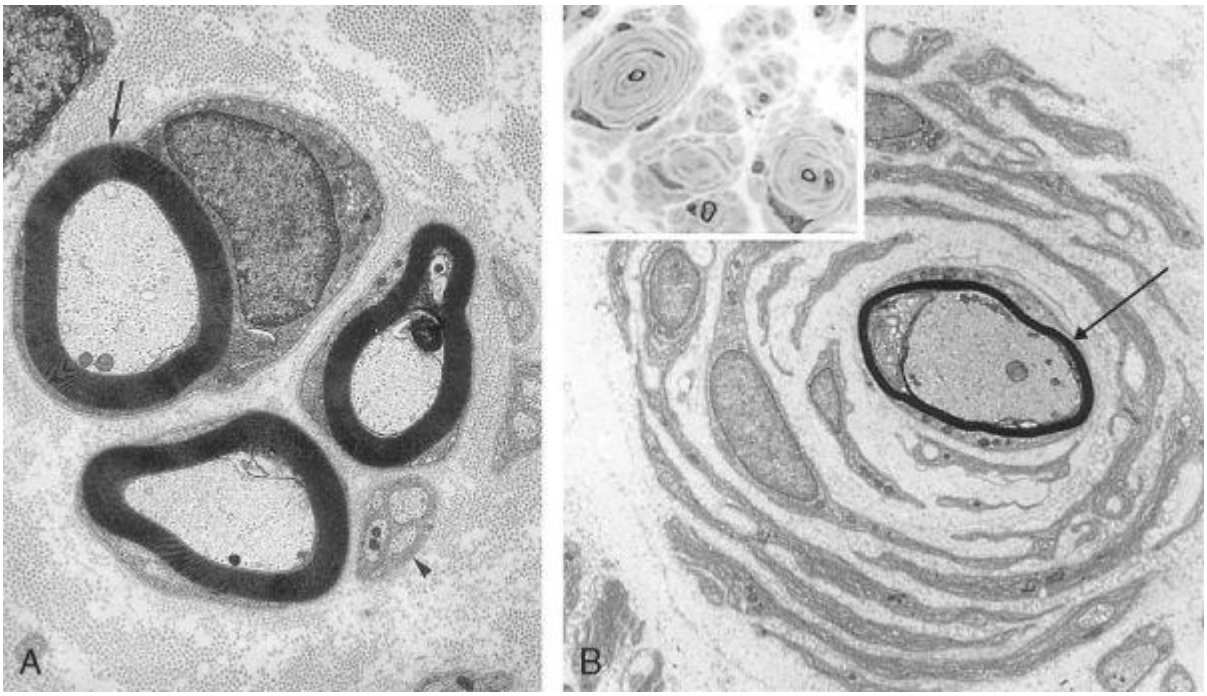

FIGURE 27-2 Compared with the normal ultrastructure of nerve (**A**), an "onion bulb" (**B**) is composed of a thinly myelinated axon *(arrow)* surrounded by concentrically arranged Schwann cells. *Inset*, Light-microscopic appearance of an onion bulb neuropathy, characterized by "onion bulbs" surrounding axons. *(**B**, Courtesy of G. Richard Dickersin, MD, from Diagnostic Electron Microscopy: A Text Atlas. New York, Igaku-Shoin Medical Publishers, 2000, p 984.)*

AXONAL DEGENERATION AND MUSCLE FIBER ATROPHY

Axonal degeneration is the result of primary destruction of the axon, with secondary disintegration of its myelin sheath (see Fig. 27-1). Damage to the axon may be due to a focal event occurring at some point along the length of the nerve (such as trauma or ischemia) or to a more generalized abnormality affecting the neuron cell body *(neuronopathy)* or its axon *(axonopathy)*. When axonal injury occurs as the result of a focal lesion, such as traumatic transection of a nerve, the distal portion of the fiber undergoes *Wallerian degeneration* (Fig. 27-3). Within a day the axon begins to break down, and the affected Schwann cells begin to catabolize myelin and later engulf axon fragments, forming small oval compartments *(myelin ovoids)*.[2] Macrophages are recruited into the area and participate in the phagocytosis of axonal and myelin-derived debris. The stump of the proximal portion of the severed nerve shows degenerative changes involving only the most distal two or three internodes and then undergoes regenerative activity. In the slowly evolving neuronopathies or axonopathies, evidence of axonal degeneration is scant because only a few fibers are actively degenerating at any given time.

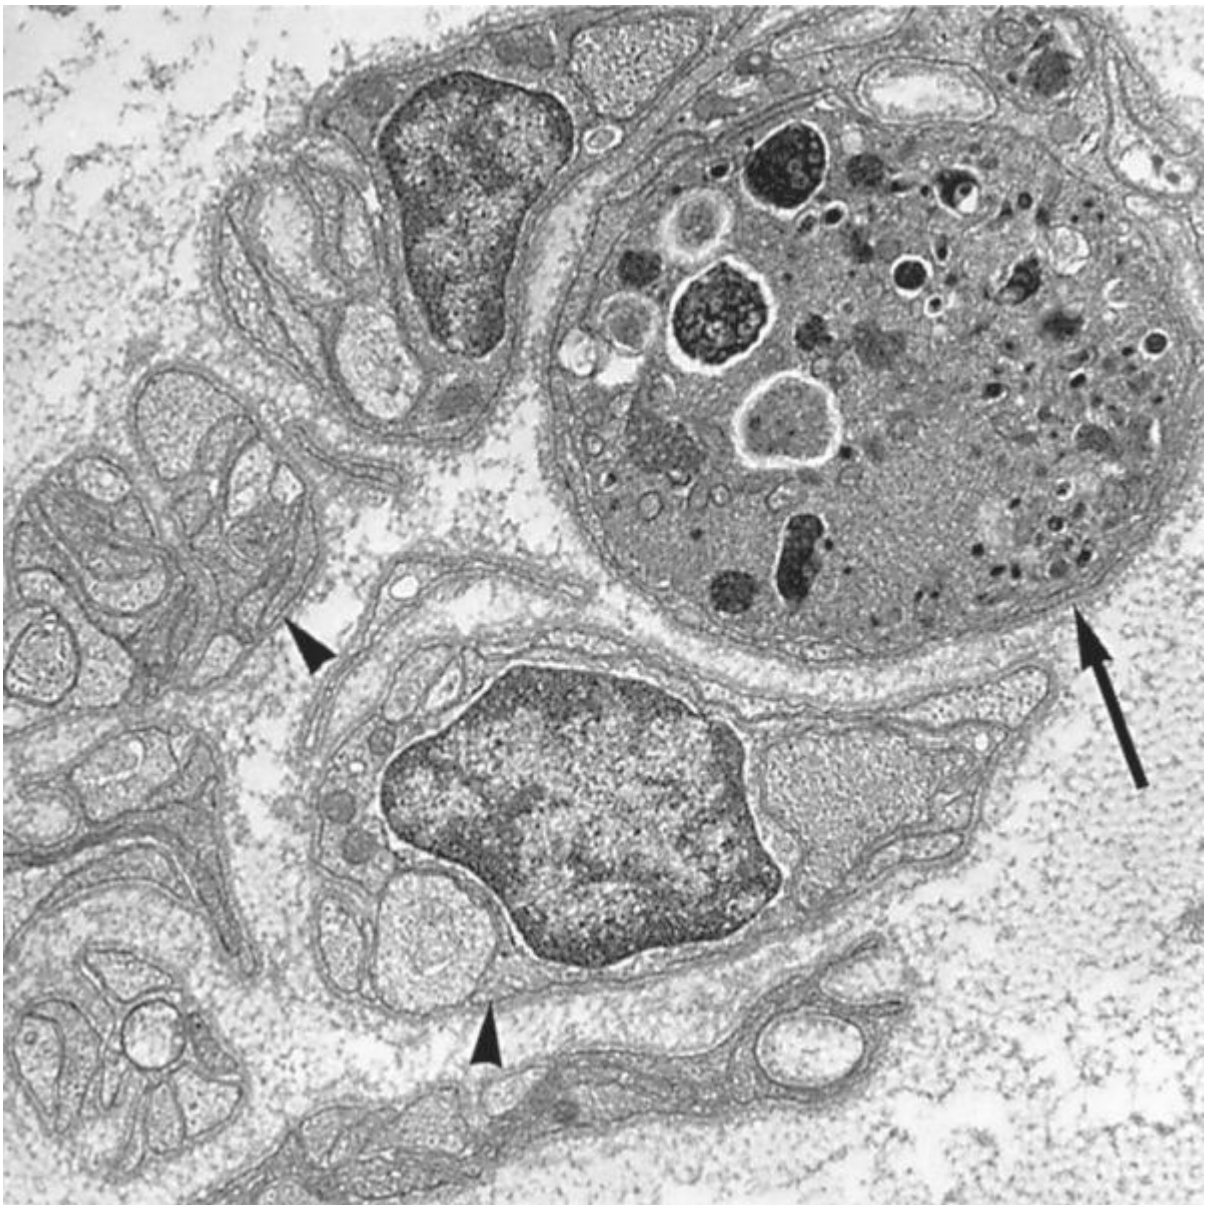

FIGURE 27-3 Electron micrograph of a degenerating axon *(arrow)* adjacent to several intact unmyelinated fibers *(arrowheads)*. The axon is markedly distended and contains numerous degenerating organelles and dense bodies.

When axonal degeneration occurs, the muscle fibers within the affected motor unit lose their neural input and undergo *denervation atrophy*. Denervation of muscle leads to breakdown of myosin and actin, with a decrease in cell size and resorption of myofibrils, but cells remain viable. In cross-section, the atrophic fibers are smaller than normal and have a roughly triangular ("angulated") shape. There is also cytoskeletal reorganization of some muscle cells, which results in a rounded zone of disorganized myofibers in the center of the fiber *(target fiber)*.

NERVE REGENERATION AND REINNERVATION OF MUSCLE

The proximal stumps of degenerated axons sprout and elongate, and they may develop new growth cones during the process of axonal regeneration. These growth cones use the Schwann cells vacated by

the degenerated axons to guide them. The presence of multiple closely aggregated, thinly myelinated small-caliber axons is evidence of regeneration *(regenerating cluster)*. This regrowth of axons is apparently limited by the rate of the slow component of axonal transport, and the movement of tubulin, actin, and intermediate filaments, proceeding at about 1 mm per day. Despite its slow pace, axonal regeneration accounts for some of the functional recovery after nerve injury and can be accelerated with marrow stromal cell transplants.[4]

The reinnervation of skeletal muscle changes its composition, altering the distribution of the two major types of fibers, *type 1* and *type 2*. The fiber types, defined on the basis of histochemistry and physiology (Table 27-1), are determined by the neuron of the motor unit, and their properties are imparted through innervation. Type 1 fibers are high in myoglobin and oxidative enzymes and have many mitochondria, in keeping with their ability to perform tonic contraction; operationally, they are most often defined by their dark staining for adenosine triphosphatase (ATPase) at pH 4.2 but light staining at pH 9.4. Type 2 fibers are rich in glycolytic enzymes and are involved in rapid phasic contractions; they are dark staining on ATPase stain performed at pH 9.4 but light staining at pH 4.2. *Since the motor neuron determines fiber type, all muscle fibers of a single unit are of the same type*. The fibers of a single motor unit are distributed across the muscle, giving rise to a checkerboard pattern of alternating fiber types, as is demonstrated especially well with staining for ATPase (Fig. 27-4A). Normally, there is some variability in the relative abundance of type 1 and type 2 fibers among different muscles. The mnemonic "*one* (type 1 fiber) *slow* (twitch) *fat* (lipid-rich) *red* (appearance) *ox* (oxidative)" is useful to keep the physiology and histochemistry of the fiber types in mind.

TABLE 27-1 -- Muscle Fiber Types

	Type 1	Type 2
Action	Sustained force	Sudden movements
Strength	Weight-bearing	Purposeful motion
Enzyme content	NADH-TR dark staining	NADH light staining
	ATPase at pH 4.2, dark staining	ATPase at pH 4.2, light staining
	ATPase at pH 9.4, light staining	ATPase at pH 9.4, dark staining
Lipids	Abundant	Scant
Glycogen	Scant	Abundant
Ultrastructure	Many mitochondria	Few mitochondria
	Wide Z-band	Narrow-Z-band
Physiology	Slow-twitch	Fast-twitch
Color	Red	White
Prototype	Soleus (pigeon)	Pectoral (pigeon)

ATPase, adenosine triphosphatase; NADH-TR, nicotinamide adenine dinucleotide, reduced form, tetrazolium reductase.

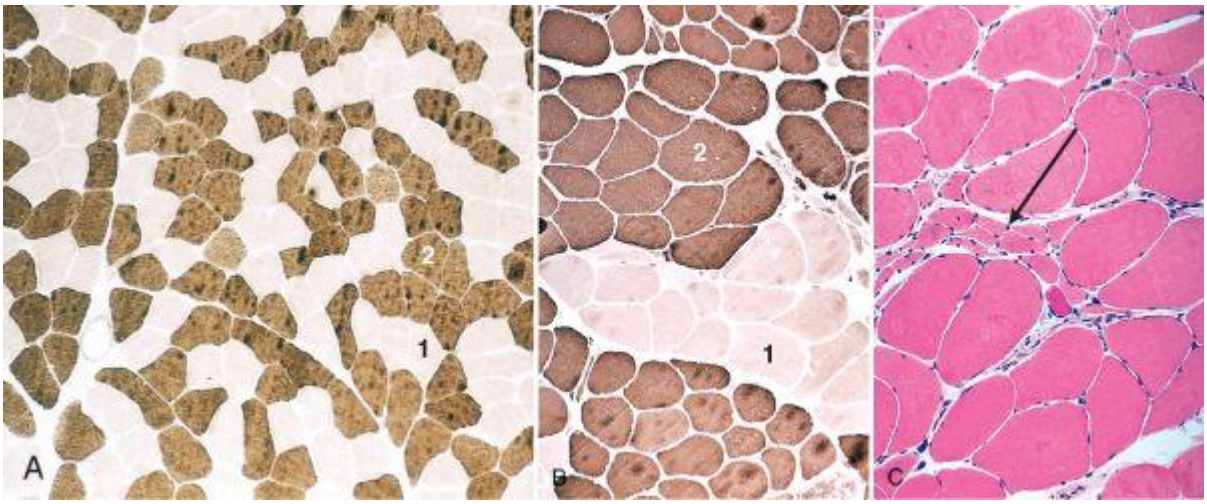

FIGURE 27-4 A, ATPase histochemical staining, at pH 9.4, of normal muscle showing checkerboard distribution of intermingled type 1 *(light)* and type 2 *(dark)* fibers. **B**, In contrast, fibers of both histochemical types are grouped together after reinnervation of muscle. **C**, A cluster of atrophic fibers (group atrophy) in the center *(arrow)*.

Reinnervation of the atrophic muscle fibers within an injured motor unit occurs when the axons belonging to an unaffected neighboring motor unit extend sprouts to reinnervate the denervated myocytes and incorporate them into the healthy motor unit. The number of muscle fibers within the healthy reinnervating motor unit can thus be increased. Furthermore, since muscle fiber type is imparted by the innervating neuron, the newly adopted reinnervated fibers assume the fiber type of their neighboring new siblings. The result of reinnervation is the loss of the checkerboard pattern and the occurrence of a patch of contiguous myocytes having the same histochemical type *(type grouping)* (Fig. 27-4B). *Group atrophy* ensues when a type group in turn becomes denervated, because it is affected in the course of disease progression (Fig. 27-4C).

Type-specific atrophy is characteristic of some disease states. Type 2 fiber atrophy is a relatively common finding and is associated with inactivity or disuse. This type of "disuse atrophy" may occur after fracture of a limb and application of a plaster cast, in pyramidal tract degeneration, or in neurodegenerative diseases. Type 2 fiber atrophy may also occur during therapy with glucocorticoids and is characteristic of "steroid myopathy."

REACTIONS OF THE MUSCLE FIBER

Although a wide spectrum of diseases may affect muscle, the pathologic reactions of myocytes are relatively limited. Pathologic changes may be seen in myopathies as well as in diseases that secondarily involve the muscle cells. The most common forms of reaction include the following:

- *Segmental necrosis*, destruction of a portion of the length of a myocyte, may be followed by *myophagocytosis* as macrophages infiltrate the region. The loss of muscle fibers in time leads to extensive deposition of collagen and fatty infiltration.
- *Vacuolation, alterations in structural proteins or organelles, and accumulation of intracytoplasmic deposits* may be seen in many diseases.
- *Regeneration* occurs when satellite precursor cells proliferate and reconstitute the destroyed portion of the fiber. The regenerating portion of the muscle fiber has large internalized nuclei and prominent nucleoli, and the cytoplasm, laden with RNA, is basophilic.

- Fiber *hypertrophy* occurs in response to increased load, either in the setting of exercise or in pathologic conditions in which muscle fibers are injured. Large fibers may divide longitudinally *(muscle fiber splitting)*, so that in cross-section, a single large fiber contains a cell membrane traversing its diameter, often with adjacent nuclei.

3.17.2 Diseases of Peripheral Nerve

Peripheral nerve is susceptible to the same wide range of categories of disease (inflammatory, traumatic, metabolic, toxic, genetic, neoplastic) as are other tissues. The pattern of disease, however, reflects the unique structure and function of nerves.

INFLAMMATORY NEUROPATHIES

These diseases are characterized by inflammatory cell infiltrates in peripheral nerves, roots, and sensory and autonomic ganglia. In some, an infectious agent elicits the inflammatory responses; in others, immune mechanisms are presumed to be the primary cause of the inflammation.

Immune-Mediated Neuropathies

Guillain-Barré Syndrome (Acute Inflammatory Demyelinating Polyradiculoneuropathy)

Guillain-Barré syndrome is a life-threatening disease of the peripheral nervous system, with an overall annual incidence of one to three cases per 100,000 persons throughout the world.[5] The disease is characterized clinically by weakness beginning in the distal limbs but rapidly advancing to affect proximal muscle function ("ascending paralysis"), and histologically by inflammation and demyelination of spinal nerve roots and peripheral nerves (radiculoneuropathy).

Pathogenesis.

Guillain-Barré syndrome is thought to be an acute-onset *immune-mediated demyelinating neuropathy*. Approximately two thirds of cases are preceded by an acute, influenza-like illness from which the affected individual has recovered by the time the neuropathy becomes symptomatic. Infections with *Campylobacter jejuni*, cytomegalovirus, Epstein-Barr virus, and *Mycoplasma pneumoniae*, or prior vaccination, have been shown to have a significant epidemiologic association with Guillain-Barré syndrome.[6] There has been no consistent demonstration of an infectious agent in peripheral nerves in these patients, and an immunological reaction is generally favored as the underlying cause. A similar inflammatory disease of peripheral nerves can be induced in experimental animals by immunization with a peripheral nerve myelin protein. A T cell–mediated immune response ensues, accompanied by segmental demyelination induced by activated macrophages. Transfer of these T cells to a naive animal results in comparable lesions. Moreover, lymphocytes from individuals with Guillain-Barré syndrome have been shown to produce demyelination in tissue cultures of myelinated nerve fibers. Circulating antibodies may also play a part, and plasmapheresis can be an effective treatment.[6]

Morphology. The dominant histopathologic finding is **inflammation of peripheral nerve**, manifested as perivenular and endoneurial infiltration by lymphocytes, macrophages, and a few plasma cells. Inflammatory foci and demyelination are widely distributed throughout the peripheral nervous system, although their intensity is variable. The most intense inflammatory reaction is often localized in spinal and cranial motor roots and the adjacent parts of the spinal and cranial nerves. Segmental demyelination affecting peripheral nerves is the primary lesion, but damage to axons is also characteristic, particularly when the disease is severe. Electron microscopy has identified an early effect on myelin sheaths. The cytoplasmic processes of macrophages penetrate the basement membrane of Schwann cells, particularly in the vicinity of the nodes of Ranvier, and extend between

the myelin lamellae, stripping away the myelin sheath from the axon. Ultimately, the remnants of the myelin sheath are engulfed by the macrophages. Remyelination follows the demyelination.

Clinical Course.

The clinical picture is dominated by the ascending paralysis. Deep tendon reflexes disappear early in the process; although sensory involvement can often be detected, it is less troublesome than the weakness. The nerve conduction velocity is slowed because of the multifocal destruction of myelin segments involving many axons within a nerve. There is elevation of the CSF protein due to inflammation and altered permeability of the microcirculation within the spinal roots as they traverse the subarachnoid space. Inflammatory cells are contained within the roots, however, and there is little to no CSF pleocytosis. Many patients spend weeks in hospital intensive-care units before recovering normal function. With improved respiratory care and support, the mortality rate has fallen from 25% in the past but is still considerable; some 2% to 5% die of respiratory paralysis, autonomic instability, cardiac arrest, or the complications of treatment. Up to 20% of hospitalized patients have long-term disability.[5,][6]

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

In some patients, inflammatory demyelinating polyradiculoneuropathy follows a subacute or chronic course, usually with relapses and remissions over a period of several years, rather than the acute course of Guillain-Barré syndrome.[7] In these cases there is often a symmetric, mixed sensorimotor polyneuropathy, although some patients have predominantly sensory or motor impairment. Clinical remissions may occur with steroid treatment and plasmapheresis. Biopsies of sural nerves show evidence of recurrent demyelination and remyelination associated with well-developed onion bulb structures.[8]

INFECTIOUS POLYNEUROPATHIES

Many infectious processes affect peripheral nerve. Leprosy, diphtheria, and varicella-zoster cause unique and specific pathologic changes in nerves and are also discussed as systemic infectious diseases in Chapter 8 .

Leprosy (Hansen Disease)

Peripheral nerves are involved in both lepromatous and tuberculoid leprosy (discussed in Chapter 8).[9] In lepromatous leprosy, Schwann cells are invaded by *Mycobacterium leprae*, which proliferate and eventually infect other cells. There is evidence of segmental demyelination and remyelination and loss of both myelinated and unmyelinated axons. As the infection advances, endoneurial fibrosis and multilayered thickening of the perineurial sheaths occur. Affected individuals develop a symmetric polyneuropathy affecting the cool extremities (due to lower temperatures favoring mycobacterial growth). The infection prominently involves pain fibers, and the resulting loss of sensation contributes to injury, since the patient is rendered unaware of injurious stimuli and damaged tissues. Thus, large traumatic ulcers may develop in the extremities. Tuberculoid leprosy shows evidence of active cell-mediated immune response to *M. leprae*, with nodules of granulomatous inflammation situated in the dermis. The inflammation injures cutaneous nerves in the vicinity; axons, Schwann cells, and myelin are lost, and there is fibrosis of the perineurium and endoneurium. In tuberculoid leprosy, affected individuals have much more localized nerve involvement.

Diphtheria

Peripheral nerve involvement results from the effects of the diphtheria exotoxin and begins with paresthesias and weakness[10]; early loss of proprioception and vibratory sensation is common. The earliest changes are seen in the sensory ganglia, where the incomplete blood-nerve barrier allows entry of the toxin. There is selective demyelination of axons that extends into adjacent anterior and posterior roots as well as into mixed sensorimotor nerves. The mechanism of action of diphtheria toxin is described in Chapter 8 .

Varicella-Zoster Virus

Varicella-zoster virus is one of the most common viral infections of the peripheral nervous system.[11] Following chickenpox, a latent infection persists within neurons in the sensory ganglia of the spinal cord and brain stem, and reactivation leads to a painful, vesicular skin eruption in the distribution of sensory dermatomes *(shingles)*, most frequently thoracic or trigeminal. The virus may be transported along the sensory nerves to the skin, where it establishes an active infection of epidermal cells. In a small proportion of patients, weakness is also apparent in the same distribution. Although the factors that give rise to reactivation are not fully understood, decreased cell-mediated immunity is of major importance in some cases.

Affected ganglia show neuronal destruction and loss, usually accompanied by abundant mononuclear inflammatory infiltrates; regional necrosis with hemorrhage may also be found. Peripheral nerve shows axonal degeneration after the death of the sensory neurons. Focal destruction of the large motor neurons of the anterior horns or cranial nerve motor nuclei may be seen at the corresponding levels. Intranuclear inclusions generally are not found in the peripheral nervous system.

HEREDITARY NEUROPATHIES

This is a group of heterogeneous, typically progressive, and often disabling syndromes that affect peripheral nerves. The genetic and molecular basis of many of the hereditary peripheral neuropathies is being elucidated,[12,][13] and as they are further defined, adjustments in the current classification scheme can be anticipated. They can be divided into several groups:

- *Hereditary motor and sensory neuropathies* (HMSNs): The most common form of hereditary neuropathies, these disorders affect both strength and sensation (sensorimotor neuropathies). *They present as a spectrum of disorders, all caused by mutations in genes whose products are involved in peripheral nerve function*. Different mutations within the same gene may give rise to diseases with varying clinical features.[14] The different forms of HMSN are described below.
- *Hereditary sensory and autonomic neuropathies* (HSANs, summarized in Table 27-2): Symptoms in HSAN are usually limited to numbness, pain, and autonomic dysfunction such as orthostatic hypotension, but without weakness.
- *Familial amyloid polyneuropathies*: These are hereditary peripheral neuropathies characterized by the deposition of amyloid within the peripheral nervous system. Most kindreds show mutations of the *transthyretin* gene, located on chromosome 18q11.2–q12.1. Their clinical presentation is similar to that of HSAN. The amyloid fibrils are composed of transthyretin (Chapter 6), a protein involved in serum binding and transport of thyroid hormone.
- *Peripheral neuropathy accompanying inherited metabolic disorders*: Several hereditary metabolic disorders are accompanied by prominent peripheral neuropathy during the course of the disease; the molecular basis and the clinicopathologic characteristics of some of these are presented in Table 27-3 .

TABLE 27-2 -- Hereditary Sensory and Autonomic Neuropathies (HSANs)

Disease and Inheritance	Gene and Locus	Clinical and Pathologic Findings
HSAN I; autosomal dominant	Serine palmitoyl transferase, long-chain base, subunit 1 (*SPTLC1*) gene; 9q22.1–q22.3	Predominantly sensory neuropathy, presenting in young adults; axonal degeneration (mostly myelinated fibers)

Disease and Inheritance	Gene and Locus	Clinical and Pathologic Findings
HSAN II; autosomal recessive (some cases are sporadic)	*HSN2* gene; 12q13.3	Predominantly sensory neuropathy, presenting in childhood; axonal degeneration (mostly myelinated fibers)
HSAN III; (Riley-Day syndrome; familial dysautonomia; most often in Jewish children); autosomal recessive	IKAP histone acetyltransferase (*IKAP*) gene; 9q31	Predominantly autonomic neuropathy, presenting in infancy; axonal degeneration (mostly unmyelinated fibers); atrophy and loss of sensory and autonomic ganglion cells
HSAN IV; autosomal recessive dysautonomia, type II;	Neurotrophic tyrosine kinase receptor, type 1, or *NTRK1* gene; 1q21–q22	Congenital insensitivity to pain and anhidrosis; presentation in infancy; nearly complete loss of small myelinated and unmyelinated fibers
HSAN V; autosomal recessive	Nerve growth factor β subunit (*NGFB*) gene; 1p13.1	Congenital insensitivity to pain and temperature; presentation in infancy; nearly complete loss of small myelinated fibers

TABLE 27-3 -- Hereditary Neuropathies Accompanying Inherited Metabolic Disease

Disease	Genetic Defect	Inheritance	Clinical Findings	Pathologic Findings
Adrenoleukodystrophy	ATP-binding cassette (ABC), transporter protein, subfamily D, member 1 (*ABCD1*); Xq28	X-linked; 4% of female carriers are symptomatic	Mixed motor and sensory neuropathy, adrenal insufficiency, spastic paraplegia; onset between 10 and 20 years for males with leukodystrophy, between 20 and 40 years for females with myeloneuropathy	Segmental demyelination, with onion bulbs; axonal degeneration (myelinated and unmyelinated); electron microscopy—linear inclusions in Schwann cells
Familial amyloid polyneuropathies	Transthyretin (*TTR*) gene (rarely other genes); 18q11.2–q12.1	Autosomal dominant	Sensory and autonomic dysfunction; age at onset varies with site of mutation	Amyloid deposits in vessel walls and endoneurium with axonal degeneration
Porphyria, acute intermittent (AIP) or variegate coproporphyria	Enzymes involved in heme synthesis (acute intermittent porphyria—porphobilinogen deaminase deficiency; 11q24.1–q24.2)	Autosomal dominant	Acute episodes of neurologic dysfunction, psychiatric disturbances, abdominal pain, seizures, proximal weakness, autonomic dysfunction; attacks may be precipitated by drugs	Acute and chronic axonal degeneration; regenerating clusters
Refsum disease	Peroxisomal enzyme phytanoyl CoA α-hydroxylase (*PAHX*) gene; 10pter–p11.2 (a rare genetically distinct infantile form also exists)	Autosomal recessive	Mixed motor and sensory neuropathy; palpable nerves; ataxia, night blindness, retinitis pigmentosa, ichthyosis; age at onset before 20 years	Severe onion bulb formation

ATP, adenosine triphosphate; CoA, coenzyme A.

The most common hereditary neuropathy, HMSN I, results in demyelination of peripheral nerve and slowing of the velocity of axonal conduction. The other hereditary neuropathies are axonal neuropathies that have fiber loss as their most prominent pathologic finding.

Hereditary Motor and Sensory Neuropathy Type I

HMSN I, also referred to as *Charcot-Marie-Tooth (CMT) disease, demyelinating type*, usually presents in childhood or early adulthood. A characteristic progressive muscular atrophy of the leg below the knee seen in these patients gives rise to the common clinical term *peroneal muscular atrophy*. Affected individuals may be asymptomatic, but when they present, it is often with symptoms such as distal muscle weakness, atrophy of the leg below the knee, or secondary orthopedic problems of the foot (such as *pes cavus*).

Pathogenesis and Molecular Genetics.

The disease is genetically heterogeneous. The most common subtype (known as HMSN IA or CMT1A) has a duplication of a large region of chromosome 17p11.2, resulting in "segmental trisomy" of this region. The duplicated segment includes the gene that encodes peripheral myelin protein 22 (PMP22), a transmembrane protein expressed in compacted myelin. PMP22 and a set of related proteins are involved in the compaction of myelin in the peripheral nervous system (Fig. 27-5). Mutations affecting these myelin-associated genes result in demyelinating neuropathies of the HMSN I phenotype.[14] Mutations in another gene, on chromosome 1, which codes for myelin protein zero (MPZ), produce an identical clinical phenotype (HMSN IB). Additional pedigrees with hereditary demyelinating neuropathy show mutations in genes encoding structural proteins (connexin-32), protein degradation pathways (LITAF), and myelination induction genes (early growth response 2, EGR2).[12,][14]

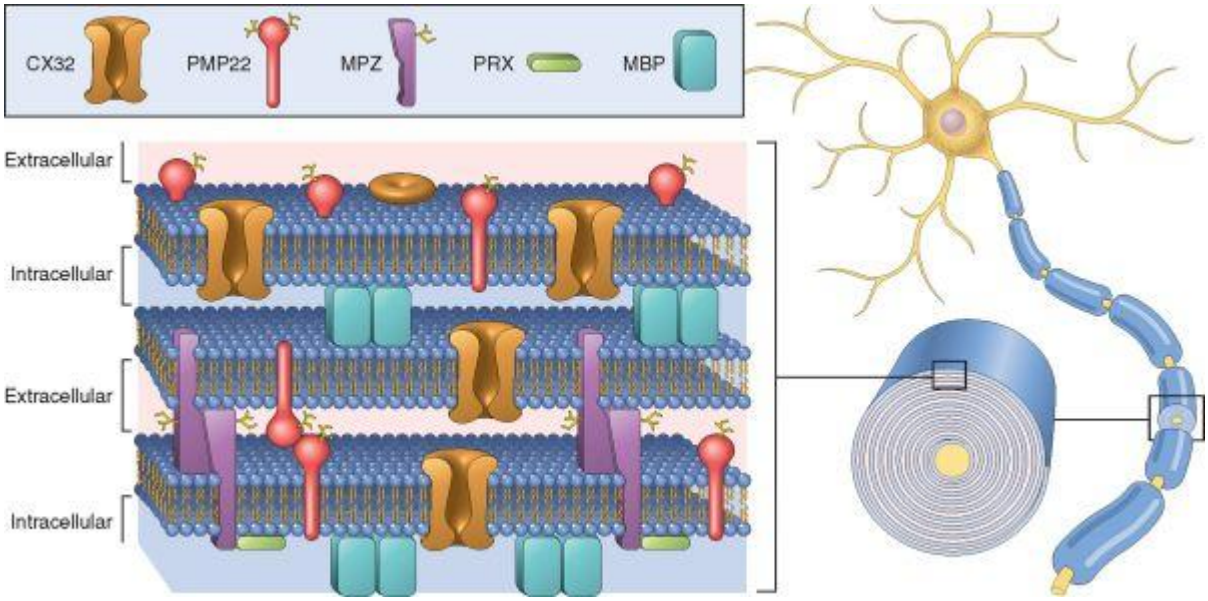

FIGURE 27-5 Relationship between the proteins of compacted myelin and the lipid bilayers. Myelin basic protein (MBP) is an intracellular protein that has a role in myelin compaction. Mutant forms of myelin protein zero (MPZ), peripheral myelin protein 22 (PMP22), and periaxin (PRX) cause hereditary demyelinating neuropathies of the Charcot-Marie-Tooth, type 1 category.

Morphology. HMSN I is a demyelinating neuropathy. Histologic examination shows the

consequences of repetitive demyelination and remyelination, with multiple onion bulbs, more pronounced in distal nerves than in proximal nerves (see Fig. 27-2). The axon is often present in the center of the onion bulb, and the myelin sheath is usually thin or absent. The redundant layers of Schwann cell hyperplasia surrounding individual axons are associated with enlargement of involved peripheral nerves that may become palpable, which has led to the term **hypertrophic neuropathy**. In the longitudinal plane, the axon may show evidence of segmental demyelination. Autopsy studies of affected individuals have shown degeneration of the posterior columns of the spinal cord.

Clinical Course.

The disorder is most often autosomal dominant, and although it is slowly progressive, the disability of sensorimotor deficits and associated orthopedic problems such as pes cavus are usually limited in severity, and a normal life span is typical.

Other Hereditary Motor and Sensory Neuropathies

HMSN II

The axonal form of autosomal dominant CMT HMSN II (CMT-2) presents with signs and symptoms similar to those of HMSN I, although nerve enlargement is not seen and the disease presents at a slightly later age. This form is less common than HMSN I. Some cases (designated HMSN IIA1 or CMT2A1) are caused by mutations in a gene encoding a kinesin family member, KIF1B.[15] Additional, less common mutations in other genes have been identified; these are classified as CMT2B to 2L.[23] Nerve biopsy specimens in HMSN II show loss of myelinated axons as the predominant finding. Segmental demyelination of internodes is infrequent. These findings suggest that the site of primary cellular dysfunction is the axon or neuron.

Dejerine-Sottas Neuropathy (HMSN III)

Dejerine-Sottas neuropathy is a slowly progressive, autosomal recessive disorder that begins in early childhood, and is manifested by delay in developmental milestones, such as the acquisition of motor skills. In contrast to HMSN I and HMSN II, in which muscular atrophy is limited to the leg, both trunk and limb muscles are involved in Dejerine-Sottas disease. On physical examination, *enlarged peripheral nerves* can be detected by inspection and palpation. The deep tendon reflexes are depressed or absent, and nerve conduction velocity is slowed. HMSN III is genetically heterogeneous, and arises from mutations in the same myelin-associated genes that are mutated in HMSN I. These include genes encoding PMP22, MPZ, periaxin (PRX), and EGR2.[16] Morphologically, the size of individual peripheral nerve fascicles is increased, often markedly, with abundant onion bulb formation as well as segmental demyelination. There is usually evidence of axonal loss, and the axons that remain are often of diminished caliber. Distal portions of peripheral nerves are most severely affected; however, autopsy studies have shown that the spinal roots are also involved.

ACQUIRED METABOLIC AND TOXIC NEUROPATHIES

Functional and structural changes in peripheral nerves develop in response to various metabolic alterations—either from endogenous disorders or from exogenous agents. The most common of these processes are discussed here.

Peripheral Neuropathy in Adult-Onset Diabetes Mellitus

The prevalence of peripheral neuropathy in individuals with diabetes mellitus depends on the duration of the disease; up to 50% of diabetics overall have peripheral neuropathy clinically, and up to 80% of those who have had the disease for more than 15 years. Several distinct clinicopathologic patterns of

diabetes-related peripheral nerve abnormalities have been recognized (Chapter 24). They are categorized as *distal symmetric sensory or sensorimotor neuropathy*, *autonomic neuropathy*, and *focal or multifocal asymmetric neuropathy*. Individuals may develop any combination of these lesions; in fact, the first two (sensorimotor and autonomic) are often found together. The mechanism of diabetic neuropathy is not completely resolved, but there is evidence for involvement of both the polyol pathway and the nonenzymatic glycation of proteins.[17]

Morphology. In individuals with a distal symmetric sensorimotor neuropathy, the predominant pathologic finding is an axonal neuropathy. As with other chronic axonal neuropathies, there is often some segmental demyelination. There is a relative loss of small myelinated fibers and of unmyelinated fibers, but large fibers are also affected. Endoneurial arterioles show thickening, hyalinization, and intense periodic acid–Schiff positivity in their walls and extensive reduplication of the basement membrane[18] (Fig. 27-6).

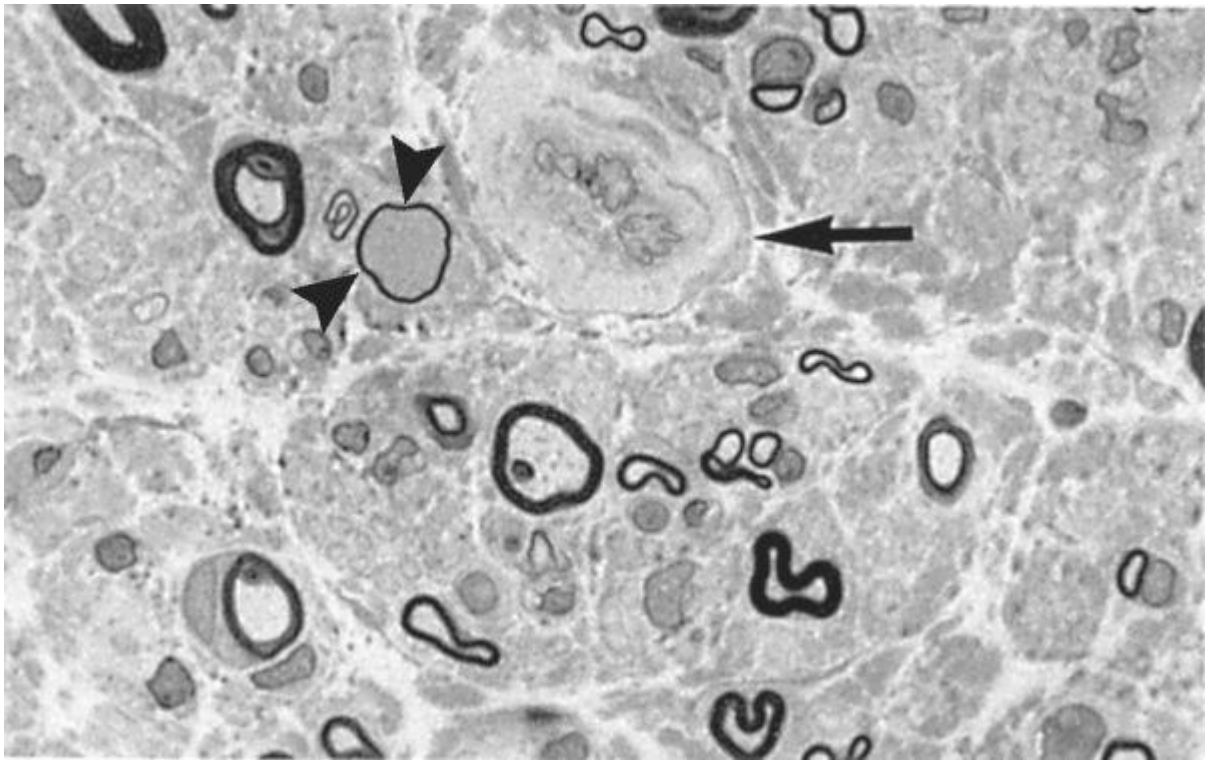

FIGURE 27-6 Diabetic neuropathy with marked loss of myelinated fibers, a thinly myelinated fiber *(arrowheads)*, and thickening of endoneurial vessel wall *(arrow)*.

Clinical Course.

The most common peripheral neuropathy in type 2 diabetes mellitus is the symmetric neuropathy that involves distal sensory and motor nerves. Individuals with the neuropathy develop decreased sensation in the distal extremities with less evident motor abnormalities. The loss of pain sensation can result in the development of ulcers, which heal poorly because of the diffuse vascular injury in diabetes and are a major cause of morbidity. Another manifestation of diabetic neuropathy is dysfunction of the autonomic nervous system; this affects 20% to 40% of individuals with diabetes mellitus, nearly always in association with a distal sensorimotor neuropathy.[17] Diabetic autonomic neuropathy has protean

manifestations, including postural hypotension, incomplete emptying of the bladder resulting in recurrent infections, and sexual dysfuction. Some affected individuals, especially elderly adults with a long history of diabetes, develop a peripheral neuropathy that manifests itself as a disorder of single individual peripheral or cranial (oculomotor nerve) nerves (mononeuropathy), or of several individual nerves in an asymmetric distribution (multiple mononeuropathy or mononeuropathy multiplex). The pathogenesis of mononeuropathies in adult-onset diabetes is thought to involve vascular insufficiency, and ischemia of the affected peripheral nerve.[17]

Metabolic and Nutritional Peripheral Neuropathies

Most individuals with renal failure have a peripheral neuropathy *(uremic neuropathy)*.[19] This is typically a distal, symmetric neuropathy that may be asymptomatic or may be associated with muscle cramps, distal dysesthesias, and diminished deep tendon reflexes. In these patients axonal degeneration is the primary event; occasionally there is secondary demyelination. Regeneration and recovery are common after dialysis.

Peripheral neuropathy can also develop in individuals with chronic liver disease, chronic respiratory insufficiency, and thyroid dysfunction. *Thiamine deficiency* is associated with axonal neuropathy, a clinical condition termed *neuropathic beriberi*. Axonal neuropathies also occur with deficiencies of vitamins B_{12} (cobalamin), B_6 (pyridoxine), and E (α-tocopherol). Excessive chronic consumption of ethyl alcohol often leads to axonal neuropathy. There is a strong contribution of associated dietary deficiency, and affected individuals often have signs of thiamine deficiency. However, ethyl alcohol may have a direct toxic effect on peripheral nerve, since some affected individuals have adequate thiamine intake.[20]

Neuropathies Associated with Malignancy

Direct infiltration or compression of peripheral nerves by tumor is a common cause of mononeuropathy and may be the presenting symptom of cancer. These neuropathies include *brachial plexopathy* from neoplasms of the apex of the lung, *obturator palsy* from pelvic malignant neoplasms, and *cranial nerve palsies* from intracranial tumors and tumors of the base of the skull. A *polyradiculopathy* involving the lower extremity may develop when the cauda equina is involved by meningeal carcinomatosis.

In contrast, a diffuse, symmetric peripheral neuropathy may occur in individuals with a distant carcinoma as a *paraneoplastic* effect (Chapters 7 and 28 . The most common type is a sensorimotor neuropathy characterized by weakness and sensory deficits that are often more pronounced in the lower extremities and that progress during months to years.[21] The neuropathy is most frequently associated with small-cell carcinoma of the lung; as many as 2% to 5% of people with lung cancer have clinical evidence of peripheral neuropathy. Patients with the less frequent pure sensory neuropathy present with numbness and paresthesias that may precede the diagnosis of the malignancy by 6 to 15 months. An immunological mechanism for the neuropathy has been suggested based on the presence of inflammatory infiltrates within the dorsal root ganglia and the identification of IgG antibodies that bind a 35- to 38-kD RNA-binding protein expressed by neurons and the tumor.[22] The severity of clinical symptoms correlates with antibody titer, suggesting a causative relationship.

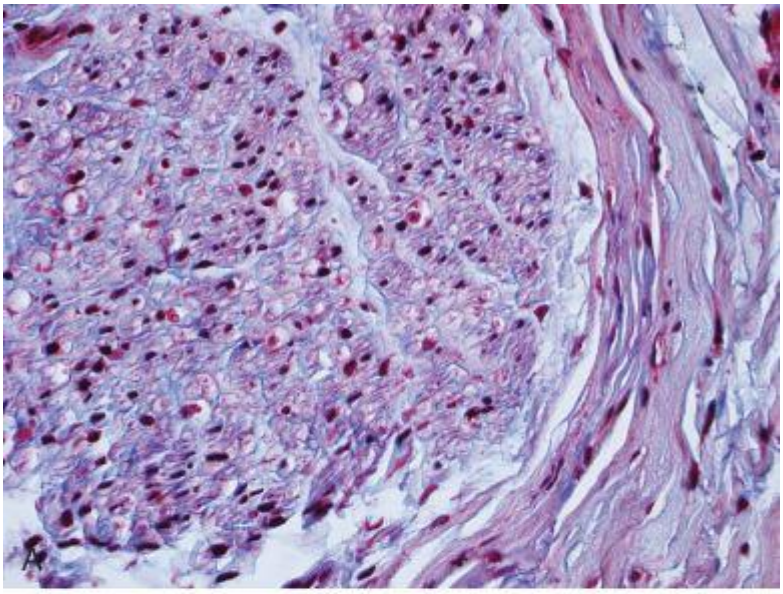
Paraneoplastic neuropathy may also develop in individuals with plasma cell neoplasms in one of two ways. The first is through the deposition of light-chain (AL type) amyloid in peripheral nerves (Chapter 6). The second is related to the production of monoclonal immunoglobulin that recognizes a major protein of myelin, myelin-associated glycoprotein.[23]

Toxic Neuropathies

Peripheral neuropathies can occur after exposure to industrial or environmental chemicals, biologic toxins, or therapeutic drugs.[24] Prominent among the environmental chemicals are heavy metals, including lead and arsenic (Chapter 9). In addition, many organic compounds are known to be toxic to the peripheral nervous system, leading to peripheral neuropathy.

TRAUMATIC NEUROPATHIES

Peripheral nerves are commonly injured in the course of trauma. *Lacerations* result from cutting injuries and can complicate fractures when a sharp fragment of bone lacerates the nerve. *Avulsions* occur when tension is applied to a peripheral nerve, often as the result of a force applied to one of the limbs. Regeneration of peripheral nerve axons following these types of injuries does occur, albeit slowly. Regrowth may be complicated by discontinuity between the proximal and distal portions of the nerve sheath as well as by the misalignment of individual fascicles. Axons, even in the absence of correctly positioned distal segments, may continue to grow, resulting in a mass of tangled axonal processes known as a *traumatic neuroma (pseudoneuroma* or *amputation neuroma).* Within this mass, small bundles of axons appear randomly oriented; each, however, is surrounded by organized layers containing Schwann cells, fibroblasts, and perineurial cells (Fig. 27-7).



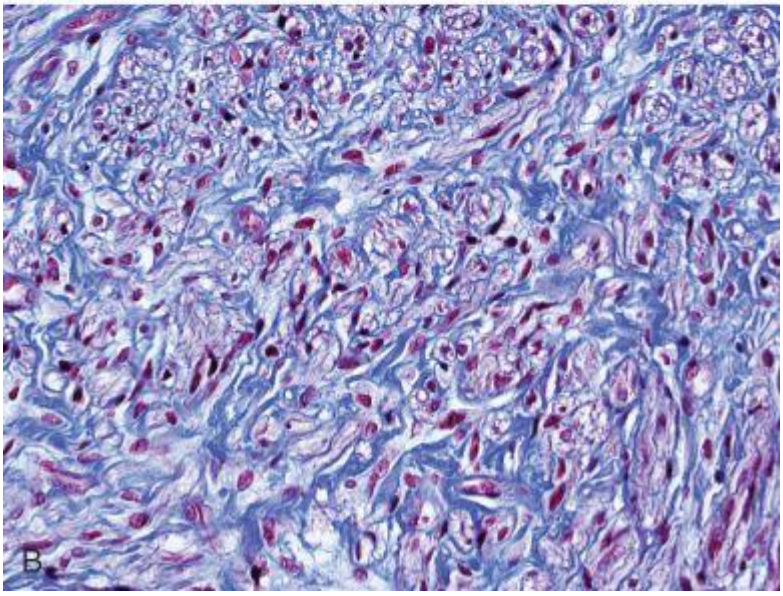


FIGURE 27-7 Normal appearance of peripheral nerve (**A**), with all the axons aligned in a single plane with sheaths of connective tissue, as compared with traumatic neuroma (**B**) showing disordered orientation of axons *(pale purple)* intermixed with connective tissue *(blue)*.

Compression neuropathy (entrapment neuropathy) occurs when a peripheral nerve is compressed, often within an anatomic compartment. *Carpal tunnel syndrome*, the most common entrapment neuropathy, results from compression of the median nerve at the level of the wrist within the compartment delimited by the transverse carpal ligament.[25] Women are more commonly affected than men, and the problem is frequently bilateral. The disorder may be observed in association with many conditions including tissue edema, pregnancy, inflammatory arthritis, hypothyroidism, amyloidosis (especially that related to β_2-microglobulin deposition in individuals on renal dialysis), acromegaly, diabetes mellitus, and excessive repetitive motions of the wrist. Symptoms are limited to dysfunction of the median nerve, including numbness and paresthesias of the tips of the thumb and first two digits. Other nerves prone to compression neuropathies include the ulnar nerve at the level of the elbow, the peroneal nerve at the level of the knee, and the radial nerve in the upper arm; the latter occurs from sleeping with the arm in an awkward position ("Saturday night palsy"). Another form of compression neuropathy is found in the foot, affecting the interdigital nerve at intermetatarsal sites. This problem, which occurs more often in women than in men, leads to foot pain (metatarsalgia). The histologic findings of the lesion *(Morton neuroma)* include evidence of chronic compression injury.

TUMORS OF PERIPHERAL NERVE

Both benign and malignant tumors can be derived from elements of the nerve sheath. These are discussed with tumors of the central nervous system (Chapter 28).

3.17.3 Diseases of Skeletal Muscle

DENERVATION ATROPHY

Neurogenic atrophy of muscle is caused by disorders that affect motor neurons (see Fig. 27-1). The response of muscle to denervation and the histologic changes associated with reinnervation have been described earlier.

Spinal Muscular Atrophy (Infantile Motor Neuron Disease)

Motor neuron diseases are progressive neurologic illnesses that selectively destroy the anterior horn cells in the spinal cord and cranial nerve motor neurons. Motor neuron diseases in adults are discussed in Chapter 28 . Spinal muscular atrophy (SMA) is a distinctive group of autosomal recessive motor neuron diseases that begin in childhood or adolescence. SMA is discussed here because the disease is commonly considered with the childhood myopathies and because the pathologic findings in skeletal muscle are characteristic.

Genetics.

All forms of SMA are associated with mutations affecting survival motor neuron 1 (*SMN1*), a gene on chromosome 5 that is required for motor neuron survival. This region of chromosome 5 also contains variable numbers of copies of a second highly homologous gene, *SMN2*. Homozygous deletions of *SMN1* (or less commonly, intragenic mutations) cause SMA.[26] The number of copies of the homologous *SMN2* modifies the clinical phenotype, with more copies being associated with milder neurologic phenotype. *SMN* genes are expressed in all tissues, so why mutations or deletions of these

genes cause only neuronal loss is not clear. It is postulated that the SMN protein is critical for normal axonal transport and integrity of neuromuscular junctions, and thus promotes survival of motor neurons.

Morphology. The typical histologic finding in muscle is large numbers of atrophic fibers, often only a few micrometers in diameter (Fig. 27-8). This is unlike the groups of angulated atrophic fibers seen in denervation atrophy of muscle in adults. In SMA the muscle fiber atrophy often involves an entire fascicle, a feature known as **panfascicular atrophy**. There are also scattered large fibers that are two to four times normal size.

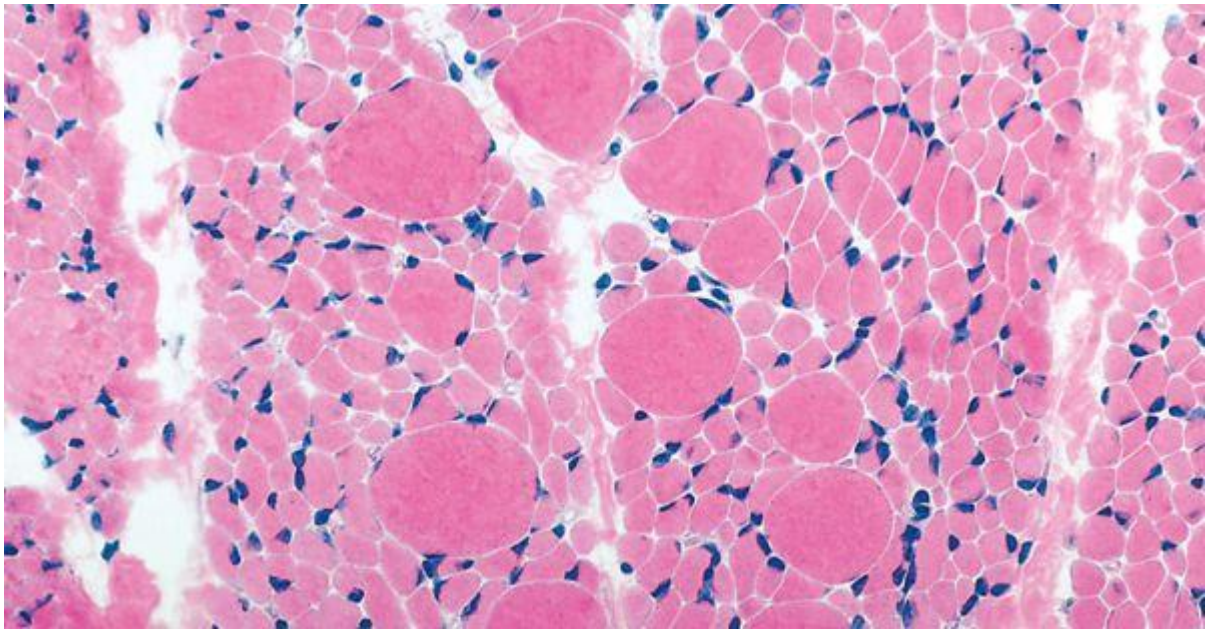

FIGURE 27-8 Spinal muscular atrophy with groups of round atrophic muscle fibers, or panfascicular atrophy, resulting from denervation atrophy.

Clinical Course.

The most common form of SMA, Werdnig-Hoffmann disease (SMA type 1), has its onset at birth or within the first 4 months of life with severe hypotonia (lack of muscle tone and "floppiness"). It usually leads to death within the first 3 years of life. The other two forms (SMA 2 and SMA 3) present at later ages, either in early childhood (between 3 and 15 months of age in SMA 2) or in later childhood (after 2 years of age in SMA 3). Those with SMA 2 usually die in childhood after age 4, whereas those with SMA 3 often survive into adulthood.

MUSCULAR DYSTROPHIES

The muscular dystrophies are a heterogeneous group of inherited disorders of muscle, often beginning in childhood, that lead to progressive weakness and muscle wasting. Histologically, in advanced cases muscle fibers undergo degeneration and are replaced by fibrofatty tissue and collagen. This feature distinguishes dystrophies from myopathies (described later), which also present with muscle weakness.

X-Linked Muscular Dystrophy (Duchenne Muscular Dystrophy and Becker Muscular Dystrophy)

The two most common forms of muscular dystrophy are X linked: *Duchenne muscular dystrophy* (DMD) and *Becker muscular dystrophy* (BMD). DMD is the most severe and common form of muscular dystrophy, with an incidence of about 1 per 3500 live male births. DMD becomes clinically manifest by the age of 5 years. It leads to wheelchair dependence by 10 to 12 years of age, and thereafter progresses relentlessly. Although BMD involves the same genetic locus, it is less common and much less severe than DMD.

Pathogenesis and Molecular Genetics.

DMD and BMD are caused by abnormalities in *DMD*, a gene that is located in the Xp21 region. *DMD* is one of the largest human genes, spanning 2.3 million base pairs, and 79 exons. It encodes a 427-kD protein named *dystrophin*. A large proportion of the genetic abnormalities are deletions, with frameshift and point mutations accounting for the rest.[27] Approximately two thirds of the cases are familial, and the remainder represent new mutations. In the affected families females are carriers; they are clinically asymptomatic but often have elevated serum creatine kinase and show minimal histologic abnormalities on muscle biopsy. Female carriers and affected males who survive into adulthood are also at risk for developing dilated cardiomyopathy.[27]

Dystrophin is a cytoplasmic protein located adjacent to the sarcolemmal membrane in myocytes (Fig. 27-9). It is concentrated at the plasma membrane over Z-bands, where it forms a strong mechanical link to cytoplasmic actin. Thus, *dystrophin and the dystrophin-associated protein complex form an interface between the intracellular contractile apparatus and the extracellular connective tissue matrix*. The role of this complex of proteins in transferring the force of contraction to connective tissue has been proposed to be the basis for the myocyte degeneration that occurs in the absence of dystrophin[28] or various other proteins that interact with dystrophin (see later). Muscle biopsy specimens from individuals with DMD show little or no dystrophin by both staining and western blot analysis (Fig. 27-10). People with BMD, who also have mutations in the dystrophin gene, have diminished amounts of dystrophin, usually of an abnormal molecular weight, reflecting mutations that allow synthesis of an abnormal protein of smaller size (Fig. 27-10B).

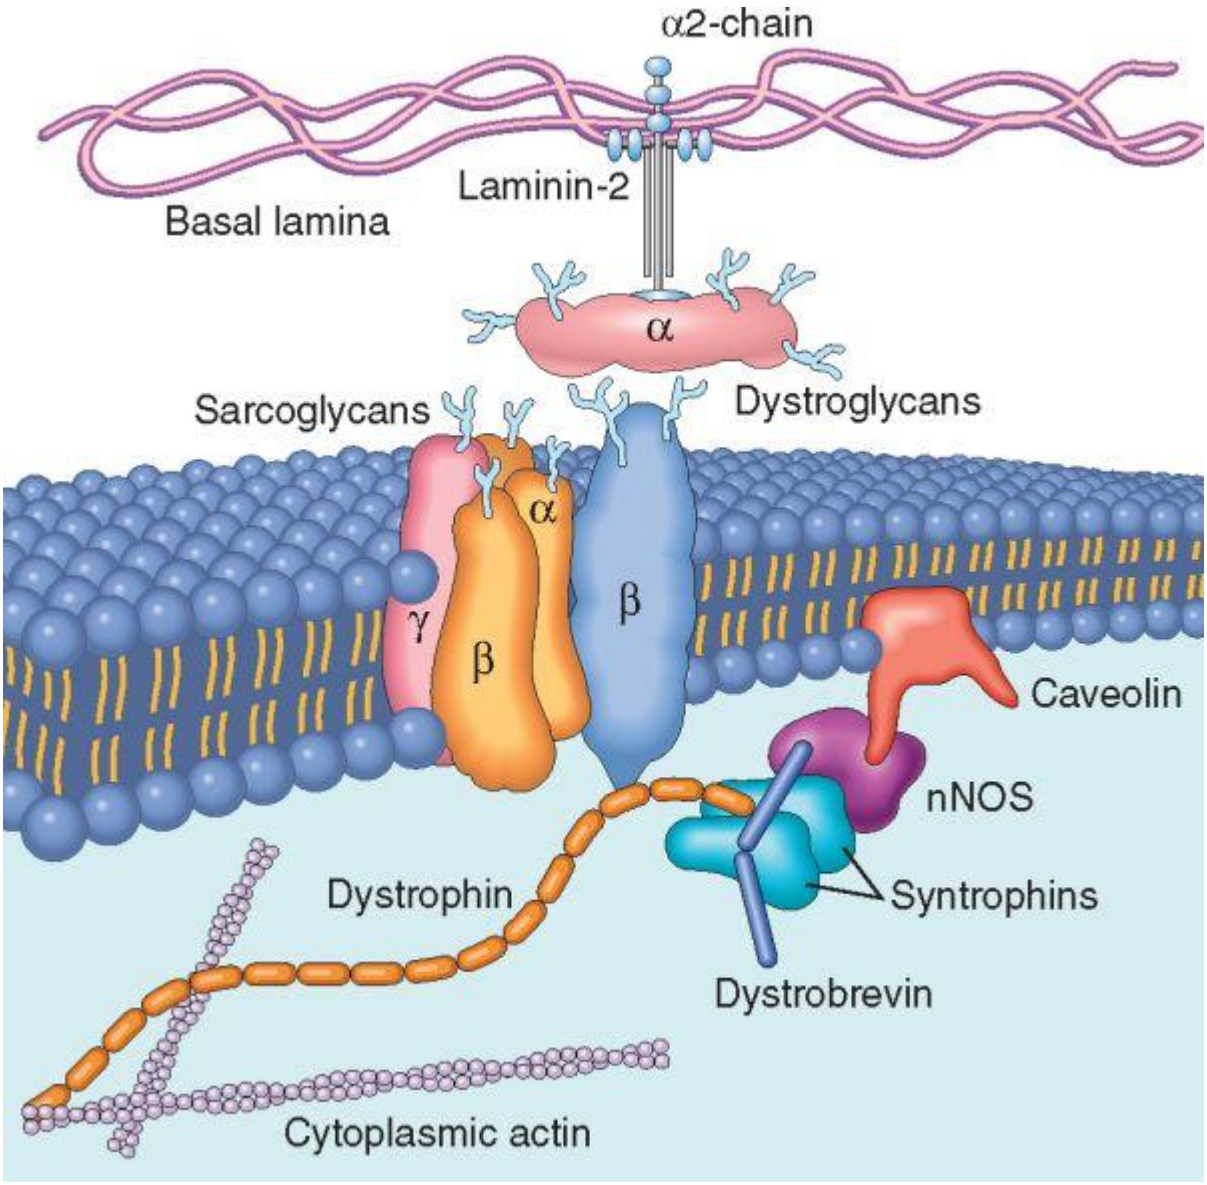

FIGURE 27-9 Relationship between the cell membrane (sarcolemma) and the sarcolemmal associated proteins. Dystrophin, an intracellular protein, forms an interface between the cytoskeletal proteins and a group of transmembrane proteins, the dystroglycans and the sarcoglycans. These transmembrane proteins have interactions with the extracellular matrix, including the laminin proteins. Dystrophin also interacts with dystrobrevin and the syntrophins, which form a link with neuronal-type nitric oxide synthetase (nNOS) and caveolin. Mutations in dystrophin are associated with the X-linked muscular dystrophies; mutations in caveolin and the sarcoglycan proteins with the limb-girdle muscular dystrophies, which can be autosomal dominant or recessive disorders; and mutations in the α2-laminin (merosin) with autosomal recessive congenital muscular dystrophy.

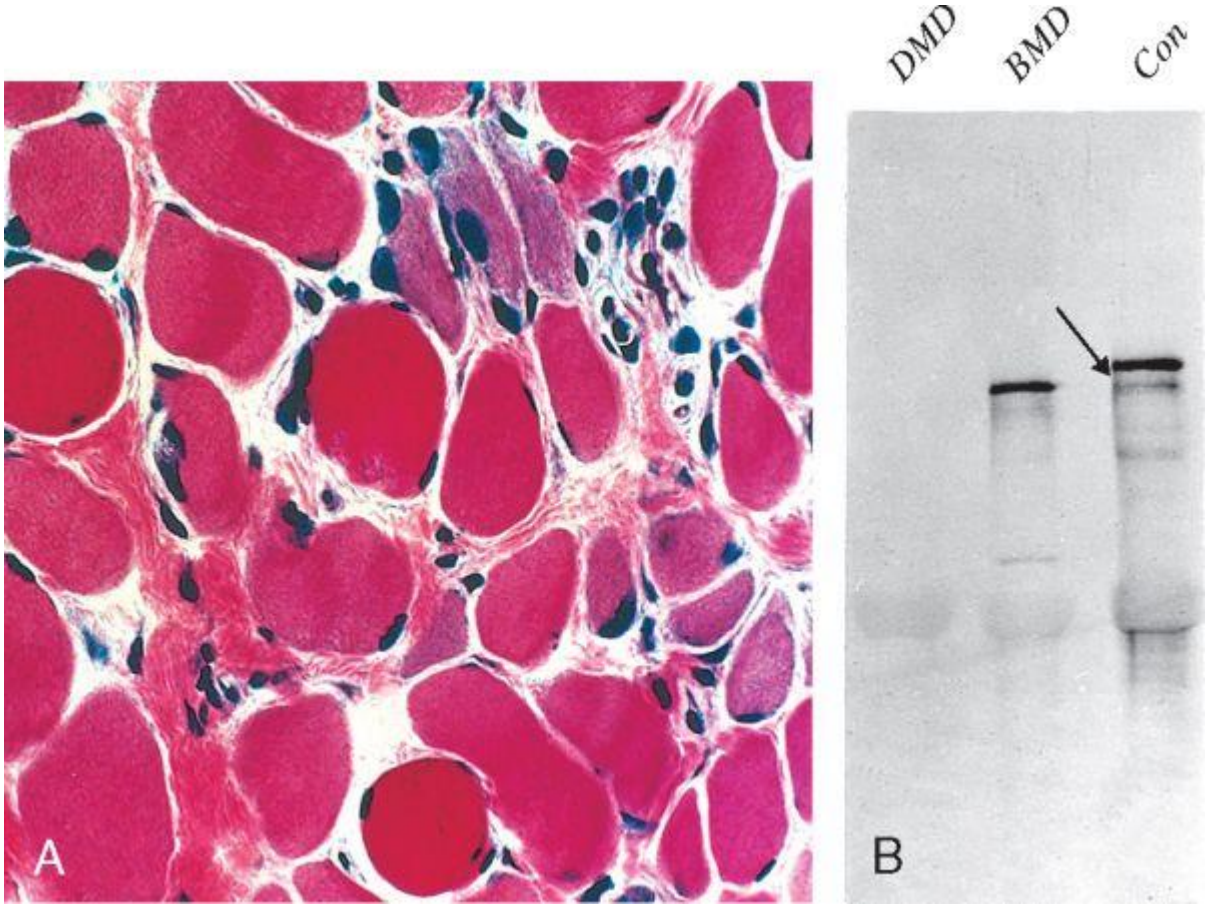

FIGURE 27-10 A, Duchenne muscular dystrophy (DMD) showing variation in muscle fiber size, increased endomysial connective tissue, and regenerating fibers *(blue hue)*. **B**, Western blot showing absence of dystrophin in DMD and altered dystrophin size in Becker muscular dystrophy (BMD) compared with control *(arrow) (Con). (Courtesy of Dr. L. Kunkel, Children's Hospital, Boston, MA.)*

Morphology. Histopathologic abnormalities common to DMD and BMD include (1) **variation in fiber size** (diameter) due to the presence of both small and enlarged fibers, sometimes with fiber splitting; (2) **increased numbers of internalized nuclei** (beyond the normal range of 3% to 5%); (3) **degeneration, necrosis, and phagocytosis of muscle fibers**; (4) **regeneration of muscle fibers**; and (5) **proliferation of endomysial connective tissue** (see Fig. 27-10A). DMD cases also often show enlarged, rounded, hyaline fibers that have lost their normal cross-striations; such fibers, believed to be hypercontracted, are rare in BMD. Both type 1 and type 2 fibers are involved, and no alterations in the proportion or distribution of fiber types are evident. Histochemical reactions sometimes fail to identify distinct fiber types in DMD. In later stages **the muscles eventually become almost totally replaced by fat and connective tissue**. Cardiac involvement, when present, consists of interstitial fibrosis, which is more prominent in the subendocardium.

Clinical Course.

Boys with DMD are normal at birth, and early motor milestones are met on time. Walking, however, is often delayed, and the first indications of muscle weakness are clumsiness and inability to keep up with peers. Weakness begins in the pelvic girdle muscles and then extends to the shoulder girdle.

Enlargement of the muscles of the lower leg associated with weakness, a phenomenon termed *pseudohypertrophy*, is an important clinical finding. The increased muscle bulk is caused initially by an increase in the size of the muscle fibers and then, as the muscle atrophies, by an increase in fat and connective tissue. Pathologic changes are also found in the heart, and patients may develop heart failure or arrhythmias.[27] Although there are no well-established structural abnormalities of the central nervous system, cognitive impairment is a component of the disease and is sometimes severe enough to be considered a form of mental retardation. Serum creatine kinase is elevated during the first decade of life but returns to normal as muscle mass decreases. Death results from respiratory insufficiency, pulmonary infection, and cardiac decompensation. Gene therapy has received a great deal of attention but has been hampered by the size of the *DMD* gene. There has been success in experimental animals with two delivery systems: wild-type stem cell injections directly into muscle; and systemic injection of adenoassociated viruses carrying genes engineered to produce small, but functionally competent, portions of the dystrophin protein.[29] Induction of specific exon skipping using antisense RNA has been shown to restore the open reading in certain mutated *DMD* genes, and increase dystrophin expression in muscle biopsies.[30]

Boys with BMD develop symptoms at a later age than those with DMD. The onset occurs in later childhood or in adolescence, and is followed by a slower and more variable rate of progression, although there is considerable variation between pedigrees. Many patients have a nearly normal life span. Cardiac disease is frequently seen in these patients.

Other Muscular Dystrophies

Other less common forms of muscular dystrophy share many features of DMD and BMD, but have distinct clinical and pathologic characteristics. Some of these muscular dystrophies affect specific muscle groups, and the diagnosis is based largely on the pattern of muscle weakness (Table 27-4). Several autosomal muscular dystrophies, however, affect the proximal musculature of the trunk and limbs, similar to the X-linked muscular dystrophies, and are termed *limb girdle muscular dystrophies*.

TABLE 27-4 -- Other Selected Muscular Dystrophies

Disease and Inheritance	Gene and Locus	Clinical Findings	Pathologic Findings
Fascioscapulohumeral muscular dystrophy; autosomal dominant	Type 1A—deletion of variable number of 3.3-kilobase subunits of a tandemly arranged repeat (*D4Z4*) on 4q35 Type 1B (*FSHMD1B*)—locus unknown	Variable age at onset (most commonly 10–30 years); weakness of muscles of face, neck, and shoulder girdle	Dystrophic myopathy, often associated with inflammatory infiltrates in muscle
Oculopharyngeal muscular dystrophy; autosomal dominant	Poly(A)-binding protein-2 (*PABP2*) gene; 14q11.2–q13	Onset in mid-adult life; ptosis and weakness of extraocular muscles; difficulty in swallowing	Dystrophic myopathy, but often including rimmed vacuoles in type 1 fibers
Emery-Dreifuss muscular dystrophy; X-linked	Emerin (*EMD1*) gene; Xq28	Variable onset (most commonly 10–20 years); prominent contractures, especially of elbows and ankles	Mild myopathic changes; absent emerin by immunohistochemistry

Disease and Inheritance	Gene and Locus	Clinical Findings	Pathologic Findings
Congenital muscular dystrophies; autosomal recessive (also called muscular dystrophy, congenital, subtypes MDC1A, MDC1B, MDC1C)	Type 1A (merosin-deficient type)—laminin α2 (merosin) gene; 6q22–q23) Type 1B—locus at 1q42; gene unknown Type 1C; fukutin-related protein gene; 19q13.3	Neonatal hypotonia, respiratory insufficiency, delayed motor milestones	Variable fiber size and extensive endomysial fibrosis
Congenital muscular dystrophy with CNS malformations (Fukuyama type); autosomal recessive	Fukutin; 9q31	Neonatal hypotonia and mental retardation	Variable muscle fiber size and endomysial fibrosis; CNS malformations such as polymicrogyria
Congenital muscular dystrophy with CNS and ocular malformations (Walker-Warburg type)	Protein *O*-mannosyl transferases (*POMT1*, 9q34.1; *POMT2*, 14q24.3)	Neonatal hypotonia and mental retardation with cerebral and ocular malformations	Variable muscle fiber size and endomysial fibrosis; CNS and ocular malformations

CNS, central nervous system.

Limb girdle muscular dystrophies (LGMDs) are inherited in either an autosomal dominant (type 1) or autosomal recessive (type 2) pattern (Table 27-5). Six subtypes of the dominant LGMDs (1A to 1F) and eleven subtypes of the recessive LGMDs (2A to 2K) have been identified. Mutations of the *sarcoglycan complex of proteins* have been identified in four of the limb girdle muscular dystrophies (2C, 2D, 2E, and 2F).[31,][32] These membrane proteins interact with dystrophin through another transmembrane protein, β-dystroglycan (see Fig. 27-9).

TABLE 27-5 -- Limb-Girdle Muscular Dystrophies (LGMDs)

Type	Locus	Protein	Clinicopathologic Features
AUTOSOMAL DOMINANT			
1A	5q31	Myotilin	Facial sparing, dysarthric speech
1B	1q21.2	Lamin A/C	Arrhythmias and cardiomyopathy
1C	3p25	Caveolin 3	Mild course
1D	7q	unknown	Adult onset
1E	6q23	unknown	Arrhythmias and cardiomyopathy
1F	7q32.1	unknown	No cardiac involvement
1G	4q21	unknown	Adult onset, lower limb/pelvic involvement
AUTOSOMAL RECESSIVE			
2A	15q15	Calpain 3	Slow progression
2B	2p13	Dysferlin	Mild clinical course
2C	13q12	γ-sarcoglycan	Severe course, Duchenne-like
2D	17q21	α-sarcoglycan	Severe course, Duchenne-like

Type	Locus	Protein	Clinicopathologic Features
2E	4q12	β-sarcoglycan	Severe course, Duchenne-like
2F	5q33	δ-sarcoglycan	Severe course, Duchenne-like
2G	17q12	Telethonin (titin cap)	Rimmed vacuoles
2H	9q31	TRIM 32	Sarcotubular myopathy
2I	19q13.3	Fukutin related protein (FKRP)	Cardiomyopathy
2J	2q24.3	Titin	Mild or severe, tibial myopathy
2K	9q34.1	Protein O-mannosyl transferase 1 (POMT1)	Childhood onset with mental retardation

Myotonic Dystrophy

Myotonia, the sustained involuntary contraction of a group of muscles, is the cardinal symptom in this disease. Patients often complain of "stiffness" and have difficulty in releasing their grip, for instance, after a handshake. Myotonia can often be elicited by percussion of the thenar eminence.

Pathogenesis.

Inherited as an autosomal dominant trait, myotonic dystrophy is associated with a CTG trinucleotide repeat expansion on chromosome 19q13.2–q13.3. This expansion affects the mRNA for the dystrophia myotonia protein kinase (DMPK).[33] In normal subjects, fewer than 30 repeats are present; disease develops with expansion of this repeat, and several thousand repeats may be present in severely affected individuals. The mutation is not stable within a pedigree; with each generation more repeats accumulate, and the disease becomes more severe, a phenomenon called *anticipation* (Chapter 5). Expansion of the trinucleotide repeat influences the eventual concentration of protein product. However, it is not established if the disease is caused by abnormality of the protein affected by the trinucleotide repeat, or if this alters splicing of other RNAs.

Morphology. Skeletal muscle may show variation in fiber size. In addition, there is a striking increase in the number of internal nuclei, which on longitudinal section may form conspicuous chains. Another well-recognized abnormality is the **ring fiber**, with a subsarcolemmal band of cytoplasm that appears distinct from the center of the fiber. The rim contains myofibrils that are oriented circumferentially around the longitudinally oriented fibrils in the rest of the fiber. The ring fiber may be associated with an irregular mass of sarcoplasm **(sarcoplasmic mass)** extending outward from the ring. These sarcoplasmic masses stain blue with hematoxylin and eosin, red with Gomori trichrome, and intensely blue with the NAD–tetrazolium reductase histochemical reaction. Histochemical techniques have demonstrated a relative atrophy of type 1 fibers early in the course in some cases. Of all the dystrophies, only myotonic dystrophy shows pathologic changes in the intrafusal fibers of muscle spindles, with fiber splitting, necrosis, and regeneration.

Clinical Course.

The disease often presents in late childhood with abnormalities in gait secondary to weakness of foot dorsiflexors and subsequently progresses to weakness of the hand intrinsic muscles and wrist extensors. Atrophy of muscles of the face and ptosis ensue, leading to the typical facial appearance. Cataracts, which are present in virtually every patient, may be detected early in the course by slit-lamp examination. Other associated abnormalities include frontal balding, gonadal atrophy, cardiomyopathy, smooth muscle involvement, decreased plasma IgG, and abnormal glucose tolerance. Dementia has been reported in some cases.

ION CHANNEL MYOPATHIES (CHANNELOPATHIES)

The *ion channel myopathies*, or *channelopathies*, are a group of familial diseases featuring myotonia, relapsing episodes of hypotonic paralysis (induced by vigorous exercise, cold, or a high-carbohydrate meal), or both. Hypotonia variants associated with elevated, depressed, or normal serum potassium levels at the time of the attack are called *hyperkalemic, hypokalemic, and normokalemic periodic paralysis*, respectively.

Pathogenesis.

As their name indicates, these diseases are caused by mutations in genes that encode ion channels.[34] Hyperkalemic periodic paralysis results from mutations in the gene that encodes a skeletal muscle sodium channel protein (SCN4A), which regulates the entry of sodium into muscle during contraction. The gene for hypokalemic periodic paralysis encodes a voltage-gated L-type calcium channel.

Malignant hyperpyrexia (malignant hyperthermia) is a rare clinical syndrome characterized by a marked hypermetabolic state (tachycardia, tachypnea, muscle spasms, and later hyperpyrexia) triggered by anesthetics, most commonly halogenated inhalational agents and succinylcholine. The clinical syndrome may occur in predisposed individuals with hereditary muscle diseases, including congenital myopathies, dystrophinopathies, and metabolic myopathies. Mutations in several genes have been identified in families with susceptibility to malignant hyperthermia, including genes encoding L-type voltage-dependent calcium channel, notably the rynodine receptor (RyR1).[35] Upon exposure to anesthetic, the mutant receptor allows uncontrolled efflux of calcium from the sarcoplasm. This leads to tetany, increased muscle metabolism, and excessive heat production. Diagnosis can be made either by identifying the genetic mutation or by exposing biopsied muscle to the anesthetic agent and observing contraction.

CONGENITAL MYOPATHIES

The congenital myopathies are a group of disorders defined largely on the basis of the pathologic findings within muscle.[36] Most of these conditions share common clinical features, including onset in early life, nonprogressive or slowly progressive course, proximal or generalized muscle weakness, and hypotonia. Those affected at birth or in early infancy may present as “floppy infants” because of hypotonia or may have severe joint contractures *(arthrogryposis)*; however, both hypotonia and arthrogryposis may also be caused by other neuromuscular dysfunction.

The best-characterized congenital myopathies are listed in Table 27-6 . Figure 27-11 shows the structural characteristics of nemaline myopathy, one of the most distinctive types.

TABLE 27-6 -- Congenital Myopathies

Disease and Inheritance	Gene and Locus	Clinical Findings	Pathologic Findings
Central-core disease; autosomal dominant	Ryanodine receptor-1 (*RYR1*) gene; 19q13.1	Early-onset hypotonia and weakness; “floppy infant”; associated skeletal deformities; may develop malignant hyperthermia	Cytoplasmic cores are lightly eosinophilic and distinct from surrounding sarcoplasm; found only in type 1 fibers, which usually predominate, best seen on NADH-TR stain
Nemaline myopathy (ENM)	AD NEM1—α-tropomyosin 3 (*TPM3*) gene; 1q22–q23	Childhood weakness	Aggregates of subsarcolemmal spindle-shaped particles *(nemaline rods)*; occur predominantly in type 1 fibers; derived from Z-band material (α-actinin) and best seen on modified Gomori stain
	AR NEM2—nebulin	Hypotonia at birth; “floppy	

Disease and Inheritance	Gene and Locus	Clinical Findings	Pathologic Findings
	(*NEB*) gene; 2q22	infant"	
	AR NEM3—α-actin-1 (*ACTA*) gene; 1q42	Variable presentation; both infantile and adult onset	
	AR NEM4—tropomyosin-2 (*TPM2*) gene; 19p13.2–p13.1	Childhood-onset weakness	
	AR NEM5—troponin T1 (*TNNT1*) gene; 19q13.4	Childhood onset in Amish families, with tremors	
	AR NEM7—coffilin-2 (*CFL2*) gene; 14q12	Infant hypotonia; "floppy infant"	
Myotubular (centronuclear) myopathy	XL—myotubularin (*MTM1*) gene; Xq28	Severe congenital hypotonia, "floppy infant"; poor prognosis	Abundance of centrally located nuclei involving the majority of muscle fibers; central nuclei are usually confined to type 1 fibers, which are small in diameter, but can occur in both fiber types
	AD—dynamin-2 (and others) *DNM2* gene; 19p13.2	Childhood or young-adult weakness; slowly progressive weakness	
	AR—amphiphysin-2(*BIN1*) gene; 2q14)	Childhood to adolescent presentation; severe weakness and hypotonia with survival into early adulthood	

AD, autosomal dominant; AR, autosomal recessive; NADH, nicotinamide adenine dinucleotide, reduced-form; XL, X-linked.

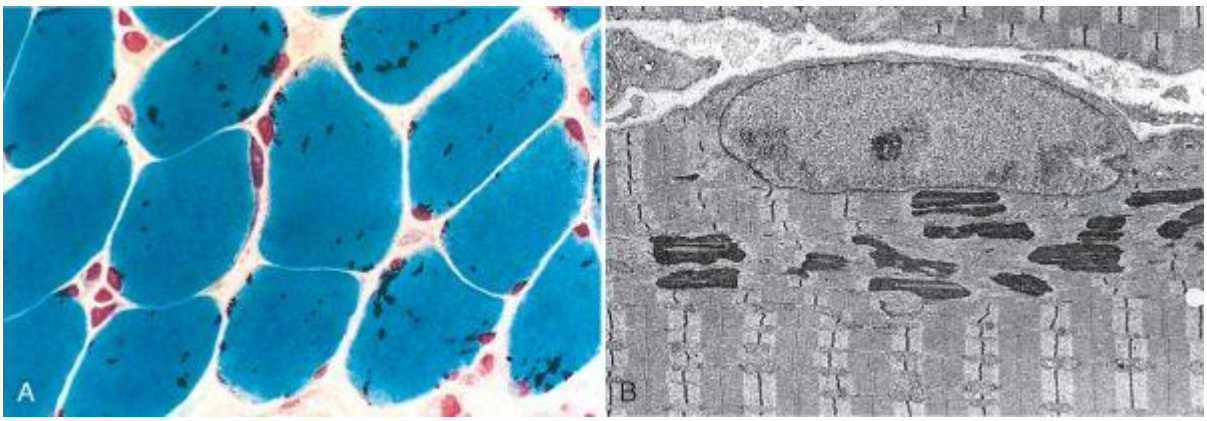

FIGURE 27-11 **A**, Nemaline myopathy with numerous rod-shaped, intracytoplasmic inclusions *(dark purple structures)*. **B**, Electron micrograph of subsarcolemmal nemaline bodies, showing material of Z-band density located adjacent to nucleus, with normal sarcomeres (Z-band to Z-band) creating the typical cross-striation pattern of skeletal muscle.

MYOPATHIES ASSOCIATED WITH INBORN ERRORS OF METABOLISM

Many of the myopathies associated with metabolic disease involve disorders of glycogen synthesis and degradation (Chapter 5). Combinations of clinical, pathologic, and molecular information are used to arrive at a specific diagnosis.[37] Myopathies can also result from disorders of mitochondrial function.

Lipid Myopathies

Abnormalities of carnitine transport or deficiencies of the mitochondrial dehydrogenase enzyme systems can lead to blocks in fatty acid oxidation and accumulation of lipid droplets within muscle (lipid myopathies).[38,][39] Patients with these disorders develop muscle pain, tightness, and myoglobinuria following prolonged exercise or exercise during fasting states. Fatty acids provide energy for muscle contraction, especially when glycogen stores are depleted (as in fasting). With a metabolic block in fatty acid oxidation, the required energy is not available, resulting in symptoms. Concomitant cardiomyopathies and fatty liver may also occur.

Mitochondrial Myopathies (Oxidative Phosphorylation Diseases)

Approximately one fifth of the proteins involved in oxidative phosphorylation are encoded by the mitochondrial genome (mtDNA); additionally, this circular genome encodes 22 mitochondrial-specific transfer RNAs and 2 ribosomal RNA species. The remainder of the mitochondrial enzyme complexes are encoded in the nuclear genome. Mutations in both nuclear and mitochondrial genes cause the so-called *mitochondrial myopathies*.[40] Diseases that involve the mtDNA show maternal inheritance, since only the oocyte contributes mitochondria to the embryo (Chapter 5). There is a high mutation rate for mtDNA compared with nuclear DNA. The mitochondrial diseases may present in young adulthood and manifest with proximal muscle weakness, sometimes with severe involvement of the extraocular muscles involved in eye movements (external ophthalmoplegia). The weakness may be accompanied by other neurologic symptoms, lactic acidosis, and cardiomyopathy, so this group of disorders is sometimes classified as mitochondrial encephalomyopathies (Chapter 28).[41]

Morphology. The most consistent pathologic finding in skeletal muscle is aggregates of abnormal mitochondria that are demonstrable only by special techniques.[42] These occur under the sarcolemma in early stages, but with severe involvement, they may extend throughout the fiber. Since they are also associated with distortion of the myofibrils, the muscle fiber contour becomes irregular on cross-section, and the descriptive term **ragged red fibers** has been applied to them (Fig. 27-12A). Electron microscopy shows increased numbers of mitochondria with irregular shapes. Some contain paracrystalline **parking lot inclusions** or alterations in the structure of cristae (Fig. 27-12B). Cytochrome oxidase–negative fibers may be present in several mitochondrial myopathies, as assessed by histochemistry.

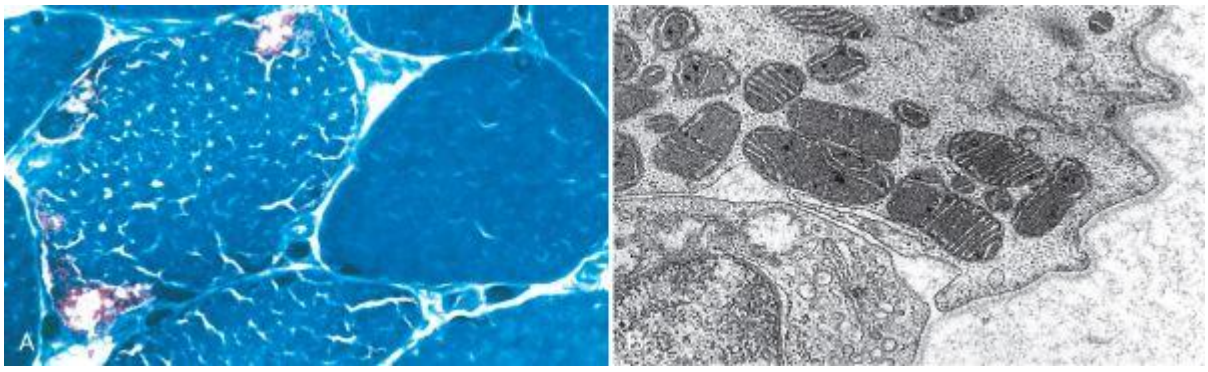

FIGURE 27-12 A, Mitochondrial myopathy showing an irregular fiber with subsarcolemmal collections of mitochondria that stain red with the modified Gomori trichrome stain *(ragged red fiber)*. **B**, Electron micrograph of mitochondria from biopsy specimen in **A** showing "parking lot" inclusions.

Clinical Course and Genetics.

The relationship between clinical course and the genetic alterations in the mitochondrial disorders is not straightforward; however, three general types of mutations have been defined. One consists of *point mutations in mtDNA*. Disorders associated with these show a maternal pattern of inheritance; some examples include myoclonic epilepsy with ragged red fibers, Leber hereditary optic neuropathy, and mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes. As in other diseases caused by mutations in mtDNA, the expression of the disease is quite variable due to unequal distribution of mtDNA in affected cells (Chapter 5). A second set of mutations involves *genes encoded by nuclear DNA* and shows autosomal dominant or autosomal recessive inheritance. Some cases of subacute necrotizing encephalopathy (Leigh syndrome), exertional myoglobinuria, and infantile X-linked cardioskeletal myopathy (Barth syndrome) are due to mutations in nuclear DNA. The final subset of mitochondrial myopathies is caused by *deletions or duplications of mtDNA*. Examples include chronic progressive external ophthalmoplegia, characterized by a myopathy with prominent weakness of external ocular movements. Kearns-Sayre syndrome, another myopathy in this group, is also characterized by ophthalmoplegia but, in addition, includes pigmentary degeneration of the retina and complete heart block.

INFLAMMATORY MYOPATHIES

There are three subgroups of inflammatory muscle diseases: infectious, noninfectious inflammatory, and systemic inflammatory diseases that involve muscle along with other organs. Infectious myositis (Chapter 8) and systemic inflammatory diseases (Chapter 6) are discussed elsewhere.

Noninfectious Inflammatory Myopathies

Noninfectious inflammatory myopathies are a heterogeneous group of disorders that are most likely immune mediated and are characterized by injury and inflammation of skeletal muscle. Three relatively distinct disorders, *dermatomyositis*, *polymyositis*, and *inclusion body myositis*, are included in this category.[43] These may occur as an isolated myopathy or as one component of an immune-mediated systemic disease, particularly systemic sclerosis (Chapter 6). The clinical features of each disorder are presented first to facilitate discussion of pathogenesis and morphologic changes.

Dermatomyositis.

As the name implies, individuals with dermatomyositis have an inflammatory disorder of the skin as well as skeletal muscle. It is characterized by a distinctive skin rash that may accompany or precede the onset of muscle disease. The *classic rash takes the form of a lilac or heliotrope discoloration of the upper eyelids associated with periorbital edema* (Fig. 27-13A). It is often accompanied by a scaling erythematous eruption or dusky red patches over the knuckles, elbows, and knees (Grotton lesions). *Muscle weakness* is slow in onset, bilaterally symmetric, and often accompanied by myalgias. *It typically affects the proximal muscles first*. As a result, tasks such as getting up from a chair and climbing steps become increasingly difficult. Fine movements controlled by distal muscles are affected only late in the disease. Dysphagia resulting from involvement of oropharyngeal and esophageal muscles occurs in one third of the affected individuals. Extramuscular manifestations, including interstitial lung disease, vasculitis, and myocarditis, may be present in some cases. Compared with the

control populations, adults with dermatomyositis have a higher risk of developing visceral cancers. According to several studies, 20% to 25% of adults with dermatomyositis have cancer.[44]

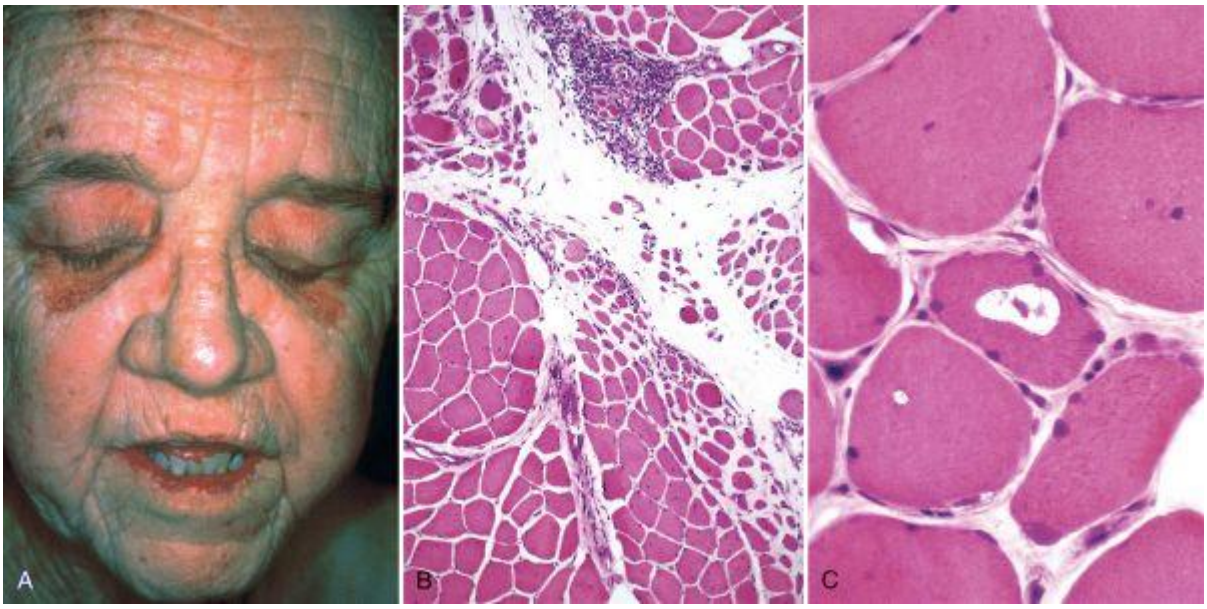

FIGURE 27-13 **A**, Dermatomyositis. Note the heliotrope rash affecting the eyelids. **B**, Dermatomyositis. The histologic appearance of muscle shows perifascicular atrophy of muscle fibers and inflammation. **C**, Inclusion body myositis showing a vacuole within a myocyte. *(Courtesy of Dr. Dennis Burns, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)*

Juvenile dermatomyositis[45] causes a similar onset of rash and muscle weakness but more often is accompanied by abdominal pain and involvement of the gastrointestinal tract. Mucosal ulceration, hemorrhage, and perforation may occur as the result of the dermatomyositis-associated vasculopathy. Calcinosis, which is uncommon in adult dermatomyositis, occurs in one third of youths with juvenile dermatomyositis.

Polymyositis.

This inflammatory myopathy is characterized by symmetric proximal muscle involvement, similar to that seen in dermatomyositis. It *differs from dermatomyositis by the lack of cutaneous involvement and its occurrence mainly in adults*. Similar to dermatomyositis, there may be inflammatory involvement of heart, lungs, and blood vessels.

Inclusion Body Myositis.

In contrast with the other two entities, inclusion body myositis begins with the *involvement of distal muscles*, especially extensors of the knee (quadriceps) and flexors of the wrists and fingers.[46] Furthermore, the weakness may be *asymmetric*. It is an insidiously developing disorder that typically affects individuals over the age of 50 years. Most cases are sporadic, but familial cases have been recognized as “inclusion body myopathy.”

Etiology and Pathogenesis.

The cause of inflammatory myopathies is unknown, but the tissue injury is most likely mediated by immunological mechanisms. Capillaries seem to be the principal targets in dermatomyositis. Deposits of antibodies and complement are present in small blood vessels, and are associated with foci of myocyte necrosis. B cells and CD4+ T cells are present within the muscle, but there is a paucity of lymphocytes within the areas of myofiber injury. The perifascicular distribution of myocyte injury also suggests a vascular pathogenesis.

In contrast, polymyositis seems to be caused by cellmediated injury of myocytes. CD8+ cytotoxic T cells and macrophages are seen near damaged muscle fibers, and the expression of HLA class I and class II molecules is increased on the sarcolemma of normal fibers. Similar to other immune-mediated diseases, antinuclear antibodies are present in a variable number of cases, regardless of the clinical category (Chapter 6). The specificities of autoantibodies are quite varied, but those directed against transfer RNA synthetases seem to be more or less specific for inflammatory myopathies.[47]

The pathogenesis of inclusion body myositis is less clear. As in polymyositis, CD8+ cytotoxic T cells are found in the muscle, but in contrast to the other two forms of myositis, immunosuppressive therapy is not beneficial. Intracellular deposits of β-amyloid protein, amyloid β–pleated sheet fibrils, and hyperphosphorylated tau protein, features shared with Alzheimer disease, have drawn attention to a possible relationship to aging. The protein deposition may result from abnormal protein folding. The two hereditary forms of inclusion body myopathy have a similar morphology. The autosomal recessive form is caused by mutations in the *GNE* gene (encoding UDP-*N*-acetylglucosamine 2-epimerase/*N*-acetylmannosamine kinase), and the autosomal dominant form is caused by mutations in the gene encoding myosin heavy chain IIa.[46,][48]

Morphology. The histologic features of the individual forms of myositis are quite distinctive and are described separately.

***Dermatomyositis*.** The inflammatory infiltrates in dermatomyositis are located predominantly around small blood vessels and in the perimysial connective tissue. Typically, groups of atrophic fibers are particularly prominent at the periphery of fascicles. This “perifascicular atrophy” is sufficient for diagnosis, even if the inflammation is mild or absent (Fig. 27-13B), and is most likely related to a relative state of hypoperfusion of the periphery of muscle fascicles. Quantitative analyses reveal a marked reduction in the intramuscular capillaries, believed to result from vascular endothelial injury and fibrosis. Necrotic muscle fibers and regeneration may also be seen throughout the fascicle, as in polymyositis.

***Polymyositis*.** In this condition, the inflammatory cells are found in the endomysium. CD8+ lymphocytes and other lymphoid cells surround and invade healthy muscle fibers. Both necrotic and regenerating muscle fibers are scattered throughout the fascicle, without the perifascicular atrophy seen in dermatomyositis. There is no evidence of vascular injury in polymyositis.

Inclusion Body Myositis. The diagnostic finding in inclusion body myositis is the presence of rimmed vacuoles (Fig. 27-13C). The vacuoles are present within myocytes, and they are highlighted by basophilic granules at their periphery. In addition, the vacuolated fibers may also contain amyloid deposits that reveal typical staining with Congo red. Under the electron microscope, tubular and filamentous inclusions are seen in the cytoplasm and the nucleus that are composed of β-amyloid or hyperphosphorylated tau. The inflammatory cell infiltrate is similar to that seen in polymyositis.

The diagnosis of myositis is based on clinical symptoms, electromyography, elevated creatinine kinase in serum, and biopsy. Electromyography (EMG) is particularly informative; mixed neurogenic and myopathic changes on EMG are suggestive of inflammatory myopathy. As might be expected, muscle injury is associated with elevated serum levels of creatine kinase. Biopsy is required for definitive diagnosis. Immunosuppressive therapy is beneficial in adult and juvenile dermatomyositis and in polymyositis but not in inclusion-body myositis.

TOXIC MYOPATHIES

Thyrotoxic Myopathy

Thyrotoxic myopathy presents most commonly as an acute or chronic proximal muscle weakness that may precede the onset of other signs of thyroid dysfunction. *Exophthalmic ophthalmoplegia* is characterized by swelling of the eyelids, edema of the conjunctiva, and diplopia. In *hypothyroidism* there may be cramping or aching of muscles, and movements and reflexes are slowed. Findings include fiber atrophy, an increased number of internal nuclei, glycogen aggregates, and, occasionally, deposition of mucopolysaccharides in the connective tissue.

In thyrotoxic myopathy, there is myofiber necrosis, regeneration, and interstitial lymphocytosis. In chronic thyrotoxic myopathy, there may be only slight variability of muscle fiber size, mitochondrial hypertrophy, and focal myofibril degeneration; fatty infiltration of muscle is seen in severe cases. Exophthalmic ophthalmoplegia is limited to the extraocular muscles, which may be edematous and enlarged.

Ethanol Myopathy

Binge drinking of alcohol produces an acute toxic syndrome of rhabdomyolysis with accompanying myoglobinuria, which may lead to renal failure. Clinically, the affected individual may develop acute pain that is either generalized or confined to a single muscle group. Some patients have a complicated clinicopathologic syndrome consisting of proximal muscle weakness and electrophysiologic evidence of myopathy superimposed on alcoholic neuropathy. On histologic examination there is swelling of myocytes, fiber necrosis, myophagocytosis, and regeneration. There may also be evidence of denervation.

Drug-Induced Myopathies

Proximal muscle weakness and atrophy can occur as a result of the deleterious effects of steroids on muscle, whether in Cushing syndrome or during therapeutic administration of steroids, a condition known as *steroid myopathy*. The severity of clinical disability is variable and not directly related to the steroid level or the therapeutic regimen. It is characterized by muscle fiber atrophy, predominantly of type 2 fibers. When the myopathy is severe, there may be a bimodal distribution of fibers due to the presence of type 1 fibers of nearly normal caliber and markedly atrophic type 2 fibers. Electron microscopy has shown dilation of the sarcoplasmic reticulum and thickening of the basal laminae.

Chloroquine, originally used in the treatment of malaria but subsequently used in other clinical settings, can produce a proximal myopathy in humans. The most prominent finding is the presence of vacuoles within myocytes. Two types of vacuoles have been described: (1) autophagic membrane-bound vacuoles containing membranous debris; and (2) curvilinear bodies with short curved membranous structures with alternating light and dark zones. Vacuoles can be seen in as many as 50% of the myocytes, most commonly type 1 fibers, and with progression, myocyte necrosis may develop. A similar vacuolar myopathy occurs in some individuals treated with hydrochloroquine.

Statins are very frequently prescribed in the United States to reduce cholesterol and the risks of acute ischemic cardiac events and stroke. Myopathy is the most common complication of statins.[49] "Statin-induced myopathy" can occur with use of any of the statins (e.g., atorvastatin, simvastatin, pravastatin). The incidence is approximately 1.5% of users, and is unrelated to dose, cumulative dose, or statin subtype. Drug metabolism characteristics that can be predicted with pharmacogenetic predictors, on the other hand, may help to identify individuals at risk for myopathy.

DISEASES OF THE NEUROMUSCULAR JUNCTION

Myasthenia Gravis

Myasthenia gravis is a muscle disease caused by immune-mediated loss of acetylcholine receptor. It has a prevalence of about 30 in 100,000 persons.[50] When arising before age 40 years it is most commonly seen in women, but it occurs equally in both sexes in older patients. Thymic hyperplasia is found in 65% and thymoma in 15% of affected patients. Analysis of neuromuscular transmission in myasthenia gravis shows a decrease in the number of muscle acetylcholine receptors (AChRs), and circulating antibodies to the AChR are present in nearly all cases. The disease can be passively transferred to animals with serum from affected individuals.

Pathogenesis.

In most instances the autoantibodies against the AChR lead to loss of functional AChRs at the neuromuscular junction by (1) fixing complement and causing direct injury to the postsynaptic membrane, (2) increasing the internalization and degradation of the receptors, and (3) inhibiting binding of acetylcholine. Electrophysiologic studies are notable for diminished motor responses after repeated stimulation; nerve conduction is normal. Sensory as well as autonomic functions are not affected. Despite the evidence that antibodies to AChR have a critical pathogenic role, there is not always a correlation between antibody titers and the neuromuscular deficit. Interestingly, in light of the immune-mediated etiology of the disease, thymic abnormalities are common in these patients, but the precise link between thymic function and autoimmunity is uncertain. Regardless of the type of thymic pathology, most affected individuals improve after thymectomy.

Morphology. By light microscopic examination, muscle biopsy specimens are usually unrevealing. In severe cases type 2 fiber atrophy due to disuse may be found. By electron microscopy the postsynaptic membrane is simplified, and there is loss of AChRs from the region of the synapse. Immune complexes and the complement membrane attack complex (C5–C9) can be found along the postsynaptic membrane as well.

Clinical Course.

Typically, weakness begins with the extraocular muscles; drooping eyelids (ptosis) and double vision (diplopia) cause the affected individual to seek medical attention. However, the initial symptoms may take the form of generalized weakness. The weakness fluctuates over days, hours, or even minutes, and intercurrent medical conditions can lead to exacerbations. Patients show improvement in strength in response to administration of anticholinesterase agents, which remains a useful clinical test. Respiratory compromise was a major cause of mortality in the past; 95% of affected individuals now survive more than 5 years after diagnosis because of improved methods of treatment and better ventilatory support. Effective forms of treatment include anticholinesterase drugs, prednisone, plasmapheresis, and thymectomy when thymic lesions are present.[50]

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome is a disease of the neuromuscular junction that is distinct from myasthenia gravis. It is usually a paraneoplastic process, most commonly with small-cell carcinoma of the lung (60% of cases), but can occur in the absence of underlying malignant disease. Affected individuals develop proximal muscle weakness and autonomic dysfunction. Unlike myasthenia gravis, no clinical improvement is produced by anticholinesterase agents, and electrophysiologic studies show evidence of enhanced neurotransmission with repetitive stimulation. These clinical features allow this disorder to be distinguished from myasthenia gravis.

The content of anticholinesterase is normal in neuromuscular junction synaptic vesicles, and the postsynaptic membrane is normally responsive to anticholinesterase, but fewer vesicles are released in response to each presynaptic action potential. Some affected individuals have antibodies that recognize presynaptic PQ-type voltage-gated calcium channels, and a similar disease can be transferred to animals with these antibodies, suggesting that autoimmunity to the calcium channel causes the disease.

TUMORS OF SKELETAL MUSCLE

Skeletal muscle tumors are discussed with other soft-tissue tumors (Chapter 26).

3.18 28. The Central Nervous System

3.18.1 Cellular Pathology of the Central Nervous System

MATTHEW P. FROSCH,
DOUGLAS C. ANTHONY,
UMBERTO DE GIROLAMI

The principal functional unit of the central nervous system (CNS) is the neuron. Of all the cells in the body, neurons have a unique ability to receive, store, and transmit information. Neurons of different types and in different locations have distinct properties, including functional roles, distribution of their connections, neurotransmitters used, metabolic requirements, and levels of electrical activity at a given moment. A set of neurons, not necessarily clustered together in a region of the brain, may thus show *selective vulnerability* to various insults because it shares one or more of these properties. Since most mature neurons are incapable of cell division, destruction of even a small number of neurons essential for a specific function may leave the individual with a neurologic deficit. Stem cell populations in the brain may represent a potential mechanism for repair after injury.[1] The CNS is affected by a number of unique neurological disorders, and also responds to common insults (e.g., ischemia, infection) in a manner that is distinct from other tissues.[2,][3]

Cellular Pathology of the Central Nervous System

Reactions of Neurons to Injury.

Neurons vary considerably in structure and size throughout the nervous system and within a given brain region. Structural specializations associated with neuronal function include those related to synaptic transmission as well as axonal and dendritic differentiation. Neurons share pathways for response to injury, including apoptotic mechanisms, with cells in other tissues. During development, neuronal apoptosis has an important role in defining neuronal number; it comes into play in a variety of disease states as well, including certain neurodegenerative diseases. The principal patterns of neuronal injury are the following:

- *Acute neuronal injury ("red neurons")* refers to a spectrum of changes that accompany acute CNS hypoxia/ischemia or other acute insults and reflect cell death, either necrosis or apoptosis (see Fig. 28-13B). "Red neurons" are evident with hematoxylin and eosin (H&E) preparations at about 12 to 24 hours after an irreversible hypoxic/ischemic insult. The morphologic features consist of shrinkage of the cell body, pyknosis of the nucleus, disappearance of the nucleolus, and loss of Nissl substance, with intense eosinophilia of the cytoplasm.
- *Subacute and chronic neuronal injury ("degeneration")* refers to neuronal death occurring as a result of a progressive disease process of some duration, as is seen in certain slowly evolving neurologic diseases such as amyotrophic lateral sclerosis (ALS). The characteristic histologic feature is cell loss, often selectively involving functionally related groups of neurons, and reactive gliosis. When the process is at an early stage, the cell loss is difficult to detect; the associated reactive glial changes are often the best indicator of the pathologic process. For many of these diseases, there is evidence that cell loss is because of apoptosis. Neuronal *trans-synaptic degeneration* is seen when there is a destructive process that interrupts the majority of the afferent input to a group of neurons.
- *Axonal reaction* refers to the reaction within the cell body that attends *regeneration* of the axon; it is best seen in anterior horn cells of the spinal cord when motor axons are cut or seriously damaged. There is increased protein synthesis associated with axonal sprouting. This is reflected in enlargement and rounding up of the cell body, peripheral displacement of the nucleus, enlargement of the nucleolus, and dispersion of Nissl substance from the center to the periphery of the cell *(central chromatolysis)*.
- Neuronal damage may be associated with a wide range of subcellular alterations in the neuronal organelles and cytoskeleton. *Neuronal inclusions* may occur as a manifestation of aging, when there are intracytoplasmic accumulations of complex lipids *(lipofuscin)*, proteins, or carbohydrates. Abnormal cytoplasmic deposition of complex lipids and other substances also occurs in genetically determined disorders of metabolism in which substrates or intermediates accumulate (Chapter 5). Viral infection can lead to abnormal intranuclear inclusions, as seen in herpetic infection (Cowdry body), cytoplasmic inclusions, as seen in rabies (Negri body), or both nucleus and cytoplasm as in cytomegalovirus (CMV) infection.
- Some degenerative diseases of the CNS are associated with neuronal intracytoplasmic inclusions, such as neurofibrillary tangles of Alzheimer disease and Lewy bodies of Parkinson disease; others cause abnormal vacuolization of the perikaryon and neuronal cell processes in the neuropil (Creutzfeldt-Jakob disease). These aggregates are highly resistant to degradation, contain proteins with altered conformation, and may result from mutations that affect protein folding, ubiquitination, and intracellular trafficking (see discussion of protein folding in Chapter 1). The disorders may be referred to as *proteinopathies*. There is increasing evidence in many of these diseases that the visible aggregates are not the basis of cellular injuries; rather, small multimers of the proteins (oligomers) are the critical mediators of the damage.[4]

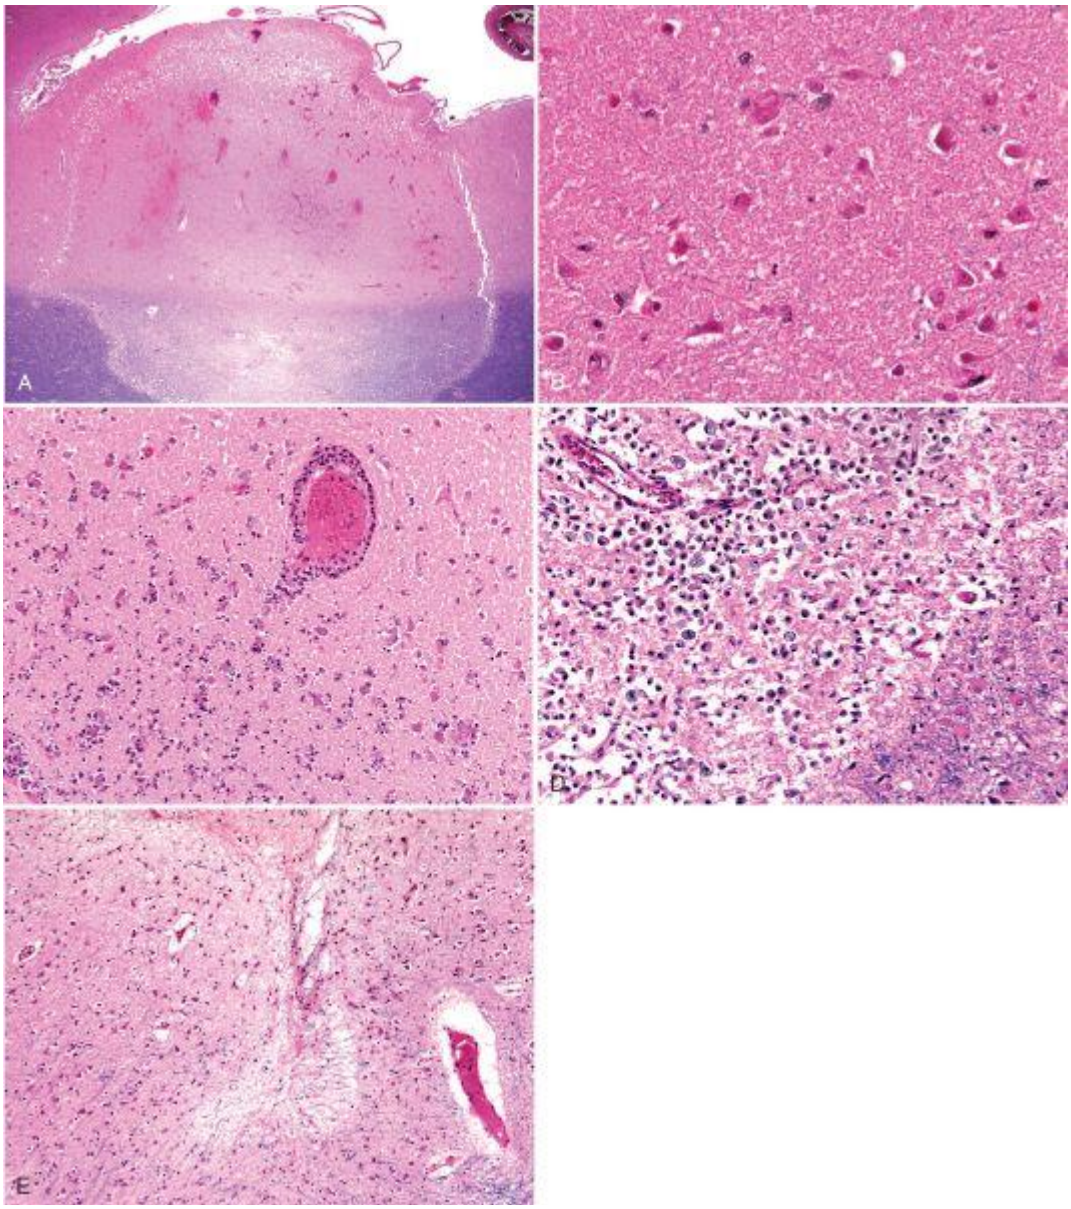

FIGURE 28-13 Cerebral infarction. **A**, At low magnification it is possible to see the demarcated areas of an acute infarction. In the underlying white matter, the areas of infarction are well shown by the myelin stain. **B**, Acute ischemic injury causes diffuse eosinophilia of neurons, which are beginning to shrink. **C**, Infiltration of a cerebral infarct by neutrophils begins at the edges of the lesion where vascular supply has remained intact. **D**, After about 10 days, an area of infarction is characterized by the presence of macrophages and surrounding reactive gliosis. **E**, Remote small intracortical infarcts are seen as areas of tissue loss with residual gliosis.

Reactions of Astrocytes to Injury.

The astrocyte derives its name from its star-shaped appearance. These cells have multipolar, branching cytoplasmic processes that emanate from the cell body and contain the glial fibrillary acidic protein (GFAP), a cell type–specific intermediate filament (Fig. 28-1). Astrocytes act as metabolic buffers and detoxifiers within the brain. Additionally, through the foot processes, which surround capillaries or extend to the subpial and subependymal zones, they contribute to barrier functions controlling the flow of macromolecules between the blood, the cerebrospinal fluid (CSF), and the brain. *Gliosis* (or astrogliosis) is the most important histopathologic indicator of CNS injury, regardless of etiology, and is characterized by both hypertrophy and hyperplasia. In this reaction, the nuclei of astrocytes, which are

typically round to oval (10 μm wide) with evenly dispersed, pale chromatin, enlarge, become vesicular, and develop prominent nucleoli. The previously scant cytoplasm expands to a bright pink, somewhat irregular swath around an eccentric nucleus, from which emerge numerous stout, ramifying processes; these cells are called *gemistocytic astrocytes*.

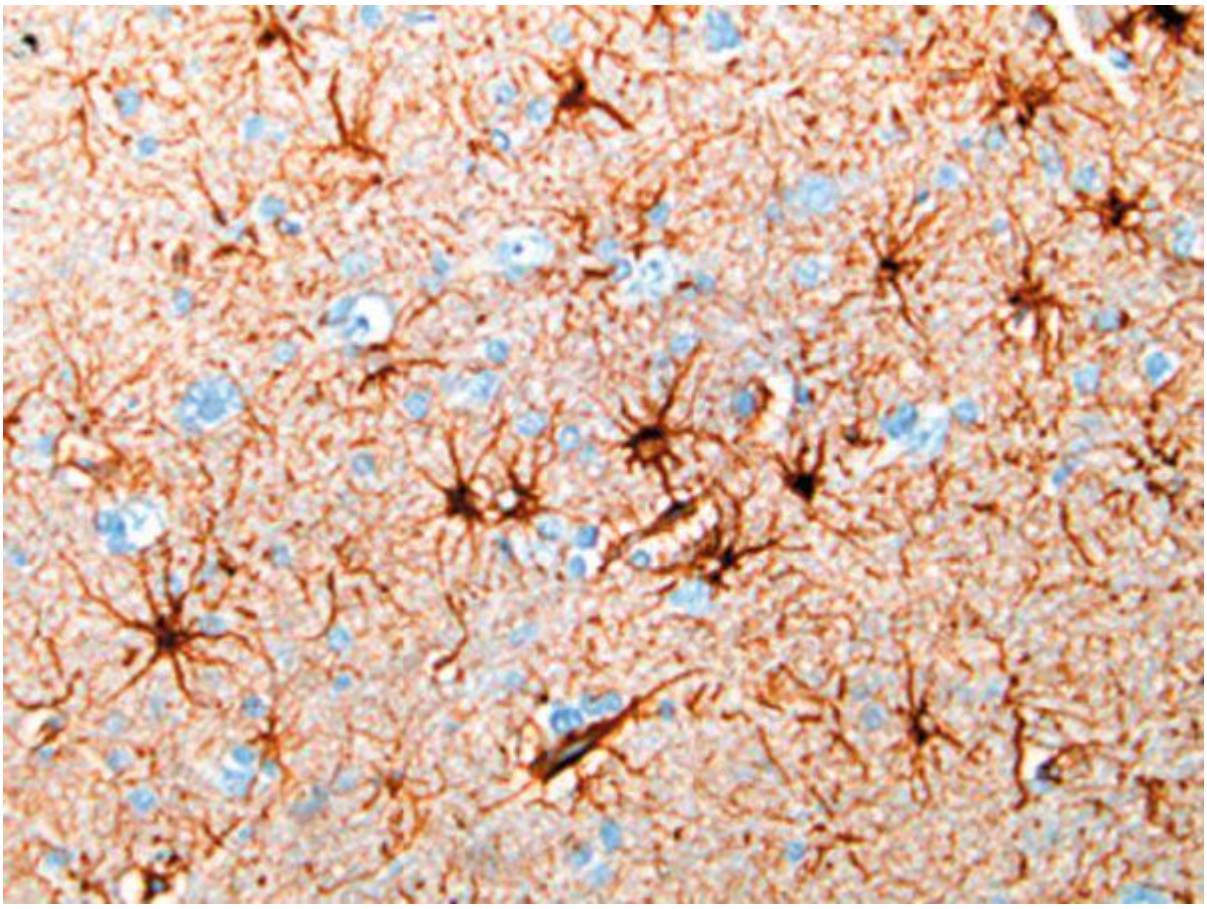

FIGURE 28-1 Astrocytes and their processes. Immunohistochemical staining for GFAP reveals astrocytic perinuclear cytoplasm and well-developed processes *(brown)*.

When directly injured, astrocytes can react with cytoplasmic swelling. This is seen in acute insults that cause the cell's ATP-dependent ion channels to fail, as occurs in hypoxia, hypoglycemia, and toxic injuries. The *Alzheimer type II astrocyte* is a gray-matter cell with a large (two to three times normal) nucleus, pale-staining central chromatin, an intranuclear glycogen droplet, and a prominent nuclear membrane and nucleolus. Its name is a misnomer, as it is mainly seen not in Alzheimer disease but in individuals with long-standing hyperammonemia due to chronic liver disease, Wilson disease, or hereditary metabolic disorders of the urea cycle.

Astrocytes are not spared from processes that cause the formation of cytoplasmic inclusion bodies. *Rosenthal fibers* are thick, elongated, brightly eosinophilic, somewhat irregular structures that occur within astrocytic processes, and contain two heat-shock proteins (αB-crystallin and hsp27) as well as ubiquitin. Rosenthal fibers are typically found in regions of long-standing gliosis; they are also characteristic of one type of glial tumor, pilocytic astrocytoma. In *Alexander disease*, a leukodystrophy associated with a mutations in the gene encoding GFAP, abundant Rosenthal fibers are found in

periventricular, perivascular, and subpial locations. More commonly seen are *corpora amylacea*, or polyglucosan bodies. These are round, faintly basophilic, periodic acid–Schiff (PAS)–positive, concentrically lamellated structures of 5 to 50 μm in diameter that are located wherever there are astrocytic end processes, especially in the subpial and perivascular zones. Though consisting primarily of glycosaminoglycan polymers, they also contain heat-shock proteins and ubiquitin. They occur in increasing numbers with advancing age and are thought to represent a degenerative change in the astrocyte. The *Lafora bodies* that are seen in the cytoplasm of neurons (as well as hepatocytes, myocytes, and other cells) in myoclonic epilepsy (Lafora body myoclonus with epilepsy) have a similar structure and biochemical composition.

Reactions of Other Glial Cells to Injury.

In contrast to astrocytes, oligodendrocytes and ependyma do not participate in the active response to CNS injury and show a more limited repertoire of reactions. Oligodendroglial cytoplasmic processes wrap around exons and form myelin. Each oligodendrocyte myelinates numerous internodes on multiple axons. Injury or apoptosis of oligodendroglial cells is a feature of acquired demyelinating disorders and leukodystrophies. Oligodendroglial nuclei may harbor viral inclusions in progressive multifocal leukoencephalopathy. *Glial cytoplasmic inclusions*, primarily composed of α-synuclein, are found in oligodendrocytes in multiple system atrophy (MSA).

Ependymal cells, the ciliated columnar epithelial cells lining the ventricles, do not have specific patterns of reaction. When there is inflammation or marked dilation of the ventricular system, disruption of the ependymal lining is paired with proliferation of subependymal astrocytes to produce small irregularities on the ventricular surfaces *(ependymal granulations)*. Certain infectious agents, particularly CMV, may produce extensive ependymal injury, with viral inclusions in ependymal cells.

Reactions of Microglia to Injury.

Microglia are mesoderm-derived cells whose primary function is to serve as a fixed macrophage system in the CNS. They share many surface markers with peripheral monocytes/macrophages (such as CR3 and CD68). They respond to injury by (1) proliferating; (2) developing elongated nuclei *(rod cells)*, as in neurosyphilis; (3) forming aggregates about small foci of tissue necrosis *(microglial nodules)*; or (4) congregating around cell bodies of dying neurons *(neuronophagia)*. In addition to resident microglia, blood-derived macrophages are the principal phagocytic cells present in inflammatory foci.

3.18.2 Cerebral Edema, Hydrocephalus & Raised Intracranial Pressure & Herniation

The brain and spinal cord are protected by the rigid compartment defined by the skull, vertebral bodies, and dura mater. Generalized brain edema, increased CSF volume (hydrocephalus), and focally expanding mass lesions may increase intracranial pressure. Depending on the degree and rapidity of this increase and the nature of the underlying lesion, the consequences range from subtle neurologic deficits to death.

CEREBRAL EDEMA

Cerebral edema or, more precisely, brain parenchymal edema, is of two principal types:

- *Vasogenic edema* is caused by blood-brain barrier disruption and increased vascular permeability, allowing fluid to shift from the intravascular compartment to the intercellular spaces of the brain. The paucity of lymphatics greatly impairs the resorption of excess extracellular fluid. Vasogenic edema may be either localized (e.g., adjacent to inflammation or neoplasms) or generalized.
- *Cytotoxic edema* is an increase in intracellular fluid secondary to neuronal, glial, or endothelial cell membrane injury, as might be encountered in someone with a generalized hypoxic/ischemic insult or with

metabolic damage.

In practice, conditions associated with generalized edema often have elements of both vasogenic and cytotoxic edema.

Interstitial edema (hydrocephalic edema) occurs especially around the lateral ventricles when an increase in intravascular pressure causes an abnormal flow of fluid from the intraventricular CSF across the ependymal lining to the periventricular white matter. In generalized edema, the gyri are flattened, the intervening sulci are narrowed, and the ventricular cavities are compressed. As the brain expands, herniation may occur.

HYDROCEPHALUS

The choroid plexus within the ventricular system produces CSF, which normally circulates through the ventricular system and enters the cisterna magna at the base of the brain stem through the foramina of Luschka and Magendie. Subarachnoid CSF bathes the superior cerebral convexities and is absorbed by the arachnoid granulations. *Hydrocephalus* refers to the accumulation of excessive CSF within the ventricular system (Fig. 28-2). Most cases occur as a consequence of impaired flow and resorption of CSF; only rarely is overproduction the cause of hydrocephalus (e.g., with tumors of the choroid plexus). An increased volume of CSF within the ventricles expands them and can elevate the intracranial pressure.

FIGURE 28-2 Hydrocephalus. Dilated lateral ventricles seen in a coronal section through the midthalamus.

When hydrocephalus develops in infancy before closure of the cranial sutures, there is enlargement of the head, manifested by an increase in head circumference. Hydrocephalus developing after this period, in contrast, is associated with expansion of the ventricles and increased intracranial pressure, without a change in head circumference. If only a portion of the ventricular system is enlarged because of excess CSF, as may occur because of a mass in the third ventricle, the pattern is called *noncommunicating hydrocephalus*. In *communicating hydrocephalus* there is enlargement of the entire ventricular system. The term *hydrocephalus ex vacuo* refers to dilation of the ventricular system with a compensatory increase in CSF volume secondary to a loss of brain parenchyma.

RAISED INTRACRANIAL PRESSURE AND HERNIATION

When the volume of the brain increases beyond the limit permitted by compression of veins and displacement of CSF, the pressure within the skull will increase. Most cases are associated with a mass effect, either diffuse, as in generalized brain edema, or focal, as with tumors, abscesses, or hemorrhages. Elevated intracranial pressure may also reduce perfusion of the brain, further exacerbating cerebral edema. Because the cranial vault is divided by rigid dural folds (the falx and tentorium), localized expansion of the brain may cause it to be displaced in relation to these partitions. If the expansion is sufficiently severe, a *herniation syndrome* may occur (Fig. 28-3).

- *Subfalcine (cingulate) herniation* occurs when unilateral or asymmetric expansion of a cerebral hemisphere displaces the cingulate gyrus under the falx cerebri. This may lead to compression of branches of the anterior cerebral artery.
- *Transtentorial (uncinate, mesial temporal) herniation* occurs when the medial aspect of the temporal lobe is compressed against the free margin of the tentorium. With increasing displacement of the temporal lobe, the third cranial nerve is compromised, resulting in pupillary dilation and impairment of ocular movements on the side of the lesion. The posterior cerebral artery may also be compressed, resulting in ischemic injury to the territory supplied by that vessel, including the primary visual cortex. When the extent of herniation is large enough the contralateral cerebral peduncle may be compressed, resulting in hemiparesis ipsilateral to the side of the herniation; the change in the peduncle in this setting is known as *Kernohan's notch*. Progression of transtentorial herniation is often accompanied by hemorrhagic lesions in the midbrain and pons, termed *secondary brainstem*, or *Duret*, *hemorrhages* (Fig. 28-4). These linear or flame-shaped lesions usually occur in the midline and paramedian regions and are believed to be due to distortion or tearing of penetrating veins and arteries supplying the upper brainstem.
- *Tonsillar herniation* refers to displacement of the cerebellar tonsils through the foramen magnum. This pattern of herniation is life-threatening because it causes brainstem compression and compromises vital respiratory and cardiac centers in the medulla oblongata.

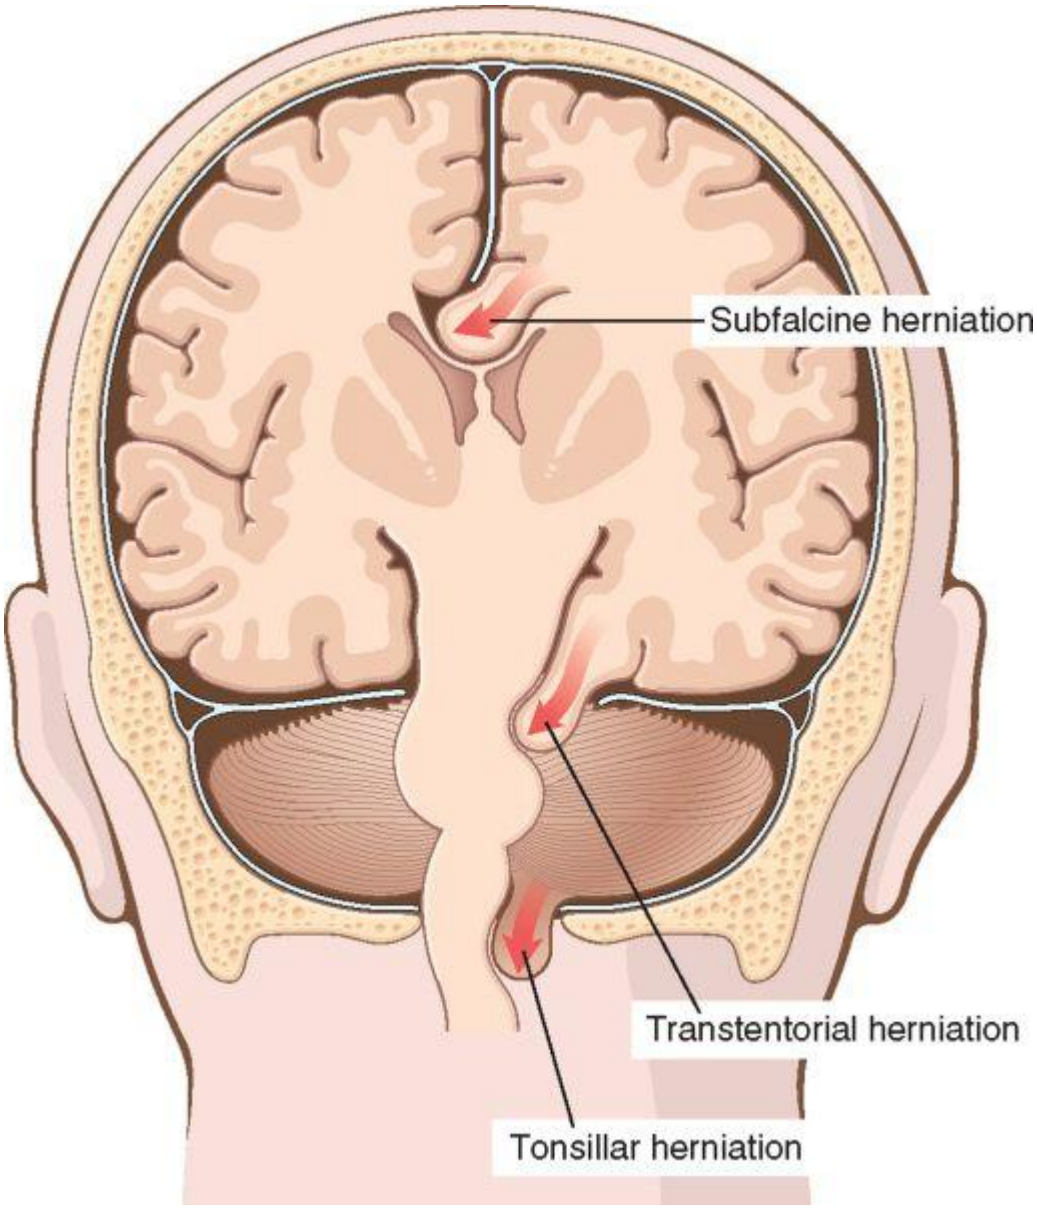

FIGURE 28-3 Major herniation syndromes of the brain: subfalcine, transtentorial, and tonsillar.

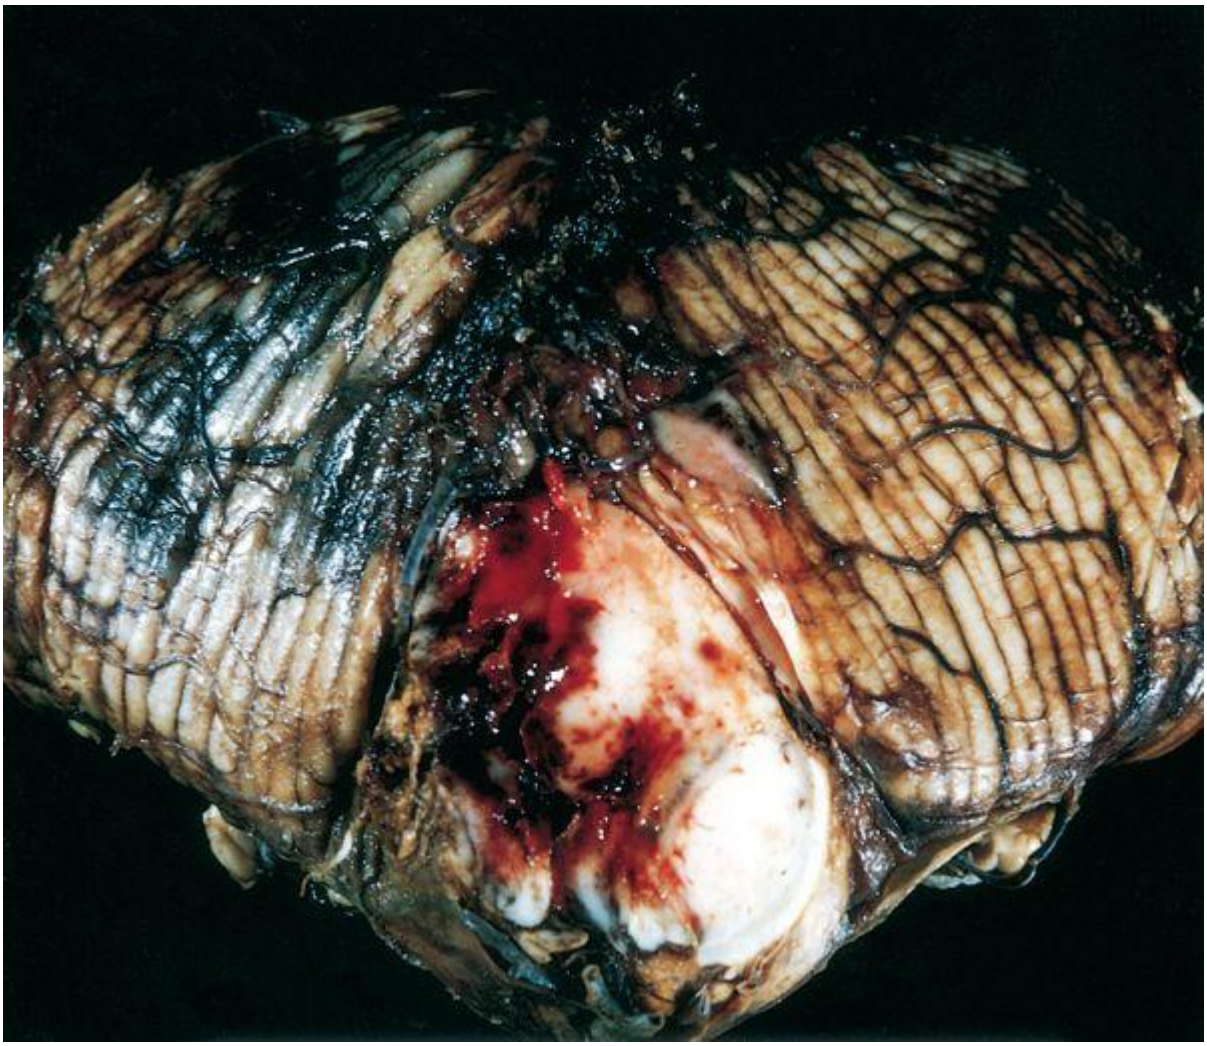

FIGURE 28-4 Duret hemorrhage involving the brainstem at the junction of the pons and midbrain.

3.18.3 Malformations & Developmental Diseases

Although the pathogenesis and etiology of CNS malformations are largely unknown, both genetic and environmental influences appear to be involved. Aberrations of signaling molecules and mutations of homeotic genes that control body patterning are being increasingly identified as causes of developmental disorders of the CNS. Many toxic compounds and infectious agents are also known to have teratogenic effects.[5]

NEURAL TUBE DEFECTS

Failure of a portion of the neural tube to close, or reopening of a region of the tube after successful closure, may lead to one of several malformations.[6] All are characterized by abnormalities involving some combination of neural tissue, meninges, and overlying bone or soft tissues. An *encephalocele* is a diverticulum of malformed CNS tissue extending through a defect in the cranium. It most often occurs in the occipital region or in the posterior fossa. Collectively, neural tube defects account for most CNS malformations.

The most common neural tube defects involve the spinal cord and are caused by a failure of closure or by reopening of the caudal portions of the neural tube. *Spinal dysraphism* or *spina bifida* may be an asymptomatic bony defect (spina bifida occulta) or a severe malformation with a flattened, disorganized segment of spinal cord, associated with an overlying meningeal outpouching. *Myelomeningocele* (or meningomyelocele) refers to extension of CNS tissue through a defect in the vertebral column; the term *meningocele* applies when there is only a meningeal extrusion. Myelomeningoceles occur most commonly in the lumbosacral region, and affected individuals manifest clinical deficits referable to motor and sensory function in the lower extremities as well as disturbances of bowel and bladder control from both the structural abnormality of the cord itself and superimposed infection that extends from the thin, overlying skin.

The frequency of neural tube defects varies widely among different ethnic groups. Both genetic and environmental factors are involved. The concordance rate is high among monozygotic twins, and the overall recurrence rate for a neural tube defect in subsequent pregnancies has been estimated at 4% to 5%. Folate deficiency during the initial weeks of gestation has been implicated as a risk factor; differences in rates of neural tube defects between populations can be attributed in part to polymorphisms in enzymes of folic acid metabolism. Folate deficiency may affect cell division during critical periods that coincide with closure of the neural tube. Antenatal diagnosis is based on imaging and the screening of maternal blood samples for elevation of α-fetoprotein.

Anencephaly is a malformation of the anterior end of the neural tube, with absence of the brain and calvarium. Forebrain development is disrupted at approximately 28 days of gestation, and all that remains in its place is the *area cerebrovasculosa*, a flattened remnant of disorganized brain tissue with admixed ependyma, choroid plexus, and meningothelial cells. The posterior fossa structures may be spared, depending on the extent of the skull deficit; descending tracts associated with disrupted structures are, as expected, absent.

FOREBRAIN ANOMALIES

The volume of brain may be abnormally large *(megalencephaly)* or small *(microencephaly)*. Microencephaly, by far the more common of the two, can occur in a wide range of settings, including chromosome abnormalities, fetal alcohol syndrome, and human immunodeficiency virus 1 (HIV-1) infection acquired in utero. It is postulated that the underlying anomaly is a reduction in the number of neurons that reach the neocortex and this leads to a simplification of the gyral folding—a model supported by experimental results in mouse models. The pool of proliferating precursor cells in the developing brain lies adjacent to the ventricular system. Neuronal number is determined by the fraction of proliferating cells that undergo transition into migrating cells with each cell cycle. Early on, most cell divisions yield two more progenitor cells, while as development progresses there are more asymmetric divisions yielding both a progenitor cell and a cell headed for the developing cortex. If excess cells exit the proliferating pool too early, then the overall generation of neurons is reduced; if too few exit during early rounds of division, then the geometric expansion of the proliferating population results in an eventual overproduction of neurons. [7] [8] [9]

Among the recognizable malformations[10] are conditions that can range from a noticeable decrease in the number of gyri to total absence, leaving a smooth-surfaced brain, *lissencephaly (agyria)* (Fig. 28-5). A variety of forms of lissencephaly with distinct genetic causes have been described. One of the best understood causes is mutations in the gene encoding the microtubule-associated protein LIS-1, which complexes with dynein and affects the function of the centrosome in nuclear movement. Lissencephaly can also occur from a series of mutations in the genes encoding enzymes responsible for the glycosylation of α-dystroglycan; when this receptor for extracellular matrix components does not have appropriate post-translational modifications, its stability is diminished.

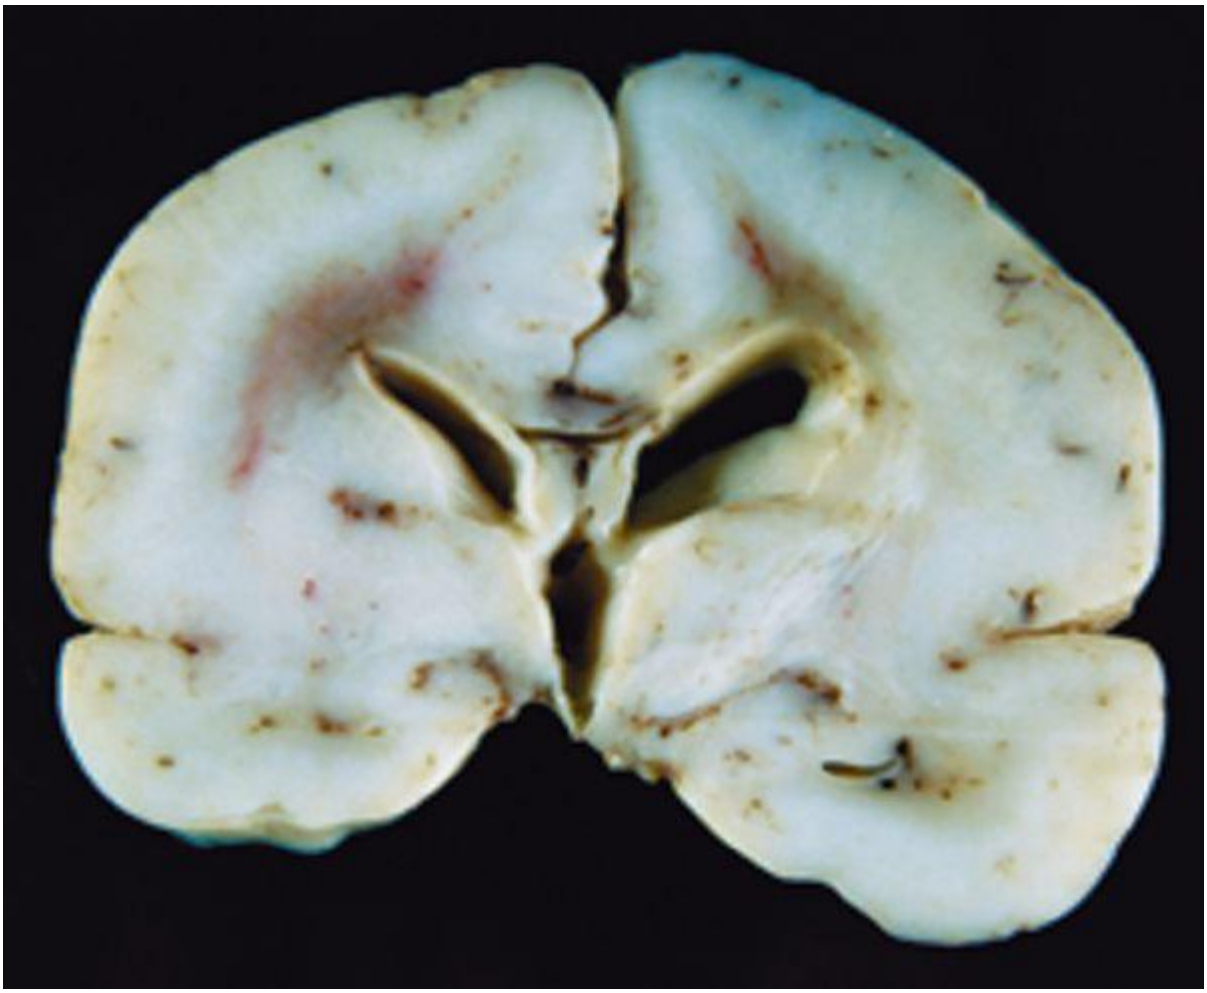

FIGURE 28-5 Lissencephaly. The absence of cortical gyri defines this abnormality, seen here in the brain from a full-term infant.

Polymicrogyria is characterized by small, unusually numerous, and irregularly formed cerebral convolutions. The gray matter is composed of four layers (or fewer), with entrapment of apparent meningeal tissue at points of fusion that would otherwise be the cortical surface. Polymicrogyria can be induced by localized tissue injury toward the end of neuronal migration, although genetically determined forms, which are typically bilateral and symmetric, are also recognized.[11]

Neuronal heterotopias are a group of migrational disorders that are commonly associated with epilepsy.[12] They consist of collections of neurons in inappropriate locations along the migrational pathways. As might be expected, one location in which heterotopias can be found is along the ventricular surface—as though the cells never managed to leave their place of birth. Periventricular heterotopias can be caused by mutations in the gene encoding filamin A, an actin-binding protein responsible for assembly of complex meshworks of filaments. This gene is on the X chromosome, and the mutant allele causes male lethality; in females the process of X inactivation separates neurons into those with a normal allele (in the correct location) and those with the mutant allele (in the heterotopia). Another microtubule-associated protein, doublecortin (DCX), is also encoded by a gene on the X chromosome; mutations in this gene result in lissencephaly in males and in subcortical band

heterotopias in females. These heterotopias may consist of discrete nodules of neurons sitting in the subcortical white matter or complete ribbons that parody the overlying cortex.

Holoprosencephaly is a spectrum of malformations characterized by incomplete separation of the cerebral hemispheres across the midline. Severe forms manifest midline facial abnormalities, including cyclopia; less severe variants (arrhinencephaly) show absence of the olfactory cranial nerves and related structures. Intrauterine diagnosis of severe forms by ultrasound examination is now possible. Holoprosencephaly is associated with trisomy 13 as well as other genetic syndromes.[13] Sonic hedgehog is a member of a family of secreted proteins synthesized by the notochord and neural plate during neural development. Mutations affecting sonic hedgehog or its signaling pathway may result in holoprosencephaly.

In *agenesis of the corpus callosum*, a relatively common malformation, there is an absence of the white matter bundles that carry cortical projections from one hemisphere to the other (Fig. 28-6). Radiologic imaging studies show misshapen lateral ventricles (“bat-wing” deformity); on coronal whole-mount sections of the brain, bundles of anteroposteriorly oriented white matter can be demonstrated. Agenesis of the corpus callosum can be associated with mental retardation or may occur in clinically normal individuals. It can be present in isolation or can be associated with a wide range of other malformations. Unlike patients with surgical callosal section, who show clinical evidence of hemispheric disconnection, individuals with this malformation can have minimal deficits.

FIGURE 28-6 Agenesis of the corpus callosum. The midsagittal view of the left hemisphere shows the lack of a corpus callosum and

cingulate gyrus above the third ventricle.

POSTERIOR FOSSA ANOMALIES

The *Dandy-Walker malformation* is characterized by an enlarged posterior fossa. The cerebellar vermis is absent or present only in rudimentary form in its anterior portion. In its place is a large midline cyst that is lined by ependyma and is contiguous with leptomeninges on its outer surface. This cyst represents the expanded, roofless fourth ventricle in the absence of a normally formed vermis. Dysplasias of brainstem nuclei are commonly found in association with Dandy-Walker malformation.

The *Arnold-Chiari malformation* (Chiari type II malformation) consists of a small posterior fossa, a misshapen midline cerebellum with downward extension of vermis through the foramen magnum (Fig. 28-7), and, almost invariably, hydrocephalus and a lumbar myelomeningocele. Other associated changes may include caudal displacement of the medulla, malformation of the tectum, aqueductal stenosis, cerebral heterotopias, and hydromyelia (see later). In the *Chiari I malformation*, low-lying cerebellar tonsils extend down into the vertebral canal. In contrast to the significant clinical consequences of the preceding two malformations, this may be a silent abnormality or may cause symptoms referable to obstruction of CSF flow and medullary compression; if present, these symptoms can usually be corrected by neurosurgical intervention.

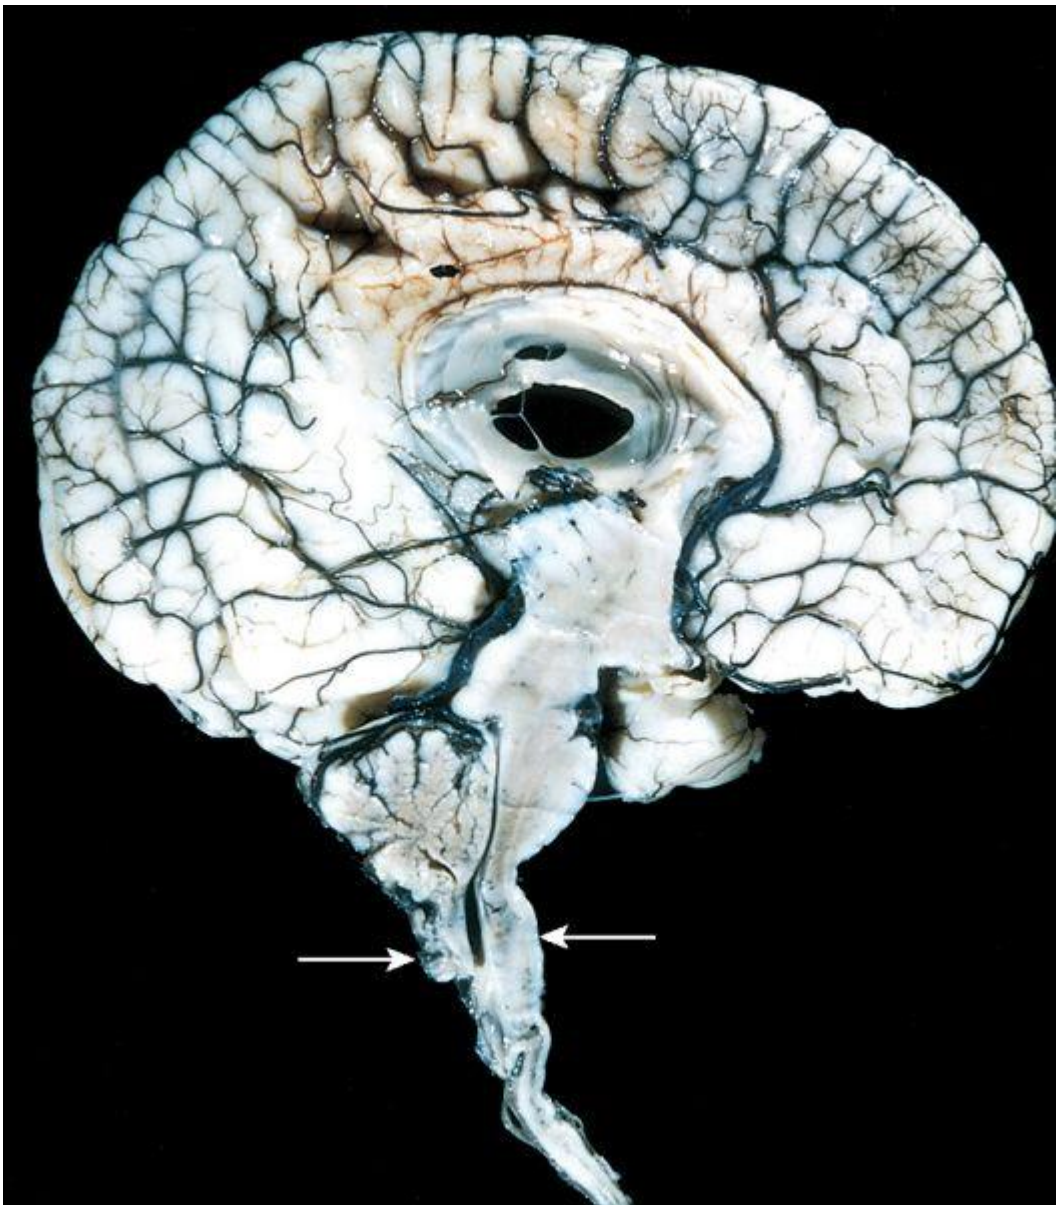

FIGURE 28-7 Arnold-Chiari malformation. Midsagittal section showing small posterior fossa contents, downward displacement of the cerebellar vermis, and deformity of the medulla (*arrows* indicate the approximate level of the foramen magnum).

SYRINGOMYELIA AND HYDROMYELIA

These are disorders characterized by a discontinuous multisegmental or confluent expansion of the ependyma-lined central canal of the cord *(hydromyelia)* or by the formation of a fluid-filled cleftlike cavity in the inner portion of the cord *(syringomyelia, syrinx)* that may extend into the brainstem *(syringobulbia)*.

Syringomyelia may be associated with the Chiari I malformation; it may also occur in association with intraspinal tumors or following traumatic injury. In general, the histologic appearance is similar in all these conditions, with destruction of the adjacent gray and white matter, surrounded by a dense feltwork of reactive gliosis. The disease generally becomes manifest in the second or third decade of life. The distinctive symptoms and signs of a syrinx are the isolated loss of pain and temperature sensation in the

upper extremities because of the predilection for early involvement of the crossing anterior spinal commissural fibers of the spinal cord.

3.18.4 Perinatal Brain Injury

Brain injury occurring in the perinatal period is an important cause of childhood neurologic disability. Injuries that occur early in gestation may destroy brain tissue without evoking the usual "reactive" changes in the parenchyma and may be difficult to distinguish from malformations.

The broad clinical term *cerebral palsy* refers to a nonprogressive neurologic motor deficit characterized by combinations of spasticity, dystonia, ataxia/athetosis, and paresis attributable to insults occurring during the prenatal and perinatal periods. Signs and symptoms may not be apparent at birth and only later declare themselves, as development proceeds. Postmortem examinations of children with this syndrome have shown a wide range of neuropathologic findings, including destructive lesions traced to remote events that may have caused hemorrhage and infarction.

In premature infants there is an increased risk of *intraparenchymal hemorrhage* within the germinal matrix, often near the junction between the thalamus and the caudate nucleus. Hemorrhages may remain localized or extend into the ventricular system and thence to the subarachnoid space, sometimes leading to hydrocephalus.

Infarcts may occur in the supratentorial periventricular white matter *(periventricular leukomalacia),* especially in premature infants. These are chalky yellow plaques consisting of discrete regions of white matter necrosis and calcification. When both gray and white matter are involved by extensive ischemic damage, large destructive cystic lesions develop throughout the hemispheres; this condition is termed *multicystic encephalopathy* (Fig. 28-8).

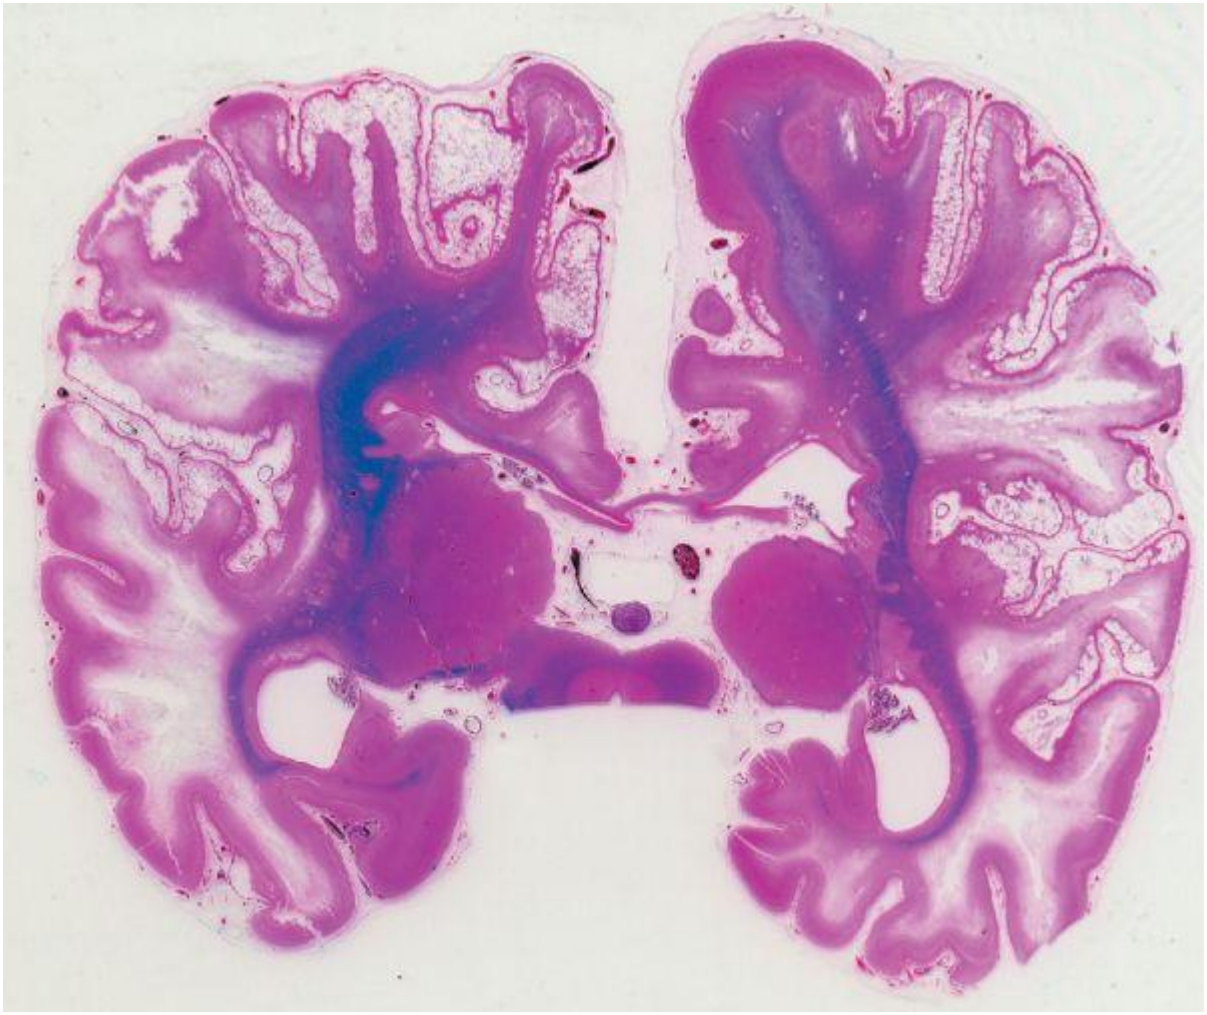

FIGURE 28-8 Multicystic leukoencephalopathy. Numerous cystic spaces representing the consequences of widespread ischemic injury are present.

In perinatal ischemic lesions of the cerebral cortex, the depths of sulci bear the brunt of injury and result in thinned-out, gliotic gyri *(ulegyria)*. The basal ganglia and thalamus may also suffer ischemic injury, with patchy neuronal loss and reactive gliosis. Later, aberrant and irregular myelinization gives rise to a marble-like appearance of the deep nuclei: *status marmoratus*. Because the lesions are in the caudate, putamen, and thalamus, choreoathetosis and related movement disorders are common clinical sequelae.

3.18.5 Trauma

The anatomic location of the lesion and the limited capacity of the brain for functional repair are major determinants of the consequences of CNS trauma. Injury of several cubic centimeters of brain parenchyma may be clinically silent (e.g., in the frontal lobe), severely disabling (in the spinal cord), or fatal (in the brainstem).

The physical forces associated with head injury may result in *skull fractures*, *parenchymal injury*, and *vascular injury*; all three can coexist. The magnitude and distribution of a traumatic brain lesion depend on the shape of the object causing the trauma, the force of impact, and whether the head is in motion at the time of injury. A blow to the head may be *penetrating* or *blunt*; it may cause either an *open* or a *closed injury*.

SKULL FRACTURES

A fracture in which bone is displaced into the cranial cavity by a distance greater than the thickness of the bone is called a *displaced skull fracture*. The thickness of the cranial bones varies; therefore, their resistance to fracture differs greatly. Also, the relative incidence of fractures among skull bones is related to the pattern of falls. When an individual falls while awake, such as might occur when stepping off a ladder, the site of impact is often in the occipital portion of the skull; in contrast, a fall that follows loss of consciousness, as might follow a syncopal attack, commonly results in a frontal impact. Symptoms referable to the lower cranial nerves or the cervicomedullary region, and the presence of orbital or mastoid hematomas distant from the point of impact, raise the suspicion of a basal skull fracture, which typically follows impact to the occiput or sides of the head. CSF discharge from the nose or ear and infection (meningitis) may follow. The kinetic energy that causes a fracture is dissipated at a fused suture; fractures that cross sutures are termed *diastatic*. With multiple points of impact or repeated blows to the head, the fracture lines of subsequent injuries do not extend across fracture lines of prior injury.

PARENCHYMAL INJURIES

Concussion

Concussion is a clinical syndrome of altered consciousness secondary to head injury typically brought about by a change in the momentum of the head (when a moving head is suddenly arrested by impact on a rigid surface). The characteristic neurologic picture includes instantaneous onset of transient neurologic dysfunction, including loss of consciousness, temporary respiratory arrest, and loss of reflexes. Although neurologic recovery is complete, amnesia for the event persists. The pathogenesis of the sudden disruption of neurologic function is unknown; it probably involves dysregulation of the reticular activating system in the brainstem. Postconcussive neuropsychiatric syndromes, typically associated with repetitive injuries, are well recognized.

Direct Parenchymal Injury

Contusion and *laceration* are lesions associated with direct parenchymal injury of the brain, either through transmission of kinetic energy to the brain and bruising analogous to what is seen in soft tissues (contusion) or by penetration of an object and tearing of tissue (laceration). As with any other organ, a blow to the surface of the brain, transmitted through the skull, leads to rapid tissue displacement, disruption of vascular channels, and subsequent hemorrhage, tissue injury, and edema (Fig. 28-9). The crests of gyri are most susceptible, since this is where the direct force is greatest. The most common locations for contusions correspond to the most frequent sites of direct impact and to regions of the brain that overlie a rough and irregular inner skull surface, such as the frontal lobes along the orbital ridges and the temporal lobes. Contusions are less frequent over the occipital lobes, brainstem, and cerebellum unless these sites are adjacent to a skull fracture *(fracture contusions)*.

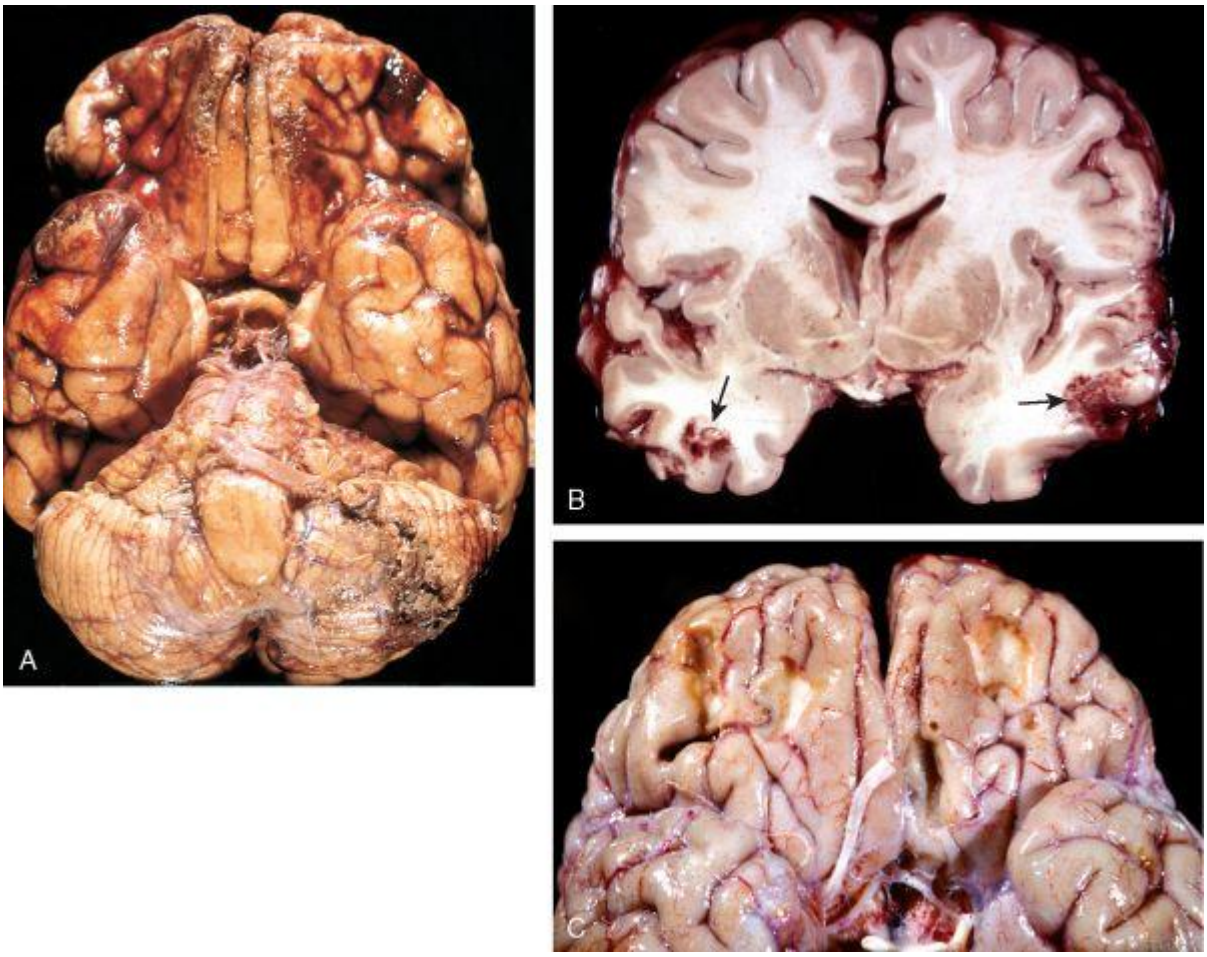

FIGURE 28-9 **A**, Multiple contusions involving the inferior surfaces of frontal lobes, anterior temporal lobes, and cerebellum. **B**, Acute contusions are present in both temporal lobes, with areas of hemorrhage and tissue disruption (*arrows*). **C**, Remote contusions are present on the inferior frontal surface of this brain, with a yellow color (associated with the term *plaque jaune*).

A person who suffers a blow to the head may develop a contusion at the point of contact (a *coup* injury) or a contusion on the brain surface diametrically opposite to it (a *contrecoup* injury). Since their macroscopic and microscopic appearance is indistinguishable, the distinction between them is based on forensic identification of the point of impact and the circumstances attending the incident. In general, if the head is immobile at the time of trauma, only a coup injury is found. If the head is mobile, both coup and contrecoup lesions may be found. Whereas the coup lesion is caused by the contact between brain and skull at the site of impact, the contrecoup contusion is thought to develop when the brain strikes the opposite inner surface of the skull after sudden deceleration.

Sudden impacts that result in violent posterior or lateral hyperextension of the neck (as occurs when a pedestrian is struck from the rear by a vehicle) may avulse the pons from the medulla or the medulla from the cervical cord, causing instantaneous death.

Morphology. When seen on cross-section, contusions are wedge shaped, with the broad base lying along the surface, deep to the point of impact (Fig. 28-9B). The histologic appearance of contusions is independent of the type of trauma. In the earliest stages, there is edema and hemorrhage, which is

often pericapillary. During the next few hours, the extravasation of blood extends throughout the involved tissue, across the width of the cerebral cortex, and into the white matter and subarachnoid space. Morphologic evidence of neuronal injury (pyknosis of the nucleus, eosinophilia of the cytoplasm, and disintegration of the cell) takes about 24 hours to appear, although functional deficits may occur earlier. Axonal swellings develop in the vicinity of damaged neurons or at great distances away. The inflammatory response to the injured tissue follows its usual course, with the appearance of neutrophils followed by macrophages. Old traumatic lesions on the surface of the brain have a characteristic macroscopic appearance. They are depressed, retracted, yellowish brown patches involving the crests of gyri most commonly located at the sites of contrecoup lesions (inferior frontal cortex, temporal and occipital poles). The term **plaque jaune** is applied to these lesions (Fig. 28-9C); they can become epileptic foci. More extensive hemorrhagic regions of brain trauma give rise to larger cavitated lesions, which can resemble remote infarcts. In sites of old contusions, gliosis and residual hemosiderin-laden macrophages predominate.

Diffuse Axonal Injury

Although it is most often affected, the surface of the brain is not the only region of damage in traumatic injury. Also affected may be the deep white matter regions (the corpus callosum, paraventricular, and hippocampal areas in the supratentorial compartment), cerebral peduncles, brachium conjunctivum, superior colliculi, and deep reticular formation in the brainstem. The microscopic findings include axonal swelling, indicative of *diffuse axonal injury*, and focal hemorrhagic lesions. Angular acceleration alone, in the absence of impact, can cause diffuse axonal injury as well as hemorrhage. As many as 50% of individuals who develop coma shortly after trauma, even without cerebral contusions, are believed to have diffuse axonal injury. The mechanical forces associated with trauma are believed to damage the integrity of the axon at the node of Ranvier, with subsequent alterations in axoplasmic flow.

Morphology. Diffuse axonal injury is characterized by the widespread but often asymmetric axonal swellings that appear within hours of the injury and may persist for much longer. These are best demonstrated with silver impregnation techniques or with immunoperoxidase stains for axonally transported proteins, including amyloid precursor protein and α-synuclein. Later, there are increased numbers of microglia in related areas of the cerebral cortex and, subsequently, degeneration of the involved fiber tracts.

TRAUMATIC VASCULAR INJURY

Vascular injury is a frequent component of CNS trauma. It results from direct trauma and disruption of the vessel wall, and leads to hemorrhage. Depending on the anatomic posi tion of the ruptured vessel, hemorrhage may occur in the *epidural*, *subdural*, *subarachnoid*, and *intraparenchymal* compartments, sometimes in combination (Fig. 28-10). Subarachnoid and intraparenchymal hemorrhages most often occur concomitantly in the setting of brain trauma that also results in superficial contusions and lacerations. A traumatic tear of the carotid artery where it traverses the carotid sinus may lead to the formation of an arteriovenous fistula.

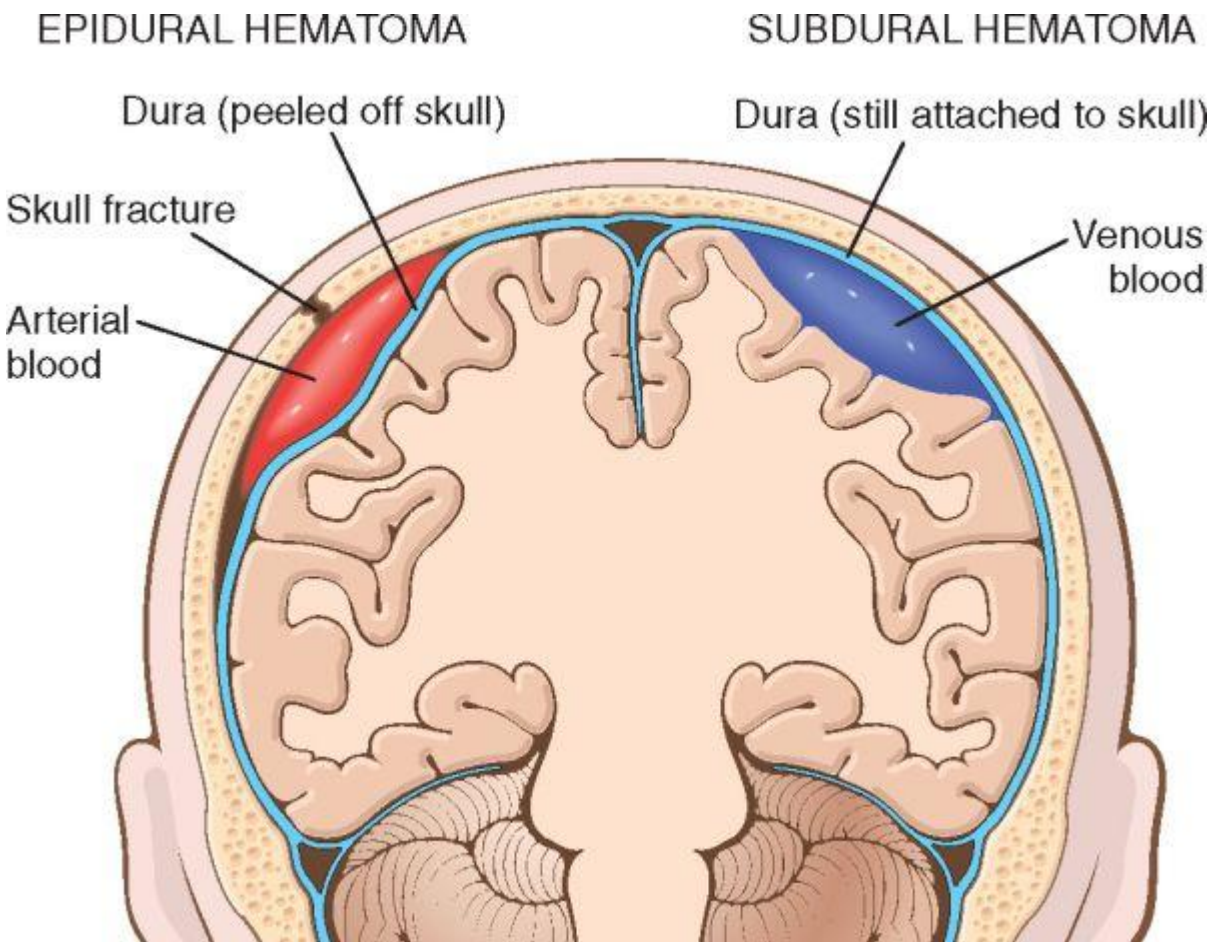

FIGURE 28-10 Epidural hematoma *(left)* in which rupture of a meningeal artery, usually associated with a skull fracture, leads to accumulation of arterial blood between the dura and the skull. In a subdural hematoma *(right)*, damage to bridging veins between the brain and the superior sagittal sinus leads to the accumulation of blood between the dura and the arachnoid.

Epidural Hematoma

Normally the dura is fused with the periosteum on the internal surface of the skull. Dural arteries, most importantly the middle meningeal artery, are vulnerable to injury, particularly with temporal skull fractures in which the fracture lines cross the course of the vessel. In children, in whom the skull is deformable, a temporary displacement of the skull bones leading to laceration of a vessel can occur in the absence of a skull fracture.

Once a vessel has been torn, the extravasation of blood under arterial pressure can cause the dura to separate from the inner surface of the skull (Fig. 28-11). The expanding hematoma has a smooth inner contour that compresses the brain surface. When blood accumulates slowly patients may be lucid for several hours before the onset of neurologic signs. An epidural hematoma may expand rapidly and is a neurosurgical emergency requiring prompt drainage.

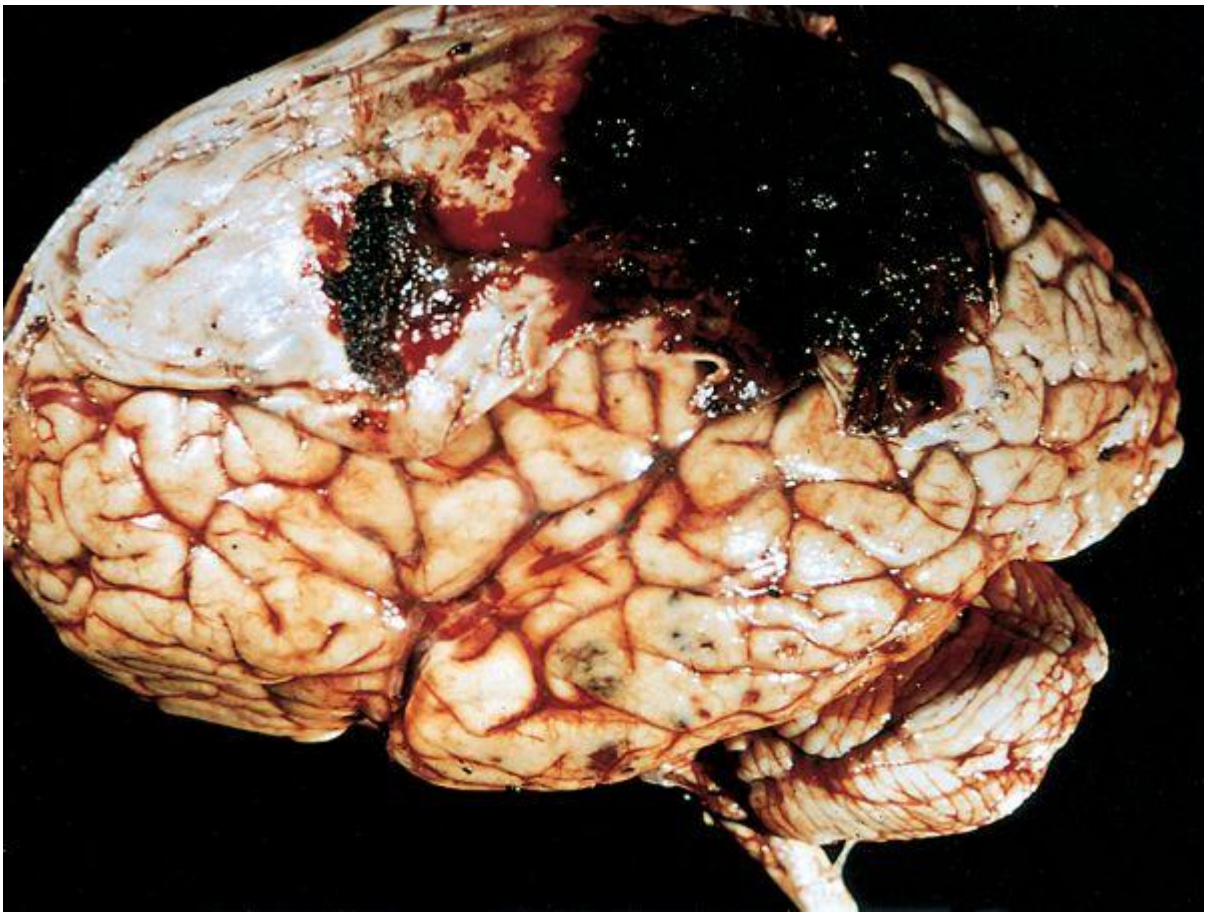

FIGURE 28-11 Epidural hematoma covering a portion of the dura. Also present are multiple small contusions in the temporal lobe. *(Courtesy of the late Dr. Raymond D. Adams, Massachusetts General Hospital, Boston, MA.)*

Subdural Hematoma

Between the inner surface of the dura mater and the outer arachnoid layer of the leptomeninges lies the subdural space. *Bridging veins* travel from the convexities of the cerebral hemispheres through the subarachnoid space and the subdural space to empty into the superior sagittal sinus. Similar anatomic relationships exist with other dural sinuses. These vessels are particularly prone to tearing along their course through the subdural space and are the source of bleeding in most cases of subdural hematoma. It is thought that the brain, floating freely bathed in CSF, can move within the skull, but the venous sinuses are fixed. The displacement of the brain that occurs in trauma can tear the veins at the point where they penetrate the dura. In elderly individuals with brain atrophy, the bridging veins are stretched out and the brain has additional space for movement, hence the increased rate of subdural hematomas in these patients, even after relatively minor head trauma. Infants are also particularly susceptible to subdural hematomas because their bridging veins are thin-walled.

Morphology. On macroscopic examination, the **acute subdural hematoma** appears as a collection of freshly clotted blood along the brain surface, without extension into the depths of sulci (Fig. 28-12). The underlying brain is flattened and the subarachnoid space is often clear. Typically, venous bleeding is self-limited; breakdown and organization of the hematoma take place over time. This

usually occurs in the following sequence:

- Lysis of the clot (about 1 week)
- Growth of fibroblasts from the dural surface into the hematoma (2 weeks)
- Early development of hyalinized connective tissue (1 to 3 months)

Typically, the organized hematoma is firmly attached by fibrous tissue only to the inner surface of the dura and is not adherent to the underlying smooth arachnoid, which does not contribute to its formation. The lesion can eventually retract as the granulation tissue matures, until there is only a thin layer of reactive connective tissue ("subdural membranes"). A common finding in subdural hematomas, however, is the occurrence of multiple episodes of repeat bleeding (**chronic subdural hematomas**), presumably from the thin-walled vessels of the granulation tissue. The risk of repeat bleeding is greatest in the first few months after the initial hemorrhage.

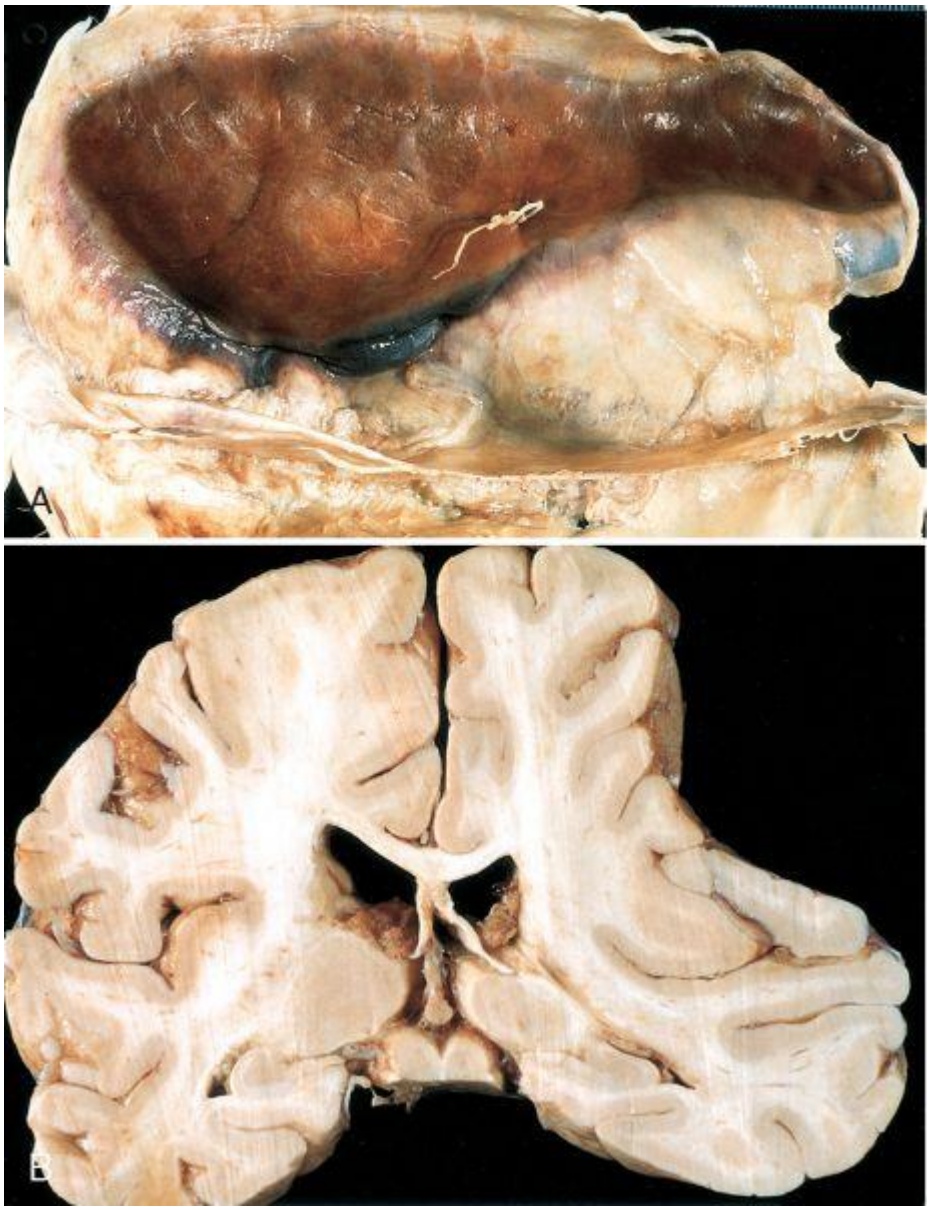

FIGURE 28-12 **A**, Large organizing subdural hematoma attached to the dura. **B**, Coronal section of the brain showing compression of the

hemisphere underlying the subdural hematoma shown in **A**.

Clinical Features.

Subdural hematomas most often manifest within 48 hours of injury. They are most common over the lateral aspects of the cerebral hemispheres and are bilateral in about 10% of cases. Neurologic signs commonly observed are attributable to the pressure exerted on the adjacent brain. There may be focal signs, but often the clinical manifestations are nonlocalizing and include headache and confusion. Slowly progressive neurologic deterioration is typical, but acute decompensation may occur. The treatment of subdural hematomas is to remove the blood and associated organizing tissue.

SEQUELAE OF BRAIN TRAUMA

A broad range of neurologic syndromes may become manifest months or years after brain trauma of any cause. These have gained increasing notice in the context of legal medicine and litigation involving issues of compensation for those in the civilian work force and the military services. *Post-traumatic hydrocephalus* is largely due to obstruction of CSF resorption from hemorrhage into the subarachnoid spaces. *Post-traumatic dementia* and the *punch-drunk syndrome* (dementia pugilistica) follow repeated head trauma during a protracted period; the neuropathologic findings include hydrocephalus, thinning of the corpus callosum, diffuse axonal injury, neurofibrillary tangles (mainly in the medial temporal areas), and diffuse amyloid β (Aβ)-positive plaques (see "Alzheimer Disease"). Other important sequelae of brain trauma include post-traumatic epilepsy, tumors (meningioma), infectious diseases, and psychiatric disorders.[3]

SPINAL CORD TRAUMA

The spinal cord, normally protected within the bony vertebral canal, is vulnerable to trauma from its skeletal encasement. Most injuries that damage the cord are associated with displacement of the vertebral column, either rapid and temporary or persistent. The level of cord injury determines the extent of neurologic manifestations: lesions involving the thoracic vertebrae or below can lead to paraplegia; cervical lesions result in quadriplegia; those above C4 can, in addition, lead to respiratory compromise from paralysis of the diaphragm. Segmental damage to the descending and ascending white matter tracts isolates the distal spinal cord from its cortical connections with the cerebrum and brainstem; this interruption, rather than the segmental gray matter damage that may occur at the level of the impact, is the principal cause of neurological deficits.

Morphology. The histologic changes of traumatic injury of the spinal cord are similar to those found at other sites in the CNS. At the level of injury the acute phase consists of hemorrhage, necrosis, and axonal swelling in the surrounding white matter. The lesion tapers above and below the level of injury. In time the central necrotic lesion becomes cystic and gliotic; cord sections above and below the lesion show secondary ascending and descending wallerian degeneration, respectively, involving the long white-matter tracts affected at the site of trauma.

3.18.6 Cerebrovascular Diseases

Cerebrovascular disease is the third leading cause of death (after heart disease and cancer) in the United States; it is also the most prevalent neurologic disorder in terms of both morbidity and mortality.

Cerebrovascular diseases include the expected three major categories, thrombosis, embolism, and hemorrhage, with patient management differing between groups. “Stroke” is the clinical designation that applies to all these conditions, particularly when symptoms begin acutely. From the standpoint of pathophysiology and pathologic anatomy, it is convenient to consider cerebrovascular disease as two processes:

- Hypoxia, ischemia, and infarction resulting from impairment of blood supply and oxygenation of CNS tissue
- Hemorrhage resulting from rupture of CNS vessels

The most common cerebrovascular disorders are global ischemia, embolism, hypertensive intraparenchymal hemorrhage, and ruptured aneurysm.

HYPOXIA, ISCHEMIA, AND INFARCTION

The brain requires a constant supply of glucose and oxygen, which is delivered by the blood. Although the brain accounts for only 1% to 2% of body weight, it receives 15% of the resting cardiac output and accounts for 20% of the total body oxygen consumption. Cerebral blood flow remains relatively constant over a wide range of blood pressure and intracranial pressure because of autoregulation of vascular resistance. The brain is a highly aerobic tissue, in which oxygen rather than metabolic substrate is limiting. The brain may be deprived of oxygen by several mechanisms: *hypoxia* caused by a low partial pressure of oxygen (Po_2), impairment of the blood's oxygen-carrying capacity, or inhibition of oxygen use in the tissue; or *ischemia*, either transient or permanent, after interruption of the normal circulatory flow. Cessation of blood flow can result from a reduction in perfusion pressure (as in hypotension), small- or large-vessel obstruction, or both.

When blood flow to a portion of the brain is reduced, the survival of the tissue at risk depends on the presence of collateral circulation, the duration of ischemia, and the magnitude and rapidity of the reduction of flow. These factors determine, in turn, the precise anatomic site and size of the lesion and, consequently, the clinical deficit. Two principal types of acute ischemic injury are recognized:

- *Global cerebral ischemia* (ischemic/hypoxic encephalopathy) occurs when there is a generalized reduction of cerebral perfusion, as in cardiac arrest, shock, and severe hypotension.
- *Focal cerebral ischemia* follows reduction or cessation of blood flow to a localized area of the brain due to large-vessel disease (such as embolic or thrombotic arterial occlusion, often in a setting of atherosclerosis) or to small-vessel disease (such as vasculitis or occlusion secondary to arteriosclerotic lesions seen in hypertension).

The general biochemical changes that attend cellular ischemia are discussed in Chapter 1 . Here we describe several special responses to ischemia in the CNS. [14] [15] [16] The metabolic depletion of energy associated with ischemia can result in inappropriate release of excitatory amino acid neurotransmitters such as glutamate, initiating cell damage by allowing excessive influx of calcium ions through NMDA-type glutamate receptors. This elevation of cellular calcium ions can, in turn, trigger a wide range of processes including inappropriate activation of signaling cascades, free radical generation, and mitochondrial injury. All told, these together result in cell death, mostly through necrosis. In the region of transition between necrotic tissue and the normal brain, there is an area of “at-risk” tissue, referred to as the penumbra. This region can be rescued from injury in many animal models with a variety of anti-apoptotic interventions, implying that it may undergo damage by apoptosis as well.

Hypotension, Hypoperfusion, and Low-Flow States (Global Cerebral Ischemia)

The clinical outcome of a severe hypotensive episode that produces *global cerebral ischemia (diffuse hypoxic/ischemic encephalopathy)* varies with the severity of the insult. In mild cases there may be only a transient post-ischemic confusional state followed by complete recovery and no irreversible tissue damage. However, irreversible damage to CNS tissue may occur in some individuals who suffer mild or transient global ischemic insults. There is a hierarchy of sensitivity among CNS cells: neurons are the most sensitive, although glial cells (oligodendrocytes and astrocytes) are also vulnerable. There is also variability in the susceptibility of populations of neurons in different regions of the CNS *(selective vulnerability)*, based in part on differences in regional cerebral blood flow and cellular metabolic requirements. With severe global cerebral ischemia, widespread neuronal death occurs, irrespective of regional vulnerability. Patients who survive this injury often remain in a persistent vegetative state. Other patients meet the current clinical criteria for "brain death," including evidence of irreversible diffuse cortical injury (isoelectric, or "flat," electroencephalogram) and brainstem damage, such as absent reflexes and respiratory drive, and absent cerebral perfusion. When individuals with this pervasive form of injury are maintained on mechanical ventilation, the brain gradually undergoes an autolytic process—so-called "respirator brain."

Border zone ("watershed") infarcts occur in the regions of the brain or spinal cord that lie at the most distal reaches of the arterial blood supply, the border zones between arterial territories. In the cerebral hemispheres, the border zone between the anterior and the middle cerebral artery distributions is at greatest risk. Damage to this region produces a sickle-shaped band of necrosis over the cerebral convexity a few centimeters lateral to the interhemispheric fissure. Border zone infarcts are usually seen after hypotensive episodes.

Morphology. In the setting of global ischemia, the brain is swollen, the gyri are widened, and the sulci are narrowed. The cut surface shows poor demarcation between gray and white matter. The microscopic changes of irreversible ischemic injury (infarction) are grouped into three categories. **Early changes**, occurring 12 to 24 hours after the insult, include acute neuronal changes (red neurons; Figs. 28-13A and Figs. 28-13B) characterized at first by microvacuolization, then eosinophilia of the neuronal cytoplasm, and later nuclear pyknosis and karyorrhexis. Similar acute changes occur somewhat later in astrocytes and oligodendroglia. Pyramidal cells in CA1 of the hippocampus (Sommer sector), Purkinje cells of the cerebellum, and cortical pyramidal neurons are the most susceptible to global ischemia of short duration. After the acute injury, the reaction to tissue damage begins with infiltration by neutrophils (Fig. 28-13C). **Subacute changes**, occurring at 24 hours to 2 weeks, include necrosis of tissue, influx of macrophages, vascular proliferation, and reactive gliosis (Fig. 28-13D). **Repair**, robust after approximately 2 weeks, is characterized by eventual removal of all necrotic tissue, loss of normally organized CNS structure, and gliosis (Fig. 28-13E). In the cerebral cortex the neuronal loss and gliosis produce an uneven destruction of the neocortex, with preservation of some layers and involvement of others, a pattern termed **pseudolaminar necrosis**.

Infarction from Obstruction of Local Blood Supply (Focal Cerebral Ischemia)

Cerebral arterial occlusion may lead to focal ischemia and, if sustained, to infarction of a specific region within the territory of distribution of the compromised vessel. The size, location, and shape of the infarct and the extent of tissue damage that results are determined by modifying factors mentioned earlier, the most important being the adequacy of collateral flow. The major source of collateral flow is the circle of Willis (supplemented by the external carotid-ophthalmic pathway). Partial and inconstant reinforcement is available over the surface of the brain for the distal branches of the anterior, middle, and posterior cerebral arteries through cortical-leptomeningeal anastomoses. In contrast, there is little if

any collateral flow for the deep penetrating vessels supplying structures such as the thalamus, basal ganglia, and deep white matter.

Occlusive vascular disease of severity sufficient to lead to cerebral infarction may be due to *in situ thrombosis, embolization* from a distant source, or various forms of vasculitides; the basic pathology of these conditions is discussed in Chapters 4 and 11 .

The majority of thrombotic occlusions are due to atherosclerosis. The most common sites of primary thrombosis causing cerebral infarction are the carotid bifurcation, the origin of the middle cerebral artery, and either end of the basilar artery. The evolution of arterial stenosis varies from progressive narrowing of the lumen and thrombosis, which may be accompanied by anterograde extension, to fragmentation and distal embolization. Another important aspect of occlusive cerebrovascular disease is its frequent association with systemic diseases such as hypertension and diabetes.

Embolism to the brain occurs from a wide range of origins. Cardiac mural thrombi are among the most common sources; myocardial infarct, valvular disease, and atrial fibrillation are important predisposing factors. Next in importance are thromboemboli arising in arteries, most often originating over atheromatous plaques within the carotid arteries. Other sources of emboli include paradoxical emboli, particularly in children with cardiac anomalies; emboli associated with cardiac surgery; and emboli of other material (tumor, fat, or air). The territory of distribution of the middle cerebral artery—the direct extension of the internal carotid artery—is most frequently affected by embolic infarction; the incidence is about equal in the two hemispheres. Emboli tend to lodge where blood vessels branch or in areas of preexisting luminal stenosis. “Shower embolization,” as in fat embolism, may occur after fractures; affected individuals manifest generalized cerebral dysfunction with disturbances of higher cortical function and consciousness, often without localizing signs. Widespread hemorrhagic lesions involving the white matter are characteristic of embolization of bone marrow after trauma (Fig. 28-14).

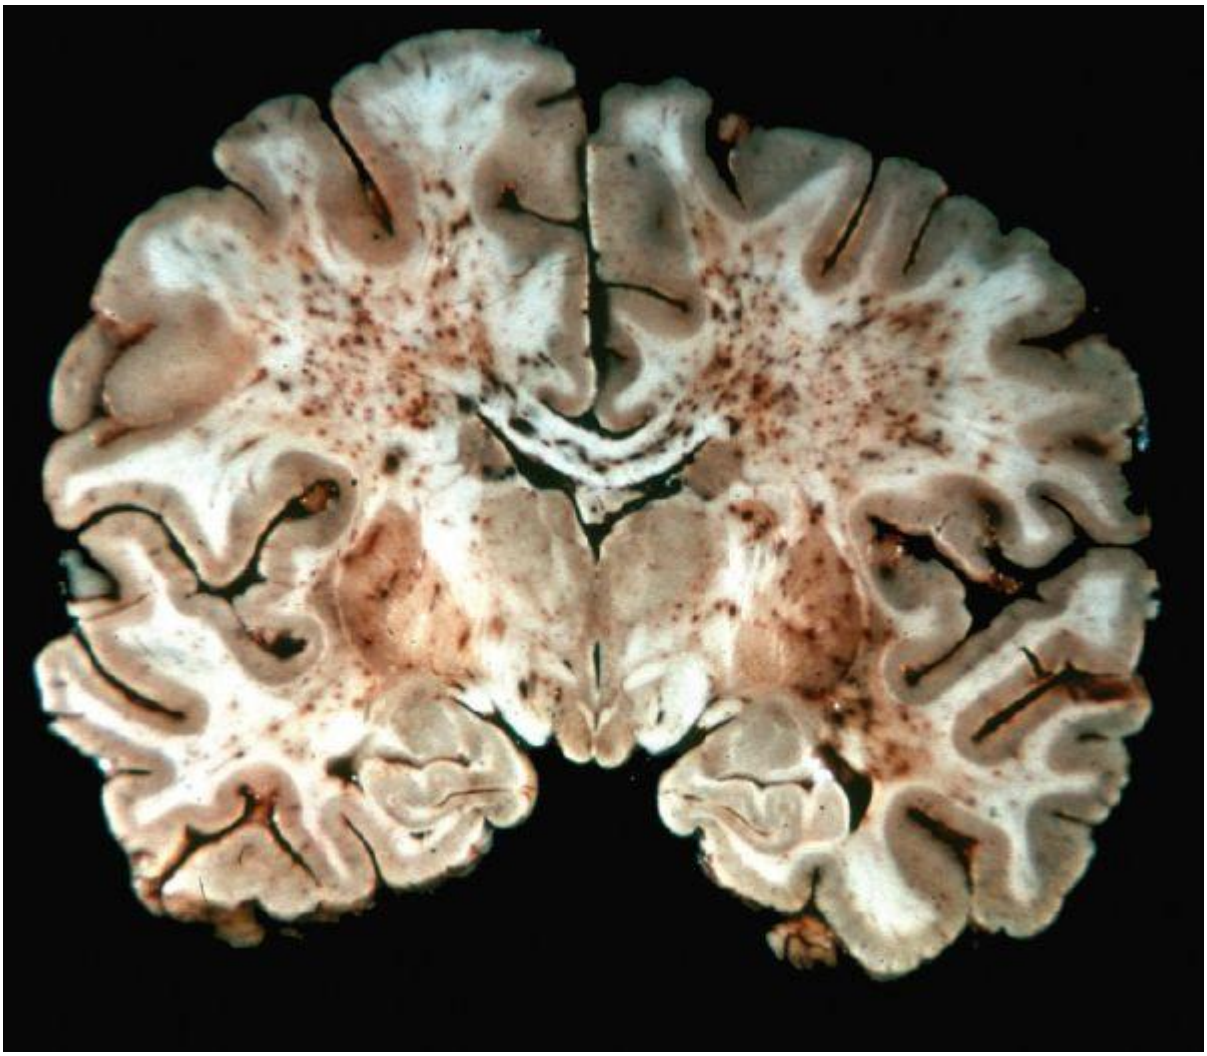

FIGURE 28-14 Widespread white-matter hemorrhages are characteristic of bone marrow embolization.

A variety of inflammatory processes that involve blood vessels may also lead to luminal narrowing and cerebral infarcts. While *infectious vasculitis* of small and large vessels was once most commonly associated with syphilis and tuberculosis, it is now more common in the setting of immunosuppression and opportunistic infection (such as aspergillosis or CMV encephalitis). *Polyarteritis nodosa* and other non-infections vasculitides may involve cerebral vessels and cause single or multiple infarcts throughout the brain. *Primary angiitis of the CNS* is an inflammatory disorder that involves multiple small- to medium-sized parenchymal and subarachnoid vessels and is characterized by chronic inflammation, multinucleated giant cells, and destruction of the vessel wall. Granulomas may be found in association with the giant cells, leading to the alternative name of granulomatous angiitis of the nervous system. Affected individuals manifest a diffuse encephalopathic or multifocal clinical picture, often with cognitive dysfunction; patients improve with steroid and immunosuppressive treatment. Other conditions that may cause thrombosis and infarction (and intracranial hemorrhage) include hypercoagulable states, dissecting aneurysm of extracranial arteries in the neck supplying the brain, and drug abuse (amphetamines, heroin, cocaine).

Infarcts are subdivided into two broad groups based on the presence of hemorrhage. *Hemorrhagic (red) infarction*, characterized by multiple, sometimes confluent, petechial hemorrhages, is typically associated with embolic events (Fig. 28-15A). The hemorrhage is presumed to be secondary to reperfusion of damaged vessels and tissue, either through collaterals or directly after dissolution of intravascular occlusive material. In contrast, *nonhemorrhagic (pale, bland, anemic) infarcts* are usually associated with thrombosis (Fig. 28-15B). The clinical management of patients with these two types of infarcts differs greatly as thrombolytic therapy may be used in cases of thrombosis but is contraindicated in hemorrhagic infarcts. Thrombolytic therapy is beneficial only during a narrow time window after onset of symptoms; therefore, rapid medical attention is essential.

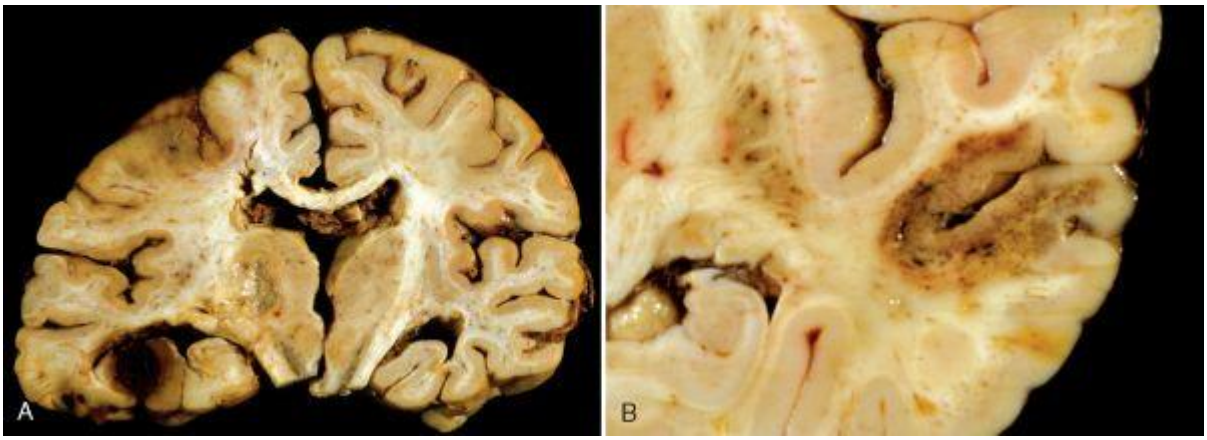

FIGURE 28-15 A, A hemorrhagic infarction is present in the inferior temporal lobe of the left side of this brain. **B**, A bland infarct with punctate hemorrhages, consistent with ischemia-reperfusion injury, is present in the temporal lobe.

Morphology. The macroscopic appearance of a **nonhemorrhagic infarct** varies with the time after loss of blood supply. During the first 6 hours of irreversible injury, little can be observed. By 48 hours the tissue becomes pale, soft, and swollen, and the corticomedullary junction becomes indistinct. From 2 to 10 days, the brain becomes gelatinous and friable, and the previously ill-defined boundary between normal and abnormal tissue becomes more distinct as edema resolves in the adjacent tissue that has survived. From 10 days to 3 weeks, the tissue liquefies, eventually leaving a fluid-filled cavity lined by dark gray tissue, which gradually expands as dead tissue is removed (Fig. 28-16).

On microscopic examination the tissue reaction evolves along the following sequence: *After the first 12 hours*, ischemic neuronal change (red neurons; see earlier) and both cytotoxic and vasogenic edema predominate. There is loss of the usual tinctorial characteristics of white- and gray-matter structures. Endothelial and glial cells, mainly astrocytes, swell, and myelinated fibers begin to disintegrate. *Up to 48 hours*, neutrophilic emigration progressively increases and then falls off. Phagocytic cells, derived from circulating monocytes and activated microglia, are evident at 48 hours and become the predominant celltype in the ensuing *2 to 3 weeks*. The macrophages become stuffed with the products of myelin breakdown or blood and may persist in the lesion for months to years. As the process of liquefaction and phagocytosis proceeds, astrocytes at the edges of the lesion progressively enlarge, divide, and develop a prominent network of cytoplasmic extensions. Reactive astrocytes can be seen as early as *1 week* after the insult.

After several months, the astrocytic response recedes, leaving behind a dense meshwork of glial fibers admixed with new capillaries and some perivascular connective tissue. In the cerebral cortex, the

cavity is separated from the meninges and subarachnoid space by a gliotic layer of tissue, derived from the molecular layer of the cortex. The pia and arachnoid are not affected and do not contribute to the healing process. Infarcts undergo these reactive and reparative stages from the edges inward; thus, different areas of a lesion may look different, particularly during the early stages, revealing the natural progression of the response.

The microscopic picture and evolution of **hemorrhagic infarction** parallel ischemic infarction, with the addition of blood extravasation and resorption. In individuals receiving anticoagulant treatment, hemorrhagic infarcts may be associated with extensive intracerebral hematomas. Venous infarcts are often hemorrhagic and may occur after thrombotic occlusion of the superior sagittal sinus or other sinuses or occlusion of the deep cerebral veins. Carcinoma, localized infections, and other conditions leading to a hypercoagulable state increase the risk for venous thrombosis.

Spinal cord infarction may be seen in the setting of hypoperfusion or as a consequence of interruption of the feeding tributaries derived from the aorta. Occlusion of the anterior spinal artery is rarer and may occur as a result of embolism or vasculitis.

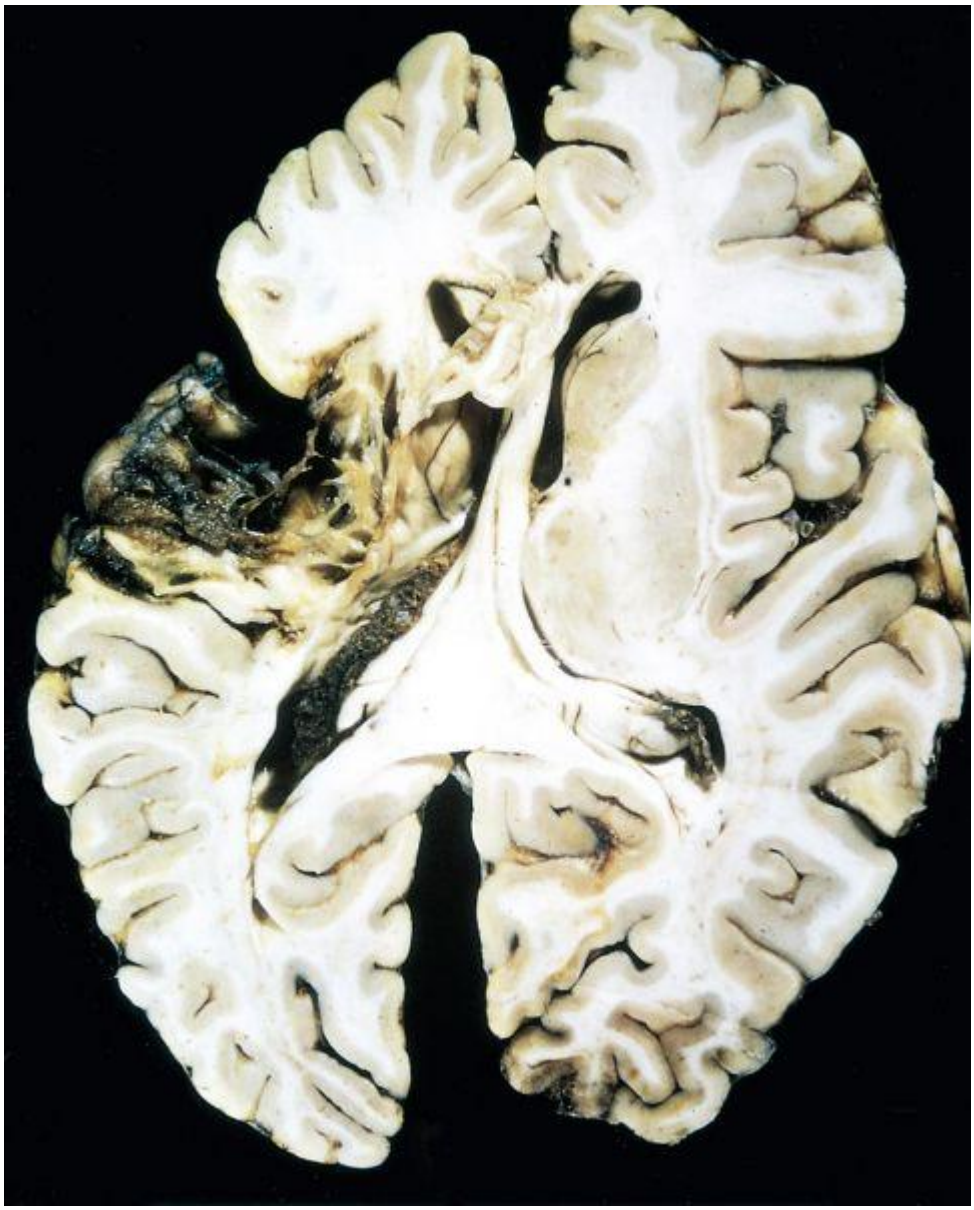

FIGURE 28-16 Old cystic infarct showing destruction of cortex with cavitation.

Clinical Features.

Deficits associated with infarction are determined by the brain region involved rather than the underlying pathologic process. Neurologic symptoms referable to the area of injury often develop rapidly, over minutes, and may continue to evolve over hours. There can be improvement in severity of symptoms associated with reversal of injury in the ischemic penumbra as well as with resolution of associated local edema. In general, there is often a degree of slow improvement during a period of months. Because strokes are frequently associated with atherosclerosis, many of the genetic and lifestyle risk factors are the same as those for atherosclerotic disease.

HYPERTENSIVE CEREBROVASCULAR DISEASE

The most important effects of hypertension on the brain include lacunar infarcts, slit hemorrhages, and hypertensive encephalopathy, as well as massive hypertensive intracerebral hemorrhage. The incidence of these disorders is likely to decline with increased screening for hypertension and aggressive management of blood pressure.

Lacunar Infarcts

Hypertension affects the deep penetrating arteries and arterioles that supply the basal ganglia and hemispheric white matter as well as the brainstem. These cerebral vessels develop *arteriolar sclerosis* and may become occluded; the structural changes are similar to those described in the systemic vessels of individuals with hypertension (Chapter 11). An important clinical and pathologic consequence of CNS arterial lesions is the development of single or multiple, small, cavitary infarcts known as *lacunae* (Fig. 28-17). These are lake-like spaces, less than 15 mm wide, which occur in the lenticular nucleus, thalamus, internal capsule, deep white matter, caudate nucleus, and pons, in descending order of frequency. On microscopic examination they consist of areas of tissue loss with scattered lipid-laden macrophages and surrounding gliosis. Depending on their location in the CNS, lacunae can either be clinically silent or cause severe neurologic impairment. Affected vesselsmay also be associated with widening of the perivascular spaces but without tissue infarction *(état criblé)*.

FIGURE 28-17 Lacunar infarcts in the caudate and putamen (*arrows*).

Slit Hemorrhages

Hypertension also gives rise to rupture of the small-caliber penetrating vessels and the development of small hemorrhages. In time these hemorrhages resorb, leaving behind a slitlike cavity *(slit hemorrhage)* surrounded by brownish discoloration; on microscopic examination, slit hemorrhages show focal tissue destruction, pigment-laden macrophages, and gliosis.

Hypertensive Encephalopathy

Acute hypertensive encephalopathy is a clinicopathologic syndrome arising in an individual with malignant hypertension, and is characterized by diffuse cerebral dysfunction, including headaches, confusion, vomiting, and convulsions, sometimes leading to coma. Rapid therapeutic intervention to reduce the accompanying increased intracranial pressure is required, since the syndrome often does not remit spontaneously. At postmortem examination such individuals may show an edematous brain with or without transtentorial or tonsillar herniation. Petechiae and fibrinoid necrosis of arterioles in the gray and white matter may be seen microscopically.

Individuals who, over the course of many months and years, suffer multiple, bilateral, gray matter (cortex, thalamus, basal ganglia) and white matter (centrum semiovale) infarcts may develop a distinctive clinical syndrome characterized by dementia, gait abnormalities, and pseudobulbar signs, often with superimposed focal neurologic deficits. The syndrome, generally referred to as *vascular (multi-infarct) dementia*, is caused by multifocal vascular disease of several types, including (1) cerebral atherosclerosis, (2) vessel thrombosis or embolization from carotid vessels or from the heart, and (3) cerebral arteriolar sclerosis from chronic hypertension. When the pattern of injury preferentially

involves large areas of the subcortical white matter with myelin and axon loss, the disorder is referred to as *Binswanger disease*; this distribution of vascular white-matter injury must be distinguished clinically and radiologically from other diseases that affect the hemispheral white matter.

INTRACRANIAL HEMORRHAGE

Hemorrhages may occur at any site within the CNS. In some instances they may be a secondary phenomenon occurring, for example, within infarcts in arterial border zones or in infarcts caused by only partial or transient vascular obstruction. Primary hemorrhages within the epidural or subdural space are typically related to trauma and were discussed earlier with traumatic lesions. Hemorrhages within the brain parenchyma and subarachnoid space, in contrast, are more often a manifestation of underlying cerebrovascular disease, although trauma may also cause hemorrhage in these sites.

Intracerebral (Intraparenchymal) Hemorrhage

Spontaneous (nontraumatic) intraparenchymal hemorrhages occur most commonly in middle to late adult life, with a peak incidence at about age 60 years. Most are caused by rupture of a small intraparenchymal vessel. When the hemorrhages occur in the basal ganglia and thalamus, they are designated ganglionic hemorrhages to distinguish them from those that occur in the lobes of the cerebral hemispheres, which are called lobar hemorrhages. The two major underlying etiologies of this form of cerebrovascular disease are hypertension and cerebral amyloid angiopathy (CAA). In addition, other local and systemic factors may cause or contribute to nontraumatic hemorrhage, including systemic coagulation disorders, neoplasms, vasculitis, aneurysms, and vascular malformations.

Hypertension is the most common underlying cause of primary brain parenchymal hemorrhage, accounting for more than 50% of clinically significant hemorrhages and for roughly 15% of deaths among individuals with chronic hypertension. Hypertension causes a number of abnormalities in vessel walls, including accelerated atherosclerosis in larger arteries; hyaline arteriolosclerosis in smaller vessels; and, in severe cases, proliferative changes and frank necrosis of arterioles. Arteriolar walls affected by hyaline change are presumably weaker than are normal vessels and are therefore more vulnerable to rupture. In some instances chronic hypertension is associated with the development of minute aneurysms, termed *Charcot-Bouchard microaneurysms*, which may be the site of rupture. Charcot-Bouchard aneurysms, not to be confused with saccular aneurysms of larger intracranial vessels, occur in vessels that are less than 300 μm in diameter, most commonly within the basal ganglia.

Morphology. Hypertensive intraparenchymal hemorrhage may originate in the putamen (50% to 60% of cases), thalamus, pons, cerebellar hemispheres (rarely), and other regions of the brain (Fig. 28-18A). Acute hemorrhages, independent of etiology, are characterized by extravasation of blood with compression of the adjacent parenchyma. Old hemorrhages show an area of cavitary destruction of brain with a rim of brownish discoloration. On microscopic examination the early lesion consists of a central core of clotted blood surrounded by a rim of brain tissue showing anoxic neuronal and glial changes as well as edema. Eventually the edema resolves, pigment- and lipid-laden macrophages appear, and proliferation of reactive astrocytes is seen at the periphery of the lesion. The cellular events then follow the same time course that is observed after cerebral infarction.

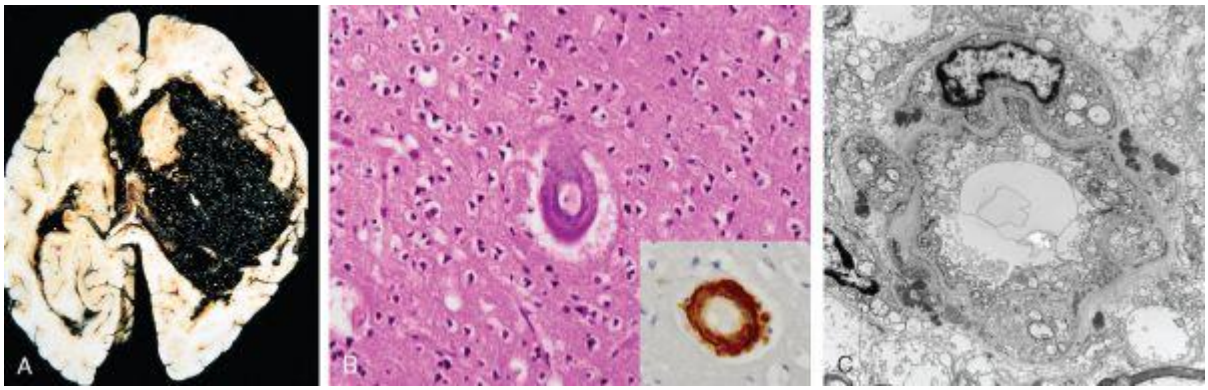

FIGURE 28-18 **A**, Massive hypertensive hemorrhage rupturing into a lateral ventricle. **B**, Amyloid deposition in a cortical arteriole in cerebral amyloid angiopathy; *inset*, Immunohistochemical staining for Aβ shows the deposited material in the vessel wall. **C**, Electron micrograph shows granular osmophilic material in a case of CADASIL.

CAA is a condition in which amyloidogenic peptides, nearly always the same one found in Alzheimer disease ($A\beta_{40}$; see the discussion below), deposit in the walls of medium- and small-caliber meningeal and cortical vessels. This deposition can result in weakening of the vessel wall and risk of hemorrhage. As with Alzheimer disease, in which there is a relationship between a polymorphism in the gene that encodes apolipoprotein E (ApoE) and risk of disease, there is an effect of the ApoE genotype on the risk of recurrence of hemorrhage from sporadic CAA. The presence of either an ε2 or ε4 allele increases the risk of repeat bleeding. While some mutations in the precursor protein for the Aβ peptide (amyloid precursor protein, APP) cause familial Alzheimer disease, others result in autosomal dominant forms of CAA.

Morphology. The underlying vascular abnormality of CAA is typically restricted to the leptomeningeal and cerebral cortical arterioles and capillaries, although involvement of the molecular layer of the cerebellum can be observed as well. Involved vessels appear "stiff" on microscopic sections, remaining open with round lumens through tissue processing. Unlike with arteriolar sclerosis, there is no fibrosis; rather, dense and uniform deposits of amyloid are present (Fig. 28-18B).

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a rare hereditary form of stroke caused by mutations in the gene encoding the Notch3 receptor.[17] The disease is characterized clinically by recurrent strokes (usually infarcts, less often hemorrhages) and dementia. Histopathologic study has shown abnormalities of white matter and leptomeningeal arteries (also involving non-CNS vessels) consisting of concentric thickening of the media and adventitia. Basophilic, PAS-positive deposits, which appear as osmiophilic compact granular material by electron microscopy, have been consistently detected in the walls of affected vessels, as has loss of smooth muscle cells (Fig. 28-18C). The diagnosis can be made through the identification of these deposits in other tissues, such as skin or muscle biopsies, or through genetic approaches. Many of the causative mutations disrupt the normal folding of the extracellular domain of Notch3, and the characteristic deposits appear to be comprised of Notch3 ectodomains. How these deposits relate to the disease is not understood; a toxic gain-of-function mechanism affecting vascular smooth muscle has been proposed.[17]

Clinical Features.

Intracerebral hemorrhage, independent of cause, can be clinically devastating if it affects large portions of the brain and extends into the ventricular system, or it can affect small regions and either be clinically silent or evolve like an infarct. Over weeks or months there is a gradual resolution of the hematoma, sometimes with considerable clinical improvement. Again, the location of the hemorrhage determines the clinical manifestations.

Subarachnoid Hemorrhage and Ruptured Saccular Aneurysms

The most frequent cause of clinically significant subarachnoid hemorrhage is rupture of a *saccular* (*berry) aneurysm*. Subarachnoid hemorrhage may also result from extension of a traumatic hematoma, rupture of a hypertensive intracerebral hemorrhage into the ventricular system, vascular malformation, hematologic disturbances, and tumors.

Saccular aneurysm is the most common type of intracranial aneurysm. Other aneurysm types include atherosclerotic (fusiform; mostly of the basilar artery), mycotic, traumatic, and dissecting. These latter three, like saccular aneurysms, are most often found in the anterior circulation, but differ in that they more often cause cerebral infarction rather than subarachnoid hemorrhage.

Saccular aneurysms are found in about 2% of the population according to recent data from community-based radiologic studies. About 90% of saccular aneurysms are found near major arterial branch points in the anterior circulation (Fig. 28-19); multiple aneurysms exist in 20% to 30% of cases in autopsy series.

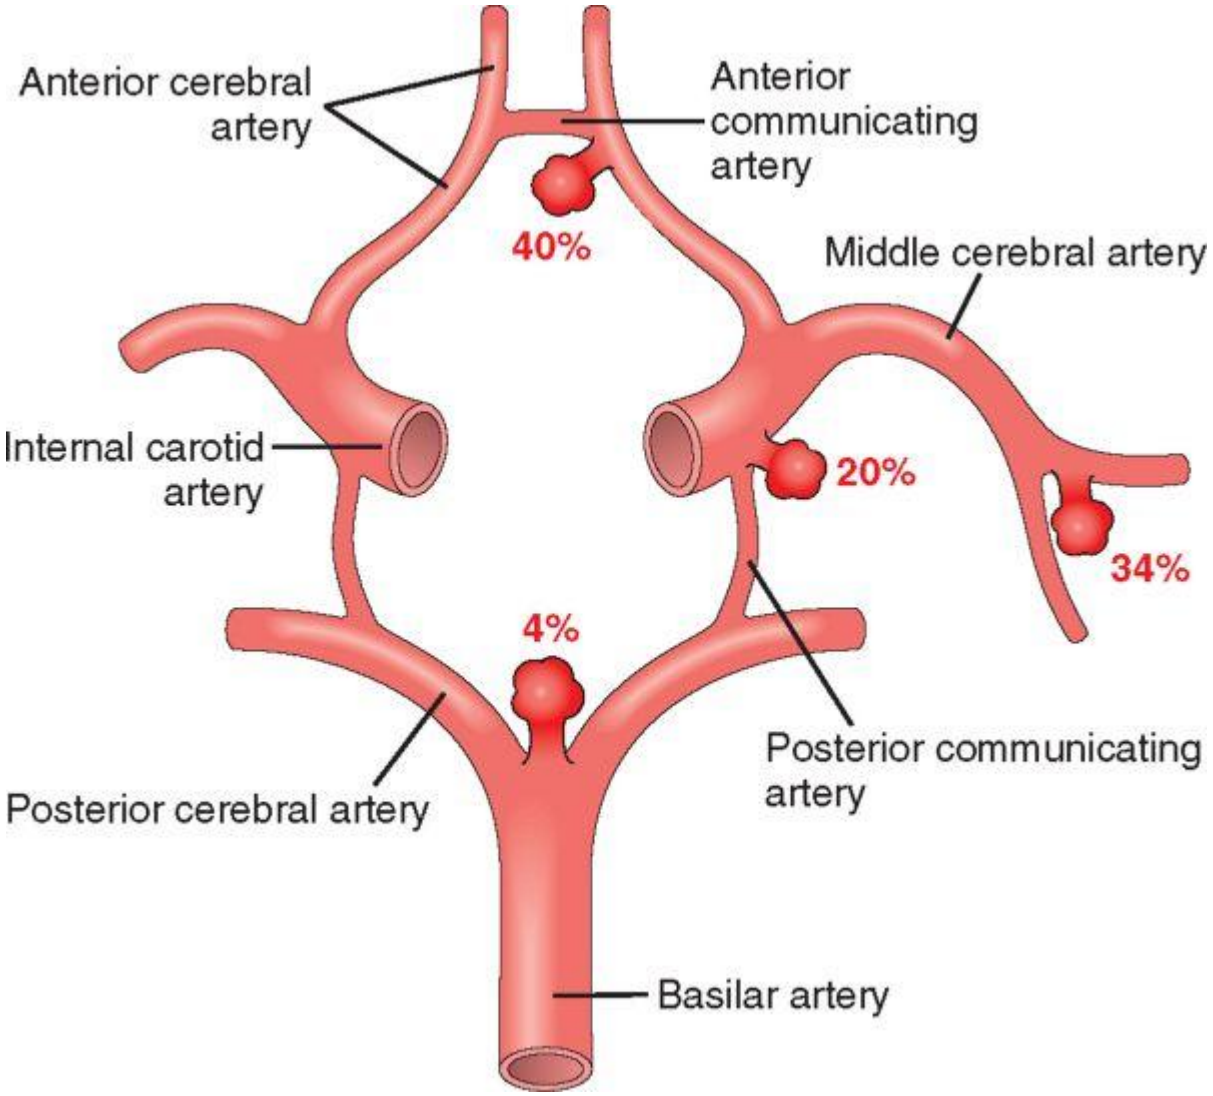

FIGURE 28-19 Common sites of saccular (berry) aneurysms in the circle of Willis.

Pathogenesis of Saccular Aneurysms.

The etiology of saccular aneurysms is unknown. Although the majority occur sporadically, genetic factors may be important in their pathogenesis, since there is an increased incidence of aneurysms in first-degree relatives of those affected. There is also an increased incidence in individuals with certain mendelian disorders (such as autosomal dominant polycystic kidney disease, Ehlers-Danlos syndrome type IV, neurofibromatosis type 1 [NF1], and Marfan syndrome), fibromuscular dysplasia of extracranial arteries, and coarctation of the aorta. The predisposing factors include cigarette smoking and hypertension (estimated to be present in about half of these patients). Although they are sometimes referred to as congenital, theaneurysms are not present at birth but develop over time because of an underlying defect in the media of the vessel.

Morphology. An unruptured saccular aneurysm is a thin-walled outpouching, usually at an arterial branch point along the circle of Willis or a major vessel just beyond. Saccular aneurysms measure

from a few millimeters to 2 or 3 cm in diameter and have a bright red, shiny surface and a thin, translucent wall (Fig. 28-20). Atheromatous plaques, calcification, or thrombotic occlusion of the sac may be found in the wall or lumen of the aneurysm. Brownish discoloration of the adjacent brain and meninges is evidence of prior hemorrhage. The neck of the aneurysm may be either wide or narrow. Rupture usually occurs at the apex of the sac with extravasation of blood into the subarachnoid space, the substance of the brain, or both. The arterial wall adjacent to the neck of the aneurysm often shows some intimal thickening and gradual attenuation of the media as it approaches the neck. At the neck of the aneurysm, the muscular wall and intimal elastic lamina stop short and are absent from the aneurysm sac itself. The sac is made up of thickened hyalinized intima. The adventitia covering the sac is continuous with that of the parent artery.

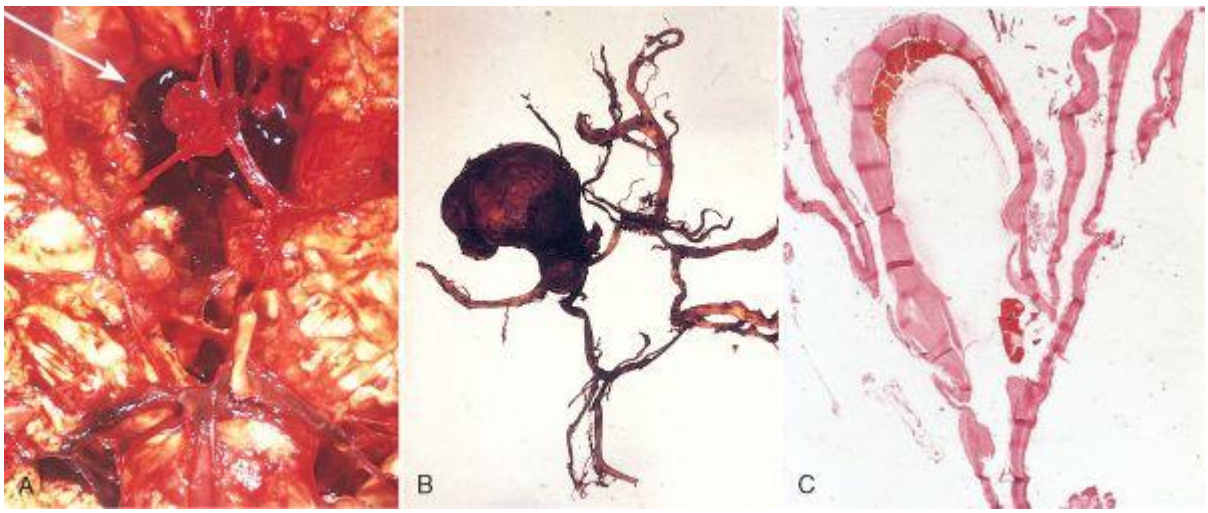

FIGURE 28-20 A, View of the base of the brain, dissected to show the circle of Willis with an aneurysm of the anterior cerebral artery *(arrow)*. **B**, Dissected circle of Willis to show large aneurysm. **C**, Section through a saccular aneurysm showing the hyalinized fibrous vessel wall (H&E).

Clinical Features.

Rupture of an aneurysm with clinically significant subarachnoid hemorrhage is most frequent in the fifth decade and is slightly more frequent in females. Overall, the rate of bleeding is roughly 1.3% per year, with the probability of rupture increasing with the size of the lesion. Aneurysms greater than 10 mm in diameter have a roughly 50% risk of bleeding per year. Rupture may occur at any time, but in about one third of cases it is associated with acute increases in intracranial pressure, such as with straining at stool or sexual orgasm. Blood under arterial pressure is forced into the subarachnoid space and affected individuals are stricken with a sudden, excruciating headache (“the worst headache I've ever had”), rapidly losing consciousness. Between 25% and 50% of patients die with the first rupture, but patients who survive often improve and recover consciousness in minutes. Repeat bleeding is common in survivors, and it is currently not possible to predict in which patients repeat bleeding will occur. With each episode of bleeding, the prognosis is worse.

The clinical consequences of blood in the subarachnoid space can be separated into acute events, occurring within hours to days after the hemorrhage, and late sequelae associated with the healing process. In the first few days after a subarachnoid hemorrhage, regardless of the etiology, there is an increased risk of additional ischemic injury from vasospasm affecting vessels bathed in the extravasated blood. This problem is of greatest significance in cases of basal subarachnoid hemorrhage, in which

vasospasm can involve major vessels of the circle of Willis. Various mediators have been proposed to have a role in this reactive process, including endothelins, nitric oxide, and arachidonic acid metabolites. In the healing phase of subarachnoid hemorrhage, meningeal fibrosis and scarring occur, sometimes leading to obstruction of CSF flow as well as interruption of the normal pathways of CSF resorption.

Vascular Malformations

Vascular malformations of the brain are classified into four principal groups: arteriovenous malformations, cavernous malformations, capillary telangiectasias, and venous angiomas. Of these, the first two are the types associated with risk of hemorrhage and development of neurologic symptoms.

Morphology. Arteriovenous malformations (AVM) involve vessels in the subarachnoid space extending into brain parenchyma or may occur exclusively within the brain. This tangled network of wormlike vascular channels has prominent, pulsatile arteriovenous shunting with high blood flow. They are composed of greatly enlarged blood vessels separated by gliotic tissue, often with evidence of prior hemorrhage. Some vessels can be recognized as arteries with duplication and fragmentation of the internal elastic lamina, while others show marked thickening or partial replacement of the media by hyalinized connective tissue.

Cavernous malformations consist of greatly distended, loosely organized vascular channels with thin, collagenized walls and are devoid of intervening nervous tissue (thus distinguishing them from capillary telangiectasias). They occur most often in the cerebellum, pons, and subcortical regions, in decreasing order of frequency, and have a low flow without arteriovenous shunting. Foci of old hemorrhage, infarction, and calcification frequently surround the abnormal vessels. **Capillary telangiectasias** are microscopic foci of dilated, thin-walled vascular channels separated by relatively normal brain parenchyma and occurring most frequently in the pons. **Venous angiomas** (varices) consist of aggregates of ectatic venous channels. **Foix-Alajouanine disease** (angiodysgenetic necrotizing myelopathy) is a venous angiomatous malformation of the spinal cord and overlying meninges, most often in the lumbosacral region, associated with ischemic myelomalacia and slowly progressive neurologic symptoms.

Clinical Features.

Arteriovenous malformations are the most common type of clinically significant vascular malfor mation. Males are affected twice as frequently as females, and the lesion is often recognized clinically between the ages of 10 and 30 years, presenting as a seizure disorder, an intracerebral hemorrhage, or a subarachnoid hemorrhage. The most common site is the territory of the middle cerebral artery, particularly its posterior branches. Large arteriovenous malformations occurring in the newborn period can lead to congestive heart failure because of shunt effects, especially if the malformation involves the vein of Galen. Cavernous malformations are unique among this class of lesion in that familial forms are relatively common, with a variety of identified genetic loci.[18] Multiplicity of lesions is an additional hallmark of these autosomal dominant disorders with high penetrance.

3.18.7 Infections

With infection, damage to nervous tissue may be the consequence of direct injury of neurons or glia by the infectious agent or may occur indirectly through the elaboration of microbial toxins, destructive effects of the inflammatory response, or the result of immune-mediated mechanisms. There are four principal routes by which infectious microbes enter the nervous system. *Hematogenous spread* is the most common means of entry; infectious agents ordinarily enter through the arterial circulation, but retrograde venous spread can occur through anastomoses with veins of the face. *Direct implantation* of

microorganisms is almost invariably traumatic or is associated with congenital malformations (such as meningomyelocele). *Local extension* can come from any of several adjacent structures (air sinuses, an infected tooth, cranial or spinal osteomyelitis). Transport along the *peripheral nervous system* occurs with certain viruses, such as rabies and herpes zoster. General aspects of the pathology of infectious agents are discussed in Chapter 8 ; here we focus on some of the distinctive forms of CNS infections.

ACUTE MENINGITIS

Meningitis refers to an inflammatory process of the leptomeninges and CSF within the subarachnoid space, while *meningoencephalitis* combines this with inflammation of the brain parenchyma. Meningitis is usually caused by an infection, but may also occur in response to a nonbacterial irritant introduced into the subarachnoid space *(chemical meningitis)*. Infectious meningitis is broadly classified into *acute pyogenic* (usually bacterial meningitis), *aseptic* (usually acute viral meningitis), and *chronic* (usually tuberculous, spirochetal, or cryptococcal) on the basis of the characteristics of inflammatory exudate on CSF examination and the clinical evolution of the illness.

Acute Pyogenic (Bacterial) Meningitis

The microorganisms that cause acute pyogenic meningitis vary with the age of the affected individual. In neonates, they include *Escherichia coli* and the group B streptococci; at the other extreme of life, *Streptococcus pneumoniae* and *Listeria monocytogenes* are more common. Among adolescents and in young adults, *Neisseria meningitidis* is the most common pathogen, with clusters of cases causing frequent public health concerns. The introduction of immunization against *Haemophilus influenzae* has markedly reduced the incidence of meningitis associated with this organism in the developed world; the population that was previously at highest risk (infants) now has a much lower overall risk of meningitis, with *S. pneumoniae* being the most prevalent organism.

Affected individuals typically show systemic signs of infection superimposed on clinical evidence of meningeal irritation and neurologic impairment, including headache, photophobia, irritability, clouding of consciousness, and neck stiffness. A spinal tap yields cloudy or frankly purulent CSF, under increased pressure, with as many as 90,000 neutrophils per cubic millimeter, an increased protein concentration, and a markedly reduced glucose content. Bacteria may be seen on a smear or can be cultured, sometimes a few hours before the neutrophils appear. Untreated pyogenic meningitis can be fatal, while effective antimicrobial agents markedly reduce mortality. The Waterhouse-Friderichsen syndrome results from meningitis-associated septicemia with hemorrhagic infarction of the adrenal glands and cutaneous petechiae (Chapter 24). It occurs most often with meningococcal and pneumococcal meningitis. In the immunosuppressed individual, purulent meningitis may be caused by other agents, such as *Klebsiella* or an anaerobic organism, and may have an atypical course and uncharacteristic CSF findings, all of which make the diagnosis more difficult.

Morphology. The normally clear CSF is cloudy and sometimes frankly purulent. In acute meningitis, an exudate is evident within the leptomeninges over the surface of the brain (Fig. 28-21). The meningeal vessels are engorged and stand out prominently. The location of the exudate varies; in *H. influenzae* meningitis, for example, it is usually basal, whereas in pneumococcal meningitis it is often densest over the cerebral convexities near the sagittal sinus. From the areas of greatest accumulation, tracts of pus can be followed along blood vessels on the surface of the brain. When the meningitis is fulminant, the inflammation may extend to the ventricles, producing ventriculitis.

On microscopic examination, neutrophils fill the subarachnoid space in severely affected areas and are found predominantly around the leptomeningeal blood vessels in less severe cases. In untreated

meningitis, Gram stain reveals varying numbers of the causative organism, although they are frequently not demonstrable in treated cases. In fulminant meningitis, the inflammatory cells infiltrate the walls of the leptomeningeal veins and may extend into the substance of the brain (focal cerebritis). Phlebitis may also lead to venous thrombosis and hemorrhagic infarction of the underlying brain.

Leptomeningeal fibrosis may follow pyogenic meningitis and cause hydrocephalus. In some infections, particularly in pneumococcal meningitis, large quantities of the capsular polysaccharide of the organism produce a particularly gelatinous exudate that encourages arachnoid fibrosis, called **chronic adhesive arachnoiditis**.

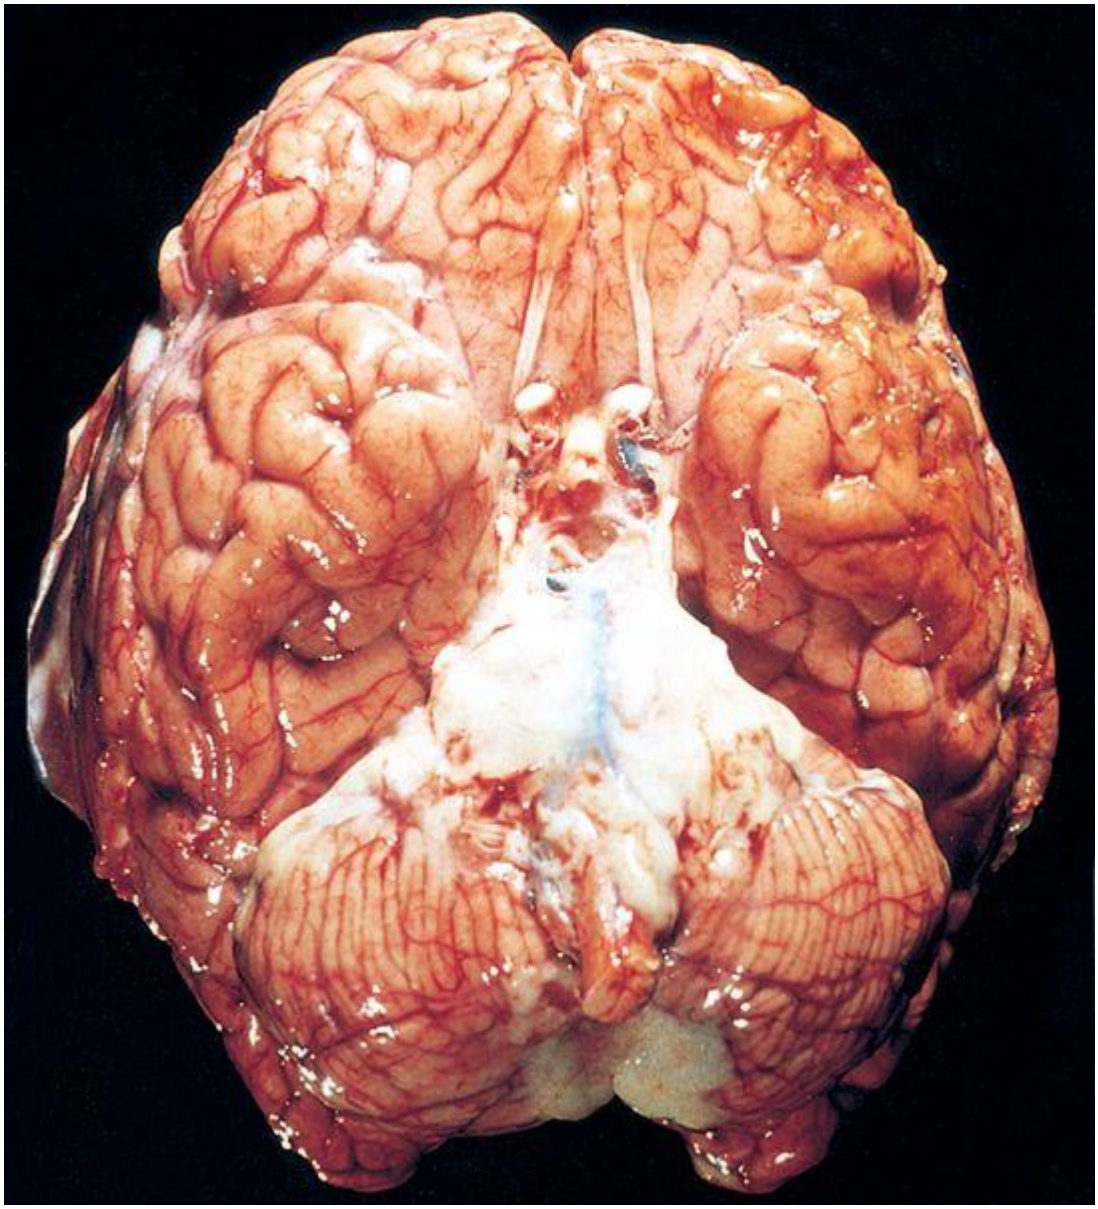

FIGURE 28-21 Pyogenic meningitis. A thick layer of suppurative exudate covers the brainstem and cerebellum and thickens the leptomeninges. *(From Golden JA, Louis DN: Images in clinical medicine: acute bacterial meningitis. N Engl J Med 333:364, 1994.)*

Acute Aseptic (Viral) Meningitis

Aseptic meningitis is a clinical term referring to the absence of recognizable organisms in a patient with meningeal irritation, fever, and alterations of consciousness of relatively acute onset. The name is a misnomer, as the disease is generally of viral, and rarely of bacterial or other, etiology. The clinical course is less fulminant than that of pyogenic meningitis, and the CSF findings also differ; in aseptic meningitis there is a lymphocytic pleocytosis, the protein elevation is only moderate, and the glucose content is nearly always normal. The viral aseptic meningitides are usually self-limiting and are treated symptomatically. Remarkably, even with molecular methods for detection of pathogens, the etiologic agent is identified in only a minority of cases.[19] The spectrum of pathogens varies seasonally and geographically. An aseptic meningitis–like picture may also develop subsequent to rupture of an epidermoid cyst into the subarachnoid space or the introduction of a chemical irritant ("chemical" meningitis). In these cases the CSF is sterile, there is pleocytosis with neutrophils and an increased protein concentration, but the sugar content is usually normal.

ACUTE FOCAL SUPPURATIVE INFECTIONS

Brain Abscess

Brain abscesses may arise by direct implantation of organisms, local extension from adjacent foci (mastoiditis, paranasal sinusitis), or hematogenous spread (usually from a primary site in the heart, lungs, or distal bones or after tooth extraction). Predisposing conditions include *acute bacterial endocarditis*, which tends to produce multiple abscesses; *congenital heart disease* with right-to-left shunting and loss of pulmonary filtration of organisms; *chronic pulmonary sepsis*, as can be seen with bronchiectasis; and *immunosuppression*. Streptococci and staphylococci are the most common offending organisms identified in nonimmunosuppressed populations.

Morphology. Grossly, abscesses are discrete lesions with central liquefactive necrosis surrounded by fibrosis and swelling (Fig. 28-22). On microscopic examination there is exuberant granulation tissue with neovascularization around the necrosis that is responsible for marked vasogenic edema. A collagenous capsule is produced by fibroblasts derived from the walls of blood vessels. Outside the fibrous capsule is a zone of reactive gliosis with numerous gemistocytic astrocytes.

FIGURE 28-22 Frontal abscesses *(arrows)*.

Cerebral abscesses are destructive lesions and patients almost invariably present clinically with progressive focal deficits in addition to the general signs of raised intracranial pressure. The CSF is under increased pressure, the white cell count is raised, and protein concentration is increased, but the glucose content is normal. The source of infection may be apparent, or it may be a small systemic focus that is not symptomatic. The increased intracranial pressure and progressive herniation can be fatal, and abscess rupture can lead to ventriculitis, meningitis, and venous sinus thrombosis. With surgery and antibiotics, the otherwise high mortality rate can be reduced to less than 10%.

Subdural Empyema

Bacterial or occasionally fungal infection of the skull bones or air sinuses can spread to the subdural space, producing a subdural empyema. The underlying arachnoid and subarachnoid spaces are usually unaffected, but a large subdural empyema may produce a mass effect. Further, a thrombophlebitis may develop in the bridging veins that cross the subdural space, resulting in venous occlusion and infarction of the brain. With treatment, including surgical drainage, resolution of the empyema occurs from the dural side, and, if it is comp lete, a thickened dura may be the only residual finding. Symptoms include those referable to the source of the infection. In addition, most patients are febrile, with headache and neck stiffness, and, if untreated, may develop focal neurologic signs, lethargy, and coma. The CSF profile is similar to that seen in brain abscesses, because both are parameningeal infectious processes. If diagnosis and treatment are prompt, complete recovery is usual.

Extradural Abscess

Extradural abscess, commonly associated with osteomyelitis, often arises from an adjacent focus of infection, such as sinusitis or a surgical procedure. When the process occurs in the spinal epidural space, it may cause spinal cord compression and constitute a neurosurgical emergency.

CHRONIC BACTERIAL MENINGOENCEPHALITIS

Chronic bacterial infection of the meninges and the brain may be caused by *M. tuberculosis*, *T. pallidum*, and *Borrelia* species. Each of these is briefly described next.

Tuberculosis

Tuberculosis of the brain may be part of systemic disease or apparently isolated, the brain having been seeded from a silent, usually pulmonary, lesion. It may involve the meninges or the brain, often together.

Morphology. On macroscopic examination, the subarachnoid space contains a gelatinous or fibrinous exudate, most often at the base of the brain, obliterating the cisterns and encasing cranial nerves. There may be discrete, white granules scattered over the leptomeninges. The most common pattern of involvement is a diffuse **meningoencephalitis**. On microscopic examination, there are mixtures of lymphocytes, plasma cells, and macrophages. Florid cases show well-formed granulomas, often with caseous necrosis and giant cells. Arteries running through the subarachnoid space may show **obliterative endarteritis** with inflammatory infiltrates in their walls and marked intimal thickening. Organisms can often be seen with acid-fast stains. The infectious process may spread to the choroid plexus and ependymal surface, traveling through the CSF. In cases of long-standing duration, a dense, fibrous adhesive arachnoiditis may develop, most conspicuous around the base of the brain. Hydrocephalus may result.

Another manifestation of the disease is the development of a single (or often multiple) wellcircumscribed intraparenchymal mass **(tuberculoma)**, which may be associated with meningitis. A tuberculoma may be as large as several centimeters in diameter, causing significant mass effect. On microscopic examination, there is usually a central core of caseous necrosis surrounded by a typical tuberculous granulomatous reaction; calcification may occur in inactive lesions.

Clinical Features.

Patients with tuberculous meningitis usually have symptoms of headache, malaise, mental confusion, and vomiting. There is only a moderate CSF pleocytosis made up of mononuclear cells or a mixture of polymorphonuclear and mononuclear cells; the protein concentration is elevated, often strikingly so; and the glucose content typically is moderately reduced or normal. The most serious complications of chronic tuberculous meningitis are arachnoid fibrosis producing hydrocephalus, and obliterative endarteritis producing arterial occlusion and infarction of underlying brain. When the process involves the spinal cord subarachnoid space, nerve roots may also be affected. With tuberculomas, the symptoms are typical of space-occupying lesions of the brain, and have to be distinguished from CNS tumors.

Infection by *Mycobacterium tuberculosis* in individuals with acquired immunodeficiency syndrome (AIDS) is often similar to that in individuals not suffering from AIDS, but there may be less host reaction. HIV-positive individuals are also at risk for infection by *M. avium-intracellulare*, usually in the setting of disseminated infection. These lesions typically contain confluent sheets of macrophages filled with organisms, with little or no associated granulomatous reaction.

Neurosyphilis

Neurosyphilis is a manifestation of the tertiary stage of syphilis and occurs in only about 10% of individuals with untreated infection. The major patterns of CNS involvement are meningovascular neurosyphilis, paretic neurosyphilis, and tabes dorsalis; affected individuals often show incomplete or mixed pictures, most commonly the combination of tabes dorsalis and paretic disease (taboparesis). Individuals infected with HIV are at increased risk for neurosyphilis, particularly as an acute syphilitic meningitis or meningovascular disease, because of impaired cell-mediated immunity. The rate of progression and severity of the disease seem to be accelerated, possibly for the same reason.

Morphology. Meningovascular neurosyphilis is a chronic meningitis involving the base of the brain and more variably the cerebral convexities and the spinal leptomeninges. In addition, there may be an associated obliterative endarteritis (Heubner arteritis) accompanied by a distinctive perivascular inflammatory reaction rich in plasma cells and lymphocytes. Cerebral gummas (plasma cell–rich mass lesions) may also occur in the meninges and extend into the parenchyma.

Paretic neurosyphilis is caused by invasion of the brain by *Treponema pallidum* and is clinically manifested as insidious but progressive mental deficits associated with mood alterations (including delusions of grandeur) that terminate in severe dementia **(general paresis of the insane)**. On microscopic examination, inflammatory lesions are associated with parenchymal damage in the cerebral cortex (particularly the frontal lobe but also affecting other areas of the isocortex) characterized by loss of neurons, proliferations of microglia (rod cells), gliosis, and iron deposits. The latter are demonstrable with the Prussian blue stain perivascularly and in the neuropil, and are presumably the sequelae of small bleeds stemming from damage to the microcirculation. The spirochetes can, at times, be demonstrated in tissue sections. There is often an associated hydrocephalus with damage to the ependymal lining and proliferation of subependymal glia, called **granular ependymitis**.

Tabes dorsalis is the result of damage by the spirochetes to the sensory nerves in the dorsal roots, which produces impaired joint position sense and resultant ataxia (locomotor ataxia); loss of pain sensation, leading to skin and joint damage (Charcot joints); other sensory disturbances, particularly the characteristic “lightning pains”; and absence of deep tendon reflexes. On microscopic examination there is loss of both axons and myelin in the dorsal roots, with corresponding pallor and atrophy in the dorsal columns of the spinal cord. Organisms are not demonstrable in the cord lesions.

Neuroborreliosis (Lyme Disease)

Lyme disease is caused by the spirochete *Borrelia burgdorferi*, transmitted by various species of *Ixodes* tick; involvement of the nervous system is referred to as neuroborreliosis. Neurologic symptoms are highly variable and include aseptic meningitis, facial nerve palsies and other polyneuropathies, as well as encephalopathy. The rare cases that have come to autopsy have shown a focal proliferation of microglial cells in the brain as well as scattered extracellular organisms (identified by Dieterle stain).

VIRAL MENINGOENCEPHALITIS

Viral encephalitis is a parenchymal infection of the brain almost invariably associated with meningeal inflammation (meningoencephalitis) and sometimes with simultaneous involvement of the spinal cord (encephalomyelitis).

Some viruses tend to infect the nervous system. Such neural tropism takes several forms: some viruses infect specific cell types (such as oligodendrocytes), while others preferentially involve particular areas

of the brain (such as medial temporal lobes or the limbic system). *Latency* is an important facet of several viral infections of the CNS (e.g., herpes zoster, progressive multifocal leukoencephalopathy). Systemic viral infections in the absence of direct evidence of viral penetration into the CNS may be followed by an *immune-mediated disease*, such as perivenous demyelination (see "Acute Disseminated Encephalomyelitis and Acute Necrotizing Hemorrhagic Encephalomyelitis"). Intrauterine viral infection may cause *congenital malformations*, as occurs with rubella. A slowly progressive degenerative disease syndrome may follow many years after a viral illness; an example is *post-encephalitic parkinsonism* after the 1918 viral influenza pandemic.

Arthropod-Borne Viral Encephalitis

Arboviruses are an important cause of epidemic encephalitis, especially in tropical regions of the world, and they are capable of causing serious morbidity and high mortality. In the Western hemisphere the most important types are Eastern and Western equine, West Nile, Venezuelan, St. Louis, and La Crosse; elsewhere in the world, pathogenic arboviruses include Japanese B (Far East), Murray Valley (Australia and New Guinea), and tick-borne (Russia and Eastern Europe). All have animal hosts and mosquito vectors, except for the tick-borne type. Clinically, affected individuals develop generalized neurologic deficits, such as seizures, confusion, delirium, and stupor or coma, and often focal signs, such as reflex asymmetry and ocular palsies. Involvement of the spinal cord in West Nile encephalitis can lead to a polio-like syndrome with paralysis. The CSF is usually colorless but with a slightly elevated pressure and, initially, a neutrophilic pleocytosis that rapidly converts to lymphocytes; the protein concentration is elevated, but glucose content is normal.

Morphology. The encephalitides caused by various arboviruses differ in epidemiology and prognosis, but the histopathologic picture is similar, except for variations in the severity and extent of the lesions within the CNS. Characteristically, there is a lymphocytic meningoencephalitis (sometimes with neutrophils), and a tendency for inflammatory cells to accumulate perivascularly (Fig. 28-23A). Multiple foci of necrosis of gray and white matter are found; in particular, there is evidence of single-cell neuronal necrosis with phagocytosis of the debris **(neuronophagia)**. Microglial cells form small aggregates around foci of necrosis, called **microglial nodules** (Fig. 28-23B). In severe cases there may be a necrotizing vasculitis with associated focal hemorrhages. While some viruses reveal their presence by inclusion bodies, the identification of viral pathogens is most often by a combination of ultrastructural, immunohistochemical, and molecular methods.[19]

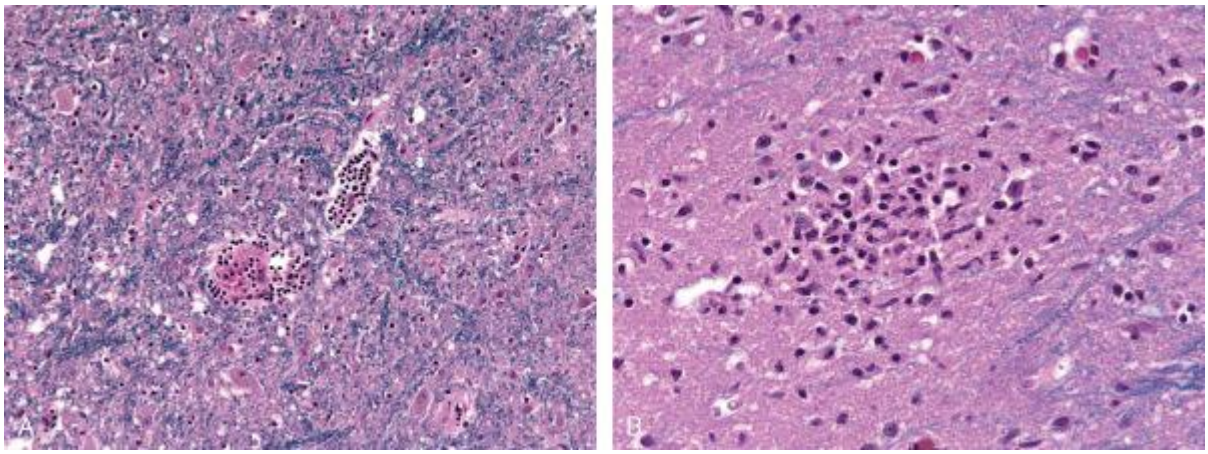

FIGURE 28-23 Characteristic findings of viral encephalitis include perivascular cuffs of lymphocytes (**A**) and microglial nodules (**B**).

Herpes Simplex Virus Type 1

Herpes simplex virus type 1 (HSV-1) encephalitis is most common in children and young adults. Only about 10% of the affected individuals have a history of prior herpes. The most commonly observed clinical presenting symptoms in herpes encephalitis are alterations in mood, memory, and behavior. Polymerase chain reaction (PCR)–based methods for virus detection in CSF samples have increased the ease of diagnosis and the recognition of a subset of patients with less severe disease. Antiviral agents now provide effective treatment in many cases, with a significant reduction in the mortality rate. In some individuals, HSV-1 encephalitis follows a subacute course with clinical manifestations (weakness, lethargy, ataxia, seizures) that evolve during a more protracted period (4 to 6 weeks).

Morphology. This encephalitis starts in, and most severely involves, the inferior and medial regions of the temporal lobes and the orbital gyri of the frontal lobes (Fig. 28-24). The infection is necrotizing and often hemorrhagic in the most severely affected regions. Perivascular inflammatory infiltrates are usually present, and Cowdry type A intranuclear viral inclusion bodies may be found in both neurons and glia. In individuals with slowly evolving HSV-1 encephalitis, there is more diffuse involvement of the brain.

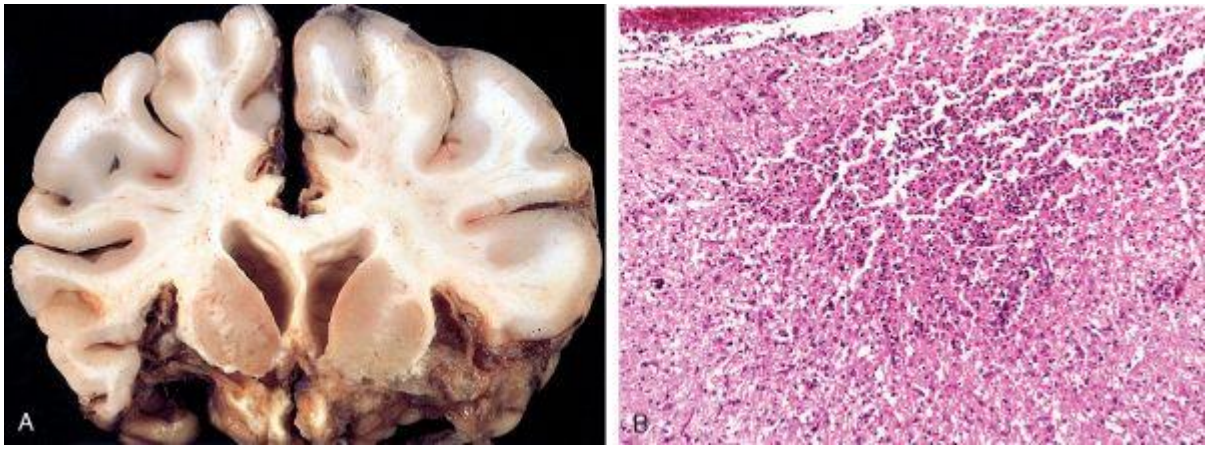

FIGURE 28-24 A, Herpes encephalitis showing extensive destruction of inferior frontal and anterior temporal lobes. **B**, Necrotizing inflammatory process characterizes acute herpes encephalitis. *(**A**, Courtesy of Dr. T.W. Smith, University of Massachusetts Medical School, Worcester, MA.)*

Herpes Simplex Virus Type 2

Herpes simplex virus type 2 (HSV-2) also infects the nervous system; in adults it causes meningitis, but as many as 50% of neonates born by vaginal delivery to women with active *primary* HSV genital infections acquire the infection during passage through the birth canal and develop severe encephalitis. In the face of active HIV infection, HSV-2 may cause an acute, hemorrhagic, necrotizing encephalitis.

Varicella-Zoster Virus (Herpes Zoster)

Primary varicella infection presents as one of the childhood exanthems (chickenpox), ordinarily without any evidence of neurologic involvement. Following the cutaneous infection, the virus enters a latent phase within sensory neurons of the dorsal root or trigeminal ganglia. Reactivation of infection in adults ("shingles") usually manifests as a painful, vesicular skin eruption in a single or limited dermatomal distribution. Herpes zoster reactivation is usually a self-limited process, but there may be a persistent postherpetic neuralgia syndrome particularly after age 60, including both persistent pain as well as painful sensation following nonpainful stimuli.

Overt CNS involvement with herpes zoster is much rarer but can be severe. Herpes zoster has been associated with a granulomatous arteritis; immunocytochemical and electron microscopic evidence of viral involvement has been obtained in a few of these cases. In immunosuppressed individuals, herpes zoster may cause acute encephalitis with numerous sharply circumscribed lesions characterized by demyelination followed by necrosis.

Cytomegalovirus

This infection of the nervous system occurs in fetuses and immunosuppressed individuals. The outcome of infection in utero is periventricular necrosis that produces severe brain destruction followed later by microcephaly and periventricular calcification. CMV is a common opportunistic viral pathogen in individuals with AIDS, with CNS involvement being common in this setting.

Morphology. In the immunosuppressed individual, the most common pattern of involvement is that of a subacute encephalitis, which may be associated with CMV inclusion-bearing cells (see Fig. 8-15). Although any type of cell within the CNS (neurons, glia, ependyma, endothelium) can be infected by CMV, there is a tendency for the virus to localize in the paraventricular subependymal regions of the brain. This results in a severe hemorrhagic necrotizing ventriculoencephalitis and a choroid plexitis. The virus can also attack the lower spinal cord and roots, producing a painful radiculoneuritis. Prominent cytomegalic cells with intranuclear and intracytoplasmic inclusions can be readily identified by conventional light microscopy and confirmed as CMV by immunohistochemistry.

Poliomyelitis

While paralytic poliomyelitis has been effectively eradicated by vaccination in many parts of the world, there are still regions where it remains a problem. In nonimmunized individuals poliovirus infection causes a subclinical or mild gastroenteritis, similar to that caused by other members of the picorna group of enteroviruses. In a small fraction of the vulnerable population, however, it secondarily invades the nervous system.

Morphology. Acute cases show mononuclear cell perivascular cuffs and neuronophagia of the **anterior-horn motor neurons of the spinal cord**. The inflammatory reaction is usually confined to the anterior horns but may extend into the posterior horns, and the damage is occasionally severe enough to produce cavitation. In situ reverse transcriptase–PCR has shown poliovirus RNA in anterior-horn cell motor neurons. The cranial motor nuclei are sometimes involved. Postmortem examination in long-term survivors of symptomatic poliomyelitis shows loss of neurons and gliosis in the affected anterior horns of the spinal cord, some residual inflammation, atrophy of the anterior (motor) spinal roots, and neurogenic atrophy of denervated muscle.

Clinical Features.

CNS infection manifests initially with meningeal irritation and a CSF picture of aseptic meningitis. The disease may progress no further or advance to involve the spinal cord. When the disease affects the motor neurons of the spinal cord, it produces a flaccid paralysis with muscle wasting and hyporeflexia in the corresponding region of the body—the permanent neurologic residue of poliomyelitis. In the acute disease, death can occur from paralysis of the respiratory muscles, and a myocarditis sometimes complicates the clinical course. Because of the destruction of motor neurons, paresis or paralysis follows; when it involves the innervation of the diaphragm and intercostal muscles, severe respiratory compromise may occur and cause long-term morbidity. *Post-polio syndrome* can develop in patients 25 to 35 years after the resolution of the initial illness. It is characterized by progressive weakness associated with decreased muscle mass and pain, and has an unclear pathogenesis.

Rabies

Rabies is a severe encephalitis transmitted to humans by the bite of a rabid animal, usually a dog or various wild mammals that form natural reservoirs. Exposure to certain species of bats, even without a known bite, can also lead to rabies.

Morphology. On macroscopic examination the brain shows intense edema and vascular congestion. On microscopic examination there is widespread neuronal degeneration and an inflammatory reaction that is most severe in the brainstem. The basal ganglia, spinal cord, and dorsal root ganglia may also be involved. **Negri bodies**, the pathognomonic microscopic finding, are cytoplasmic, round to oval, eosinophilic inclusions that can be found in pyramidal neurons of the hippocampus and Purkinje cells of the cerebellum, sites usually devoid of inflammation (Fig. 28-25). The presence of rabies virus can be detected within Negri bodies by ultrastructural and immunohistochemical examination.

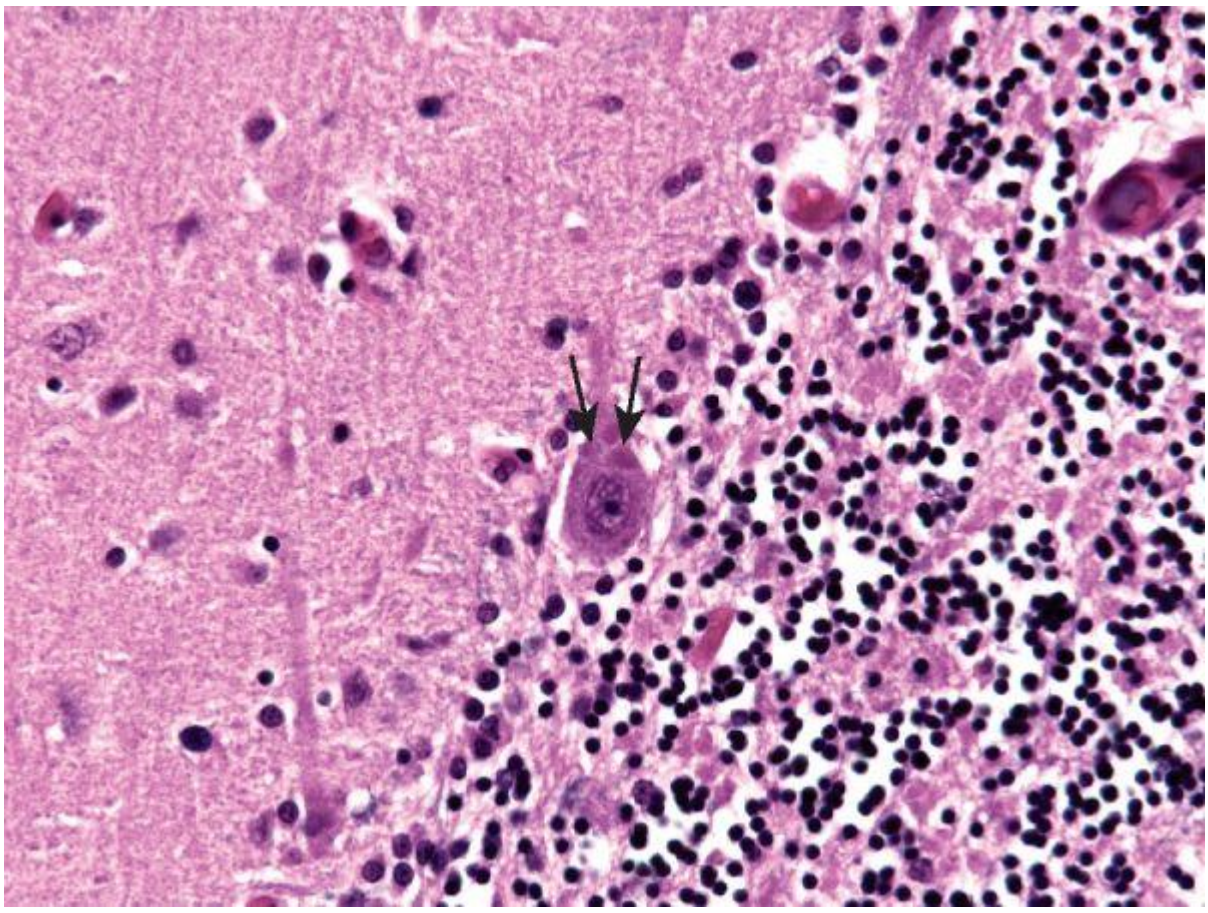

FIGURE 28-25 The diagnostic histologic finding in rabies is the eosinophilic Negri body, as seen here in a Purkinje cell *(arrows)*.

Clinical Features.

Since the virus enters the CNS by ascending along the peripheral nerves from the wound site, the incubation period (commonly between 1 and 3 months) depends on the distance between the wound and the brain. The disease begins with nonspecific symptoms of malaise, headache, and fever, but the conjunction of these symptoms with local paresthesias around the wound is diagnostic. As the infection advances, the affected individual exhibits extraordinary CNS excitability; the slightest touch is painful, with violent motor responses progressing to convulsions. Contracture of the pharyngeal musculature on swallowing produces foaming at the mouth, which may create an aversion to swallowing even water (hydrophobia). There is meningismus and, as the disease progresses, flaccid paralysis. Periods of alternating mania and stupor progress to coma and death from respiratory center failure.

Human Immunodeficiency Virus

In the period before the availability of effective anti-retroviral therapy, neuropathologic changes were demonstrated at postmortem examination in as many as 80% to 90% of cases of AIDS. These included direct effects of virus on the nervous system, opportunistic infections, and primary CNS lymphoma. Since the early days, there has been a decrease in the frequency of these secondary effects of HIV infection, in those who receive intensive multidrug anti-retroviral therapy.[20,][21]

HIV aseptic meningitis occurs within 1 to 2 weeks of seroconversion in about 10% of patients; antibodies to HIV can be demonstrated and the virus can be isolated from the CSF. The few neuropathologic studies of the early and acute phases of symptomatic or asymptomatic HIV invasion of the nervous system have shown a mild lymphocytic meningitis, perivascular inflammation, and some myelin loss in the hemispheres. Among the cell types of the CNS, only microglia have the appropriate combination of CD4 and a chemokine receptor (CCR5 or CXCR4) to allow for efficient infection by HIV.[22] During the chronic phase, an HIV encephalitis is commonly found when symptomatic individuals come to autopsy.

Morphology. HIV encephalitis is best characterized microscopically as a chronic inflammatory reaction with widely distributed infiltrates of **microglial nodules**, sometimes with associated foci of tissue necrosis and reactive gliosis (Fig. 28-26). The microglial nodules are also found in the vicinity of small blood vessels, which show abnormally prominent endothelial cells and perivascular foamy or pigment-laden macrophages. These changes occur especially in the subcortical white matter, diencephalon, and brainstem. An important component of the microglial nodule is the macrophage-derived **multinucleated giant cell**. In some cases there is also a disorder of white matter characterized by multifocal or diffuse areas of myelin pallor, axonal swelling and gliosis. HIV can be detected in CD4+ mononuclear and multinucleated macrophages and microglia by immunoperoxidase and molecular methods.

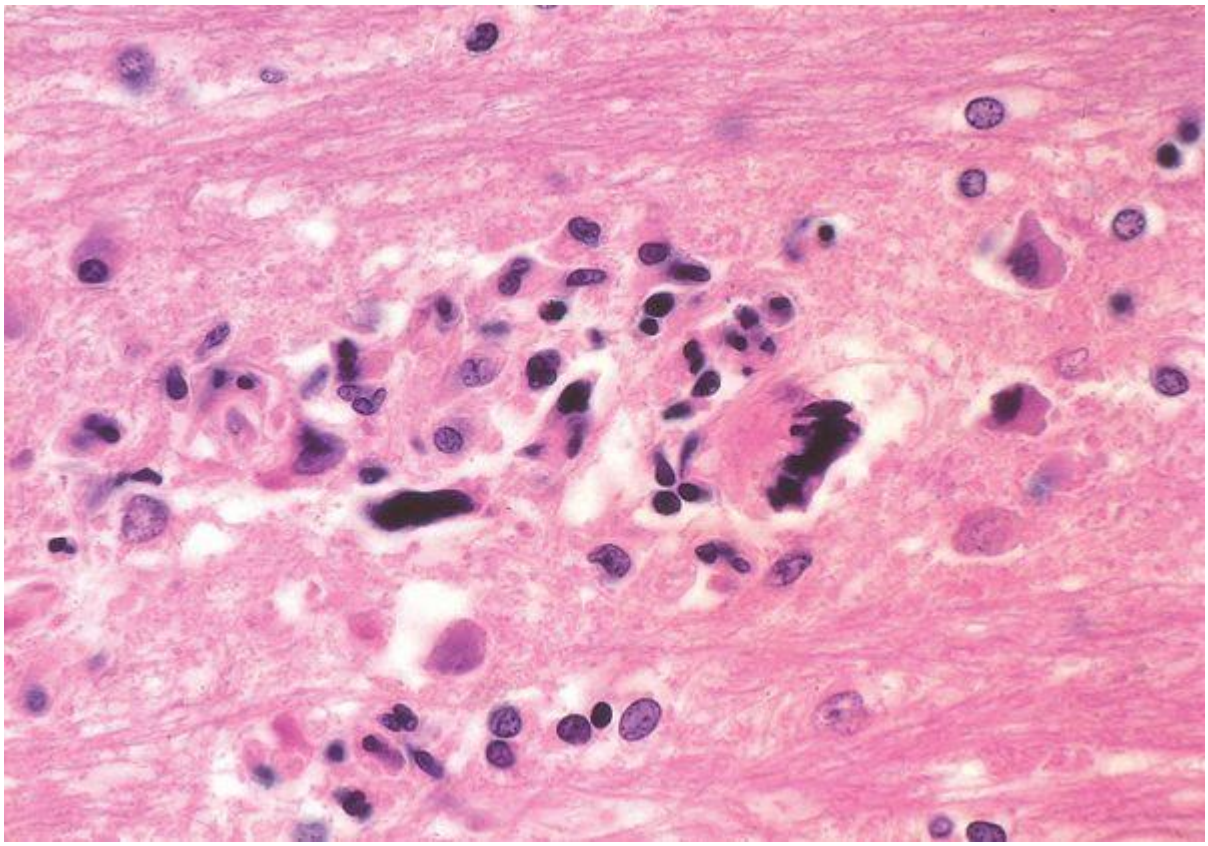

FIGURE 28-26 HIV encephalitis. Note the microglial nodule and multinucleated giant cells.

Cognitive changes, both mild and florid enough to be termed *HIV-associated dementia*, appear to have persisted into the era of effective anti-HIV treatment regimens. Rather than having a specific pathologic lesion as its correlate, this disorder is most tightly related to the extent of activated microglia in the brain, not all of which are necessarily HIV-infected. A wide range of possible mechanisms for neuronal dysfunction and injury in this setting have been proposed, including actions of cytokines and activation of an inflammatory cascade as well as a cavalcade of toxic effects of HIV-derived proteins; in all probability, each of these pathways has a contributory role in the pathogenesis of neural injury (Chapter 6).

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a viral encephalitis caused by the JC polyomavirus; because the virus preferentially infects oligodendrocytes, demyelination is its principal pathologic effect. The disease occurs almost exclusively in immunosuppressed individuals in various clinical settings, including chronic lymphoproliferative or myeloproliferative illnesses, immunosuppressive chemotherapy including monoclonal antibody therapy targeting integrins, granulomatous diseases, and HIV/AIDS.

Although most people have serologic evidence of exposure to JC virus by the age of 14 years, no clinical disease has been associated with primary infection by the virus. It is thought that PML results from the reactivation of virus in the setting of immunosuppression. Clinically, affected individuals

develop focal and relentlessly progressive neurologic symptoms and signs, and imaging studies show extensive, often multifocal, lesions in the hemispheric or cerebellar white matter.

Morphology. The lesions consist of patches of irregular, ill-defined destruction of the white matter ranging in size from millimeters to extensive involvement of an entire lobe of the brain (Fig. 28-27). On microscopic examination the typical lesion consists of a patch of demyelination, most often in a subcortical location, in the center of which are scattered lipid-laden macrophages and a reduced number of axons. At the edge of the lesion are greatly enlarged oligodendrocyte nuclei with glassy amphophilic viral inclusions (Fig. 28-27, *inset*), which contain viral antigens by immunohistochemistry. Within the lesions, there may be bizarre giant astrocytes with one to several irregular, hyperchromatic nuclei mixed with more typical reactive astrocytes.

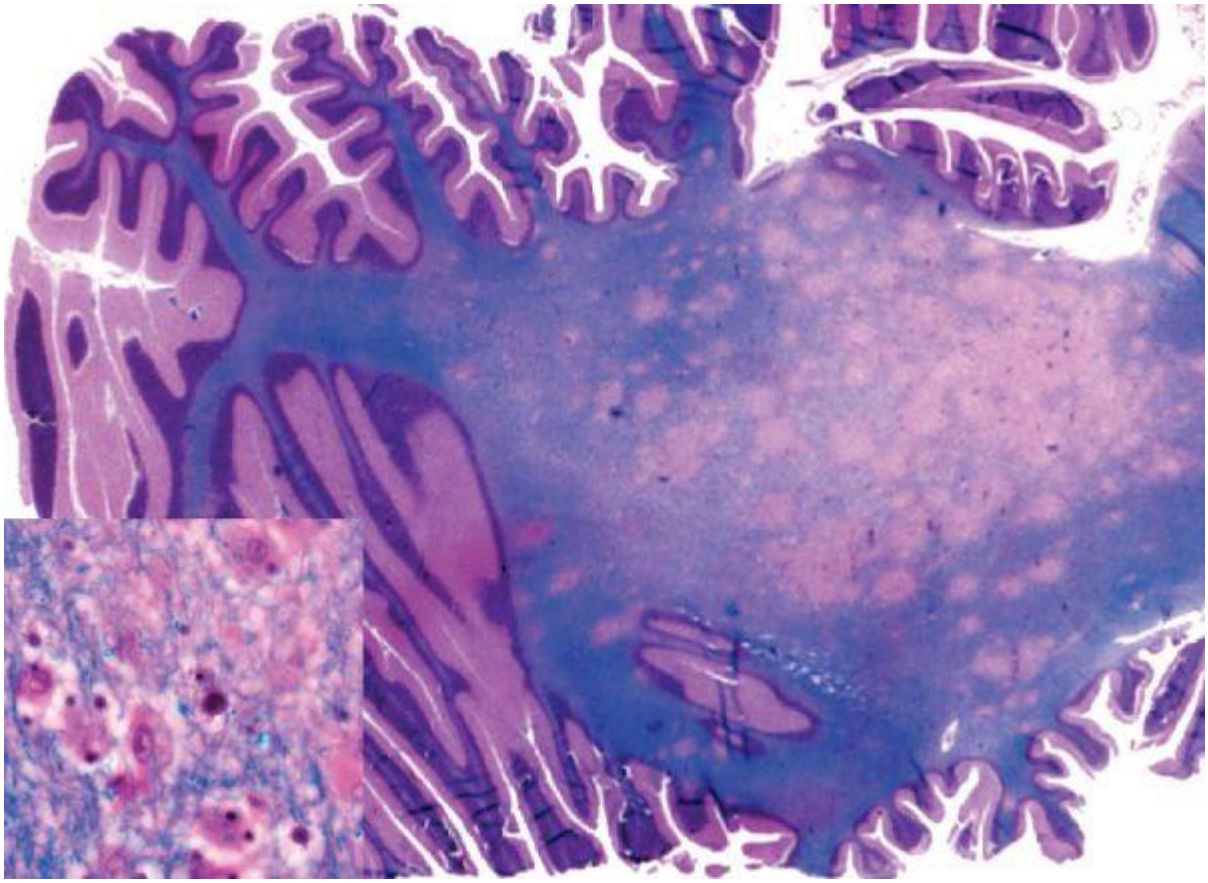

FIGURE 28-27 Progressive multifocal leukoencephalopathy. Section stained for myelin showing irregular, poorly defined areas of demyelination, which become confluent in places. *Inset*, Enlarged oligodendrocyte nucleus represents the effect of viral infection.

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare progressive clinical syndrome characterized by cognitive decline, spasticity of limbs, and seizures. It occurs in children or young adults, months or years after an initial, early-age acute infection with measles. The disease represents persistent, but nonproductive, infection of the CNS by an altered measles virus; changes in several viral genes have been associated with the disease. On microscopic examination, there are widespread gliosis and myelin

degeneration; viral inclusions, largely within the nuclei, of oligodendrocytes and neurons; variable inflammation of white and gray matter; and neurofibrillary tangles. Ultrastructural study shows that the inclusions contain nucleocapsids characteristic of measles; immunohistochemistry for measles virus antigen is positive. The disease has largely disappeared with the spread of vaccination programs; however, there are still cases being reported from nonimmunized populations.

FUNGAL MENINGOENCEPHALITIS

Fungal disease of the CNS is encountered primarily in immunocompromised individuals. The brain is usually involved when there is widespread hematogenous dissemination of the fungus, most often *Candida albicans*, *Mucor species*, *Aspergillus fumigatus*, and *Cryptococcus neoformans*. In endemic areas, pathogens such as *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis* may involve the CNS after a primary pulmonary or cutaneous infection; again, this often follows immunosuppression.

There are three main patterns of fungal infection in the CNS: chronic meningitis, vasculitis, and parenchymal invasion. Vasculitis is most frequently seen with *mucormycosis* and *aspergillosis*, both of which are characterized by direct fungal invasion of blood vessel walls, but it occasionally occurs with other infections such as *candidiasis*. The resultant vascular thrombosis produces infarction that is often strikingly hemorrhagic and that subsequently becomes septic from ingrowth of the causative fungus.

Parenchymal invasion, usually in the form of granulomas or abscesses, can occur with most of the fungi and often coexists with meningitis. The most commonly encountered fungi invading the brain are *Candida* and *Cryptococcus*. *Candidiasis* usually produces multiple microabscesses, with or without granuloma formation. Although most fungi invade the brain by hematogenous dissemination, direct extension may also occur, particularly in *mucormycosis*, most commonly in diabetics with ketoacidosis.

Cryptococcal meningitis, a common opportunistic infection in the setting of HIV/AIDS, may be fulminant and fatal in as little as 2 weeks or indolent, evolving over months or years. The CSF may contain few cells but usually has a high concentration of protein. The mucoid-encapsulated yeasts can be visualized in the CSF by India ink preparations and in tissue sections by PAS, mucicarmine, and silver stains.

Morphology. With cryptococcal infection, the brain shows a chronic meningitis affecting the basal leptomeninges, which are opaque and thickened by reactive connective tissue that may obstruct the outflow of CSF from the foramina of Luschka and Magendie, giving rise to hydrocephalus. Sections of the brain disclose a gelatinous material within the subarachnoid space and small cysts within the parenchyma (“soap bubbles”), which are especially prominent in the basal ganglia in the distribution of the lenticulostriate arteries (Fig. 28-28A). Parenchymal lesions consist of aggregates of organisms within expanded perivascular (Virchow-Robin) spaces associated with minimal or absent inflammation or gliosis (Fig. 28-28B). The meningeal infiltrates consist of chronic inflammatory cells and fibroblasts admixed with cryptococci.

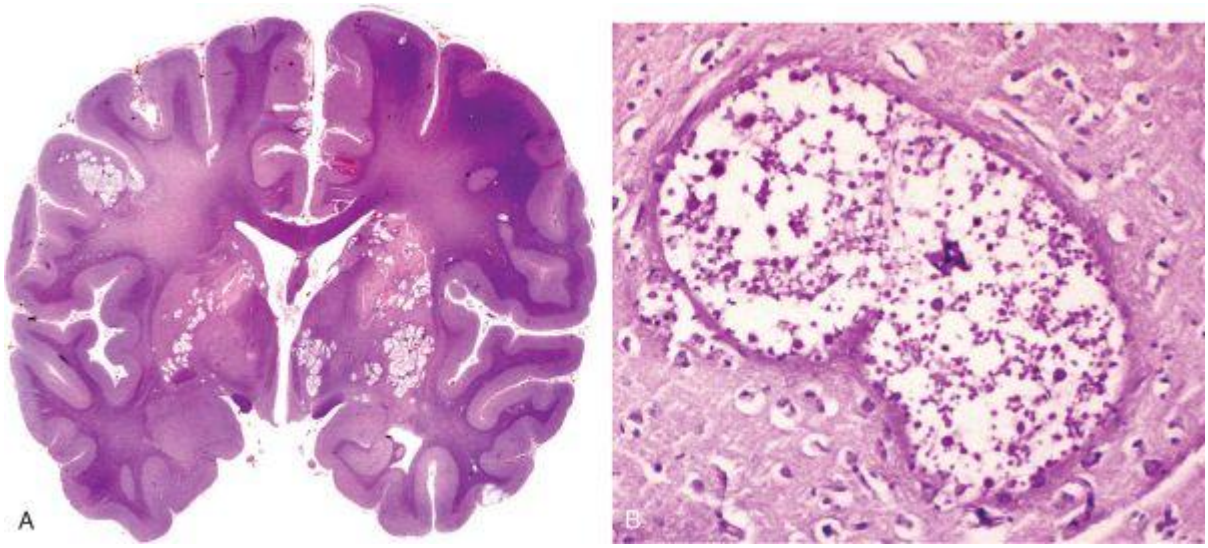

FIGURE 28-28 Cryptococcal infection. **A**, Whole-brain section showing the numerous areas of tissue destruction ("soap bubbles") associated with the spread of organisms in the perivascular spaces. **B**, At higher magnification it is possible to see the cryptococci in the lesions.

OTHER INFECTIOUS DISEASES OF THE NERVOUS SYSTEM

Protozoal diseases (including malaria, toxoplasmosis, amebiasis, and trypanosomiasis), rickettsial infections (such as typhus and Rocky Mountain spotted fever), and metazoal diseases (especially cysticercosis and echinococcosis) may also involve the CNS and are discussed in Chapter 8 .

Cerebral toxoplasmosis is another of the opportunistic infections commonly found in the setting of HIV-associated immunosuppression. The clinical symptoms of infection of the brain by *Toxoplasma gondii* are subacute, evolving during a 1- or 2-week period, and may be both focal and diffuse. Computed tomography and magnetic resonance imaging studies may show multiple ring-enhancing lesions; however, this radiographic appearance is not pathognomonic, since similar findings may be associated with CNS lymphoma, tuberculosis, and fungal infections. In nonimmunosuppressed hosts, the impact of toxoplasmosis on the brain is most often seen when primary maternal infection occurs early in the pregnancy. It may be followed by a cerebritis in the fetus, with the production of multifocal cerebral necrotizing lesions that may calcify, producing severe damage to the developing brain.

Morphology. Toxoplasmosis of the CNS produces brain abscesses, which are found most often in the cerebral cortex (near the gray-white junction) and deep gray nuclei, less often in the cerebellum and brainstem, and rarely in the spinal cord (Fig. 28-29). Acute lesions exhibit central foci of necrosis, petechial hemorrhages surrounded by acute and chronic inflammation, macrophage infiltration, and vascular proliferation. Both free tachyzoites and encysted bradyzoites (Fig. 28-29B) may be found at the periphery of the necrotic foci. The organisms are usually seen on routine H&E or Giemsa stains, but are more easily recognized by immunocytochemical methods. The blood vessels in the vicinity of these lesions may show marked intimal proliferation or even frank vasculitis with fibrinoid necrosis and thrombosis. After treatment, the lesions consist of large, well-demarcated areas of coagulation necrosis surrounded by lipid-laden macrophages. Cysts and free tachyzoites can also be found adjacent to these lesions but may be considerably reduced in number or absent if therapy has been

effective. Chronic lesions consist of small cystic spaces containing scattered lipid- and hemosiderin-laden macrophages that are surrounded by gliotic brain. Organisms are difficult to detect in these older lesions.

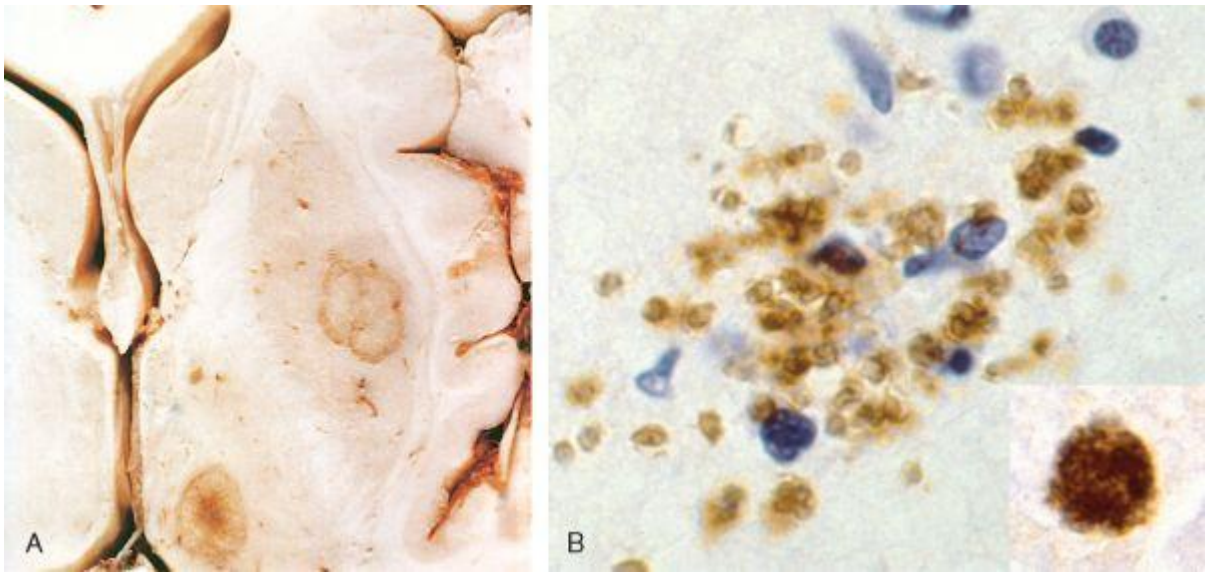

FIGURE 28-29 A, *Toxoplasma* abscesses in the putamen and thalamus. **B**, Free tachyzoites demonstrated by immunostaining; *inset*: *Toxoplasma* pseudocyst with bradyzoites highlighted by immunostaining.

Cerebrial amebiasis.

A rapidly fatal necrotizing encephalitis occurs with infection with *Naegleria* species, and a chronic granulomatous meningoencephalitis has been associated with infection with *Acanthamoeba*. The amebas may sometimes be difficult to distinguish from activated macrophages (Fig. 28-30). Methenamine silver or PAS stains are helpful in visualizing the organisms, although definitive identification ultimately depends on combined immunofluorescence studies, morphology, culture, and molecular methods.

3.18.8 Transmissible Spongiform Encephalopathies (Prion Diseases)

Prions are abnormal forms of a cellular protein that cause transmissible neurodegenerative disorders.[23,][24] This group of diseases—which includes Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker syndrome (GSS), fatal familial insomnia, and kuru in humans; scrapie in sheep and goats; mink-transmissible encephalopathy; chronic wasting disease of deer and elk; and bovine spongiform encephalopathy—share this etiologic basis that distinguishes them from other neurodegenerative and infectious diseases. While differences exist among these disorders, they are all associated with abnormal forms of a specific protein, termed *prion protein* (PrP), that is both infectious and transmissible. As the name implies, they are predominantly characterized by "spongiform change" caused by intracellular vacuoles in neurons and glia. Clinically, most of the affected patients develop progressive dementia. The most common disorder is CJD. The sporadic form of CJD has an annual incidence of approximately 1 case per 1,000,000 population and accounts for about 90% of cases; familial and transmitted forms make up the rest.

Pathogenesis and Molecular Genetics.

Normal PrP is a 30-kD cellular protein present in neurons. Disease occurs when the PrP undergoes a conformational change from its normal α-helix-containing isoform (PrP^{c}) to an abnormal β-pleated sheet isoform, usually termed PrP^{sc} (for scrapie) (Fig. 28-31). Associated with the conformational change, PrP acquires resistance to digestion with proteases, such as proteinase K. Accumulation of PrP^{sc}

in neural tissue seems to be the cause of the pathology in these diseases, but how this material induces the development of cytoplasmic vacuoles and eventual neuronal death is still unknown. Western blotting of tissue extracts after partial digestion with proteinase K allows detection of PrP^{Sc}, which is diagnostic.

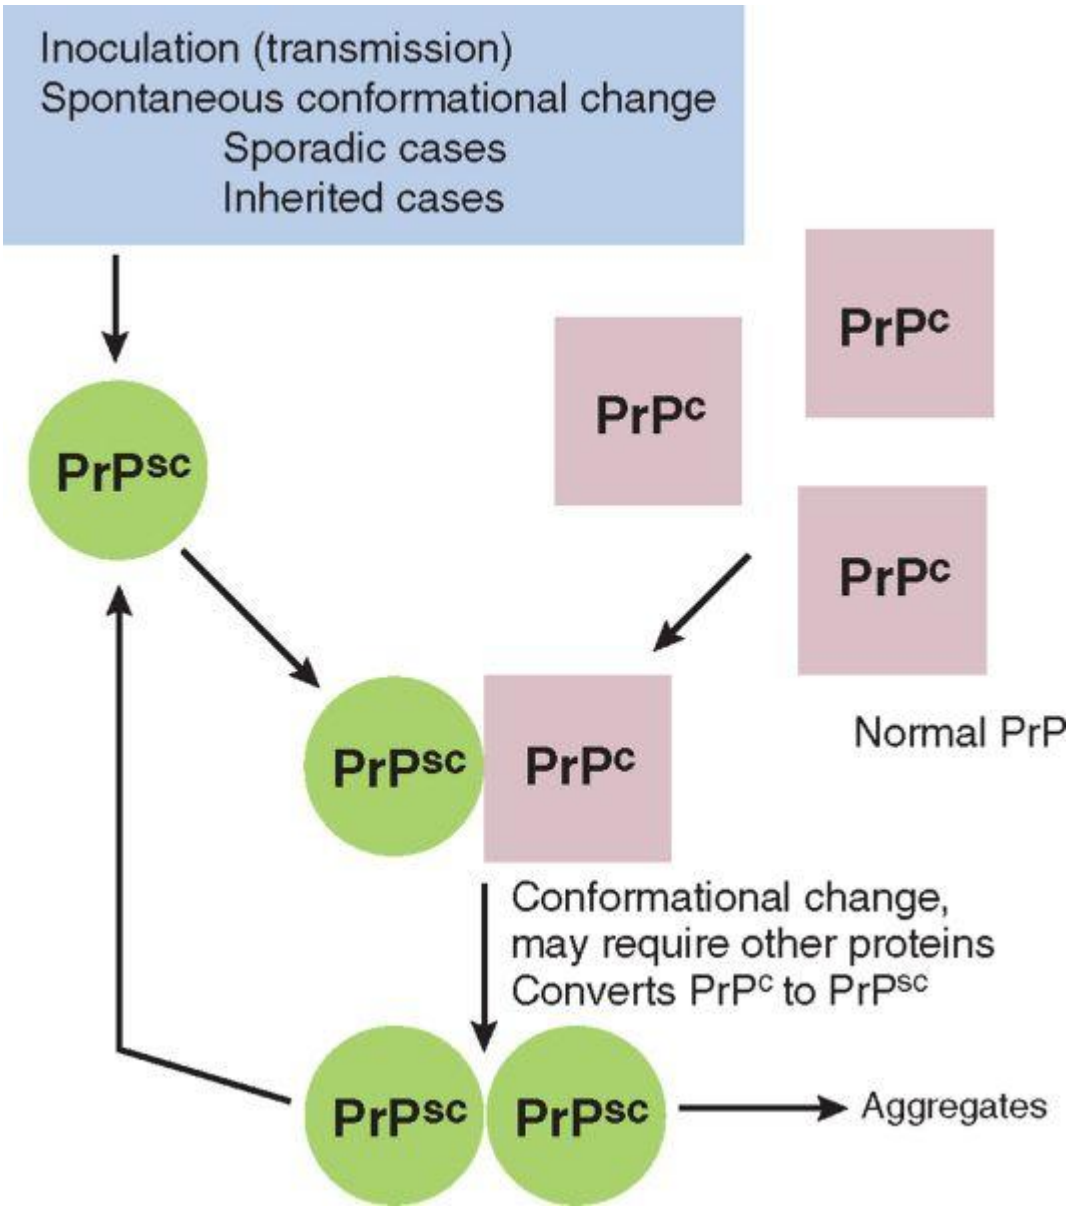

FIGURE 28-31 Proposed mechanism for the conversion of PrP^{c} through protein–protein interactions. The initiating molecules of PrP^{Sc} may arise through inoculation (as in directly transmitted cases) or through an extremely low-rate spontaneous conformational change. The effect of the mutations in PrP^{c} is to increase the rate of the conformational change once PrP^{Sc} is able to recruit and convert other molecules of PrP^{c} into the abnormal form of the protein. Although the model is drawn with no other proteins involved, it is possible that other proteins play critical roles in the conversion of PrP^{c} to PrP^{Sc}.

The conformational change resulting in PrP^{Sc} may occur spontaneously at an extremely low rate (resulting in sporadic cases) or at a higher rate if various mutations are present in PrP^{C}, such as occurs in familial forms of CJD and in GSS and fatal familial insomnia. PrP^{Sc}, independent of the means by which

it originates, then facilitates, in a cooperative fashion, the conversion of other PrP^{c} molecules to PrP^{sc} molecules. It is this activity of PrP^{sc} that accounts for the *infectious* nature of prion diseases.

The gene encoding PrP, termed *PRNP*, shows a high degree of conservation across species. A variety of mutations in *PRNP* have been found to underlie familial forms of prion diseases. In addition, a polymorphism at codon 129 that encodes either methionine (Met) or valine (Val) has been found to influence the disease: individuals who are homozygous for either Met or Val are over-represented among cases of CJD compared with the general population, implying that heterozygosity at codon 129 is protective against development of the disease. Interestingly, this protection also applies against iatrogenic CJD. It has been suggested that the amino-acid at this polymorphic site influences disease by altering the kinetics of aggregation and the conformations of PrP molecules.[25]

Creutzfeldt-Jakob Disease

CJD, the most common prion disease, is a rare disorder that manifests clinically as a rapidly progressive dementia. It is primarily sporadic (about 85% of cases) in its occurrence, and has a worldwide annual incidence of about 1 per million; familial forms also exist that are caused by mutations in *PRNP*. The disease has a peak incidence in the seventh decade. There are well-established cases of iatrogenic transmission, notably by corneal transplantation, deep implantation electrodes, and contaminated preparations of human growth hormone. The clinical onset is marked by subtle changes in memory and behavior followed by a rapidly progressive dementia, often with pronounced involuntary jerking muscle contractions on sudden stimulation (startle myoclonus). Signs of cerebellar dysfunction, usually manifested as ataxia, are present in a minority of affected individuals. The disease is uniformly fatal, with an average survival of only 7 months from the onset of symptoms, although a few patients have lived for several years. These long-surviving cases show extensive atrophy of involved gray matter.

Variant Creutzfeldt-Jakob Disease

Starting in 1995, a series of cases of a CJD-like illness came to medical attention in the United Kingdom. These new cases were different from typical CJD in several important respects: the disease affected young adults, behavioral disorders figured prominently in the early stages of the disease, and the neurologic syndrome progressed more slowly than in individuals with other forms of CJD. The neuropathologic findings and molecular features of these new cases were similar to those of CJD, suggesting a close relationship between the two illnesses. Pathologically, variant CJD (vCJD) is characterized by the presence of extensive cortical plaques with a surrounding halo of spongiform change. No alterations in the *PRNP* gene are present; nearly all affected patients are Met/Met homozygotes at codon 129. With the recent report of a case of vCJD arising in a Val/Val homozygote, the possibility of an influence of codon 129 on incubation period rather than susceptibility has emerged.[26] Several lines of evidence have linked vCJD with bovine spongiform encephalopathy, raising complex public health issues. There has also been documented transmission of vCJD by blood products.

Morphology. The progression of the dementia in CJD is usually so rapid that there is little if any grossly evident brain atrophy. On microscopic examination, the pathognomonic finding is a **spongiform** transformation of the cerebral cortex and, often, deep gray-matter structures (caudate, putamen); this multifocal process results in the uneven formation of small, apparently empty, microscopic vacuoles of varying sizes within the neuropil and sometimes in the perikaryon of neurons (Fig. 28-32A). In advanced cases there is severe neuronal loss, reactive gliosis, and sometimes expansion of the vacuolated areas into cystlike spaces (“status spongiosus”). No inflammatory infiltrate is present. Electron microscopy shows the vacuoles to be membrane-bound and located

within the cytoplasm of neuronal processes. **Kuru plaques** are extracellular deposits of aggregated abnormal protein; they are Congo red- and PASpositive and usually occur in the cerebellum (Fig. 28-32B) although they are present in abundance in the cerebral cortex in cases of vCJD, surrounded by the spongiform changes (Fig. 28-32C). In all forms of prion disease immunohistochemical staining demonstrates the presence of proteinase K–resistant PrP^{Sc} in tissue.

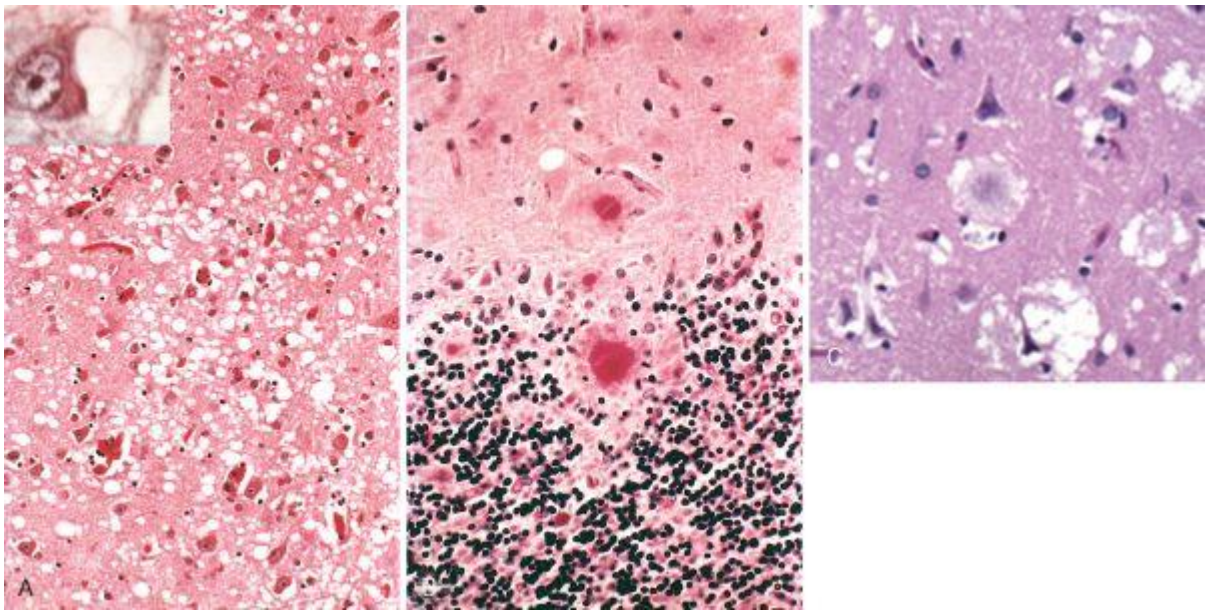

FIGURE 28-32 Prion disease. **A**, Spongiform change in the cerebral cortex. *Inset*, High magnification of neuron with vacuoles. **B**, Cerebellar cortex showing *kuru plaques* (PAS stain) representing aggregated PrP^{sc}. **C**, Cortical plaques surrounded by spongiform change in vCJD.

Fatal Familial Insomnia

Fatal familial insomnia (FFI), named in part for the sleep disturbances that characterize its initial stages, is also caused by a specific mutation in the *PRNP* gene. The mutation, which leads to an aspartate substitution for asparagine at residue 178 of PrP^{C}, results in FFI when it occurs in a *PRNP* allele encoding methionine at codon 129, but causes CJD when present in tandem with a valine at this position. How these amino acids influence disease phenotype is not understood. In the course of the illness, which typically lasts fewer than 3 years, affected individuals develop other neurologic signs, such as ataxia, autonomic disturbances, stupor, and finally coma. A noninherited form of the disorder (fatal sporadic insomnia) has also been described.

Morphology. Unlike other prion diseases, FFI does not show spongiform pathology. Instead, the most striking alteration is neuronal loss and reactive gliosis in the anterior ventral and dorsomedial nuclei of the thalamus; neuronal loss is also prominent in the inferior olivary nuclei. Proteinase K–resistant PrP^{Sc} can be detected by immunostaining or western blotting.

3.18.9 Demyelinating Diseases

Demyelinating diseases of the CNS are acquired conditions characterized by preferential damage to myelin, with relative preservation of axons. The clinical deficits are due to the effect of myelin loss on the transmission of electrical impulses along axons. The natural history of demyelinating diseases is determined, in part, by the limited capacity of the CNS to regenerate normal myelin and by the degree of secondary damage to axons that occurs as the disease runs its course.

Several disease processes can cause loss of myelin. These include destruction of myelin by immunological reactions, as in multiple sclerosis, and by infections. In progressive multifocal leukoencephalopathy, JC virus infection of oligodendrocytes results in loss of myelin (described above). In addition, inherited disorders may affect synthesis or turnover of myelin components; these are termed *leukodystrophies* and are discussed with metabolic disorders.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is an autoimmune demyelinating disorder characterized by distinct episodes of neurologic deficits, separated in time, attributable to white matter lesions that are separated in space. It is the most common of the demyelinating disorders, having a prevalence of approximately 1 per 1000 persons in most of the United States and Europe. The disease may become clinically apparent at any age, although onset in childhood or after age 50 years is relatively rare. Women are affected twice as often as are men. In most individuals with MS, the clinical course takes the form of relapsing and remitting episodes of variable duration (weeks to months to years) marked by neurologic defects, followed by gradual, partial recovery of neurologic function. The frequency of relapses tends to decrease during the course of time, but there is a steady neurologic deterioration in most affected individuals.

Pathogenesis.

The lesions of MS are caused by an immune response that is directed against the components of the myelin sheath.[27,][28] As in other autoimmune disorders, the pathogenesis of this disease involves both genetic and environmental factors (Chapter 6). The incidence of MS is 15-fold higher when the disease is present in a first-degree relative and roughly 150-fold higher with an affected monozygotic twin. Genetic linkage of MS susceptibility to the DR2 extended haplotype of the major histocompatibility complex is also well established. A recent genome-wide screen supported this association and identified additional associations with single-nucleotide polymorphisms in IL-2 and IL-7 receptor genes.[29] The current thinking is that these cytokine receptor polymorphisms may influence the balance between pathogenic effector T cells and protective regulatory T cells. These genetic associations point to the importance of the immune system in the susceptibility to MS.

Given the prominence of chronic inflammatory cells within and around MS plaques as well as this genetic validation, immune mechanisms that underlie the destruction of myelin are the focus of much investigation. The available evidence indicates that the disease is *initiated by CD4+ T_H1 and T_H17 T cells that react against self myelin antigens and secrete cytokines*. T_H1 cells secrete IFNγ, which activates macrophages, and T_H17 cells promote the recruitment of leukocytes (Chapter 6). The demyelination is caused by these activated leukocytes and their injurious products. The infiltrate in plaques and surrounding regions of the brain consists of T cells (mainly CD4+, some CD8+) and macrophages. How the autoimmune reaction is initiated is not understood; a role of viral infection (e.g., EBV) in activating self-reactive T cells has been proposed but remains controversial.

Experimental autoimmune encephalomyelitis is an animal model of MS in which demyelination and inflammation occur after immunization of animals with myelin proteins.[30] Many of our concepts of

MS pathogenesis have been derived from studies in this model. The experimental disorder can be passively transferred to other animals with T_H1 and T_H17 cells that recognize myelin antigens.

Based on the growing understanding of the pathogenesis of MS, therapies are being developed that modulate or inhibit T cell responses and block the recruitment of T cells into the brain. A potential contribution of humoral immunity has also been suspected for a long time, based on the early observation of oligoclonal bands of immunoglobulin in CSF.[31] The demonstration that B-cell depletion can decrease the incidence of demyelinating lesions lends support to this idea.[32]

Morphology. MS is a white matter disease that is best appreciated in sections of the brain and spinal cord. Lesions appear as multiple, well-circumscribed, somewhat depressed, glassy, graytan, irregularly shaped **plaques** (Fig. 28-33). In the fresh state these are firmer than the surrounding white matter **(sclerosis)**. Plaques can be found throughout the white matter and also extend into gray matter, since these have myelinated fibers running through them. The size of lesions varies considerably, from small foci that are only recognizable microscopically to confluent plaques that involve large portions of the centrum semiovale. The lesions often have sharply defined borders (Fig. 28-34). Plaques commonly occur adjacent to the lateral ventricles. They are also frequent in the optic nerves and chiasm, brainstem, ascending and descending fiber tracts, cerebellum, and spinal cord.

Microscopically, in an **active plaque** there is evidence of ongoing myelin breakdown with abundantmacrophages containing lipid-rich, PAS-positive debris. Inflammatory cells, including both lymphocytes and monocytes, are present, mostly as perivascular cuffs, especially at the outer edge of the lesion (Fig. 28-35A). Active lesions are often centered on small veins. Within a plaque there is relative preservation of axons (Fig. 28-35B) and depletion of oligodendrocytes. In time, astrocytes undergo reactive changes. As lesions become quiescent, the inflammatory cells slowly disappear. Within **inactive plaques**, little to no myelin is found, and there is a reduction in the number of oligodendrocyte nuclei; instead, astrocytic proliferation and gliosis are prominent. Axons in old gliotic plaques show severe depletion of myelin and are also greatly diminished in number.

Active plaques can also be grouped into four basic patterns: those that are sharply demarcated and centered on blood vessels, either with (pattern I) or without (pattern II) deposition of immunoglobulin and complement, and those that are less well demarcated and are not centered on vessels (patterns III and IV). These latter two are distinguished by the distribution of oligodendrocyte apoptosis (III, widespread; IV, central only). It has been observed that only one pair of patterns (I/II or III/IV) may be present in a given individual, suggesting that these may reflect distinct mechanisms rather than different stages of lesion.

In some MS plaques (**shadow plaques**) the border between normal and affected white matter is not sharply circumscribed. In this type of lesion some abnormally thinned-out myelin sheaths can be demonstrated, especially at the outer edges. This phenomenon is most commonly interpreted as evidence of partial and incomplete remyelination by surviving oligodendrocytes. Abnormally myelinated fibers have also been observed at the edges of typical plaques. Although these histologic findings suggest a limited potential for remyelination in the CNS, the remaining axons within most MS plaques remain unmyelinated; studies aimed at promoting remyelination are an important focus of research.[33]

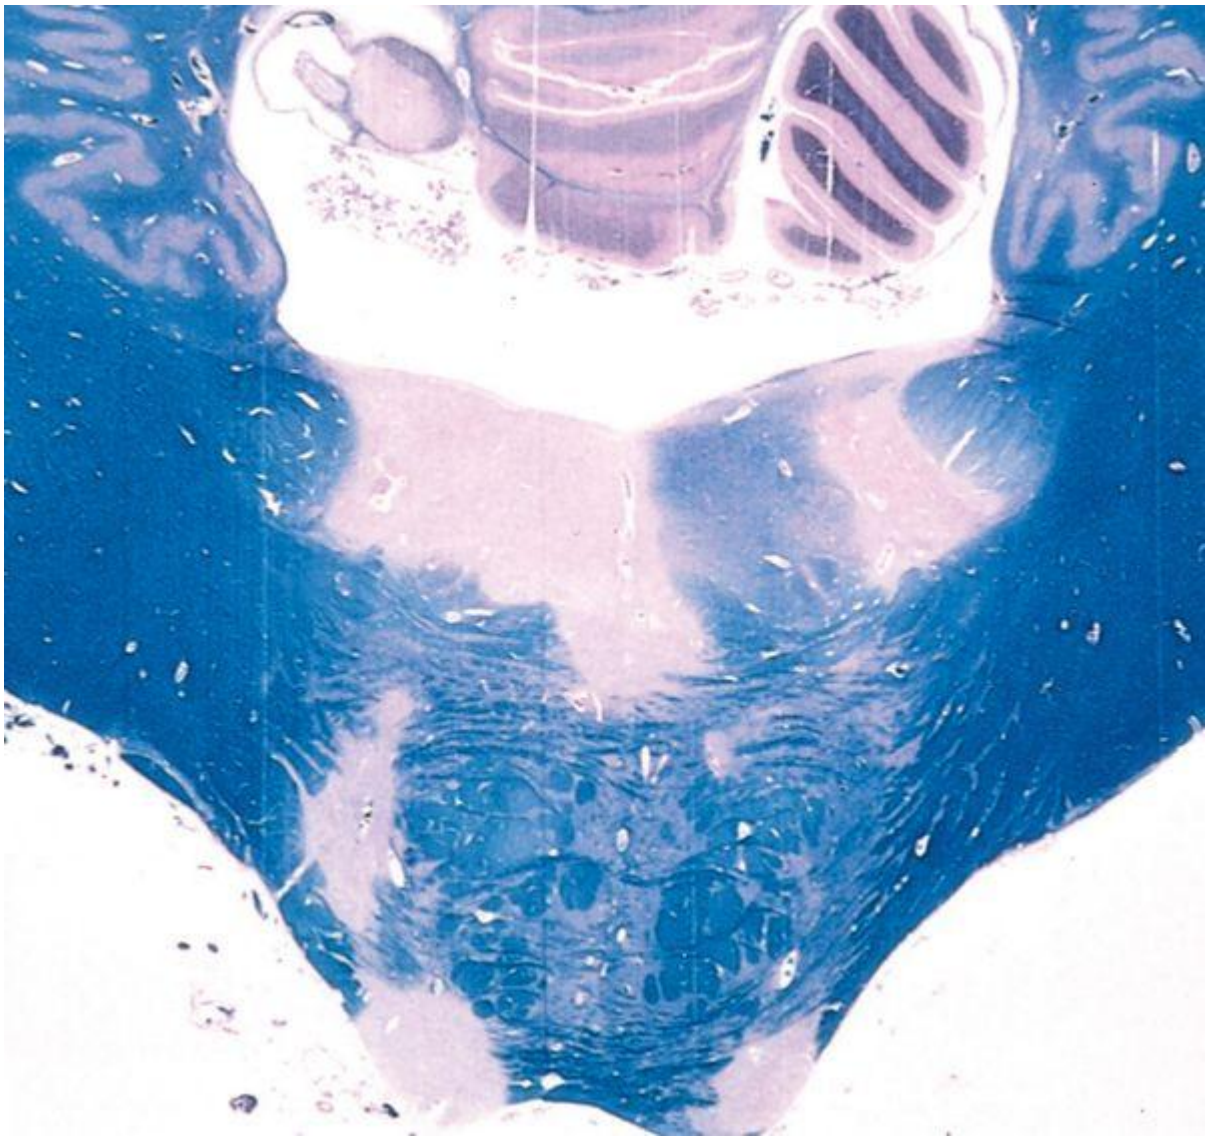

FIGURE 28-34 Multiple sclerosis (MS). Unstained regions of demyelination (MS plaques) around the fourth ventricle (Luxol fast blue PAS stain for myelin).

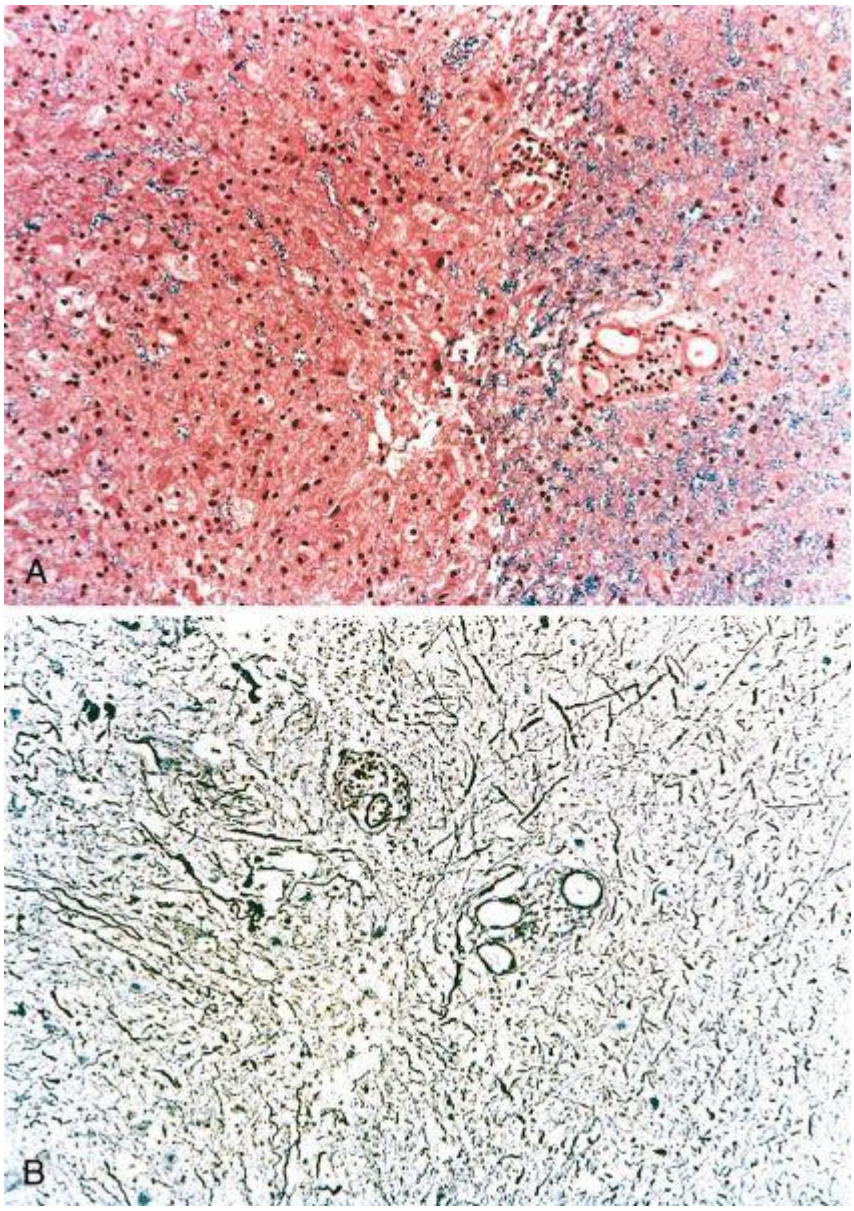

FIGURE 28-35 Multiple sclerosis. **A**, Myelin-stained section shows the sharp edge of a demyelinated plaque and perivascular lymphocytic cuffs. **B**, The same lesion stained for axons shows relative preservation.

Clinical Features.

Although MS lesions can occur anywhere in the CNS and consequently may induce a wide range of clinical manifestations, certain patterns of neurologic symptoms and signs are commonly observed. Unilateral visual impairment, due to involvement of the optic nerve *(optic neuritis, retrobulbar neuritis)*, is a frequent initial manifestation of MS. However, only some affected individuals (10% to 50%, depending on the population studied) with optic neuritis go on to develop MS. Involvement of the brainstem produces cranial nerve signs, ataxia, nystagmus, and internuclear ophthalmoplegia from interruption of the fibers of the medial longitudinal fasciculus. Spinal cord lesions give rise to motor and sensory impairment of trunk and limbs, spasticity, and difficulties with the voluntary control of bladder function. Examination of the CSF in individuals with MS shows a mildly elevated protein level, and in

one third of cases, there is moderate pleocytosis. IgG levels in the CSF are increased and oligoclonal IgG bands are usually observed on immunoelectrophoresis; these are indicative of the presence of a small number of activated B cell clones, postulated to be self-reactive, in the CNS. Radiologic studies using magnetic resonance imaging, typically based on identifying gadolinium-enhancing lesions, have taken on a prominent role in assessing disease progression; these studies, when correlated with autopsy studies as well as clinical findings, have indicated that some plaques may be clinically silent even in otherwise symptomatic patients.

NEUROMYELITIS OPTICA

The development of synchronous (or near synchronous) bilateral optic neuritis and spinal cord demyelination is referred to as *neuromyelitis optica* or *Devic disease*. White cells are common in the CSF, often including neutrophils. Within the damaged areas of white matter, there is typically necrosis, an inflammatory infiltrate including neutrophils, and vascular deposition of immunoglobulin and complement. These lesions have been suggested to be mediated by humoral immune mechanisms.[34] Many affected individuals show antibodies to aquaporins, which are in part responsible for maintenance of astrocytic foot process and thus the integrity of the blood-brain barrier.[35,][36]

ACUTE DISSEMINATED ENCEPHALOMYELITIS AND ACUTE NECROTIZING HEMORRHAGIC ENCEPHALOMYELITIS

Acute disseminated encephalomyelitis (ADEM, perivenous encephalomyelitis) is a diffuse, monophasic demyelinating disease that follows either a viral infection or, rarely, a viral immunization. Symptoms typically develop a week or two after the antecedent infection and include headache, lethargy, and coma rather than focal findings, as seen in MS. The clinical course is rapid, and as many as 20% of those affected die; the remaining patients recover completely.

Acute necrotizing hemorrhagic encephalomyelitis (ANHE, acute hemorrhagic leukoencephalitis of Weston Hurst) is a fulminant syndrome of CNS demyelination, typically affecting young adults and children. The illness is almost invariably preceded by a recent episode of upper respiratory infection, most often of unknown cause. The disease is fatal in many patients, with significant deficits present in most survivors.

Morphology. In ADEM, macroscopic examination of the brain shows only grayish discoloration around white-matter vessels. On microscopic examination, myelin loss with relative preservation of axons can be found throughout the white matter. In the early stages, polymorphonuclear leukocytes can be found within the lesions; later, mononuclear infiltrates predominate. The breakdown of myelin is associated with the accumulation of lipid-laden macrophages. In contrast with MS, all lesions appear similar, consistent with the clinically monophasic nature of the disorder.

ANHE shows histologic similarities with ADEM, including a perivenular distribution of demyelination and widespread dissemination throughout the CNS (sometimes with extensive confluence of lesions). However, the lesions are much more severe than those of ADEM and include destruction of small blood vessels, disseminated necrosis of white and gray matter with acute hemorrhage, fibrin deposition, and abundant neutrophils. Scattered lymphocytes are seen in foci of demyelination.

The lesions of ADEM are similar to those induced by immunization of animals with myelin components or with early rabies vaccines that had been prepared from brains of infected animals. This has suggested

that ADEM may represent an acute autoimmune reaction to myelin and that ANHE may represent a hyperacute variant, although no inciting antigens have been identified.

OTHER DISEASES WITH DEMYELINATION

Central pontine myelinolysis is characterized by loss of myelin (with relative preservation of axons and neuronal cell bodies) in a roughly symmetric pattern involving the basis pontis and portions of the pontine tegmentum but sparing the periventricular and subpial regions.[37] Lesions may be found more rostrally; it is extremely rare for the process to extend below the pontomedullary junction. Extra-pontine lesions occur in the supratentorial compartment, with similar appearance and apparent etiology. The condition is most commonly associated with rapid correction of hyponatremia, although it can be associated with other severe electrolyte or osmolar imbalance, as well as orthotopic liver transplantation. The clinical presentation of central pontine myelinolysis is that of a rapidly evolving quadriplegia; radiologic imaging studies localize the lesion to the basis pontis. Morphologically there is myelin loss without evidence of inflammation; neurons and axons are well preserved. Again, because of the monophasic nature of the disease all lesions appear to be at the same stage of myelin loss and reaction.

3.18.10 Degenerative Diseases

These are diseases of gray matter characterized by the progressive loss of neurons with associated secondary changes in white matter tracts. The pattern of neuronal loss is selective, affecting one or more groups of neurons while leaving others, sometimes immediately adjacent, intact. As genetic and molecular studies of these diseases have progressed certain shared features have emerged. A common theme among the neurodegenerative disorders is the *presence of protein aggregates that are resistant to degradation through the ubiquitin-proteasome system*. These aggregates are recognized histologically as inclusions, which often form the diagnostic hallmarks of these different diseases. The basis for aggregation varies across diseases. It may be directly related to an intrinsic feature of a mutated protein (e.g., expanded polyglutamine repeats in Huntington disease), a feature of a peptide derived from a larger precursor protein (e.g., Aβ in Alzheimer disease), or an unexplained alteration of a normal cellular protein (e.g., α-synuclein in sporadic Parkinson disease).

Degenerative diseases differ in terms of the distribution of disease burden and in the specific neuropathologic findings (e.g., tangles, plaques, Lewy bodies). They can be grouped using two approaches:

- *Symptomatic/anatomic:* based on the anatomic regions of the CNS that are primarily affected, which is typically reflected in the clinical symptoms (e.g., neocortical involvement resulting in cognitive impairment and dementia)
- *Pathologic:* based on the types of inclusions or abnormal structures observed (e.g., diseases with inclusions containing tau or containing synuclein)

The discussion that follows is primarily based on the first approach (diseases of cortex, basal ganglia, etc.) with a few exceptions (all of the tau diseases and the synuclein diseases are considered together).

DEGENERATIVE DISEASES AFFECTING THE CEREBRAL CORTEX

The major cortical degenerative disease is Alzheimer disease, and its principal clinical manifestation is *dementia*, that is, progressive loss of cognitive function independent of the state of attention. There are many other causes of dementia, including the various forms of frontotemporal dementia, vascular disease, dementia with Lewy bodies (considered later in the context of Parkinson disease, the other Lewy body disorder), CJD, and neurosyphilis (both considered earlier). These diseases also involve subcortical structures, but many of the clinical symptoms are related to the changes in the cerebral

cortex. Regardless of etiology, dementia is not part of normal aging and always represents a pathologic process.

Alzheimer Disease

Alzheimer disease (AD) is the most common cause of dementia in the elderly. The disease usually becomes clinically apparent as insidious impairment of higher intellectual function, with alterations in mood and behavior. Later, progressive disorientation, memory loss, and aphasia become manifest, indicating severe cortical dysfunction. Eventually, in 5 to 10 years, the affected individual becomes profoundly disabled, mute, and immobile. Patients rarely become symptomatic before 50 years of age, but the incidence of the disease rises with age, and the prevalence roughly doubles every 5 years, starting from a level of 1% for the 60- to 64-year-old population and reaching 40% or more for the 85- to 89-year-old cohort. This progressive increase in the incidence of the disease with age has given rise to major medical, social, and economic problems in countries with a growing number of elderly individuals. Most cases are sporadic, and although 5% to 10% are familial, the study of such familial cases has provided important insight into the pathogenesis of the more common sporadic form. While pathologic examination of brain tissue remains necessary for the definitive diagnosis of Alzheimer disease, the combination of clinical assessment and modern radiologic methods allows accurate diagnosis in 80% to 90% of cases.

Morphology. Grossly, the brain shows a variable degree of **cortical atrophy** marked by widening of the cerebral sulci that is most pronounced in the frontal, temporal, and parietal lobes (Fig. 28-36). With significant atrophy, there is compensatory ventricular enlargement (hydrocephalus ex vacuo) secondary to loss of parenchyma and reduced brain volume. Structures of the medial temporal lobe, including hippocampus, entorhinal cortex and amygdala, are involved early in the course and are usually severely atrophied in the later stages. The major microscopic abnormalities of AD, which form the basis of the histologic diagnosis, are **neuritic (senile) plaques** and **neurofibrillary tangles**. There is progressive and eventually severe neuronal loss and reactive gliosis in the same regions that bear the burden of plaques and tangles.

Neuritic plaques are focal, spherical collections of dilated, tortuous, neuritic processes (dystrophic neurites) often around a central amyloid core, which may be surrounded by clear halo (Fig. 28-37A). Neuritic plaques range in size from 20 to 200 μm in diameter; microglial cells and reactive astrocytes are present at their periphery. Plaques are found in the hippocampus, amygdala, and neocortex, although there is usually relative sparing of primary motor and sensory cortices (this also applies to neurofibrillary tangles). The amyloid core, which can be stained by Congo Red, contains several abnormal proteins. The dominant component of the amyloid plaque core is **A**β, a peptide derived through specific processing events from a larger molecule, amyloid precursor protein (APP) (Figs. 28-37 and 28-38). The two dominant species of Aβ, called $A\beta_{40}$ and $A\beta_{42}$, share an Nterminus and differ in length by two amino acids at the C-terminus. Other proteins are present in plaques in lesser abundance, including components of the complement cascade, pro-inflammatory cytokines, α_1-antichymotrypsin, and apolipoproteins. In some cases, there is deposition of Aβ peptides with staining characteristics of amyloid in the absence of the surrounding neuritic reaction. These lesions, termed **diffuse plaques**, are found in superficial portions of cerebral cortex as well as in basal ganglia and cerebellar cortex. Diffuse plaques appear to represent an early stage of plaque development. This conclusion is based primarily on studies of brains from individuals with trisomy 21. Recall that in patients with trisomy 21 (Down syndrome), early onset of Alzheimer disease is common (Chapter 5). In some brain regions (cerebellar cortex and striatum) these diffuse plaques represent a major manifestation of the disease, with other clear-cut findings of Alzheimer disease, or in isolation. While neuritic plaques contain both $A\beta_{40}$ and $A\beta_{42}$, diffuse plaques are predominantly made up of $A\beta_{42}$.

Neurofibrillary tangles are bundles of filaments in the cytoplasm of the neurons that displace or encircle the nucleus. In pyramidal neurons, they often have an elongated "flame" shape; in rounder cells, the basket weave of fibers around the nucleus takes on a rounded contour ("globose" tangles). Neurofibrillary tangles are visible as basophilic fibrillary structures with H&E staining (Fig. 28-37C) but are dramatically demonstrated by silver (Bielschowsky) staining (Fig. 28-37D). They are commonly found in cortical neurons, especially in the entorhinal cortex, as well as in other sites such as pyramidal cells of the hippocampus, the amygdala, the basal forebrain, and the raphe nuclei. Neurofibrillary tangles are insoluble and apparently resistant to clearance in vivo, thus remaining visible in tissue sections as "ghost" or "tombstone" tangles long after the death of the parent neuron. Ultrastructurally, neurofibrillary tangles are composed predominantly of paired helical filaments along with some straight filaments that appear to have a comparable composition. A major component of paired helical filaments is abnormally hyperphosphorylated forms of the protein **tau**, an axonal microtubule-associated protein that enhances microtubule assembly (Fig. 28-37E). Other components include MAP2 (another microtubule-associated protein) and ubiquitin. Paired helical filaments are also found in the dystrophic neurites that form the outer portions of neuritic plaques and in axons coursing through the affected gray matter as **neuropil threads**. Tangles are not specific to AD, being found in other diseases as well.

In addition to the diagnostic features of plaques and tangles, several other pathologic findings are seen in the setting of AD. **Cerebral amyloid angiopathy (CAA)** is an almost invariable accompaniment of Alzheimer disease; however, it can also be found in brains of individuals without AD (see Fig. 28-18B). Vascular amyloid is predominantly $A\beta_{40}$, as is also the case when CAA occurs without AD. **Granulovacuolar degeneration** is the formation of small (~5 μm in diameter), clear intraneuronal cytoplasmic vacuoles, each of which contains an argyrophilic granule. While it occurs with normal aging, it is most commonly found in great abundance in hippocampus and olfactory bulb in AD. **Hirano bodies**, found especially in AD, are elongated, glassy, eosinophilic bodies consisting of paracrystalline arrays of beaded filaments, with actin as their major component. They are found most commonly within hippocampal pyramidal cells.

Since both plaques and tangles may be present in low abundance in nondemented individuals, the diagnosis of Alzheimer disease is based on a combination of clinical and pathologic features. The progression of changes is fairly constant. Pathologic changes (specifically plaques, tangles, and the associated neuronal loss and glial reaction) are evident earliest in the entorhinal cortex, then spread through the hippocampal formation and isocortex, and then extend into the neocortex. Plaques are assessed semiquantitatively (absent, sparse, moderate, abundant) in each cortical area, while tangles are assessed based on how widespread they are in the brain.[38,][39] These assessments are combined in the current NIA-Reagan criteria to provide an estimate of the likelihood that AD pathology caused a particular patient's dementia.[40,][41]

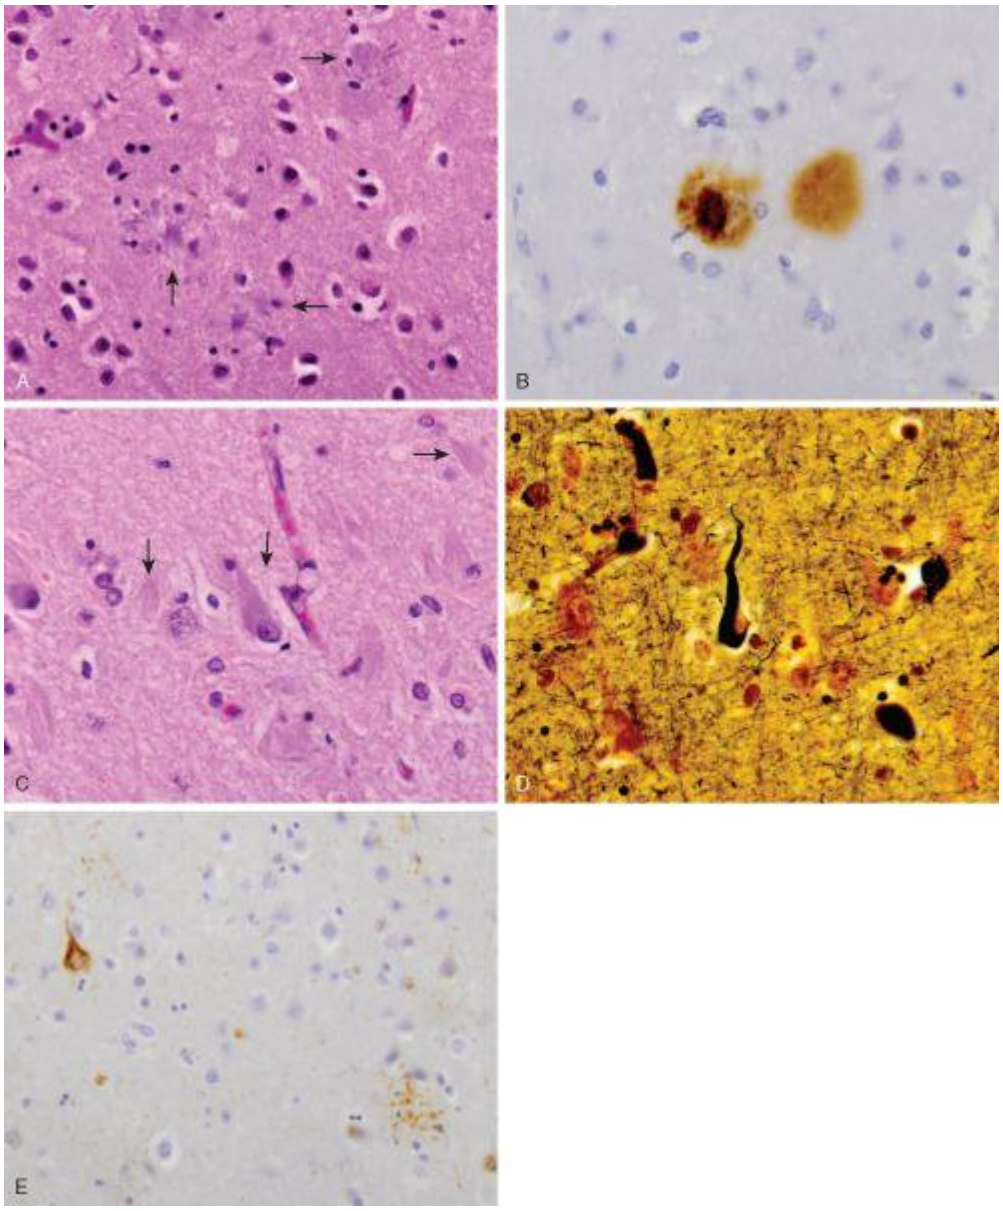

FIGURE 28-37 Alzheimer disease. **A**, Plaques with dystrophic neurites surrounding amyloid cores are visible (*arrows*). **B**, Plaque core and surrounding neuropil are immunoreactive for Aβ. **C**, Neurofibrillary tangle is present within one neuron, and several extracellular tangles are also present (*arrows*). **D**, Silver stain showing a neurofibrillary tangle within the neuronal cytoplasm. **E**, Tangle *(upper left)* and neurites around a plaque *(lower right)* contain tau, demonstrated by immunohistochemistry.

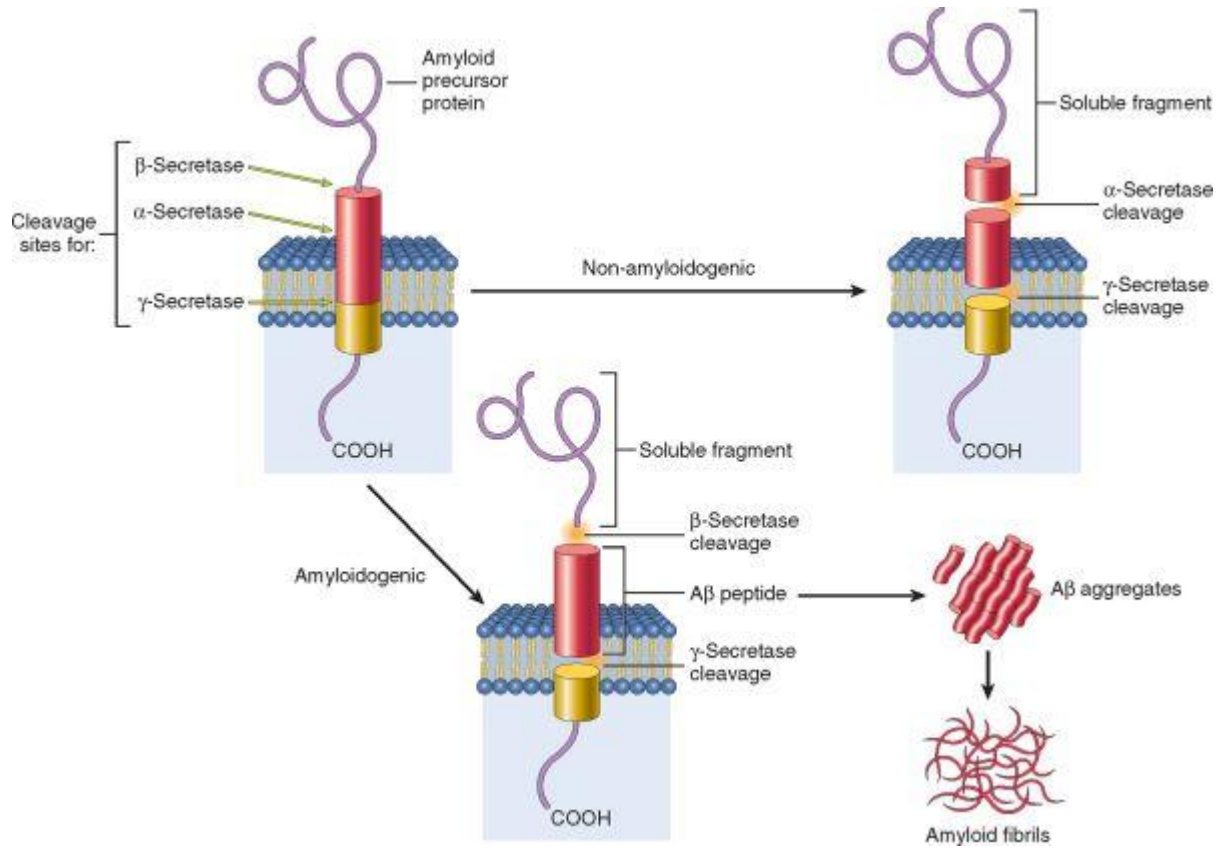

FIGURE 28-38 Mechanisms of processing of amyloid precursor protein (APP). APP can be processed by two pathways; sequential cleavage by β-secretase and γ-secretase is the pathway that results in the generation of Aβ and the formation of amyloid fibrils.

Molecular Genetics and Pathogenesis.

The fundamental abnormality in AD is the deposition of Aβ peptides, which are derived through processing of APP (Fig. 28-38). APP is a cell surface protein with a single transmembrane domain that may function as a receptor, although ligands have remained elusive. The Aβ portion of the protein extends from the extracellular region into the transmembrane domain. Processing of APP begins with cleavage in the extracellular domain, followed by an intramembranous cleavage. There are two potential pathways, determined by the type of initial proteolytic event. If the first cut occurs at the α-secretase site within the Aβ sequence, then Aβ is not generated (the nonamyloidogenic pathway). This mostly occurs at the cell surface, since the various enzymes with α-secretase activity are involved in the shedding of surface proteins. Surface APP can also be endocytosed and may undergo cleavage by β-secretase, which cuts at the N-terminal region of the Aβ sequence (the amyloidogenic pathway). Following cleavage of APP at either of these sites, the γ-secretase complex performs an intramembranous cleavage. When paired with a first cut by α-secretase, it will produce a soluble fragment, but when paired with β-secretase cleavage, it generates Aβ. The variation in peptide length ($A\beta_{40}$ vs $A\beta_{42}$) arises from alterations in the exact location of the γ-secretase cleavage. The γ-secretase complex—containing presenilin, nicastrin, pen-2, and aph-1—is also responsible for processing of Notch, a cell fate-determining molecule, as well as many other membrane proteins.[42] Once generated, Aβ is highly prone to aggregation—first into small oligomers (which may be the toxic form responsible for neuronal dysfunction), and eventually into large aggregates and fibrils.

Familial forms of AD have provided support for the central role of Aβ generation as a critical step for at least initiation of AD pathogenesis. The gene encoding APP, on chromosome 21, lies in the Down syndrome region; AD pathology is an eventual feature of the cognitive impairment of these individuals. Histologic findings appear in the second and third decades followed by neurologic decline about 20 years later. A similar gene dosage effect is produced by localized chromosome 21 duplications that span the APP locus in some patients with familial AD.[44] Point mutations in APP are another cause of familial AD. Some mutations lie near the β-secretase and γ-secretase cleavage sites, and others sit in the Aβ sequence and increase its propensity to aggregate. The two loci identified as causes of the majority of early-onset familial AD encode the two presenilins (PS1 on chromosome 14 and PS2 on chromosome 1). These mutations lead to a gain of function, such that the γ-secretase complex generates increased amounts of Aβ, particularly $A\beta_{42}$. Thus, the genetic evidence strongly supports the notion that the underlying pathogenetic event in AD is the accumulation of Aβ.

The Aβ peptides readily aggregate, and can be directly neurotoxic. There are various lines of evidence indicating that the small aggregates of Aβ can result in synaptic dysfunction, such as blocking of long-term potentiation and changes in other membrane properties.[4] While aggregates are difficult to degrade, monomeric Aβ can be degraded by a variety of proteases. Both small aggregates and larger deposits elicit an *inflammatory response* from microglia and astrocytes. This response probably assists in the clearance of the aggregated peptide, but may also stimulate the secretion of mediators that cause damage.[43] Additional consequences of the activation of these inflammatory cascades may include alterations in tau phophosrylation, along with oxidative injury to the neurons.

The genetic locus on chromosome 19 that encodes apolipoprotein E (ApoE) has a strong influence on the risk of developing AD. Three alleles exist (ε2, ε3, and ε4) based on two amino acid polymorphisms. The dosage of the ε4 allele increases the risk of AD and lowers the age of onset of the disease, such that individuals with the ε4 allele are over-represented in populations of patients with AD. This ApoE isoform promotes Aβ generation and deposition, although the mechanisms have not been established. Overall, this locus has been estimated to convey about a quarter of the risk for development of sporadic AD. It is likely that other risk factor alleles will have much smaller population effects.[45] The newly evolving approach of genome-wide association screening may help locate these loci with weaker effects.[46]

Because neurofibrillary tangles contain the tau protein, there has been much interest in the role of this protein in AD. Tau is a microtubule-associated protein present in axons in association with the microtubular network. With the development of tangles in AD, it shifts to a somatic-dendritic distribution, becomes hyperphosphorylated, and loses the ability to bind to microtubules. It is, however, thought that the primary abnormality in AD is in Aβ and not in tau, because mutations affecting Aβ lead to the formation of tangles and AD but mutations in the gene encoding tau, *MAPT*, cause one of the frontotemporal demential (see below) but neither Aβ deposition nor AD. The mechanism of tangle injury to neurons remains poorly understood.

While there remains disagreement regarding the best correlate of dementia in individuals with AD, it is clear that the presence of a large burden of plaques and tangles is highly associated with severe cognitive dysfunction. The number of neurofibrillary tangles correlates better with the degree of dementia than does the number of neuritic plaques. Biochemical markers that have been correlated with the degree of dementia include loss of choline acetyltransferase, synaptophysin immunoreactivity, and amyloid burden.

Clinical Features.

The progression of AD is slow but relentless, with a symptomatic course often running more than 10 years. Initial symptoms are forgetfulness and other memory disturbances; with progression of the

disease other symptoms emerge, including language deficits, loss of mathematical skills, and loss of learned motor skills. In the final stages of AD, affected individuals may become incontinent, mute, and unable to walk. Intercurrent disease, often pneumonia, is usually the terminal event in these individuals. Discovery of biomarkers for AD is an area of continuing interest; the amyloid-binding positron emission tomography imaging agent PiB is beginning to be used for this purpose.[47,][48]

Frontotemporal Dementias

Frontotemporal dementias (FTDs) are a group of disorders that were first classified together because they shared clinical features (progressive deterioration of language and changes in personality) corresponding to degeneration and atrophy of temporal and frontal lobes.[49] These entities have recently been better understood through a combination of immunohistochemical and biochemical, and genetic approaches. Several of the disorders to be considered share the accumulation of tau-containing deposits as their characteristic finding, giving rise to the term *tauopathy*.

Frontotemporal Dementia with Parkinsonism Linked to Tau Mutations

This is a genetically determined disorder in which the clinical syndrome of a FTD is often accompanied by parkinsonian symptoms.

Pathogenesis and Molecular Genetics.

The study of families with FTD led to the recognition that in some, but not all, pedigrees there are mutations in the *MAPT* gene encoding tau. The mutations fall into several broad categories: coding-region mutations and intronic mutations. The tau protein has six splice forms. When exon 10 is present, the protein contains four microtubule-binding domains (called 4R), and in its absence there are three such domains (3R). Some of the intronic mutations influence the inclusion of this exon and thus determine the form of the protein that is produced. The ratio of the 4R to 3R form varies in different diseases but the basis of this effect is unknown and both forms can produce tangles. Coding-region mutations seem to have several different consequences, including alterations in the interaction of tau with microtubules and in the intrinsic tendency of tau to aggregate.

Morphology. There is evidence of atrophy of frontal and temporal lobes in various combinations and to various degrees. The pattern of atrophy can often be predicted in part by the clinical symptomatology. The atrophic regions of cortex are marked by neuronal loss, gliosis, and the presence of tau-containing neurofibrillary tangles. These tangles may contain either 4R tau or a mixture of 3R and 4R tau. Nigral degeneration may also occur. Inclusions can also be found in glial cells in some forms of the disease.

Pick Disease

Pick disease (lobar atrophy) is a rare, distinct, progressive dementia characterized clinically by early onset of behavioral changes together with alterations in personality (frontal lobe signs) and language disturbances (temporal lobe signs). While most cases of Pick disease are sporadic, there have been some familial forms identified and linked to mutated tau protein.

Morphology. The brain invariably shows a pronounced, frequently asymmetric, atrophy of the frontal and temporal lobes with conspicuous sparing of the posterior two thirds of the superior temporal gyrus and only rare involvement of either the parietal or occipital lobe. The atrophy can be severe, reducing the gyri to a wafer-thin (“knife-edge”) appearance. This pattern of **lobar atrophy** is often

prominent enough to distinguish Pick disease from AD on gross examination. In addition to the localized cortical atrophy there may also be bilateral atrophy of the caudate nucleus and putamen.

Microscopically, neuronal loss is most severe in the outer three layers of the cortex. Some of the surviving neurons show a characteristic swelling **(Pick cells)**, while others contain **Pick bodies**, which are cytoplasmic, round to oval, filamentous inclusions that are only weakly basophilic but stain strongly with silver methods (Fig. 28-39). Ultrastructurally, these are composed of straight filaments, vesiculated endoplasmic reticulum, and paired helical filaments that are immunocytochemically similar to those found in AD, and contain 3R tau. Unlike the neurofibrillary tangles of AD, Pick bodies do not survive the death of their host neuron and do not remain as markers of the disease.

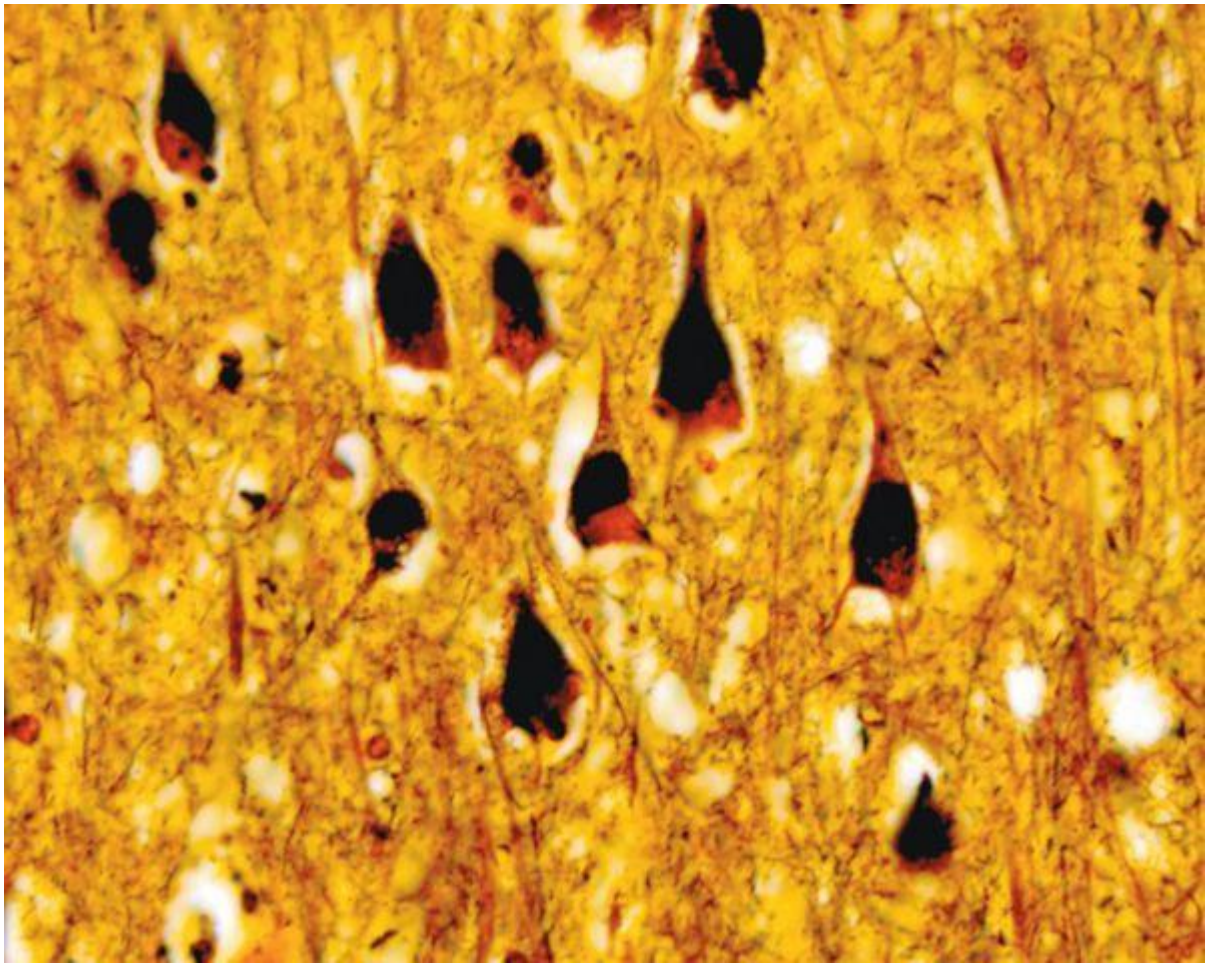

FIGURE 28-39 Pick disease. Pick bodies are round homogeneous neuronal cytoplasmic inclusions that stain intensely with silver stains.

Progressive Supranuclear Palsy

Progressive supranuclear palsy is an illness characterized clinically by truncal rigidity with dysequilibrium and nuchal dystonia; pseudobulbar palsy and abnormal speech; ocular disturbances, including vertical gaze palsy progressing to difficulty with all eye movements; and mild progressive dementia in most affected individuals. The onset of the disease is usually between the fifth and seventh

decades, and males are affected approximately twice as frequently as are females. The disease is often fatal within 5 to 7 years of onset.

Morphology. There is widespread neuronal loss in the globus pallidus, subthalamic nucleus, substantia nigra, colliculi, periaqueductal gray matter, and dentate nucleus of the cerebellum. Globose neurofibrillary tangles are found in these affected regions, in neurons as well as in glia. Ultrastructural analysis reveals 15-nm straight filaments that are composed of 4R tau.

Mutations in the *MAPT* gene have not been found in progressive supranuclear palsy. However, *MAPT* contains a series of polymorphisms in linkage dysequilibrium that fall into two haplotypes, one of which is highly over-represented in individuals with progressive supranuclear palsy. How this haplotype influences the risk of the disease is unknown.

Corticobasal Degeneration

This is a disease of the elderly, with considerable clinical and neuropathologicheterogeneity. Because of the extrapyramidal signs and symptoms in this disorder, it can also be grouped with syndromes of basal ganglia dysfunction.

Morphology. On macroscopic examination there is cortical atrophy, mainly of the motor, premotor, and anterior parietal lobes. These regions of cortex show severe loss of neurons, gliosis, and **"ballooned" neurons** (neuronal achromasia) that can be highlighted with immunocytochemical methods for phosphorylated neurofilaments. Tau immunoreactivity has been found in astrocytes ("tufted astrocytes"), oligodendrocytes ("coiled bodies"), basal ganglionic neurons, and, variably, cortical neurons. Clusters of tau-positive processes around an astrocyte ("astrocytic plaques") and the presence of tau-positive threads in gray and white matter may be the most specific pathologic findings of corticobasal degeneration. The substantia nigra and locus ceruleus show loss of pigmented neurons, neuronal achromasia, and tangles. Similar to progressive supranuclear palsy, the tau deposits in corticobasal degeneration contain predominantly 4R tau.

Clinical Features.

The disease is characterized by extrapyramidal rigidity, asymmetric motor disturbances (jerking movements of limbs), and sensory cortical dysfunction (apraxias, disorders of language); cognitive decline occurs, and may be prominent in some cases. The same *MAPT* haplotype linked to progressive supranuclear palsy is also highly associated with corticobasal degeneration.

Frontotemporal Dementias without Tau Pathology

Some cases with clinical and pathologic findings involving the frontal and temporal lobes lack tau deposition; instead, usually tau-negative, ubiquitin-containing inclusions are found in superficial cortical layers in temporal and frontal lobes and in the dentate gyrus (giving rise to the term *FTD-U* for ubiquitin). Some of these cases are familial and show linkage to chromosome 17 but are caused by mutations in the gene for progranulin (an inflammatory modulator protein), which is close to the *MAPT* locus.[50] Similar pathology is seen accompanying the cognitive impairment that sometimes occurs with amyotrophic lateral sclerosis.[51]

Vascular Dementia

While some individuals with cognitive decline due to vasculitis show improvement with treatment, there is also an irreversible and progressive cognitive disorder associated with vascular injury to the brain.[52] Various etiologies include widespread areas of infarction (abundant cortical microinfarcts, multiple lacunar infarcts, cortical laminar necrosis associated with reduced perfusion/oxygenation), and diffuse white-matter injury (hypertension, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy). Additionally, dementia has been associated with so-called strategic infarcts, which are usually embolic and involve brain regions such as the hippocampus, dorsomedial thalamus, or the cingulate gyrus of the frontal cortex. Many individuals, in fact, demonstrate a combination of pathologic changes. There is also a relationship between vascular injury and other dementing disorders, such as AD. It has been found that individuals with vascular changes above a certain threshold have a lower burden of plaques and tangles for their level of cognitive impairment than do those without vascular-based cerebral pathology.

DEGENERATIVE DISEASES OF BASAL GANGLIA AND BRAINSTEM

Diseases affecting these regions of the brain are frequently associated with movement disorders, including rigidity, abnormal posturing, and chorea. In general, they can be categorized as manifesting either a reduction of voluntary movement or an abundance of involuntary movement. The basal ganglia, especially the nigrostriatal pathway, play an important role in the system of positive and negative regulatory synaptic pathways that serve to modulate feedback from the thalamus to the motor cortex. The most important disorders in this group are those associated with parkinsonism and Huntington disease.

Parkinsonism

Parkinsonism is a clinical syndrome characterized by diminished facial expression, stooped posture, slowness of voluntary movement, festinating gait (progressively shortened, accelerated steps), rigidity, and a "pill-rolling" tremor. This type of motor disturbance is seen in a number of conditions that have in common damage to the nigrostriatal dopaminergic system. Parkinsonism may also be induced by drugs that affect this system, particularly dopamine antagonists and toxins. The principal diseases that involve the nigrostriatal system are as follows:

- Parkinson disease (PD)
- Multiple system atrophy, commonly associated with parkinsonism as well as other symptoms
- Postencephalitic parkinsonism, which was observed as a late consequence of the influenza pandemic of 1918
- Progressive supranuclear palsy and corticobasal degeneration, movement disorders that may also show cognitive impairment (discussed above with the FTDs)

Parkinson Disease

This diagnosis is made in individuals with progressive L-DOPA-responsive signs of parkinsonism (tremor, rigidity, and bradykinesia) in the absence of a toxic or other known underlying etiology. Familial forms of PD with autosomal dominant or autosomal recessive inheritance exist. Although these make up a limited number of cases, they have contributed to our understanding of the pathogenesis of the disease.

Morphology. The typical macroscopic findings are **pallor of the substantia nigra** (compare Fig. 28-40A and B) and locus ceruleus. On microscopic examination, there is loss of the pigmented, catecholaminergic neurons in these regions, associated with gliosis. Lewy bodies (Fig. 28-40C) may be found in some of the remaining neurons. These are single or multiple, cytoplasmic, eosinophilic,

round to elongated inclusions that often have a dense core surrounded by a pale halo. Ultrastructurally, Lewy bodies are composed of fine filaments, densely packed in the core but loose at the rim; these filaments are composed of α-**synuclein**. Lewy bodies may also be found in the cholinergic cells of the basal nucleus of Meynert, which is depleted of neurons (particularly in patients with abnormal mental function), as well as in other brainstem nuclei including the locus ceruleus and the dorsal motor nucleus of the vagus.

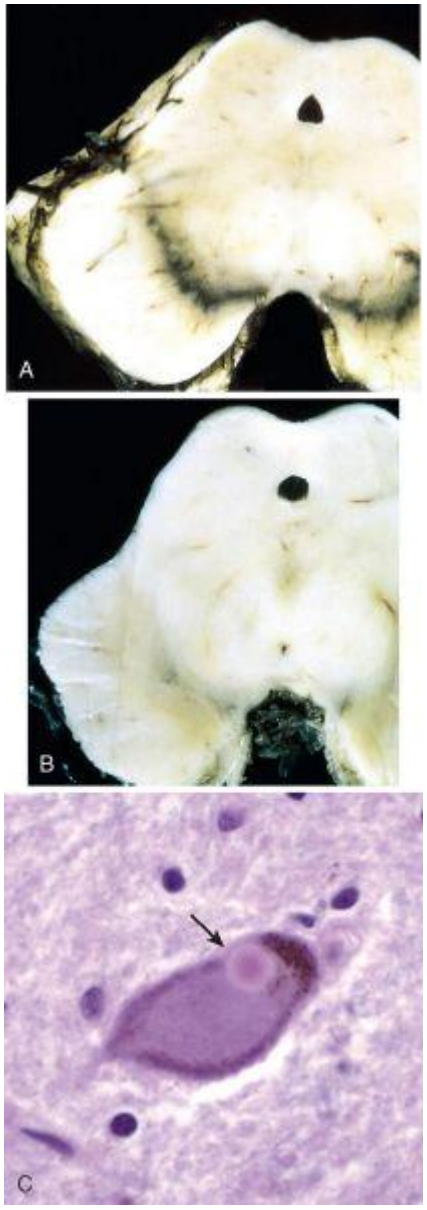

FIGURE 28-40 Parkinson disease. **A**, Normal substantia nigra. **B**, Depigmented substantia nigra in idiopathic Parkinson disease. **C**, Lewy body in a substantia nigra neuron, staining bright pink *(arrow)*.

Molecular Genetics.

More than a dozen genetic loci for PD have been identified through linkage studies. The five genes currently known to be clearly associated with the disease point to a complex set of possible disease

mechanisms.[53,][54] The first gene to be identified as a cause of autosomal dominant PD encodes α-*synuclein*, an abundant lipid-binding protein normally associated with synapses that is also a major component of the Lewy body. Mutations in α-synuclein are rare; they take the form of point mutations and amplifications of the region of chromosome 4q21 that contains the gene. The occurrence of disease caused by changes in gene copy number implies a gene dosage effect, similar to what has been observed with APP in AD, and suggests that polymorphisms in the α-synuclein promoter that alter its expression may influence the risk of PD. Mutations in the gene encoding LRRK2 (leucine-rich repeat kinase 2) are a more common cause of autosomal dominant PD and are found in some sporadic cases of the disease. Several of these pathogenic mutations increase the kinase activity of LRRK2, suggesting that gains in LRRK2 function contribute to the development of PD.

A juvenile autosomal recessive form of PD is caused by loss of function mutations in the gene encoding *parkin*, an E3 ubiquitin ligase with a wide range of substrates. The pathology of parkin-linked PD is similar to that of α-synuclein–linked or sporadic PD except that Lewy bodies are absent in most cases. Other cases of autosomal recessive PD are the result of mutations in the gene encoding DJ-1, a protein involved in regulating redox responses to stress; or the gene encoding the kinase PINK1, which appears to regulate normal mitochondrial function.

Pathogenesis.

No unifying pathogenic mechanism has emerged yet from these diverse genetic and biochemical clues, and many possibilities have been suggested, including a misfolded protein/stress response triggered by α-synuclein aggregation; defective proteosomal function due to the loss of the E3 ubiquitin ligase parkin; and altered mitochondrial function caused by the loss of DJ-1 and PINK1. Intriguingly, other lines of evidence also point to a role for mitochondrial dysfunction; for example, levels of mitochondrial complex I, a component of the oxidative phosphorylation cascade, are reduced in the brains of patients with sporadic PD, and some models of experimental PD are produced by the administration of mitochondrial inhibitors.

The dopaminergic neurons of the substantia nigra project to the striatum, and their degeneration in PD is associated with a reduction in the striatal dopamine content. The severity of the motor syndrome is proportional to the dopamine deficiency, which can, at least in part, be corrected by replacement therapy with L-DOPA (the immediate precursor of dopa mine). Treatment does not, however, reverse the morphologic changes or arrest the progress of the disease; moreover, with progression, drug therapy tends to become less effective and symptoms become more difficult to manage. An acute parkinsonian syndrome and destruction of neurons in the substantia nigra follows exposure to MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), discovered as a contaminant in the illicit synthesis of psychoactive meperidine analogues. The use of this toxin in experimental animals has proved highly useful in studies of therapeutic interventions for PD, including transplantation. Epidemiologic evidence has also suggested pesticide exposure as a risk factor for PD, while caffeine and nicotine may be protective.

Clinical Features.

In addition to the signs of parkinsonism, autonomic dysfunction is common, as is some impairment of cognitive function. Parkinson disease is sometimes accompanied by a dementia, either early in the course of the illness or as a late additional morbidity. While L-DOPA therapy is often extremely effective in symptomatic treatment, it does not significantly alter the intrinsically progressive nature of the disease. Over time, L-DOPA becomes less able to help the patient through symptomatic relief and begins to lead to fluctuations in motor function on its own. Given the wellcharacterized biochemical defect in PD, it has been the focus of early therapeutic trials for neural transplantation and gene therapy.[55] Other current neurosurgical approaches to this disease include the strategic placement of

lesions elsewhere in the extrapyramidal system to compensate for the loss of nigrostriatal function and placement of stimulating electrodes (deep brain stimulation).[56]

Dementia with Lewy Bodies

About 10% to 15% of individuals with PD develop dementia, with increasing incidence with advancing age. Characteristic features of this disorder include a fluctuating course, hallucinations, and prominent frontal signs. While some affected individuals have pathologic evidence of AD (or, less frequently, other degenerative diseases associated with cognitive changes) in combination with the findings of PD, in others the most prominent histologic correlate appears to be the presence of Lewy bodies in a wide range of cortical locations.[57,][58] These inclusions are less distinct than those observed in the brainstem but similarly contain predominantly α-synuclein. Immunohistochemical staining for α-synuclein also reveals the presence of abnormal neurites, which contain aggregated protein—called *Lewy neurites* even though he never saw them! In this setting, the gross pathologic findings typically include depigmentation of the substantia nigra and locus ceruleus, paired with relative preservation of the cortex, hippocampus, and amygdala. The burden of cortical Lewy bodies is usually extremely low, and the mechanism by which this disease wreaks havoc on cognitive functioning is not clear. It has been suggested that Lewy body diseases represent a continuum; there is evidence that Lewy bodies and Lewy neurites are found first in the medulla, progress over time to reach the midbrain (when it becomes manifest as PD), and can eventually progress across the nervous system to reach the cortex (and manifest as dementia with Lewy bodies).[59]

Multiple System Atrophy

The designation multiple system atrophy (*MSA*) describes a group of disorders characterized by the presence of glial cytoplasmic inclusions, typically within the cytoplasm of oligodendrocytes, that can have different patterns of clinical presentation.[60] The dominant symptoms can be parkinsonism (MSA-P, historically known as striatonigral degeneration), or cerebellar dysfunction (MSA-C, previously known as olivopontocerebellar atrophy), or autonomic dysfunction (MSA-A, once known as Shy-Drager syndrome). Of these, MSA-C is the least frequently observed pure syndrome. These variants appear to stem from a single disease mechanism, and many affected individuals develop symptoms during the course of the illness that fall into more than one clinical pattern.

Morphology. The gross pathology matches the clinical presentation. In cerebellar forms there is typically atrophy of the cerebellum, including the cerebellar peduncles, pons (especially the basis pontis), and medulla (especially the inferior olive), while in parkinsonian forms the atrophy involves both the substantia nigra and striatum (especially putamen). Since autonomic symptoms are related to cell loss from the catecholaminergic nuclei of the medulla and the intermediolateral cell column of the spinal cord, there are usually no specific gross findings. Atrophic brain regions show evidence of neuronal loss as well as variable numbers of neuronal cytoplasmic and nuclear inclusions.

The diagnostic glial cytoplasmic inclusions were originally demonstrated in oligodendrocytes with silver impregnation methods and contain α-synuclein as well as ubiquitin and αB-crystallin. The inclusions are ultrastructurally distinct from those found in other neurodegenerative diseases and are composed primarily of 20- to 40-nm tubules. Similar inclusions may also be found in the cytoplasm of neurons, sometimes in neuronal and glial nuclei, and in axons.

Pathogenesis.

As in PD, α-synuclein is the major component of the inclusions, but unlike PD, no mutations in the gene encoding this protein have been found in patients with MSA. Furthermore, unlike in PD, α-synuclein–

containing inclusions are found in glial cells, notably oligodendrocytes. The relationship between glial cytoplasmic inclusions and disease is supported by the observation that the inclusions are present in low numbers at earliest stages of MSA and increase in abundance as the disease progresses, although they eventually disappear as cells die in the final stages. It appears that glial cytoplasmic inclusions can occur in the absence of neuronal loss, suggesting that they may represent a primary pathologic event; for example, glial cytoplasmic inclusions are consistently observed in the white matter projecting to and from the motor cortex. The origin of the α-synuclein in oligodendrocytes remains perplexing, since this is a neuronal protein associated with synaptic vesicles. Several studies have shown that there is no up-regulation of α-synuclein expression in white matter or in oligodendrocytes in MSA, suggesting that the protein may be acquired secondarily by oligodendrocytes from injured or dying neurons. It may be that the less conspicuous neuronal inclusions of α-synuclein, which are also present in MSA, are more closely linked to the disease process.[61]

Huntington Disease

Huntington disease (HD) is an autosomal dominant disease *characterized clinically by progressive movement disorders and dementia, and histologically by degeneration of striatal neurons*. Jerky, hyperkinetic, sometimes dystonic movements involving all parts of the body (chorea) are characteristic; affected individuals may later develop parkinsonism with bradykinesia and rigidity. The disease is relentlessly progressive, with an average course of about 15 years to death.

Molecular Genetics.

Huntington disease is the prototype of the polyglutamine trinucleotide repeat expansion diseases (see Chapter 5).[62,][63] The *HD* gene, located on chromosome 4p16.3, encodes a 348-kD protein known as *huntingtin*. In the first exon of the gene there is a stretch of CAG repeats, which encodes a polyglutamine region near the N terminus of the protein. Normal *HD* genes contain 6 to 35 copies of the repeat; when the number of repeats is increased beyond this level it is associated with disease. There is an inverse relationship between repeat number and age of onset, such that longer repeats are associated with earlier onset. Because other factors modify the effect of the repeats, determination of repeat length is not an accurate predictor of age of onset. Repeat expansions occur during spermatogenesis, so that paternal transmission is associated with early onset in the next generation, the phenomenon of anticipation. Newly occurring mutations are uncommon; most apparently sporadic cases can be related to non-paternity, the death of a parent before expression of the disease, or a father as yet unaffected but with a mild repeat expansion that further enlarged during spermatogenesis.

Morphology. Macroscopically, the brain is small and shows striking **atrophy of the caudate nucleus** and, less markedly at early stages, the putamen (Fig. 28-41). The globus pallidus may be atrophied secondarily, and the lateral and third ventricles are dilated. Atrophy is frequently also seen in the frontal lobe, less often in the parietal lobe, and occasional in the entire cortex. On microscopic examination, there is severe loss of striatal neurons; the most marked changes are found in the caudate nucleus, especially in the tail and portions nearer the ventricle. The putamen is involved in the later stages of disease. Pathologic changes develop in a medial-to-lateral direction in the caudate and from dorsal to ventral in the putamen. The nucleus accumbens is the best preserved portion of the striatum. Both the large and small neurons are affected, but loss of the small neurons generally occurs first. The medium-sized, spiny neurons that use γ-aminobutyric acid as theirneurotransmitter, along with enkephalin, dynorphin, and substance P, are especially affected. Two populations of neurons are relatively spared, the diaphorasepositive neurons that contain nitric oxide synthase and the large cholinesterase-positive neurons; both appear to serve as local interneurons. There is also fibrillary gliosis that is more extensive than in the usual reaction to neuronal loss. There is a direct relationship

between the degree of degeneration in the striatum and the severity of clinical symptoms. Protein aggregates containing huntingtin can be found in neurons in the striatum and cerebral cortex (Fig. 28-41, *inset*).

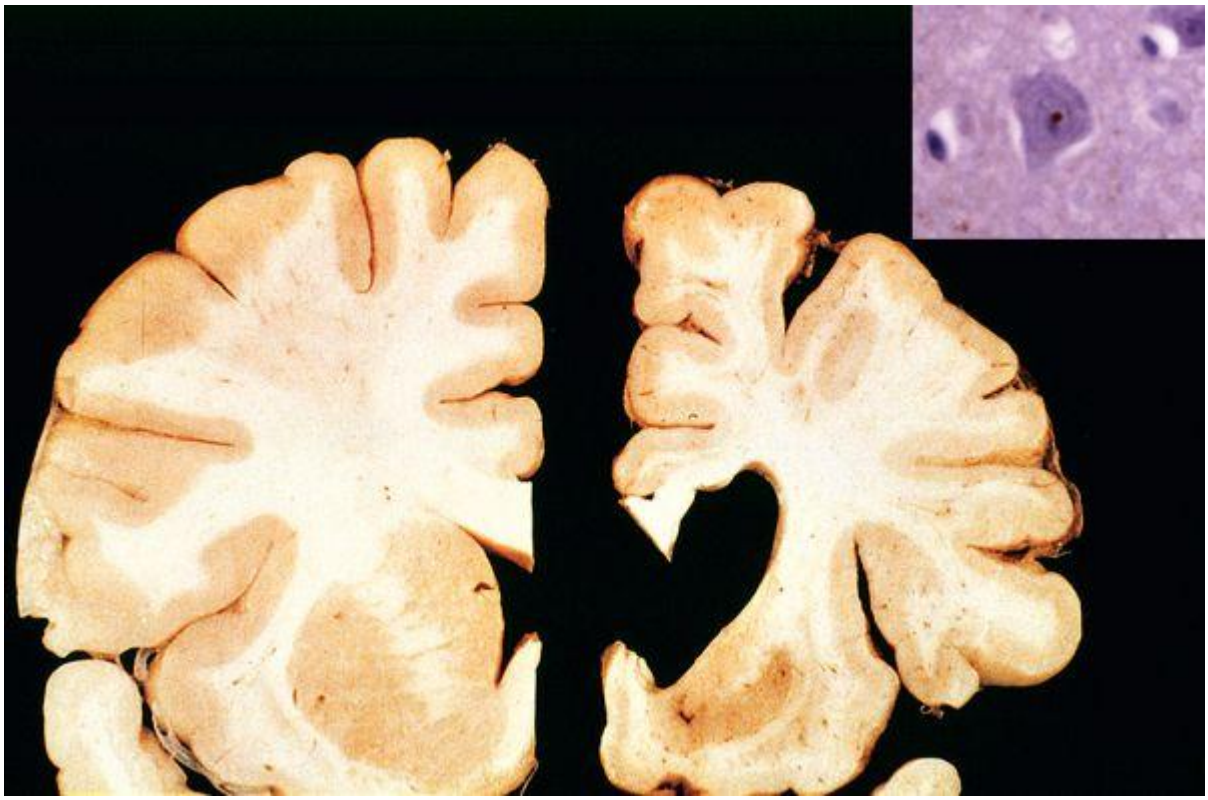

FIGURE 28-41 Huntington disease. Normal hemisphere on the *left*, compared with the hemisphere with Huntington disease on the *right* showing atrophy of the striatum and ventricular dilation.*Inset*, Intranuclear inclusions in neurons are highlighted by immunohistochemistry against ubiquitin. *(Courtesy of Dr. J.-P. Vonsattel, Columbia University, New York, NY.)*

Pathogenesis.

The loss of medium spiny striatal neurons leads to dysregulation of the basal ganglia circuitry that modulates motor output. These neurons normally function to dampen motor activity; thus, their degeneration in HD results in increased motor output, often manifested as choreoathetosis. The cognitive changes associated with the disease are probably related to the neuronal loss from cerebral cortex.

The biologic function of normal huntingtin remains unknown, but there is little evidence to suggest that the disease is caused by haploinsufficiency related to a mutated allele. Rather, the expansion of the polyglutamine region seems to bestow a toxic gain of function on huntingtin. While the expanded polyglutamine repeat results in protein aggregation and formation of intranuclear inclusions as described above, it is not established that this is a direct pathway to cellular injury. Transcriptional dysregulation has been implicated in HD, with mutant forms of huntingtin binding important transcriptional regulators such as Sp1 and CBP (cyclic adenosine monophosphate response-element binding protein). A proposed consequence of this sequestration of critical transcription factors is the

down-regulation of PGC-1α, itself a transcription factor involved in mitochondrial biogenesis and protection against oxidative injury.

Clinical Features.

The age at onset is most commonly in the fourth and fifth decades and is related to the length of the CAG repeat in the *HD* gene. Motor symptoms often precede the cognitive impairment. The movement disorder of HD is choreiform, with increased and involuntary jerky movements of all parts of the body; writhing movements of the extremities are typical. Early symptoms of higher cortical dysfunction include forgetfulness and thought and affective disorders, but there is progression to a severe dementia. Although individuals with HD have an increased risk of suicide, intercurrent infection is the most common natural cause of death. Given the ability to screen for disease-causing mutations and the devastating nature of the disease, HD is often the focal point of discussion of ethical issues in genetic diagnosis.

SPINOCEREBELLAR DEGENERATIONS

This group of diseases affects, to a variable extent, the cerebellar cortex, spinal cord, peripheral nerves, and other regions of the neuraxis. The clinical spectrum includes cerebellar and sensory ataxia, spasticity, and sensorimotor peripheral neuropathy. This is a clinically and genetically heterogeneous group of illnesses, with differences in patterns of inheritance, age at onset, and signs and symptoms. Degeneration of neurons, sometimes without other distinctive histopathologic changes, occurs in the affected areas and is associated with gliosis. Genetic analysis continues to redefine and subclassify these illnesses.

Spinocerebellar Ataxias

This is a group of genetically distinct diseases characterized by signs and symptoms referable to the cerebellum (progressive ataxia), brainstem, spinal cord, and peripheral nerves, as well as other brain regions in different subtypes. Pathologically they are characterized by neuronal loss from the affected areas and secondary degeneration of white-matter tracts.

Molecular Genetics.

The list of spinocerebellar ataxias (SCAs) has expanded to reach 29 distinct entities at this time. Three distinct types of mutations have been recognized: polyglutamine diseases linked to expansion of a CAG repeat, similar to HD; expansion of non–coding region repeats, similar to myotonic dystrophy; and other types of mutations.[64] Expanded polyglutamine repeats affecting different proteins underlie six forms of SCA (SCA1, 2, 3 [also known as Machado-Joseph disease], 6, 7, and 17). Intranuclear inclusions can be found in these forms of SCA, but just as in HD it remains unclear whether this contributes to or protects against neuronal injury. Putative disease mechanisms include sequestration and depletion of chaperone proteins by the formation of abnormal aggregates driven by the polyglutamine tracts as well as transcriptional dysregulation. In general, these forms of SCA show anticipation. The basis for the targeting of the cerebellar system for specific injury remains unknown.

In the diseases caused by non–coding region repeat expansions (SCA8, 10, and 12), the underlying mechanisms are even more obscure. Point mutations have been found in βIII spectrin (SCA5), a voltage-gated potassium channel (Kv3.3 in SCA13), protein kinase Cγ (SCA14), and fibroblast growth factor 14 (SCA27). These have been linked to a wide range of potential disease mechanisms without any obvious shared pathways of neuronal injury.

Friedreich Ataxia

Friedreich ataxia, a distinctive spinocerebellar degeneration, is an autosomal recessive progressive illness, generally beginning in the first decade of life with gait ataxia, followed by hand clumsiness and dysarthria. Deep tendon reflexes are depressed or absent, but an extensor plantar reflex is typically present. Joint position and vibratory sense are impaired, and there is sometimes loss of pain and temperature sensation and light touch. Most affected individuals develop pes cavus and kyphoscoliosis. There is a high incidence of cardiac arrhythmias and congestive heart failure. Concomitant diabetes is found in about 10% of patients. Most patients become wheelchair-bound within about 5 years of onset; the cause of death is intercurrent pulmonary infections and cardiac disease.

Friedreich ataxia is caused by expansion of a GAA trinucleotide-repeat in the first intron of a gene on chromosome 9q13 that encodes a protein called *frataxin*.[65] Affected individuals have extremely low levels of the protein, which normally localizes to the inner mitochondrial membrane, where it may have a role in regulation of iron levels. Because iron is an essential component of many of the complexes of the oxidative phosphorylation chain, mutations in frataxin have been suggested to result in generalized mitochondrial dysfunction. Thus, Friedreich ataxia shares biologic features with other SCAs (anatomic distribution of pathology and trinucleotide-repeat expansion) as well as the mitochondrial encephalopathies.

Morphology. The **spinal cord** shows loss of axons and gliosis in the posterior columns, the distal portions of corticospinal tracts, and the spinocerebellar tracts. There is degeneration of neurons in the spinal cord (Clarke column), the brainstem (cranial nerve nuclei VIII, X, and XII), the cerebellum (dentate nucleus and the Purkinje cells of the superior vermis), and the Betz cells of the motor cortex. Large dorsal root ganglion neurons are also decreased in number; their large myelinated axons, traveling both in the dorsal roots and in dorsal columns, undergo secondary degeneration. The **heart** is enlarged and may have pericardial adhesions. Multifocal destruction of myocardial fibers with inflammation and fibrosis is detectable in about half the affected individuals who come to autopsy.

Ataxia-Telangiectasia

Ataxia-telangiectasia (Chapter 7) is an autosomal recessive disorder characterized by an ataxic-dyskinetic syndrome beginning in early childhood, with the subsequent development of telangiectasias in the conjunctiva and skin; and immunodeficiency. The ataxia-telangiectasia mutated (*ATM*) gene on chromosome 11q22–q23 encodes a kinase with a critical role in orchestrating the cellular response to double-stranded DNA breaks (Chapter 7). Cells from individuals with the disease show increased sensitivity to x-ray-induced chromosome abnormalities; these cells continue to replicate damaged DNA rather than stopping to allow repair or undergoing apoptosis. The carrier frequency of ataxia-telangiectasia has been estimated at 1%; in these individuals the mutated *ATM* allele may underlie an increased risk of cancer, specifically breast cancer. The link between DNA repair mechanisms and neurodegenerative disease is harder to understand than the connection to neoplasia. It has been suggested that mutations in *ATM* result in failure to remove cells with DNA damage from the developing nervous system, predisposing it to degeneration.[66]

Morphology. The abnormalities are predominantly in the cerebellum, with loss of Purkinje and granule cells; there is also degeneration of the dorsal columns, spinocerebellar tracts, and anterior horn cells, and a peripheral neuropathy. Telangiectatic lesions have been reported in the CNS as well as in the conjunctiva and skin of the face, neck, and arms. Cells in many organs (e.g., Schwann cells in dorsal root ganglia and peripheral nerves, endothelial cells, pituicytes) show a bizarre enlargement of the nucleus to two to five times normal size and are referred to as amphicytes. The lymph nodes,

thymus, and gonads are hypoplastic.

Clinical Features.

The disease is relentlessly progressive, with death early in the second decade. Affected individuals first come to medical attention because of recurrent sinopulmonary infections and unsteadiness in walking. Later on, speech is noted to become dysarthric, and eye movement abnormalities develop. Many affected individuals develop lymphoid neoplasms, often T-cell leukemias; gliomas and carcinomas have been reported in some.

DEGENERATIVE DISEASES AFFECTING MOTOR NEURONS

These are a group of inherited or sporadic diseases that affect both lower motor neurons in the anterior horns of the spinal cord and brainstem motor nuclei and upper motor neurons in the motor cortex (also known as Betz cells).

These diseases occur in several age groups, and the course of the illnesses range from slowly progressive or nonprogressive to rapidly progressive and fatal in a period of months or a few years. Denervation of muscles from loss of lower motor neurons and their axons results in muscular atrophy, weakness, and fasciculations; the corresponding histologic changes in nerve and muscle are discussed in Chapter 27 . The clinical manifestations of upper motor neuron loss include paresis, hyperreflexia, spasticity, and extensor plantar responses (Babinski sign). Sensory systems are unaffected, but some of these diseases may be associated with manifestations of cortical dysfunction, such as behavioral abnormalities and dementia.

Amyotrophic Lateral Sclerosis (ALS; Motor Neuron Disease)

ALS is characterized by loss of lower motor neurons in spinal cord and brainstem and upper motor neurons that project in corticospinal tracts. This relatively rare disease (incidence of about 2 cases per 100,000 population) affects men slightly more frequently than women and becomes clinically manifest in the fifth decade or later. Five to 10% of cases are familial (fALS), mostly with autosomal dominant inheritance.

Molecular Genetics.

Close to a quarter of familial cases of ALS are caused by mutations in the gene encoding copper-zinc superoxide dismutase (*SOD1*) on chromosome 21.[67] A wide variety of mutations, nearly all missense mutations, have been identified throughout the gene; ALS seems to be caused by an adverse gain-of-function phenotype associated with mutant SOD1. A mutation resulting in an alanine to valine substitution in residue 4 is the most common in the United States; it is associated with a rapid course, and rarely has upper motor neuron signs. Other loci for ALS have been mapped, although none appears in linkage with as large a fraction of the patient population as *SOD1*. These mendelian loci include the genes encoding dynactin (a protein involved in retrograde axonal transport), VAMP-associated protein B (involved in regulation of vesicle transport), and alsin (containing guanine nucleotide exchange factor domains and associated with regulation of endosomal trafficking through interaction with Rab5b).

Pathogenesis.

The pathogenesis of ALS is still not understood despite the identification of numerous genetic associations. The discovery of SOD1 mutations initially suggested that a reduced capacity to detoxify free radicals (the physiologic function of SOD) may account for neuronal death in ALS. However, this hypothesis has not been proved, and currently a more accepted idea is that the mutated SOD1 protein is

misfolded and triggers an injurious unfolded protein response.[68] Mutated SOD1 in non-neuronal (glial and smooth muscle) cells may also contribute to the disease.[69] Alterations in axonal transport, neurofilament abnormalities, toxicity mediated by increased levels of the neurotransmitter glutamate, and aggregation of other proteins (such as one called TDP-43 that is sometimes found in cytoplasmic inclusions in neurons in ALS)[70], have all been suggested as mechanisms contributing to the progressive loss of motor neurons.

Morphology. On gross examination, the anterior roots of the spinal cord are thin (Fig. 28-42A). The precentral gyrus may be atrophic in especially severe cases. Microscopic examination demonstrates a reduction in the number of anterior-horn neurons throughout the length of the spinal cord with associated reactive gliosis and loss of anterior-root myelinated fibers. Similar findings are seen in the hypoglossal, ambiguus, and motor trigeminal cranial nerve nuclei. Remaining neurons often contain PAS-positive cytoplasmic inclusions, called Bunina bodies, that appear to be remnants of autophagic vacuoles. Skeletal muscles innervated by the degenerated lower motor neurons show neurogenic atrophy. Loss of the upper motor neurons leads to degeneration of the corticospinal tracts, resulting in volume loss and absence of myelinated fibers, which may be particularly evident at the lower segmental levels (Fig. 28-42B).

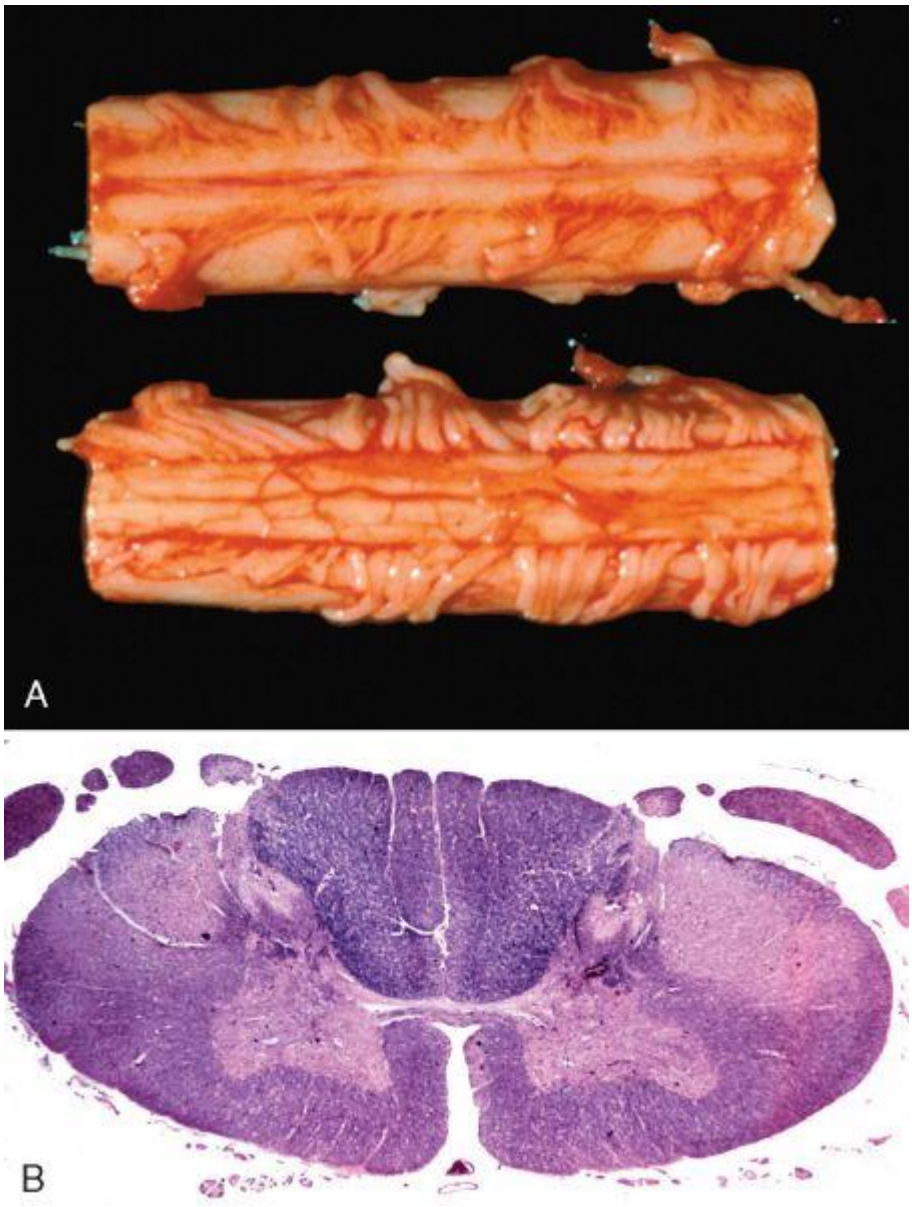

FIGURE 28-42 Amyotrophic lateral sclerosis. **A**, Segment of spinal cord viewed from anterior *(upper)* and posterior *(lower)* surfaces showing attenuation of anterior (motor) roots compared to posterior (sensory) roots. **B**, Spinal cord showing loss of myelinated fibers (lack of stain) in corticospinal tracts as well as degeneration of anterior roots.

Clinical Features.

Early symptoms include asymmetric weakness of the hands, manifested as dropping objects and difficulty in performing fine motor tasks, and cramping and spasticity of the arms and legs. As the disease progresses, muscle strength and bulk diminish, and involuntary contractions of individual motor units, termed *fasciculations,* occur. The disease eventually involves the respiratory muscles, leading to recurrent bouts of pulmonary infection. The severity of involvement of the upper and lower motor neurons is variable; the term *progressive muscular atrophy* applies to those relatively uncommon cases in which lower motor neuron involvement predominates. In some affected individuals, degeneration of the lower brainstem cranial motor nuclei occurs early and progresses rapidly, a pattern referred to as

progressive bulbar palsy or *bulbar ALS*. In these individuals, abnormalities of deglutition and phonation dominate, and the clinical course is inexorable during a 1- or 2-year period; when bulbar involvement is less severe, about half of affected individuals are alive 2 years after diagnosis. Although it has been suggested that the motor neurons innervating extra-ocular muscles were spared in ALS, it is now clear that these cells are susceptible to the disease process when individuals survive longer. Familial cases develop symptoms earlier than most sporadic cases, but the clinical course is comparable.

Bulbospinal Atrophy (Kennedy Syndrome)

This X-linked adult-onset disease is characterized by distal limb amyotrophy and bulbar signs such as atrophy and fasciculations of the tongue and dysphagia. Affected individuals manifest androgen insensitivity, gynecomastia, testicular atrophy, and oligospermia. On microscopic examination there is degeneration of lower motor neurons in the spinal cord and brainstem. The gene defect is expansion of a CAG/polyglutamine repeat in the androgen receptor (40 to 60 for affected males as opposed to 11 to 33 for normals); nuclear inclusions containing aggregated androgen receptor can be found, although it remains unclear whether these inclusions are critical to cellular injury.[71]

Spinal Muscular Atrophy

This group of diseases affects mainly the lower motor neurons in children. As in ALS, there is a selective loss of anterior-horn cells and atrophy of anterior spinal roots. It includes several entities with distinct clinical courses (Chapter 27).

3.18.11 Genetic Metabolic Diseases

A subset of genetic metabolic diseases affects the nervous system preferentially and will be discussed here; other metabolic diseases are covered elsewhere in this book. Many of these disorders express themselves in children who are normal at birth but who begin to miss developmental milestones during infancy and childhood.

- *Neuronal storage diseases* are mostly autosomal recessive disorders caused by the deficiency of a specific enzyme involved in the catabolism of sphingolipids, mucopolysaccharides, or mucolipids. They are often characterized by the accumulation of the substrate of the enzyme within the lysosomes of neurons, leading to neuronal death. Cortical neuronal involvement leads to loss of cognitive function and may also cause seizures. The relationship between the accumulated material and cell injury and death is usually unclear.
- *Leukodystrophies* are characterized by myelin abnormalities (either abnormal synthesis or turnover) and generally lack neuronal storage defects. Some of these disorders involve lysosomal enzymes; others affect peroxisomal enzymes. Diffuse involvement of white matter leads to deterioration in motor skills, spasticity, hypotonia, or ataxia. Most are autosomal recessive disorders; adrenoleukodystrophy, an X-linked disease, is a notable exception. Subtypes, or variants, exist for many of these disorders. Variants are associated with an earlier age at onset, and generally follow a more severe clinical course.
- *Mitochondrial encephalomyopathies* are a group of disorders of oxidative phosphorylation, usually resulting from mutations in the mitochondrial genome. They typically involve gray matter as well as skeletal muscle (Chapter 27).

NEURONAL STORAGE DISEASES

Neuronal Ceroid Lipofuscinoses

These are a set of inherited lysosomal storage diseases that are grouped because they share the accumulation of lipofuscin—an autofluorescent substance with a variety of ultrastructural appearances—in neurons. Neuronal dysfunction typically leads to a combination of blindness, mental and motor deterioration, and seizures. These disorders are classified based on age of onset into infantile (INCL), late infantile (LINCL), juvenile (JNCL), and adult neuronal ceroid lipofuscinoses (ANCL; Kuf disease), or on the pattern of inclusions by electron microscopy. Genetic studies indicate that there are

likely eight causative loci, which encode a variety of proteins involved in the modification and degradation of proteins.[72] The *CLN1* locus, a common cause of INCL, encodes palmitoyl protein thioesterase 1 (PPT1), which removes palmitate residues from proteins; this is similar to *CLN3*, implicated in most cases of JNCL (also known as Batten disease), which encodes palmitoyl-protein Δ-9 desaturase, another enzyme related to regulation of membrane-associated palmitoylated proteins. How the abnormalities in protein modification lead to the accumulation of lipofuscin or the neuronal dysfunction is not understood.

Tay-Sachs Disease

This disease begins in early infancy with developmental delay, followed by paralysis and loss of neurologic function, and death after several years. It is discussed in Chapter 5 along with other lysosomal storage diseases.

LEUKODYSTROPHIES

Krabbe Disease

This disease is an autosomal recessive leukodystrophy resulting from a *deficiency of galactocerebroside* β-*galactosidase* (galactosylceramidase), the enzyme required for the catabolism of galactocerebroside to ceramide and galactose. More than 40 different mutations have been found in the gene encoding this enzyme, which is located on chromosome 14q31. While accumulation of galactocerebroside occurs, this is not the direct toxic agent in this disease. Instead, it seems that an alternative catabolic pathway removes a fatty acid from this molecule, generating galactosylsphingosine, which is a cytotoxic compound that may cause oligodendrocyte injury.

The clinical course is rapidly progressive, with onset of symptoms often between the ages of 3 and 6 months. Survival beyond 2 years of age is uncommon. The clinical symptoms are dominated by motor signs, including stiffness and weakness, with gradually worsening difficulties in feeding. The brain shows loss of myelin and oligodendrocytes in the CNS and a similar process in peripheral nerves (Fig. 28-43). Neurons and axons are relatively spared. A unique and diagnostic feature of Krabbe disease is the aggregation of engorgedmacrophages *(globoid cells)* in the parenchyma and around blood vessels (Fig. 28-43, *inset*). The potential exists for treatment with cord blood transplantation in the pre-symptomatic state.[73]

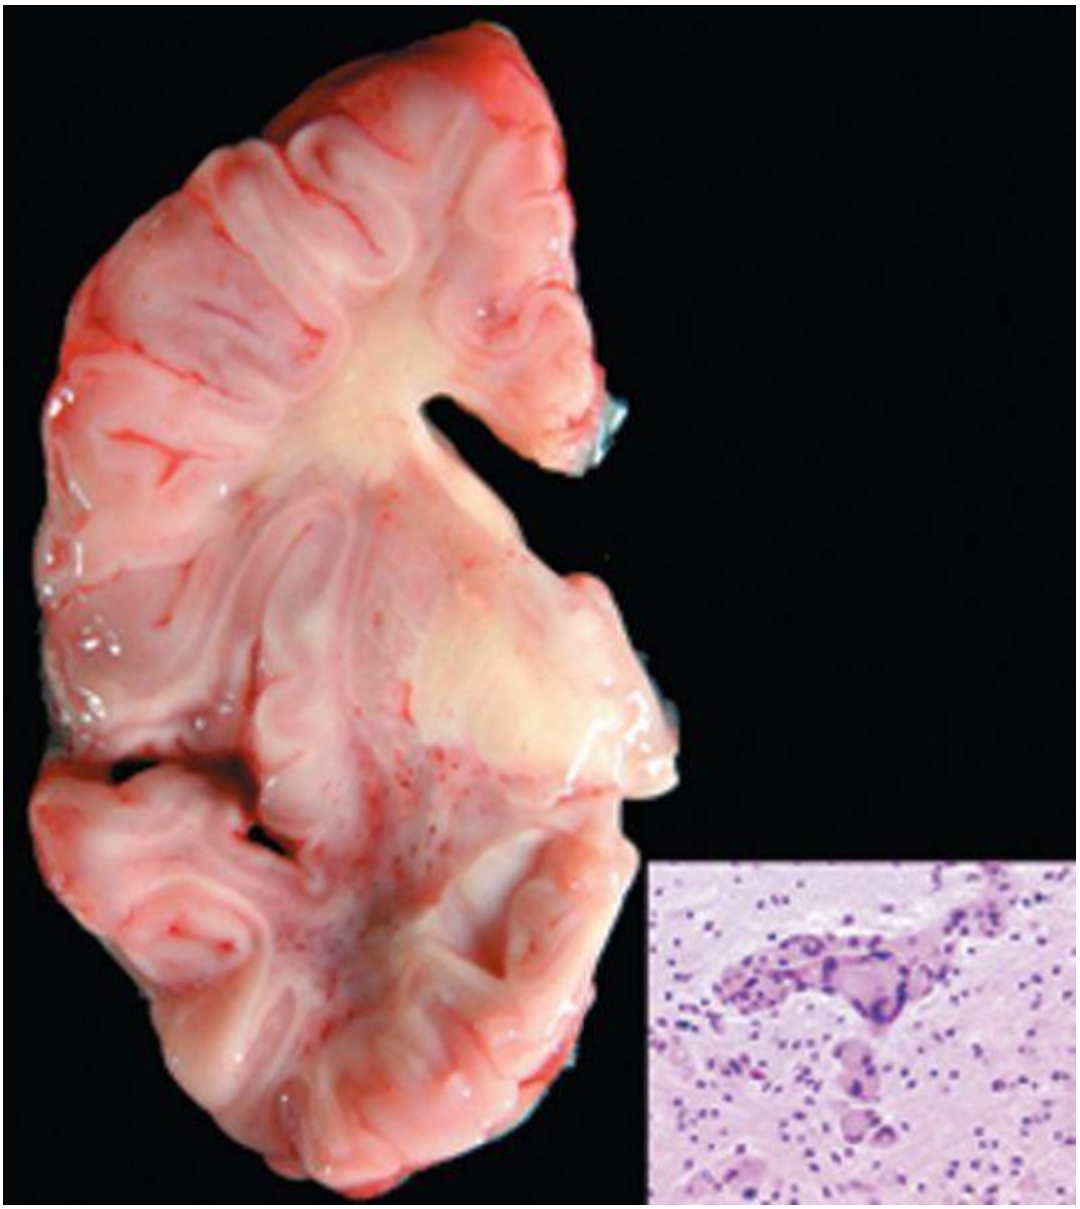

FIGURE 28-43 Krabbe disease. Much of the white matter is gray/yellow because of the loss of myelin. *Inset*, "Globoid" cells are the hallmark of the disease.

Metachromatic Leukodystrophy

This disorder is transmitted in an autosomal recessive pattern and results from a deficiency of the *lysosomal enzyme arylsulfatase A*. This enzyme, present in a variety of tissues, cleaves the sulfate from sulfate-containing lipids (sulfatides), the first step in their degradation. Enzyme deficiency leads to an accumulation of the sulfatides, especially cerebroside sulfate; how this leads to myelin breakdown is not known, although sulfatides are reported to inhibit differentiation of oligodendrocytes. The gene encoding arylsulfatase A has been localized to the distal end of chromosome 22q, and a wide range of mutations have been described. Recognized clinical subtypes of the disorder include a late infantile form (the most common), a juvenile form, and an adult form. The two forms with childhood onset often present with motor symptoms and progress gradually, leading to death in 5 to 10 years. In the adult form psychiatric or cognitive symptoms are the usual initial complaint, with motor symptoms coming later.

Approaches using various types of bone marrow stem cell transplantation have been shown to provide benefit, most commonly when performed before the neurologic deficits appear.[74]

The most striking histologic finding is demyelination with resulting gliosis. Macrophages with vacuolated cytoplasm are scattered throughout the white matter. The membrane-bound vacuoles contain complex crystalloid structures composed of sulfatides; when bound to certain dyes such as toluidine blue, sulfatides shift the absorbance spectrum of the dye, a property called *metachromasia*. Similar changes in peripheral nerves are observed. The detection of metachromatic material in the urine is also a sensitive method of establishing the diagnosis.

Adrenoleukodystrophy

This disorder, which has several clinically and genetically distinct forms, is a progressive disease with symptoms referable to myelin loss from the CNS and peripheral nerves as well as adrenal insufficiency. In general, forms with earlier onset have a more rapid course. The X-linked form usually presents in the early school years with neurologic symptoms and adrenal insufficiency and is rapidly progressive and fatal. In individuals with later onset the course is more protracted; when it develops in adults it is usually a slowly progressive disorder with predominantly peripheral nerve involvement developing over a period of decades. The disease is associated with mutations in the *ALD* gene on chromosome Xq28, which encodes a member of the ATP-binding cassette transporter family of proteins, ABCD1. However, there is little correlation between clinical course and the underlying mutations. The disease is characterized by the inability to properly catabolize very-long-chain fatty acids (VLCFAs) within peroxisomes, with elevated levels of VLCFAs in serum. There is loss of myelin, accompanied by gliosis and extensive lymphocytic infiltration. Atrophy of the adrenal cortex is present, and VLCFA accumulation can be seen in remaining cells.

Pelizaeus-Merzbacher Disease

This is an X-linked, invariably fatal leukodystrophy beginning either in early childhood or just after birth, and characterized by slowly progressive signs and symptoms resulting from widespread white-matter dysfunction. Affected individuals present with pendular eye movements, hypotonia, choreoathetosis, and pyramidal signs early in the disease, followed later by spasticity, dementia, and ataxia. Although myelin is nearly completely lost in the cerebral hemispheres, patches may remain, giving a “tigroid” appearance to tissue sections stained for myelin. The disease has been shown to arise in most cases from mutations in a gene on the X chromosome that encodes two distinct myelin proteins, distinguished by alternative splicing: proteolipid protein (PLP) and DM20. Gene duplications are the most common mutation observed, although point mutations giving rise to null alleles are also observed; it remains unclear how these distinct mutations cause the disease.[75] This same genetic locus is also the site of one form of spastic paraplegia (SPG2).

Canavan Disease

This disease is characterized by megalocephaly, severe mental deficits, blindness, and signs and symptoms of white matter injury beginning in early infancy and relentlessly progressing to death within a few years of onset. Autopsy studies show spongy degeneration of the white matter. There is accumulation of *N*-acetylaspartic acid in this disorder as a consequence of loss-of-function mutations in the gene encoding the deactylating enzyme aspartoacylase, located on chromosome 17. The mechanisms of myelin injury remain uncertain.[76]

Alexander Disease

This disease is characterized by megalencephaly, seizures, and progressive psychomotor retardation. There is white-matter loss, typically with a frontal-to-occipital gradient. The characteristic pathologic finding is the exuberant accumulation of Rosenthal fibers around blood vessels, in the subpial and subependymal zones and in the brain parenchyma. Even though Rosenthal fibers are primarily composed of various heat-shock proteins, including αB-crystallin, the basis of Alexander disease lies in mutations in the gene encoding glial fibrillary acid protein (GFAP).[77] The disease is believed to be caused by dominant gain-of-function mutations associated with decreased capacity to form filaments as well as induction of stress responses.

Vanishing-White-Matter Leukodystrophy

Vanishing-white-matter leukodystrophy, named for the characteristic progression of the disorder as revealed by imaging studies, is associated with mutations in the genes encoding any of the five subunits of eukaryotic initiation factor 2B (eIF2B).[78,][79] The disease usually begins insidiously during the first few years of life, with ataxia and seizures as common symptoms. With a relentless downward course, sometimes exacerbated by intercurrent illnesses, affected individuals typically survive for a few years after onset of symptoms. Levels of eIF2B are reduced throughout the body; the basis for selective injury to the brain, with the primary burden falling on white matter, is not known.

MITOCHONDRIAL ENCEPHALOMYOPATHIES

While many of the inherited disorders of mitochondrial oxidative phosphorylation present as muscle diseases (Chapter 27), the CNS is the second most commonly affected tissue.[80,][81] In addition to the diseases discussed below, Friedreich ataxia (considered above) is also recognized as a mitochondrial disorder associated with mutations in the frataxin gene.

Mitochondrial Encephalomyopathy, Lactic Acidosis, and Strokelike Episodes

Mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS) is the most common neurologic syndrome caused by mitochondrial abnormalities. The syndrome is characterized by recurrent episodes of acute neurologic dysfunction, cognitive changes, and evidence of muscle involvement with weakness and lactic acidosis. The stroke-like episodes are often associated with reversible deficits that do not correspond well to specific vascular territories. Pathologically, areas of infarction are observed, often with vascular proliferation and focal calcification. The most prevalent mutations associated with MELAS occurs in tRNAs; coding-gene mutations have also been reported.

Myoclonic Epilepsy and Ragged Red Fibers

Myoclonic epilepsy and ragged red fibers (MERRF) is a maternally transmitted disease in which affected individuals have myoclonus, a seizure disorder, and evidence of a myopathy. Ataxia, associated with neuronal loss from the cerebellar system (including the inferior olive in the medulla, cerebellar cortex, and deep nuclei), is also a common component. Most cases of MERRF are associated with mutations in tRNA that are distinct from those in MELAS. In some affected individuals there seems to be an overlap between MERRF and MELAS.

Leigh Syndrome (Subacute Necrotizing Encephalopathy)

This disease of early childhood is characterized by lactic acidemia, arrest of psychomotor development, feeding problems, seizures, extra-ocular palsies, and weakness with hypotonia. Death usually occurs within 1 to 2 years. On histologic examination there are multifocal, moderately symmetric regions of destruction of brain tissue with a spongiform appearance and proliferation of blood vessels. The areas that are most commonly affected include the periventricular gray matter of the midbrain, the tegmentum of the pons, and the periventricular regions of the thalamus and hypothalamus. A wide spectrum of

mutations has been identified as causing Leigh syndrome, including both nuclear and mitochondrial DNA mutations. Diverse mutations affecting mitochondrial genome–encoded components of oxidative phosphorylation complexes, as well as mitochondrial tRNA mutations, have been found; there does not seem to be a genotype-phenotype relationship. Interestingly, a point mutation in the mitochondrial gene for an ATPase subunit of complex V causes a maternally inherited form of Leigh syndrome when the cells contain a large proportion of the mutated mitochondrial DNA. However, when there is a higher fraction of normal mitochondria, the disease takes on a different clinical and pathologic appearance, as *neuropathy, ataxia, and retinitis pigmentosa* (NARP). Such unequal distribution of mitochondrial DNA among cells is called *heteroplasmy* (Chapter 5).

Kearn-Sayre Syndrome

Kearns-Sayre syndrome ("ophthalmoplegia plus") is a sporadic disorder most often associated with a large mitochondrial DNA deletion/rearrangement. The disorder presents with cerebellar ataxia, progressive external ophthalmoplegia, pigmentary retinopathy, and cardiac conduction defects. Pathologically, there is spongiform change in gray and white matter, with neuronal loss most evident in the cerebellum. The basis of the disease is large defects in the mitochondrial genome.

Alpers Disease

This disorder combines neurologic symptoms with evidence of hepatic dysfunction and pathologic findings including hepatitis and bile duct proliferation.[82] Alpers disease typically begins in the first few years of life with severe intractable seizures, followed by developmental delay, hypotonia, ataxia, and cortical blindness. There is neuronal loss in cerebral cortex and throughout deeper structures, and spongiform degeneration of gray matter. Mutations in the nuclear gene encoding DNA polymerase γ—the isoform of DNA polymerase responsible for replication of the mitochondrial genome—have been identified in Alpers disease.[83]

3.18.12 Toxic & Acquired Metabolic Diseases

Toxic and acquired metabolic diseases are relatively common causes of neurologic illnesses. These diseases were discussed in Chapter 9 ; only aspects that are relevant to CNS pathology are presented below.

VITAMIN DEFICIENCIES

Thiamine (Vitamin B_1) Deficiency

As was discussed in Chapter 9 , thiamine deficiency may result in the slowly evolving clinical disorder *beriberi*, which is associated with cardiac failure. In certain affected individuals, thiamine deficiency may also lead to the development of psychotic symptoms or ophthalmoplegia that begin abruptly, a syndrome termed *Wernicke encephalopathy*. The acute stages, if unrecognized and untreated, may be followed by a prolonged and largely irreversible condition, *Korsakoff syndrome*, characterized clinically by memory disturbances and confabulation. Because the two syndromes are closely linked, the term *Wernicke-Korsakoff syndrome* is often applied. The syndrome is particularly common in the setting of chronic alcoholism, but it may also be encountered in individuals with thiamine deficiency resulting from gastric disorders, including carcinoma, chronic gastritis, or persistent vomiting. Treatment with thiamine may reverse the manifestations of Wernicke syndrome.

Morphology. Wernicke encephalopathy is characterized by foci of hemorrhage and necrosis in the mamillary bodies and the walls of the third and fourth ventricles. Early lesions show dilated capillaries with prominent endothelial cells. Subsequently, the capillaries become leaky, producing

hemorrhagic areas. With time, there is infiltration of macrophages and development of a cystic space with hemosiderin-laden macrophages. These chronic lesions predominate in individuals with Korsakoff syndrome. Lesions in the dorsomedial nucleus of the thalamus seem to be the best correlate of the memory disturbance and confabulation.

Vitamin B_{12} Deficiency

Deficiency of vitamin B_{12} often causes anemia (Chapter 14) but can also have severe and potentially irreversible effects on the nervous system. The neurologic symptoms may present in the course of a few weeks, initially with numbness, tingling, and slight ataxia in the lower extremities, but may progress rapidly to include spastic weakness of the lower extremities. Complete paraplegia may occur, usually only later in the course. With prompt vitamin replacement therapy, clinical improvement occurs; however, if complete paraplegia has developed, recovery is poor. On microscopic examination vitamin B_{12} deficiency is associated with a swelling of myelin layers, producing vacuoles. This begins segmentally at the midthoracic level of the spinal cord in the early stages. With time, axons in both the ascending tracts of the posterior columns and the descending pyramidal tracts degenerate. While isolated involvement of descending or ascending tracts may be observed in a variety of spinal cord diseases, the combined degeneration of both ascending and descending tracts of the spinal cord is characteristic of vitamin B_{12} deficiency and has led to the designation *subacute combined degeneration of the spinal cord*.

NEUROLOGIC SEQUELAE OF METABOLIC DISTURBANCES

Hypoglycemia

Since the brain requires glucose and oxygen for its energy production, the cellular effects of diminished glucose resemble those of oxygen deprivation, as described earlier. Some regions of the brain are more sensitive to hypoglycemia than are others. Glucose deprivation initially leads to selective injury to large pyramidal neurons of the cerebral cortex, which, if severe, may result in pseudolaminar necrosis of the cortex, predominantly involving deep layers. The hippocampus is also vulnerable to glucose depletion and may show a marked loss of pyramidal neurons in Sommer sector (area CA1 of the hippocampus). Purkinje cells of the cerebellum are also sensitive to hypoglycemia, although to a lesser extent than to hypoxia. If the level and duration of hypoglycemia are of sufficient severity, there may be widespread injury to many areas of the brain.

Hyperglycemia

Hyperglycemia is most commonly found in the setting of inadequately controlled diabetes mellitus and can be associated with either ketoacidosis or hyperosmolar coma. The affected individual becomes dehydrated and develops confusion, stupor, and eventually coma. The fluid depletion must be corrected gradually; otherwise, severe cerebral edema may follow.

Hepatic Encephalopathy

The pathogenesis of hepatic encephalopathy is discussed in Chapter 18 . The cellular response in the CNS is predominantly glial. Alzheimer type II cells are evident in the cortex and basal ganglia and other subcortical gray matter regions.

TOXIC DISORDERS

Cellular and tissue injury from toxic agents is discussed in Chapter 1 . Aspects of several important toxic disorders that are of unique neurologic importance are discussed here.

Carbon Monoxide

Many of the pathologic findings that follow acute carbon monoxide exposure are the result of hypoxia from altered oxygen-carrying capacity of hemoglobin. Selective injury of the neurons of layers III and V of the cerebral cortex, Sommer sector of the hippocampus, and Purkinje cells is characteristic. Bilateral necrosis of the globus pallidus may also occur; it is more common in carbon monoxide–induced hypoxia than in hypoxia from other causes. Demyelination of white matter tracts may be a later event.

Methanol

Methanol toxicity preferentially affects the retina, where degeneration of retinal ganglion cells may cause blindness. Selective bilateral putamenal necrosis and focal white-matter necrosis also occur when the exposure is severe. Formate, a major metabolite of methanol, may have a role in the retinal toxicity.

Ethanol

Experience tells us that the effects of acute ethanol intoxication are reversible, but chronic alcohol abuse is associated with a variety of neurologic sequelae, including Wernicke-Korsakoff syndrome, considered above. The toxic effects of chronic alcohol intake may be either direct or secondary to nutritional deficits. Cerebellar dysfunction occurs in about 1% of chronic alcoholics, associated with a clinical syndrome of truncal ataxia, unsteady gait, and nystagmus. The histologic changes are atrophy and loss of granule cells predominantly in the anterior vermis (Fig. 28-44). In advanced cases there is loss of Purkinje cells and proliferation of the adjacent astrocytes *(Bergmann gliosis)* between the depleted granular cell layer and the molecular layer of the cerebellum. The fetal alcohol syndrome is discussed in Chapter 10 .

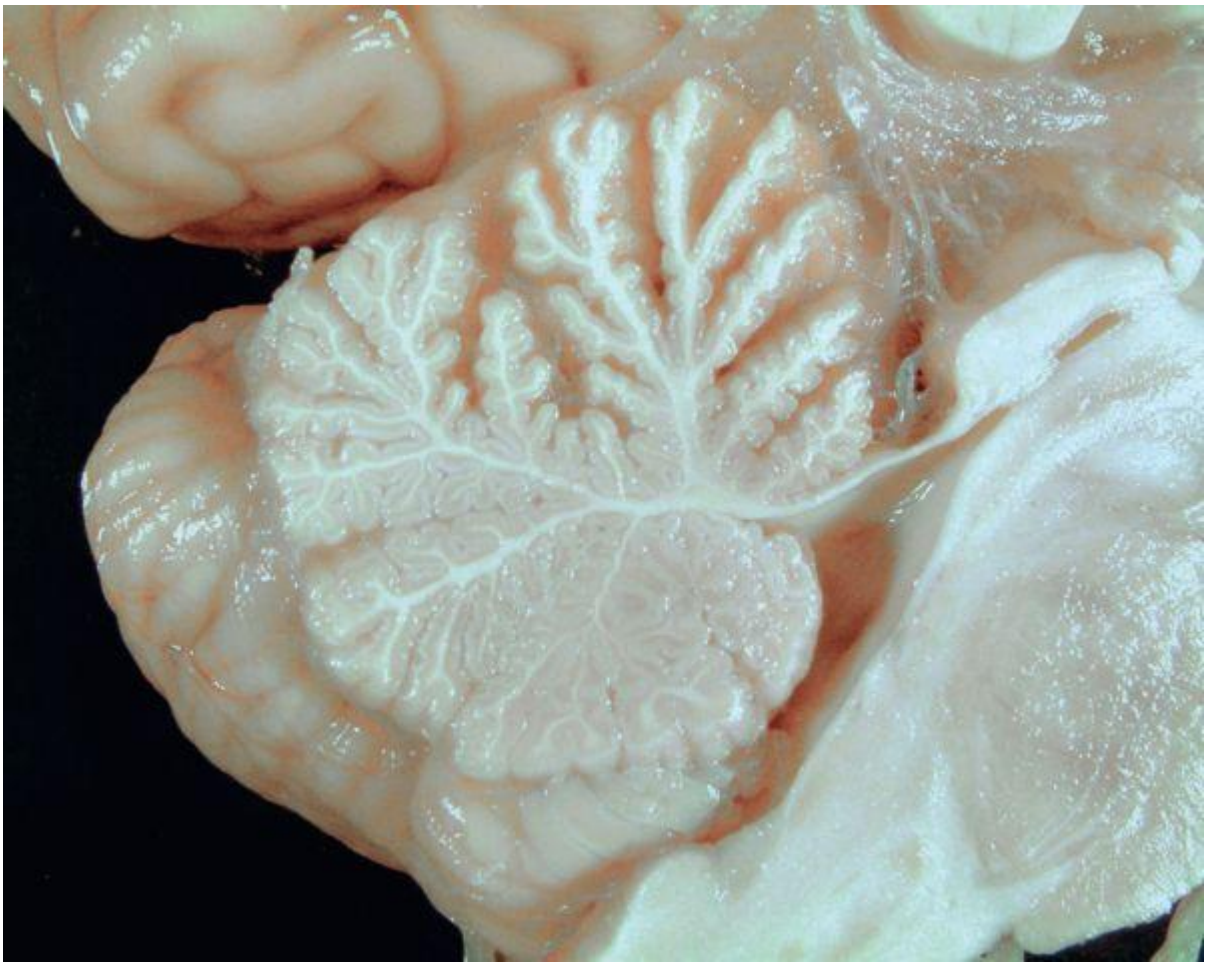

FIGURE 28-44 Alcoholic cerebellar degeneration. The anterior portion of the vermis *(upper portion of figure)* is atrophic with widened spaces between the folia.

Radiation

As discussed in Chapter 9 , exposure to very high doses of radiation (>1000 rems) can cause intractable nausea, confusion, convulsions, and rapid onset of coma, followed by death. Delayed effects of radiation can also present with rapidly evolving symptoms, including headaches, nausea, vomiting, and papilledema that may appear months to years after irradiation. The pathologic findings consist of large areas of coagulative necrosis and adjacent edema. The typical lesion is restricted to white matter, and all elements within the area undergo necrosis, including astrocytes, axons, oligodendrocytes, and blood vessels. Adjacent to the area of coagulative necrosis, proteinaceous spheroids may be identified, and blood vessels show thickened walls with intramural fibrin-like material. Radiation can also induce tumors, which usually develop years after radiation therapy and include sarcomas, gliomas, and meningiomas.

Combined Methotrexate and Radiation-Induced Injury

Methotrexate toxicity most commonly develops when the drug has been administered in association with radiation therapy, either together or at separate times. The interval between the inciting events and the onset of symptoms varies considerably but may be as long as months. Symptoms often begin with drowsiness, ataxia, and confusion, and may progress rapidly. While some affected individuals recover

function, others may become comatose; rarely, methotrexate neurotoxicity may be responsible for the patient's death. The mechanisms of these delayed effects of methotrexate are unclear.

The pathologic basis of the symptoms are focal areas of coagulative necrosis within white matter, often adjacent to the lateral ventricles but at times distributed throughout the white matter or in the brainstem. Surrounding axons are often dilated and form axonal spheroids. Axons and cell bodies in the vicinity of the lesions undergo dystrophic mineralization, and there is adjacent gliosis.

3.18.13 Tumors

The annual incidence of tumors of the CNS ranges from 10 to 17 per 100,000 persons for intra-cranial tumors and 1 to 2 per 100,000 persons for intra-spinal tumors; about half to three quarters are primary tumors, and the rest are metastatic. Tumors of the CNS account for 20% of all cancers of childhood. Seventy percent of childhood CNS tumors arise in the posterior fossa; a comparable number of tumors in adults arise within the cerebral hemispheres above the tentorium. There is great interest in identifying tumor initiating (stem) cells that maintain tumor growth and, therefore, may be key targets of new therapies.[84,][85]

While pathologists have developed classification schemes that distinguish between benign and malignant lesions on histologic grounds, the clinical course of disease is also influenced by relatively unique features of brain tumors. Thus, some glial tumors with benign histologic features (low mitotic rate, cellular uniformity, and slow growth) may infiltrate large regions of the brain and lead to serious clinical deficits and poor prognosis. Because of their infitrative behavior, it is often not feasible to resect glial neoplasms completely without compromising neurologic function. Also, any neoplasm can have lethal consequences if it is located in a critical region, as when a benign meningioma, by compressing the medulla, causes cardiorespiratory arrest. Even the most highly malignant gliomas rarely metastasize outside the CNS. The subarachnoid space provides a pathway for spread, so seeding along the brain and spinal cord can occur in highly anaplastic as well as in well-differentiated neoplasms that extend into the CSF.

Classification of tumors is one of the arts of pathology, drawing on emerging molecular methods and the traditional recognition of histologic and biologic patterns.[86,][87] Treatment protocols and experimental trials of glial tumors are usually based on the World Health Organization (WHO) grading scheme, which segregates tumors into one of four grades according to their biologic behavior, ranging from grade I to grade IV. Under the current classification scheme, lesions of different grade are always given distinct names. When tumors recur, they often show progression to a higher histologic grade and, thus, acquire a different name; this actually represents progression along a classification scheme rather than a new disease.

The major classes of primary brain tumors to be considered here include gliomas, neuronal tumors, poorly differentiated tumors, as well as a small collection of other tumors. In addition, we will discuss tumors of the meninges as well as tumors of peripheral nerves.

GLIOMAS

Gliomas, the most common group of primary brain tumors, include *astrocytomas*, *oligodendrogliomas*, and *ependymomas*.

Astrocytoma

The two major categories of astrocytic tumors are infiltrating astrocytomas and non-infiltrating neoplasms, of which the most common are the pilocytic astrocytomas. These tumor types have

characteristic histologic features, distribution within the brain, age groups typically affected, and clinical course.

Infiltrating Astrocytomas

These account for about 80% of adult primary brain tumors in adults. Usually found in the cerebral hemispheres, they may also occur in the cerebellum, brainstem, or spinal cord, most often in the fourth through sixth decades. The most common presenting signs and symptoms are seizures, headaches, and focal neurologic deficits related to the anatomic site of involvement. Infiltrating astrocytomas show a spectrum of histologic differentiation that correlates well with clinical course and outcome; within this spectrum, tumors range from *diffuse astrocytoma* (grade II/IV) through *anaplastic astrocytoma* (grade III/IV) to *glioblastoma* (grade IV/IV). (The grade I/IV category is limited to pilocytic astrocytoma.)

Morphology. The gross appearance of **diffuse astrocytoma** is that of a poorly defined, gray, infiltrative tumor that expands and distorts the invaded brain (Fig. 28-45). These tumors range in size from a few centimeters to enormous lesions that replace an entire hemisphere. The cut surface of the tumor is either firm or soft and gelatinous; cystic degeneration may be seen. The tumor may appear well demarcated from the surrounding brain tissue, but infiltration beyond the outer margins is always present.

On microscopic examination, diffuse astrocytomas are characterized by a mild to moderate increase in glial cellularity, variable nuclear pleomorphism, and an intervening feltwork of fine, GFAP-positive astrocytic processes that give the background a fibrillary appearance. The transition between neoplastic and normal tissue is indistinct, and tumor cells can be seen infiltrating normal tissue at some distance from the main lesion.

Anaplastic astrocytomas show regions that are more densely cellular and have greater nuclear pleomorphism; mitotic figures are often observed. The term **gemistocytic astrocytoma** is used for tumors in which the predominant neoplastic astrocyte shows a brightly eosinophilic cell body from which emanate abundant, stout processes.

In **glioblastoma** (previously called *glioblastoma multiforme*) variation in the gross appearance of the tumor from region to region is characteristic (Fig. 28-46). Some areas are firm and white, others are soft and yellow due to necrosis, and yet others show regions of cystic degeneration and hemorrhage. The histologic appearance of glioblastoma is similar to anaplastic astrocytoma with the additional features of **necrosis** and **vascular or endothelial cell proliferation**. Necrosis in glioblastoma often occurs in a serpentine pattern in areas of hypercellularity. Tumor cells collect along the edges of the necrotic regions, producing a histologic pattern referred to as **pseudo-palisading** (Fig. 28-47). Vascular cell proliferation is characterized by tufts of piled-up cells that bulge into the lumen; the minimal criterion for this feature is a double layer of endothelial cells. With marked vascular cell proliferation the tuft forms a ball-like structure, the glomeruloid body (see Fig. 28-47). VEGF, produced by malignant astrocytes in response to hypoxia, contributes to this distinctive vascular change. Since histologic features can be extremely variable from one region of the neoplasm to another, a single small biopsy specimen might not be representative of the worst aspects of a tumor.

In the condition called **gliomatosis cerebri**, multiple regions of the brain, in some cases the entire brain, are infiltrated by neoplastic astrocytes. Because of the widespread infiltration, this process follows an aggressive course and is considered to be a grade III/IV lesion—independent of the appearance of the individual tumor cells.

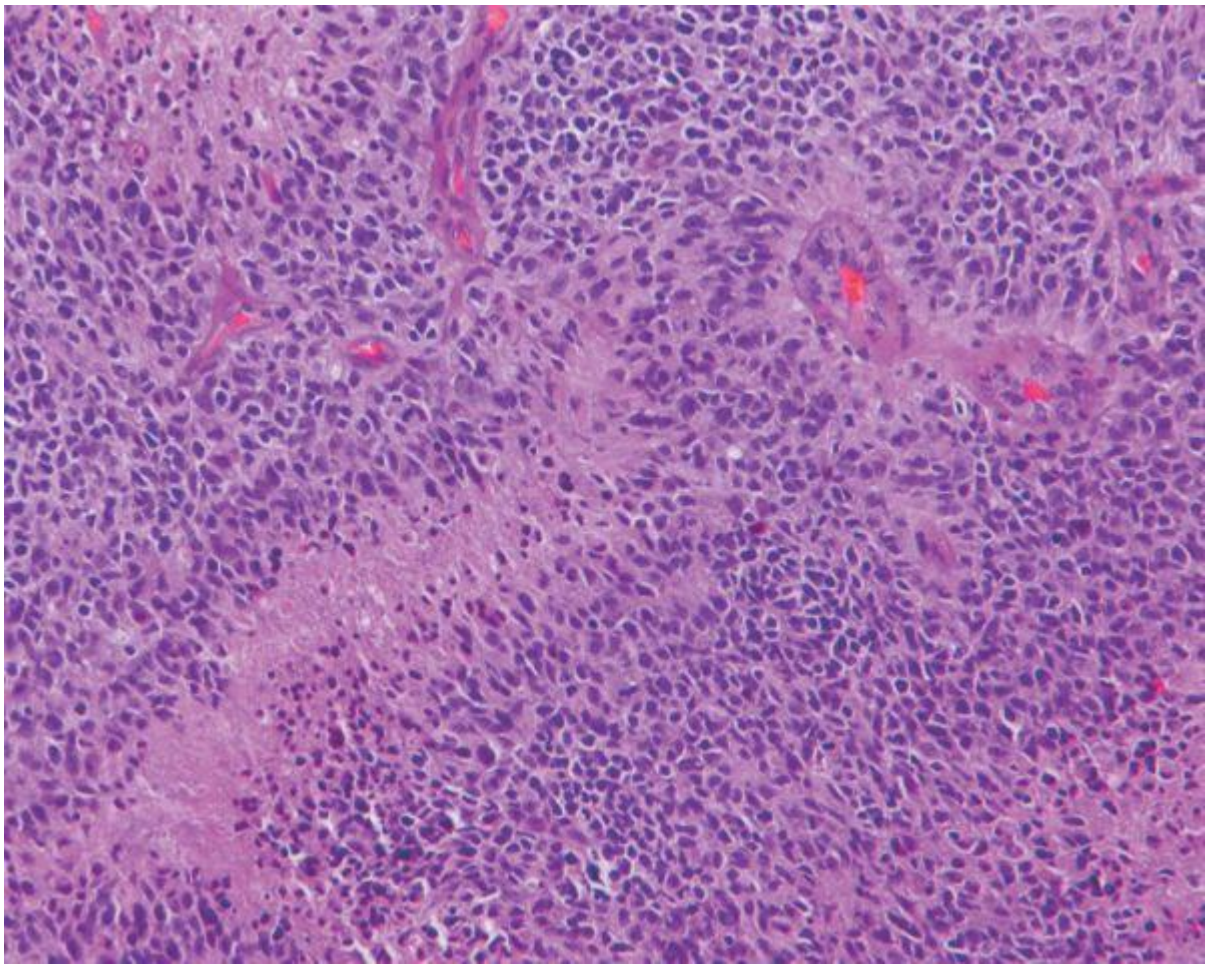

FIGURE 28-47 Glioblastoma. Foci of necrosis with pseudopalisading of malignant nuclei and endothelial cell proliferation.

Molecular Genetics.

Certain genetic alterations correlate with the progression of infiltrating astrocytomas from low to high grade, which is part of the natural course of the disease in many patients.[86,][88] Among the alterations that are most common in the low-grade astrocytomas are mutations affecting p53 and overexpression of platelet-derived growth factor α (PDGF-A) and its receptor. The transition to higher grade astrocytoma is associated with disruption of two well-known tumor suppressor genes, *RB* and *p16/CDKNaA*, and an unknown putative tumor suppressor on chromosome 19q.

It was recognized well before advances in genetic analyses that glioblastoma tends to occur in one of two clinical settings: most commonly as new onset disease, typically in older individuals *(primary glioblastoma)*, and in younger patients with a past history of lower-grade astrocytoma *(secondary glioblastoma)*. While primary and secondary glioblastomas show some molecular distinctions, the molecular lesions found in the two types of glioblastoma tend to impinge on the same pathways. For example, whereas secondary glioblastomas usually have *p53* mutations, primary astrocytomas more commonly have amplification of *MDM2*, a gene that encodes an inhibitor of p53. Similarly, while secondary glioblastomas have increased signaling through the PDGF-A receptor, primary glioblastomas often have amplified, mutated epidermal growth factor receptor (*EGFR*) genes, which encode aberrant forms of EGFR known as EGFRvIII. Both types of mutations lead to increased receptor tyrosine kinase

activity and the activation of the RAS and PI-3 kinase pathways, whichstimulate the growth and survival of tumor cells (Chapter 7). Based on whole genome sequencing, it is estimated that combinations of mutations that activate RAS and PI-3 kinase and inactivate p53 and RB are present in 80% to 90% of primary glioblastomas.[90]

Clinical Features.

The presenting symptoms of infiltrating astrocytomas depend, in part, on the location and growth rate of the tumor. Well-differentiated diffuse astrocytomas may remain static or progress only slowly over a number of years; the mean survival is more than 5 years. Eventually, however, clinical deterioration occurs that is usually due to the appearance of a more rapidly growing tumor of higher histologic grade. Radiologic studies show mass effect as well as changes in the brain adjacent to the tumor, such as edema. High-grade astrocytomas have abnormal vessels that are “leaky” and therefore demonstrate contrast enhancement on imaging studies. The prognosis for individuals with glioblastoma is very poor, although the use of newer chemotherapeutic agents has provided some benefit.[92] Methylation of the promoter for the gene encoding the DNA repair enzyme MGMT predicts responsiveness to DNA alkylating drugs—as would be expected since MGMT is critical for the repair of the chemotherapeutically induced DNA modification.[91] Treatment of primary glioblastoma patients with tyrosine kinase inhibitors that target EGFR has produced some encouraging results.[89] With current optimal treatment, consisting of resection followed by radiation therapy and chemotherapy, the mean length of survival after diagnosis has increased to 15 months; 25% of such patients are alive after 2 years. Survival is substantially shorter in older patients, for those with lower performance status, and for large unresectable lesions.

Pilocytic Astrocytoma

Pilocytic astrocytomas (grade I/IV) are distinguished from the other types by their pathologic appearance and relatively benign behavior. They typically occur in children and young adults, and are usually located in the cerebellum but may also appear in the floor and walls of the third ventricle, the optic nerves, and occasionally the cerebral hemispheres.

Morphology. On macroscopic examination, a pilocytic astrocytoma is often cystic (Fig. 28-48); if solid, it may be well circumscribed or, less frequently, infiltrative. On microscopic examination the tumor is composed of bipolar cells with long, thin “hairlike” processes that are GFAP-positive and form dense fibrillary meshworks; Rosenthal fibers and eosinophilic granular bodies, are often present. Tumors are often biphasic with a loose microcystic pattern in addition to the fibrillary areas. An increase in the number of blood vessels, often with thickened walls or vascular cell proliferation, is seen but does not imply an unfavorable prognosis; necrosis and mitoses are uncommon. Unlike diffuse fibrillary astrocytomas of any grade, pilocytic astrocytomas have a narrow infiltrative border with the surrounding brain.

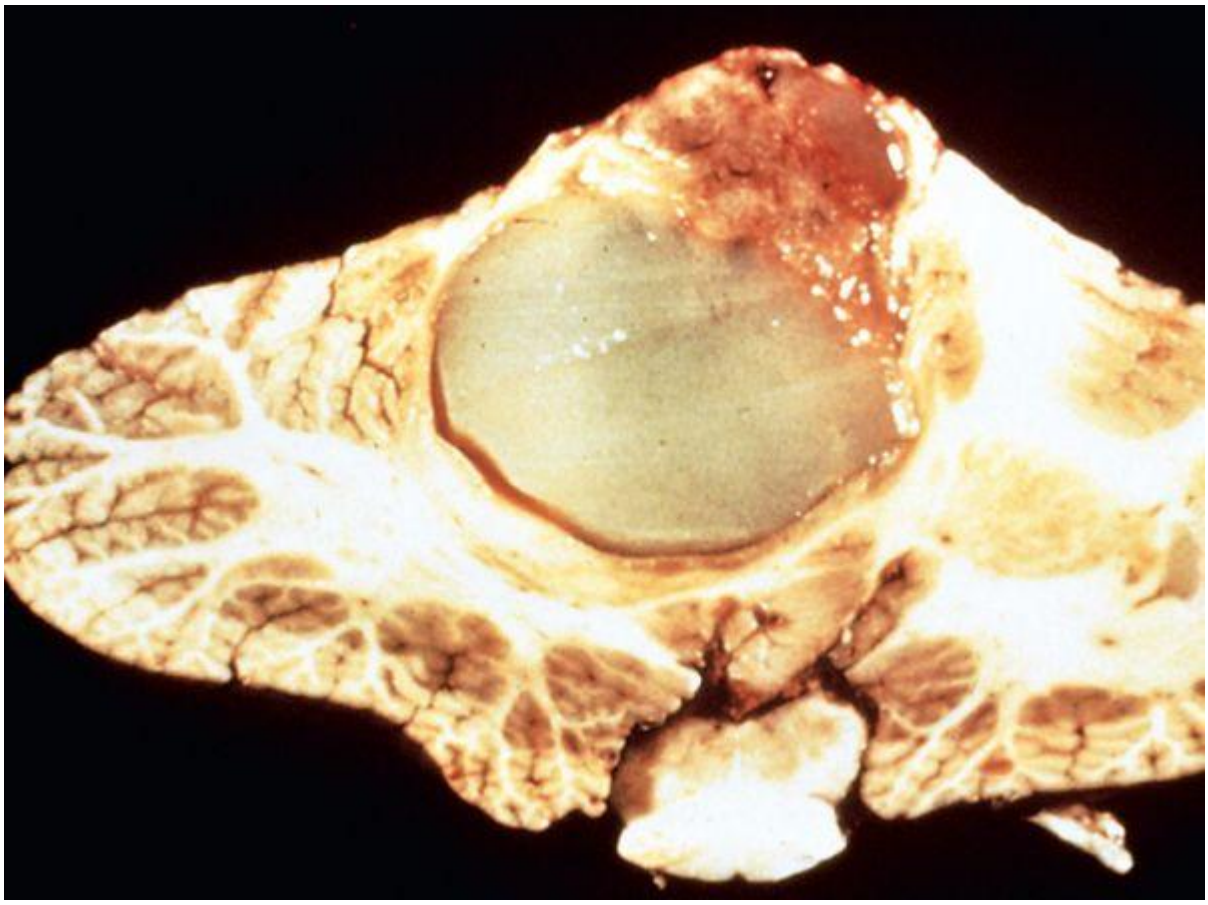

FIGURE 28-48 Pilocytic astrocytoma in the cerebellum with a nodule of tumor in a cyst.

These tumors grow very slowly, and, in the cerebellum particularly, may be treated by resection. Symptomatic recurrence of incompletely resected lesions is often associated with cyst enlargement rather than growth of the solid component. Tumors that extend into the hypothalamic region from the optic tract can have a more ominous clinical course because of their location. The histologic separation of these tumors from other astrocytomas is supported by the rarity of *p53* mutations or other genetic changes that are found in infiltrating astrocytomas. Those pilocytic astrocytomas that occur in the setting of NF1 show functional loss of neurofibromin; this genetic alteration is not observed in sporadic forms.

Pleomorphic Xanthoastrocytoma

This is a tumor that occurs most often in the temporal lobe of children and young adults, usually with a history of seizures. The tumor consists of neoplastic, occasionally bizarre, astrocytes, which are sometimes lipidized; these cells often express neuronal and glial markers. The degree of nuclear atypia can be extreme and may suggest a high-grade astrocytoma, but the presence of abundant reticulin deposits, relative circumscription, and chronic inflammatory cell infiltrates, along with the absence of necrosis and mitotic activity, redirects the pathologist toward the diagnosis. This is usually a low-grade tumor (WHO grade II/IV), with a 5 year survival rate estimated at 80%. Necrosis and mitotic activity are indicative of a higher grade tumor and predict a more aggressive course.

Brainstem Glioma

A clinical subgroup of astrocytomas, brainstem gliomas occur mostly in the first two decades of life and make up about 20% of primary brain tumors in this age group. Several distinct anatomic patterns have been defined in the pediatric age group, each differing in clinical course: intrinsic pontine gliomas (the most common, with an aggressive course and short survival); tumors, often exophytic, arising in the cervicomedullary junction region (with a less aggressive course); and tectal gliomas (with an even more benign course). Among the rarer brainstem gliomas affecting adults, most are intrinsic pontine gliomas. These can be separated into low-grade diffuse fibrillary astrocytomas and glioblastoma, with the expected differences in clinical course and survival.

Oligodendroglioma

These tumors constitute 5% to 15% of gliomas and are most common in the fourth and fifth decades. Patients may have had several years of neurologic complaints, often including seizures. The lesions are found mostly in the cerebral hemispheres, with a predilection for white matter.

Morphology. On gross examination, oligodendrogliomas are well-circumscribed, gelatinous, gray masses, often with cysts, focal hemorrhage, and calcification. On microscopic examination, the tumors are composed of sheets of regular cells with spherical nuclei containing finely granular chromatin (similar to normal oligodendrocytes) surrounded by a clear halo of cytoplasm (Fig. 28-49). The tumor typically contains a delicate network of anastomosing capillaries. Calcification, present in as many as 90% of these tumors, ranges from microscopic foci to massive depositions. As the tumor cells infiltrate cerebral cortex, there is often formation of secondary structures, often with tumor cells arrayed around neurons (perineuronal satellitosis). Mitotic activity is usually very difficult to detect, and proliferation indices are low. Oligodendrogliomas are considered to be WHO grade II/IV lesions.

Anaplastic oligodendrogliomas (WHO grade III/IV) are characterized by increased cell density, nuclear anaplasia, increased mitotic activity, and necrosis. These changes can often be found in nodules within an otherwise grade II/IV oligodendroglioma. Also often present in these higher grade lesions are discrete round cells with cytoplasmic GFAP and nuclei that resemble the other elements of the tumor. These microgemistocytes differ from gemistocytic astro cytes in that they lack abundant processes; the intermediate filaments are restricted to a small lump of cytoplasm. Some of these high-grade oligodendroglial tumors also show patterns that are indistinguishable from glioblastoma. Because several studies have shown that such appearance correlates with worse behavior, these tumors are grouped with glioblastoma.

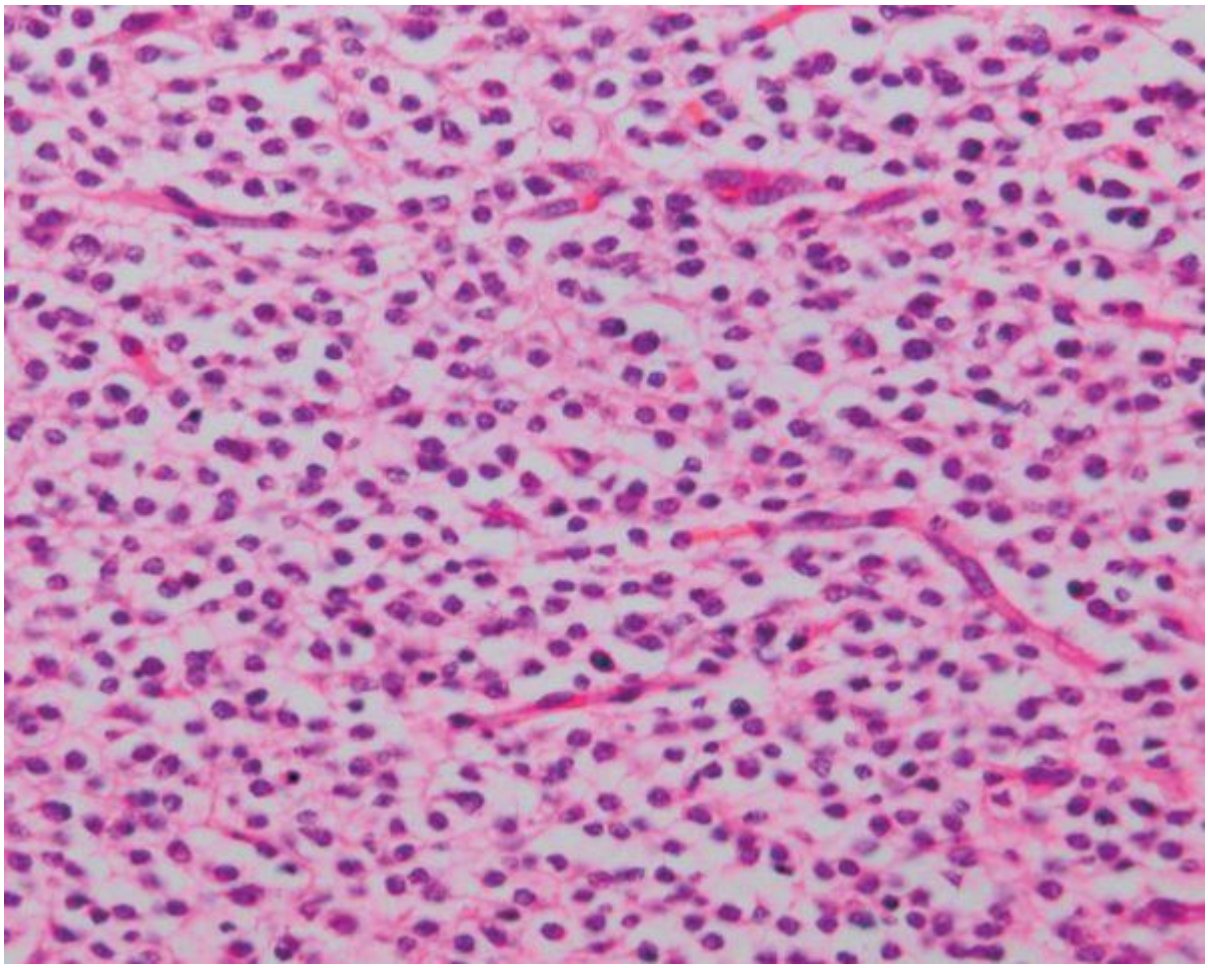

FIGURE 28-49 Oligodendroglioma. Tumor nuclei are round, with cleared cytoplasm forming "halos" and vasculature composed of thin-walled capillaries.

Molecular Genetics.

The underlying molecular abnormalities, along with histologic appearance, distinguish oligodendrogliomas from astrocytic tumors. The most common genetic alterations in oligodendrogliomas are loss of heterozygosity for chromosomes 1p and 19q, seen in up to 80% of cases (depending on the level of histologic stringency in the study). The specific tumor suppressor loci that are involved in the generation of these tumors remain unknown. Additional genetic alterations tend to accumulate with progression to anaplastic oligodendroglioma. The more common of these include loss of 9p, loss of 10q, and mutation in *CDKN2A*. In contrast to high-grade astrocytic tumors, *EGFR* gene amplification is not seen in these tumors, but a significant proportion do show increased EGFR protein levels.

In addition to having implications for the biology of the tumors, the molecular alterations in anaplastic oligodendrogliomas impact treatment. Tumors with loss of 1p and 19q but without other alterations have consistent, long-lasting responses to chemotherapy and radiation.[91] Those with additional genetic changes have shorter-lived responses, and those without loss of 1p and 19q seem to be resistant to therapy.

Clinical Features.

In general, individuals with oligodendrogliomas have a better prognosis than do those with astrocytomas. Current treatment with surgery, chemotherapy, and radiation therapy has yielded an average survival of 5 to 10 years. Individuals with anaplastic oligodendroglioma have an overall worse prognosis. Progression from low- to higher-grade lesions occurs, typically over about 6 years.

The terms *oligoastrocytoma* and *anaplastic oligoastrocytoma* refer to neoplasms consisting of distinct regions of oligodendroglioma and astrocytoma. The diagnostic criteria for these entities remain controversial. Despite their biphasic nature, these tumors are monoclonal, and show either 1p/19q deletion or *p53* mutations.

Ependymoma and Related Paraventricular Mass Lesions

Ependymomas, as would be expected, most often arise next to the ependyma-lined ventricular system, including the oft-obliterated central canal of the spinal cord. In the first two decades of life they typically occur near the fourth ventricle and constitute 5% to 10% of the primary brain tumors in this age group. In adults the spinal cord is the most common location; tumors in this site are particularly frequent in the setting of neurofibromatosis type 2 (NF2).

Morphology. In the fourth ventricle, ependymomas are typically solid or papillary masses extending from the floor of the ventricle (Fig. 28-50A). Although ependymomas are moderately well demarcated from adjacent brain, the proximity of vital pontine and medullary nuclei usually makes complete extirpation impossible. In the intra-spinal tumors this sharp demarcation sometimes makes total removal feasible. On microscopic examination ependymomas are composed of cells with regular, round to oval nuclei and abundant granular chromatin. Between the nuclei there is a variably dense fibrillary background. Tumor cells may form glandlike round or elongated structures (rosettes, canals) that resemble the embryologic ependymal canal, with long, delicate processes extending into a lumen (Fig. 28-50B); more frequently present are **perivascular pseudorosettes** (Fig. 28-50B), in which tumor cells are arranged around vessels with an intervening zone consisting of thin ependymal processes directed toward the wall of the vessel. GFAP expression is found in most ependymomas. While most ependymomas are well differentiated and behave as WHO grade II/IV lesions, anaplastic ependymomas (WHO grade III/IV) reveal increased cell density, high mitotic rates, areas of necrosis, and less evident ependymal differentiation.

Myxopapillary ependymomas are distinct but related lesions that occur in the filum terminale of the spinal cord and contain papillary elements in a myxoid background, admixed with ependymoma-like cells. Cuboidal cells, sometimes with clear cytoplasm, are arranged around papillary cores containing connective tissue and blood vessels. The myxoid areas contain neutral and acidic mucopolysaccharides. Prognosis depends on completeness of surgical resection; if the tumor has extended into the subarachnoid space and surrounded the roots of the cauda equina, recurrence is likely.

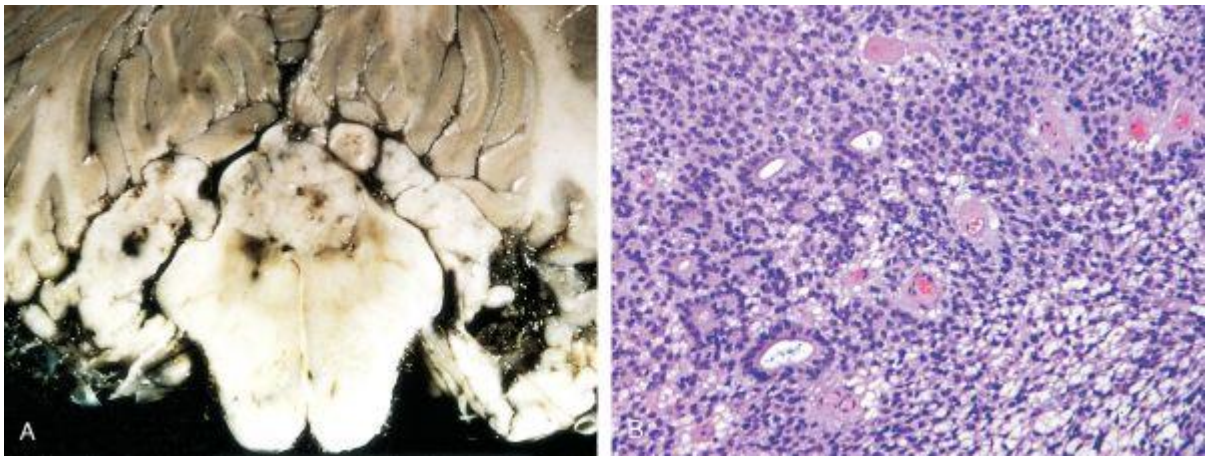

FIGURE 28-50 Ependymoma. **A**, Tumor growing into the fourth ventricle, distorting, compressing, and infiltrating surrounding structures. **B**, Microscopic appearance of ependymoma.

Molecular Genetics.

Given the association of spinal ependymomas with NF2, it is not surprising that the *NF2* gene on chromosome 22 is commonly mutated in ependymomas in the spinal cord but not at other sites. Supratentorial lesions are more likely to show alterations in chromosome 9. Ependymomas do not seem to share the genetic alterations that are found in other gliomas, such as mutations in *p53*.

Clinical Features.

Posterior fossa ependymomas often manifest with hydrocephalus secondary to progressive obstruction of the fourth ventricle rather than invasion of the pons or medulla. Because of the relationship of ependymomas to the ventricular system, CSF dissemination is a common occurrence and portends a poor prognosis. Posterior fossa lesions have the worst overall outcome, particularly in younger children, with a 5-year survival of roughly 50%. The clinical outcome for completely resected supratentorial and spinal ependymomas is better.

Several other tumors occur either immediately below the ependymal lining of the ventricle or in association with the choroid plexus, which sits in continuity with the ependyma. With the exception of the rare choroid plexus carcinoma, these are benign to low-grade lesions; however, their location may cause clinical problems.

- *Subependymomas* are solid, sometimes calcified, slow-growing nodules attached to the ventricular lining and protruding into the ventricle. They are usually asymptomatic and are incidental findings at autopsy or imaging; if they are sufficiently large or strategically located, they may cause hydrocephalus. They are most often found in the lateral and fourth ventricles and have a characteristic microscopic appearance, with clumps of ependymal-appearing nuclei scattered in a dense, fine, glial fibrillar background.
- *Choroid plexus papillomas* can occur anywhere along the choroid plexus and are most common in children, in whom they are usually found in the lateral ventricles. In adults, they more often involve the fourth ventricle. These markedly papillary growths almost exactly recapitulate the structure of the normal choroid plexus. The papillae have connective tissue stalks covered with a cuboidal or columnar epithelium. Clinically, choroid plexus papillomas usually present with hydrocephalus due to obstruction of the ventricular system by tumor or to overproduction of CSF. The far rarer *choroid plexus carcinomas* resemble adenocarcinoma. These tumors are usually found in children; in adults, they must be differentiated from the

much more common metastatic carcinoma.

- *Colloid cyst of the third ventricle* is a non-neoplastic lesion that most often occurs in young adults. The cyst is attached to the roof of the third ventricle, where it can obstruct one or both of the foramina of Monro and, as a result, causes noncommunicating hydrocephalus, which may be rapidly fatal. Headache, sometimes positional, is an important clinical symptom. The cyst has a thin, fibrous capsule and a lining of low to flat cuboidal epithelium; it contains gelatinous, proteinaceous material.

NEURONAL TUMORS

The most common CNS tumor containing mature-appearing neurons (ganglion cells) is *gangliоglioma*, since there is usually an admixed glial neoplasm. Most of these tumors are slow growing, but the glial component occasionally becomes frankly anaplastic, and the disease then progresses rapidly. Lesions that contain mixtures of neuronal and glial elements often present as a seizure disorder; surgical resection of the tumor is usually effective in controlling the seizures.

Morphology. Gangliogliomas are most commonly found in the temporal lobe and often have a cystic component. The neoplastic ganglion cells are irregularly clustered and have apparently random orientation of neurites. Binucleate forms are frequent. The glial component of these lesions usually resembles a low-grade astrocytoma, lacking mitotic activity and necrosis.

Dysembryoplastic neuroepithelial tumor is a rare, lowgrade tumor of childhood that often presents as a seizure disorder, and has a relatively good prognosis after surgical resection. These lesions are typically located in the superficial temporal lobe, although other cortical sites are seen. There is often attenuation of the overlying skull, suggesting that the lesion has been present for a long time.

Morphology. These lesions typically form multiple discrete intracortical nodules of small, round cells, arranged in columns around central cores of processes, and are associated with a myxoid background, known as the "specific glioneuronal element." There are well-differentiated "floating neurons" that sit in the pools of mucopolysaccharide-rich fluid of the myxoid background. The larger neurons and the small, round cells of the specific element express neuronal markers. Surrounding the nodules, there may be focal cortical dysplasia and sometimes low-grade astrocytoma. Lesions that show both the specific element and a glial component are termed **complex**.

Central neurocytoma typically is a low-grade neuronal neoplasm found within the ventricular system (most commonly the lateral or third ventricles), characterized by evenly spaced, round, uniform nuclei and often islands of neuropil. Although in pattern and shape the cells resemble oligodendroglioma, ultrastructural and immunohistochemical studies reveal the neuronal lineage of the tumor cells.

POORLY DIFFERENTIATED NEOPLASMS

Some tumors, though of neuroectodermal origin, express few if any of the phenotypic markers of mature cells of the nervous system and are described as poorly differentiated, or embryonal, meaning that they retain cellular features of primitive, undifferentiated cells. The most common is the *medulloblastoma*, which accounts for 20% of the brain tumors in children.

Medulloblastoma

This tumor occurs predominantly in children and exclusively in the cerebellum (by definition). Neuronal and glial markers may be expressed, but the tumor is often largely undifferentiated.

Morphology. In children, medulloblastomas are located in the midline of the cerebellum, but lateral locations are more often found in adults. Rapid growth may occlude the flow of CSF, leading to hydrocephalus. The tumor is often well circumscribed, gray, and friable, and may be seen extending to the surface of the cerebellar folia and involving the leptomeninges (Fig. 28-51A). On microscopic examination medulloblastoma is extremely cellular, with sheets of anaplastic cells (Fig. 28-51B). Individual tumor cells are small, with scant cytoplasm and hyperchromatic nuclei that are frequently elongated or crescent shaped. Mitoses are abundant, and markers of cellular proliferation, such as Ki-67, are detected in a high percentage of the cells. The tumor may express neuronal (neurosecretory granules or Homer Wright rosettes, as occur in neuroblastoma; Chapter 10) and glial (GFAP+) phenotypes. The **desmoplastic variant** is characterized by areas of stromal response, marked by collagen and reticulin deposition and nodules of cells forming "pale islands" that have more neuropil and show greater expression of neuronal markers.

At the edges of the main tumor mass, medulloblastoma cells have a propensity to form linear chains of cells infiltrating through cerebellar cortex to aggregate beneath the pia, penetrate the pia, and seed into the subarachnoid space. Dissemination through the CSF is a common complication, presenting as nodular masses elsewhere in the CNS, including metastases to the cauda equina that are sometimes termed **drop metastases**.

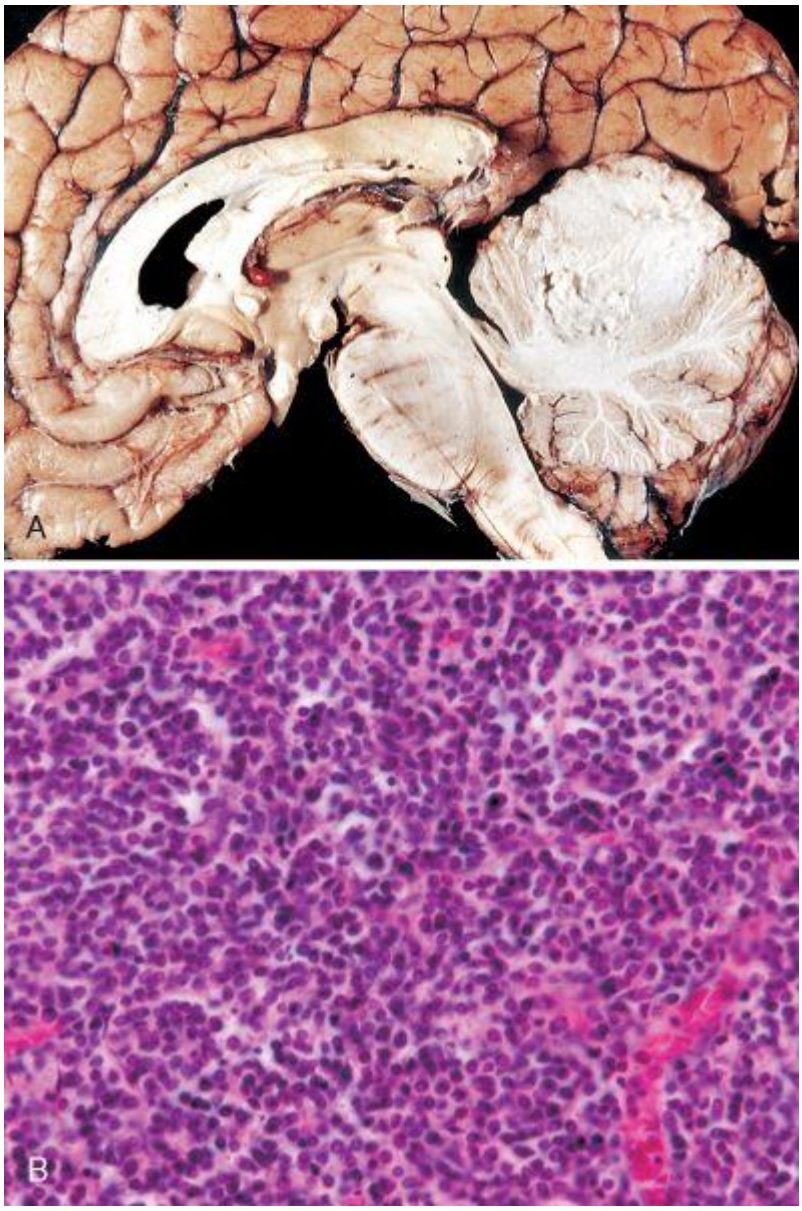

FIGURE 28-51 Medulloblastoma. **A**, Sagittal section of brain showing medulloblastoma destroying the superior midline cerebellum. **B**, Microscopic appearance of medulloblastoma.

Molecular Genetics.

The most common genetic alteration is loss of material from 17p, with an abnormal chromosome derived from duplication of this chromosome's long arm (isochromosome 17q or i(17q)). Loss of 17p signals a poor pro gnosis. *MYC* amplification may also be found and is also associated with a more aggressive clinical course. Several other signaling pathways involved in normal cerebellar development are altered in subsets of medulloblastoma. These include the sonic hedgehog–patched pathway (involved in control of normal proliferation of cerebellar granule cells), the WNT signaling pathway (including APC and β-catenin), and Notch signaling pathway. Tumors that have increased levels of neurotrophin receptor TRKC have a better clinical outcome, as do those that show nuclear accumulation of β-catenin.

Clinical Features.

The tumor is highly malignant, and the prognosis for untreated patients is dismal; however, it is exquisitely radiosensitive. With total excision and irradiation, the 5-year survival rate may be as high as 75%.

Tumors of similar histology and poor degree of differentiation, resembling medulloblastomas, can be found in the cerebral hemispheres. These lesions are known as CNS supratentorial primitive neuroectodermal tumors (CNS PNET). This term can lead to confusion with the peripheral lesion (peripheral neuroectodermal tumor), that shares a genetic alteration with Ewing sarcoma. In the CNS, PNET is genetically distinct from medulloblastoma and from the peripheral tumor.

Atypical Teratoid/Rhabdoid Tumor

This highly malignant tumor of young children occurs in the posterior fossa and supratentorial compartments in nearly equal proportions. The presence of rhabdoid cells, resembling those of a rhabdomyosarcoma, is the defining characteristic of the lesion.

Morphology. Atypical teratoid/rhabdoid tumors tend to be large, with a soft consistency, and spread along the surface of the brain. The rhabdoid cells have eosinophilic cytoplasm, sharp cell borders and eccentrically located nuclei. When these cells are smaller the cytoplasm can take on an elongated appearance that mimics a rhabdomyosarcoma cell. The cytoplasm of the rhabdoid cell contains intermediate filaments and is immunoreactive for epithelial membrane antigen and vimentin. Some other markers that may be positive include smooth muscle actin and keratins. Other muscle markers such as desmin and myoglobin are not present. Rhabdoid cells are rarely a majority of the tumor; instead, islands of tumor with this pattern of differentiation are mixed with a small-cell component, as well as other histologic patterns (including mesenchymal and epithelial). Mitotic activity is extremely prominent.

Molecular Genetics.

Consistent genetic alterations in chromosome 22 (>90% of cases) are a hallmark of rhabdoid tumor. The relevant gene is *hSNF5/INI1*, which encodes a protein that is part of a large complex involved in chromatin remodeling; functional deletions of the locus and loss of nuclear staining for INI1 protein are seen in the majority of tumors.

Clinical Features.

These are highly aggressive tumors of the very young. Nearly all tumors occurr before the age of 5 and most patients live less than a year after diagnosis.

OTHER PARENCHYMAL TUMORS

Primary CNS Lymphoma

Primary CNS lymphoma accounts for 2% of extra-nodal lymphomas and 1% of intra-cranial tumors. It is the most common CNS neoplasm in immunosuppressed individuals, including those with AIDS and immunosuppression after transplantation. In non-immunosuppressed populations, the age spectrum is relatively wide, and the frequency increases after 60 years of age.

The term *primary* emphasizes the distinction between these lesions and secondary involvement of the CNS by lymphoma arising elsewhere in the body (Chapter 13). Primary brain lymphoma is often multifocal within the brain parenchyma, yet nodal, bone marrow, or extra-nodal involvement outside of

the CNS is a rare and late complication. Conversely, lymphoma arising outside the CNS rarely involves the brain parenchyma; involvement of the nervous system, when it occurs in lymphoma, is usually manifested by the presence of malignant cells within the CSF and around intradural nerve roots, and occasionally by the infiltration of superficial areas of the cerebrum or spinal cord by malignant cells.

Most primary brain lymphomas are of B-cell origin. In the setting of immunosuppression, the cells in nearly all such tumors are latently infected by Epstein-Barr virus. Overall, primary lymphomas of the CNS are aggressive, with relatively poor response to chemotherapy compared with peripheral lymphomas.

Morphology. Lesions are frequently multiple and often involve deep gray matter as well as white matter and cortex. Periventricular spread is common. The tumors are relatively well defined in comparison with glial neoplasms but are not as discrete as metastases and often show extensive areas of central necrosis. Diffuse large-cell B-cell lymphomas are the most common histologic group. Within the tumor malignant cells infiltrate the parenchyma of the brain and accumulate around blood vessels. Reticulin stains demonstrate that the infiltrating cells are separated from one another by silver-staining material; this pattern, referred to as "hooping," is characteristic of primary brain lymphoma. In addition to expressing B-cell markers, most of the cells also express BCL-6; when tumors arise in the setting of immunosuppression, various markers of Epstein-Barr viral infection can be used as an aid in diagnosis.

Intravascular lymphoma, an unusual lymphoid malignancy in which the tumor cells grow intraluminally within small vessels, often involves the brain along with other regions of the body.[93] Instead of presenting as a mass lesion, the occlusion of vessels by malignant cells can result in widespread microscopic infarcts. Affected individuals present with evidence of multifocal lesions, with the differential diagnosis usually including processes such as vasculitis and showers of emboli.

Germ Cell Tumors

Primary brain germ cell tumors occur along the midline, most commonly in the pineal and the suprasellar regions. They account for 0.2% to 1% of brain tumors in people of European descent but up to 10% in Japanese people. They are tumors of the young, with 90% occurring during the first two decades. Germ cell tumors, particularly teratomas, are among the more common congenital tumors. Germ cell tumors in the pineal region show a strong male predominance, which is not seen in suprasellar lesions.

The source of germ cells in the CNS is not clear; they may be "rests" that remain in the CNS or perhaps migrate there from other sites late in development. Germ cell tumors share many features with their counterparts in the gonads. In contrast to lymphomas, however, metastasis of a gonadal germ cell tumor to the CNS is not uncommon; thus, the presence of a non-CNS primary tumor must be excluded before a diagnosis of primary germ cell tumor is made. The histologic classification of brain germ cell tumors is similar to that used in the testis (Chapter 21), but the tumor that is histologically similar to the seminoma in the testis is referred to as germinoma in the CNS. The responses to radiation therapy and chemotherapy roughly parallel those of similar histologic lesions at other sites. As in the periphery, CSF levels of tumor markers including α-fetoprotein and β-human chorionic gonadotropin can be used to aid in diagnosis and track response to therapy.

Pineal Parenchymal Tumors

These lesions arise from specialized cells of the pineal gland (pineocytes) that have features of neuronal differentiation. The tumors range from well-differentiated lesions (*pineocytomas*, with areas of neuropil, cells with small, round nuclei, and no evidence of mitoses or necrosis) to high-grade tumors (*pineoblastomas*, with little evidence of neuronal differentiation, densely packed small cells with necrosis, and frequent mitotic figures). High-grade pineal tumors tend to affect children, while lower-grade lesions are found more often in adults. The highly aggressive pineoblastoma commonly spreads throughout the CSF space. It occurs with increased frequency in individuals with germline mutations in *RB* (so-called trilateral retinoblastoma). Gliomas are also found in the pineal region, arising from the glial stroma of the gland. Often low grade, these gliomas can be difficult to distinguish from the glial reaction that can accompany non-neoplastic pineal region cysts.

MENINGIOMAS

Meningiomas are predominantly benign tumors of adults, usually attached to the dura, that arise from the meningothelial cell of the arachnoid. Meningiomas may be found along any of the external surfaces of the brain as well as within the ventricular system, where they arise from the stromal arachnoid cells of the choroid plexus. Prior radiation therapy, typically decades earlier, is a risk factor for development of meningiomas. Other tumors such as metastases, solitary fibrous tumors, and a range of poorly differentiated sarcomas may also grow as dural-based masses.

Morphology. Meningiomas are usually rounded masses with well-defined dural bases that compress underlying brain but are easily separated from it (Fig. 28-52A). Extension into the overlying bone may be present. The surface of the mass is usually encapsulated with thin, fibrous tissue and may have a bosselated or polypoid appearance. They may also grow **en plaque**, in which the tumor spreads in a sheetlike fashion along the surface of the dura. This form is commonly associated with hyperostotic reactive changes in the overlying bone. The lesions range from firm and fibrous to finely gritty, or they may contain numerous calcified psammoma bodies. Gross evidence of necrosis or extensive hemorrhage is not present.

Most meningiomas have a relatively low risk of recurrence or aggressive growth, and so are considered WHO grade I/IV. Various histologic patterns are observed, with no prognostic significance. These include **syncytial** ("meningothelial"), appropriately named for the whorled clusters of cells that sit in tight groups without visible cell membranes; **fibroblastic**, with elongated cells and abundant collagen deposition between them; **transitional**, which share features of the syncytial and fibroblastic types; **psammomatous**, with psammoma bodies, apparently formed from calcification of the syncytial nests of meningothelial cells (Fig. 28-52B); **secretory**, with PAS-positive intracytoplasmic droplets and intracellular lumens by electron microscopy; and **microcystic**, with a loose, spongy appearance. Xanthomatous degeneration, metaplasia (often osseous), and moderate nuclear pleomorphism are common in meningiomas. Among these lesions, proliferation index has been shown to be a predictor of biologic behavior.

Atypical meningiomas (WHO grade II/IV) are lesions with a higher rate of recurrence and more aggressive local growth, and may require radiation therapy in addition to surgery. They are distinguished from lower grade meningiomas by the presence of either a mitotic index of four or more mitoses per 10 high power fields or at least three atypical features (increased cellularity, small cells with a high nuclear-to-cytoplasmic ratio, prominent nucleoli, patternless growth, or necrosis). Certain histologic patterns (**clear cell** and **chordoid**) are also considered to be grade II/IV because of their more aggressive behavior.

Anaplastic (malignant) meningioma (WHO grade III/IV) is a highly aggressive tumor with the

appearance of a high-grade sarcoma, but retaining some histologic evidence of meningothelial origin. Mitotic rates are often extremely high (>20 mitoses per 10 high power fields). **Papillary** meningioma (with pleomorphic cells arranged around fibrovascular cores) and **rhabdoid** meningioma (with sheets of tumor cells with hyaline eosinophilic cytoplasm containing intermediate filaments) both have such a high propensity to recur that they are also considered to be WHO grade III/IV tumors.

While most meningiomas are easily separable from the brain even if they displace it, some tumors infiltrate the brain. This can occur with broad, pushing edges or as single cells. The presence of brain invasion is associated with increased risk of recurrence but does not alter the histologic grade of the lesion. Meningiomas are commonly immunoreactive for epithelial membrane antigen, in contrast to other tumors arising in this region, although with a higher grade, this may be less prominent. Keratin is restricted to lesions with the secretory pattern, and these tumors are also positive for carcinoembryonic antigen.

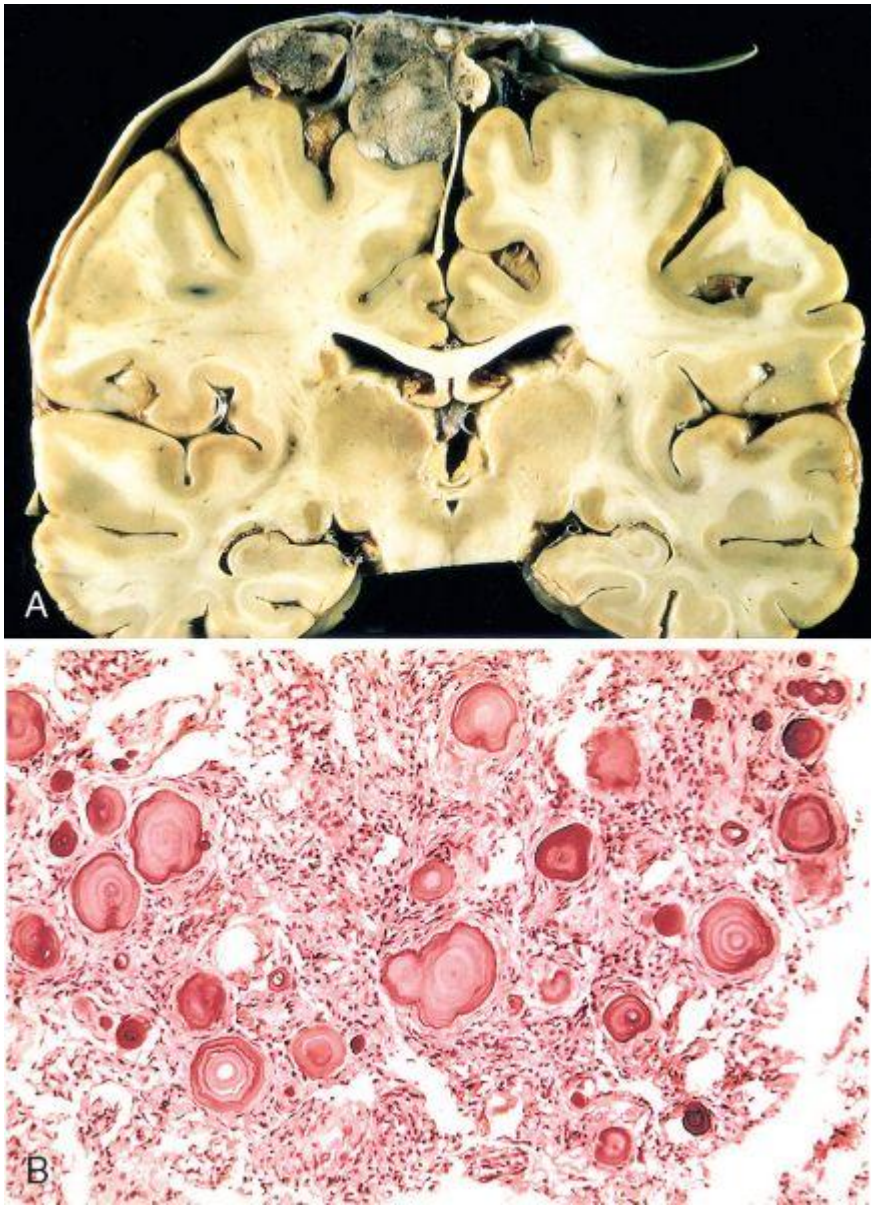

FIGURE 28-52 **A**, Parasagittal multilobular meningioma attached to the dura with compression of underlying brain. **B**, Meningioma with

a whorled pattern of cell growth and psammoma bodies.

Molecular Genetics.

The most common cytogenetic abnormality is loss of chromosome 22, especially the long arm (22q). The deletions include the region of 22q12 that harbors the *NF2* gene, which encodes the protein merlin; as expected, meningiomas are a common lesion in the setting of NF2 (see later). Of sporadic fibroblastic, transitional and psammomatous meningiomas, 50% to 60% harbor mutations in the *NF2* gene; most of these mutations are predicted to result in absence of functional merlin protein. Higher grade meningiomas often accumulate other genetic alterations as well; several studies have also supported the existence of a locus on chromosome 22 distinct from *NF2* as contributing to meningiomas.

Clinical Features.

Meningiomas are usually slow-growing lesions that present either with vague nonlocalizing symptoms or with focal findings referable to compression of underlying brain. Common sites of involvement include the parasagittal aspect of the brain convexity, dura over the lateral convexity, wing of the sphenoid, olfactory groove, sella turcica, and foramen magnum. They are uncommon in children and generally show a moderate (3 : 2) female predominance, although the ratio is 10 : 1 for spinal meningiomas, which are also commonly psammomatous. Lesions are usually solitary, but when present at multiple sites, especially in association with acoustic neuromas or glial tumors, a diagnosis of NF2 should be considered. Clonality studies indicate that multiple lesions are much more likely to represent dissemination from a single tumor rather than distinct tumors. Meningiomas often express progesterone receptors and may grow more rapidly during pregnancy.

3.18.14 Metastatic Tumors, Paraneoplastic Syndromes, Peripheral Nerve Sheath Tumors, Familial Tumor Syndromes

Metastatic lesions, mostly carcinomas, account for approximately a quarter to half of intra-cranial tumors in hospitalized patients. The five most common primary sites are lung, breast, skin (melanoma), kidney, and gastrointestinal tract, accounting for about 80% of all metastases. Some rare tumors (e.g., choriocarcinoma) have a high likelihood of metastasizing to the brain, whereas some more common tumors (e.g., prostatic carcinoma) almost never grow in the brain, even when they are metastatic to adjacent bone and dura. The meninges are also a frequent site of involvement by metastatic disease. Metastatic tumors present clinically as mass lesions and may occasionally be the first manifestation of the cancer. In general, there is a benefit to quality of life from localized treatment of solitary brain metastases. Metastases to the epidural or subdural space can cause spinal cord compression, which requires emergency treatment.

Morphology. Intraparenchymal metastases form sharply demarcated masses, often at the junction of gray matter and white matter, usually surrounded by a zone of edema. The boundary between tumor and brain parenchyma is well defined microscopically as well, although melanoma is one tumor that does not always follow this rule. Nodules of tumor, often with central areas of necrosis, are surrounded by reactive gliosis. Meningeal carcinomatosis, with tumor nodules studding the surface of the brain, spinal cord, and intradural nerve roots, is associated particularly with carcinoma of the lung and the breast.

PARANEOPLASTIC SYNDROMES

In addition to the direct and localized effects produced by metastases, *paraneoplastic syndromes* may involve the peripheral and central nervous systems, sometimes even preceding the clinical recognition of the malignant neoplasm.[94,][95] A variety of specific clinical syndromes have been described.[96] The major underlying mechanism of paraneoplastic syndromes appears to be the development of an immune response against tumor antigens that cross-react with antigens in the central or peripheral nervous systems. The relationship among the underlying malignant process, the clinical features, and the target antigens is unclear. Some tumor types are associated with multiple types of autoantibodies, and the same antibodies can be present in different clinical syndromes. Among the well-recognized syndromes are various patterns of encephalomyelitis:

- *Subacute cerebellar degeneration*, with destruction of Purkinje cells, gliosis, and a mild inflammatory infiltrate, can be present.
- *Limbic encephalitis*, characterized by subacute dementia and marked by perivascular inflammatory cuffs, microglial nodules, some neuronal loss, and gliosis, most evident in the anterior and medial portions of the temporal lobe and resembling an infectious process. A comparable process involving the brainstem can be seen in isolation or together with limbic system involvement.
- *Eye movement disorders*, most commonly opsoclonus, may be found, often in association with other evidence of cerebellar and brainstem dysfunction. In children this is most commonly associated with neuroblastoma and is found along with myoclonus.

The peripheral nervous system can also be affected:

- *Subacute sensory neuropathy* may be found in association with limbic encephalitis or in isolation. It is marked by loss of sensory neurons from dorsal root ganglia, in association with lymphocytic inflammation.
- *Lambert-Eaton myasthenic syndrome*, caused by antibodies against the voltage-gated calcium channel in the presynaptic elements of the neuromuscular junction. This can be seen in the absence of malignancy as well.

For some disorders, such as limbic encephalitis associated with antibodies against voltage-gated potassium channels, there is evidence that therapies aimed at reducing the antibody titer result in clinical improvement. In other settings there remain questions as to how an immune response to intracellular proteins elicits disease, whether the antibodies are directly pathogenic or merely a marker of the disease, and even which components of the immune system are critically involved.

PERIPHERAL NERVE SHEATH TUMORS

These tumors arise from cells of the peripheral nerve, including Schwann cells, perineurial cells, and fibroblasts. Many express Schwann cell characteristics, including the presence of S-100 antigen as well as the potential for melanocytic differentiation. There is a transition between myelination by oligodendrocytes (central myelin) and myelination by Schwann cells (peripheral myelin) that occurs within several millimeters of the substance of the brain. Thus, peripheral nerve tumors can arise within the dura, as well as along the peripheral course of nerves. The various forms of peripheral nerve sheath tumors are also associated with the two forms of neurofibromatosis (discussed below with “Familial Tumor Syndromes”).

Schwannoma

These benign tumors arise from the neural crest–derived Schwann cell and cause symptoms by local compression of the involved nerve or adjacent structures (such as brainstem or spinal cord). Schwannomas are a component of NF2, and even sporadic schwannomas are commonly associated with inactivating mutations in the *NF2* gene on chromosome 22. Loss of expression of the *NF2* gene product, *merlin,* is a consistent finding in all schwannomas. Merlin normally restricts the cell-surface expression

of growth factor receptors, such as EGFR, through interactions involving the actin cytoskeleton; in its absence, cells hyperproliferate in response to growth factors.

Morphology. Schwannomas are well-circumscribed, encapsulated masses that are attached to the nerve but can be separated from it (Fig. 28-53A). Tumors form firm, gray masses that may have areas of cystic and xanthomatous change. On microscopic examination tumors show a **mixture of two growth patterns** (Fig. 28-53B). In the **Antoni A** pattern of growth, elongated cells with cytoplasmic processes are arranged in fascicles in areas of moderate to high cellularity and scant stromal matrix; the "nuclear-free zones" of processes that lie between the regions of nuclear palisading are termed **Verocay bodies**. In the **Antoni B** pattern of growth, the tumor is less densely cellular and consists of a loose meshwork of cells, microcysts and myxoid stroma. In both areas the individual cells have an elongated shape and regular oval nuclei. Electron microscopy shows basement membrane deposits encasing single cells and collagen fibers. Because the lesion displaces the nerve of origin as it grows, silver stains or immunostains for neurofilament proteins demonstrate that axons are largely excluded from the tumor, although they may become entrapped in the capsule. The Schwann cell origin of these tumors is borne out by their S-100 immunoreactivity. A variety of degenerative changes may be found in schwannomas, including nuclear pleomorphism, xanthomatous change, and vascular hyalinization. Malignant change is extremely rare, but local recurrence can follow incomplete resection.

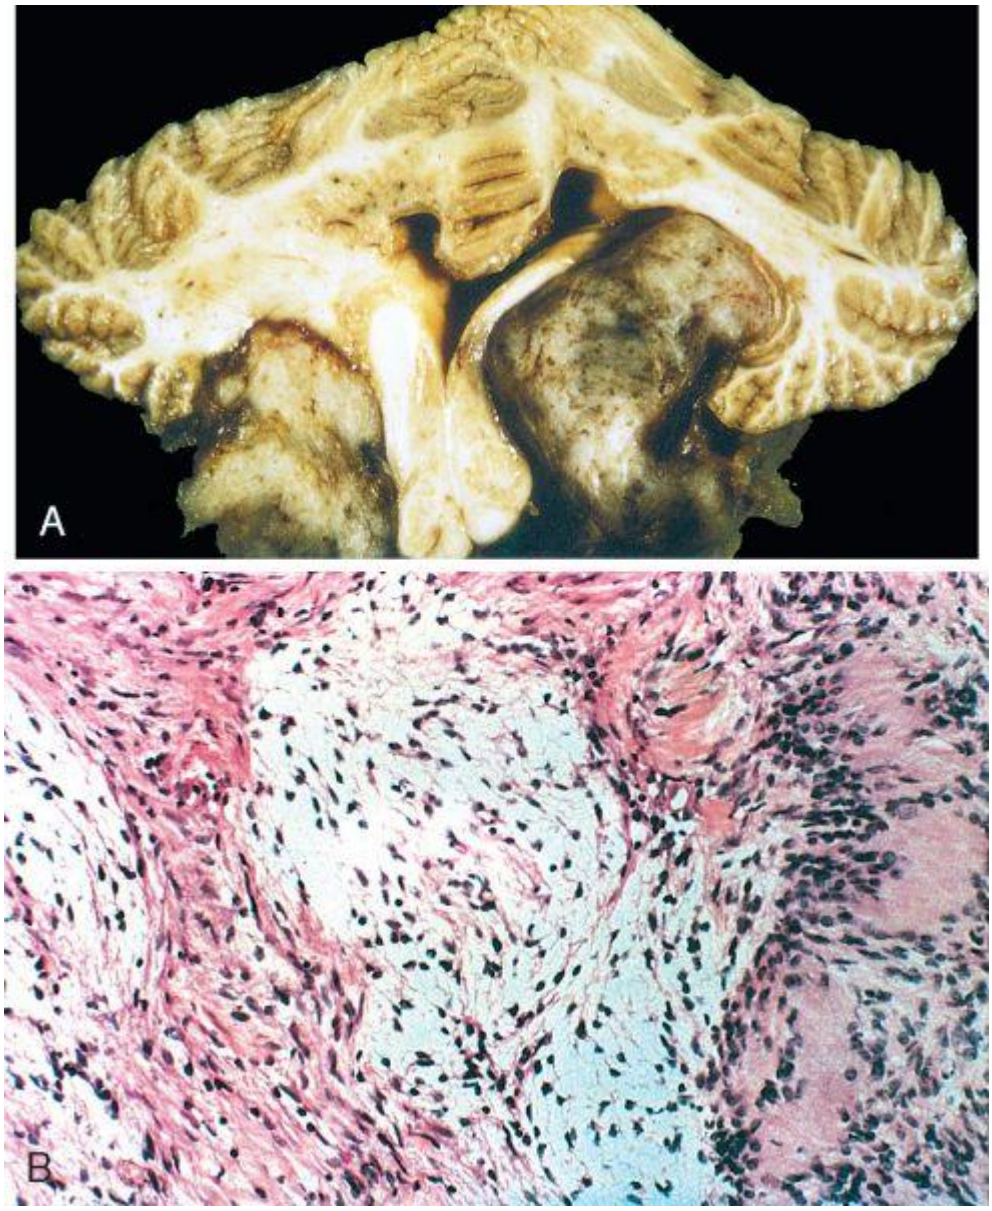

FIGURE 28-53 Schwannoma. **A**, Bilateral eighth-nerve schwannomas. **B**, Tumor showing cellular areas (Antoni A), including Verocay bodies *(far right)*, as well as looser, myxoid regions (Antoni B, *center*). ***(A**, Courtesy of the late Dr. K.M. Earle.)*

Clinical Features.

Within the cranial vault most schwannomas occur at the cerebellopontine angle, where they are attached to the vestibular branch of the eighth nerve. Affected individuals often present with tinnitus and hearing loss; the tumor is often referred to as an "acoustic neuroma," although it actually is a vestibular schwannoma. Elsewhere within the dura, sensory nerves are preferentially involved, including branches of the trigeminal nerve and dorsal roots. When extradural, schwannomas are most commonly found in association with large nerve trunks, where motor and sensory modalities are intermixed.

Neurofibroma

Neurofibromas can present as discrete localized masses—most commonly as a *cutaneous neurofibroma* or in peripheral nerve as a *solitary neurofibroma*—or as an infiltrative lesion growing within and expanding a peripheral nerve *(plexiform neurofibroma)*. The presence of either multiple neurofibromas or plexiform neurofibromas strongly suggests the diagnosis of neurofibromatosis type 1 (NF1). Skin lesions grow as nodules, sometimes with overlying hyperpigmentation; they may become large and pedunculated. The risk of malignant transformation of these tumors is extremely small, and they are mostly of cosmetic concern. In contrast, plexiform tumors may result in significant neurologic deficits when they involve major nerve trunks, are difficult to remove because of their intraneural spread, and have a significant potential for malignant transformation.

Morphology.

Cutaneous Neurofibroma. Present in the dermis and subcutaneous fat, these well-delineated but unencapsulated masses are composed of spindle cells. Although they are not invasive, the adnexal structures are sometimes enwrapped by the edges of the lesion. The stroma of these tumors is highly collagenized and contains little myxoid material. Lesions within peripheral nerves are of identical histologic appearance.

Plexiform Neurofibroma. These tumors may arise anywhere along a nerve, although the large nerve trunks are most commonly involved. They are frequently multiple. The affected nerves are irregularly expanded, as each of the fascicles is infiltrated by the neoplasm. Unlike schwannomas, it is not possible to separate the lesion from the nerve. The proximal and distal extremes of the tumor may have poorly defined margins, as fingers of tumor and individual neoplastic cells insert themselves between the nerve fibers. On microscopic examination, the lesion has a loose, myxoid background with a low cellularity. Several cell types are present, including Schwann cells with typical elongated nuclei and extensions of pink cytoplasm, larger multipolar fibroblastic cells, and a sprinkling of inflammatory cells, including mast cells. Although the myxoid stroma dominates, there are often areas of collagen bundles, which have a "shredded carrot" appearance. In contrast to schwannomas, axons can be demonstrated within the tumor.

Alterations in both copies of the *NF1* gene have been consistently observed in the Schwann cell components of plexiform neurofibromas, supporting a critical role for loss of NF1 function in the genesis of this tumor. The product of the *NF1* gene (*neurofibromin*) stimulates the activity of a GTPase that inhibits RAS activity (recall that RAS is active only when bound to GTP).

Malignant Peripheral Nerve Sheath Tumor

Malignant peripheral nerve sheath tumors are highly malignant tumors that are locally invasive, frequently with multiple recurrences and eventual metastatic spread. They are most commonly associated with medium to large nerves, rather than either cranial nerves or distal small nerves. While many occur sporadically, close to 50% of cases arise in the setting of NF1—either from transformation of a plexiform neurofibroma or following radiation therapy. *NF1* function is lost at an early stage of development of malignant peripheral nerve sheath tumors; subsequent alterations often disrupt both the p53- and RB-dependent pathways for regulation of cell proliferation.

Morphology. The lesions are poorly defined tumor masses that frequently infiltrate along the axis of the parent nerve and invade adjacent soft tissues. On microscopic examination a wide range of histologic findings can be encountered. Patterns reminiscent of fibrosarcoma or pleomorphic sarcoma

may be found. In other areas the tumor cells resemble Schwann cells, with elongated nuclei and prominent bipolar processes. Fascicle formation may be present. Mitoses, necrosis, and extreme nuclear anaplasia are common. Some but not all tumors are immunoreactive for S-100 protein. In addition, a wide variety of "divergent" histologic patterns may be admixed, including epithelial structures, rhabdomyoblastic differentiation (termed **Triton tumors**), cartilage, and even bone. **Epithelioid malignant schwannomas** are aggressive variants with tumor cells that have visible cell borders and grow in nests. They are immunoreactive for S-100 but not for keratin, allowing distinction from true epithelial tumors.

FAMILIAL TUMOR SYNDROMES

A variety of inherited diseases are associated with the occurrence of tumors. In most, the pattern of inheritance is autosomal dominant, with involvement of tumor suppressor genes.[97] In several of these syndromes, tumors of the nervous system are a prominent aspect of the disease and are discussed below. Other syndromes include tumors of the CNS as part of their spectrum, but the bulk of disease burden lies elsewhere. These include:

- *Cowden syndrome:* Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos disease), caused by mutations in *PTEN* resulting in increased activity of AKT and mTOR pathways
- *Li-Fraumeni syndrome:* Medulloblastomas, caused by mutations in *p 53* (Chapter 7)
- *Turcot syndrome:* Medulloblastoma or glioblastoma, caused by mutations in *APC* or mismatch repair genes (as for familial colon cancer; Chapter 17)
- *Gorlin syndrome:* Medulloblastoma, caused by mutations in the *PTCH* gene resulting in up-regulation of sonic hedgehog signaling pathways (Chapter 25).

Neurofibromatosis Type 1

This autosomal dominant disorder, one of the more common genetic disorders, having a frequency of 1 in 3000, is characterized by neurofibromas (plexiform and solitary), gliomas of the optic nerve, pigmented nodules of the iris *(Lisch nodules)*, and cutaneous hyperpigmented macules *(café au lait spots)*. In individuals with NF1 there is a propensity for the neurofibromas, particularly plexiform neurofibromas, to undergo malignant degeneration at a higher rate than that observed for comparable tumors in the general population. As described earlier under "Neurofibroma", the *NF1* gene, located at 17q11.2, encodes neurofibromin—a large protein with a GTPase-activating domain that inhibits RAS. The tumor cells in NF1-related tumors lack NF1 expression due to biallelic inactivation of the gene.

The course of the disease is highly variable; some individuals who carry a mutated gene have no symptoms, while others develop progressive disease with spinal deformities, disfiguring lesions, and compression of vital structures, including the spinal cord.

Neurofibromatosis Type 2 (NF2)

This is an autosomal dominant disorder resulting in a range of tumors, most commonly bilateral eighth-nerve schwannomas and multiple meningiomas. Gliomas, typically ependymomas of the spinal cord, also occur in these patients. Many individuals with NF2 also have non-neoplastic lesions, which include nodular ingrowth of Schwann cells into the spinal cord (schwannosis), meningioangiomatosis (a proliferation of meningeal cells and blood vessels that grows into the brain), and glial hamartia (microscopic nodular collections of glial cells at abnormal locations, often in the superficial and deep layers of cerebral cortex). This disorder is much less common than NF1, having a frequency of 1 in 40,000 to 50,000.

The *NF2* gene is located on chromosome 22q12, and the gene product, merlin, shows structural similarity to a series of cytoskeletal proteins; the *NF2* gene is also commonly mutated in sporadic meningiomas and schwannomas. The protein is believed to regulate membrane receptor signaling, including contact growth inhibition.[98] There is some correlation between the type of mutation and clinical symptoms, with nonsense and frameshift mutations causing a more severe phenotype than missense mutations.

Tuberous Sclerosis Complex

Tuberous sclerosis is an autosomal dominant syndrome, occurring at a frequency of approximately 1 in 6000 births. It is characterized by the development of hamartomas and benign neoplasms involving the brain and other tissues. Hamartomas within the CNS take the form of cortical tubers and subependymal nodules; subependymal giant-cell astrocytomas are low grade neoplasms that appear to develop from the hamartomatous nodules in the same location. Cortical tubers are often epileptogenic, and surgical resection can be beneficial when medical management of the seizures is difficult. Elsewhere in the body, lesions include renal angiomyolipomas, retinal glial hamartomas, pulmonary lymphangioleiomyomatosis and cardiac rhabdomyomas. Cysts may be found at various sites, including the liver, kidneys, and pancreas. Cutaneous lesions include angiofibromas, localized leathery thickenings (shagreen patches), hypopigmented areas (ash-leaf patches), and subungual fibromas.

One tuberous sclerosis locus (*TSC1*) is found on chromosome 9q34, and it encodes a protein known as hamartin; the more commonly mutated tuberous sclerosis locus (*TSC2*) is at 16p13.3 and encodes tuberin. These two proteins bind, forming a complex that inhibits the kinase mTOR, which is a key regulator of protein synthesis and other aspects of anabolic metabolism. Of note, mTOR is well-known to control cell size, and the tumors associated with tuberous sclerosis are remarkable for having voluminous amounts of cytoplasm, particularly giant-cell astrocytomas in the CNS, and cardiac rhabdomyomas. Cortical and subependymal tubers are associated with an intact copy of the wild-type allele, while in subependymal giant-cell astrocytomas there is biallelic loss. Treatment is symptomatic, including anticonvulsant therapy for control of seizures.

Morphology. Cortical hamartomas of tuberous sclerosis are firm areas of the cortex that, in contrast to the softer adjacent cortex, have been likened to potatoes, hence the appellation “tubers.” These hamartomas are composed of haphazardly arranged neurons that lack the normal laminar organization of neocortex. In addition, some large cells have appearances intermediate between glia and neurons (large vesicular nuclei with nucleoli, resembling neurons, and abundant eosinophilic cytoplasm like gemistocytic astrocytes) and often express intermediate filaments of both neuronal (neurofilament) and glial (GFAP) types. Consistent with the preservation of the wild-type allele, these cells usually stain for both tuberin and hamartin. Similar hamartomatous features are present in the subependymal nodules, where the large astrocyte-like cells cluster beneath the ventricular surface. These multiple droplike masses that bulge into the ventricular system gave rise to the term *candle-guttering*. In subependymal areas a tumor unique to tuberous sclerosis, subependymal giant-cell astrocytoma, occurs, which is marked by having very large amounts of eosinophilic cytoplasm.

Von Hippel–Lindau Disease

This is an autosomal dominant disease in which affected individuals develop hemangioblastomas and cysts involving the pancreas, liver, and kidneys, and have a propensity to develop renal cell carcinoma and pheochromocytoma. Hemangioblastomas are most common in the cerebellum and retina. The disease frequency is 1 in 30,000 to 40,000.

The gene associated with von Hippel–Lindau disease (*VHL*), a tumor suppressor gene, is located on chromosome 3p25–p26 and encodes a protein (pVHL) that, among its other functions, is a component of a ubiquitin ligase complex that down-regulates hypoxia-induced factor 1 (HIF-1), a transcription factor involved in regulating expression of vascular endothelial growth factor, erythropoietin, and other growth factors.[99] It is the dysregulation of erythropoietin that is responsible for the polycythemia observed in association with hemangioblastomas in about 10% of cases. There may be other targets of this ubiquitin ligase complex whose normal degradation is disrupted by loss of pVHL, explaining the other tumors associated with this syndrome. Missense mutations in *VHL*, but not other types of mutations, are highly likely to be associated with pheochromocytomas.

Morphology. Hemangioblastomas are highly vascular neoplasms that occur as a mural nodule associated with a large fluid-filled cyst. On microscopic examination, the lesion consists of a mixture of variable proportions of capillary-size or somewhat larger thin-walled vessels with intervening stromal cells of uncertain histogenesis characterized by vacuolated, lightly PAS-positive, lipid-rich cytoplasm and an indefinite immunohistochemical phenotype; nonetheless, studies have shown that these cells are the neoplastic element of the hemangioblastoma based on the presence of a second "hit" in the previously normal *VHL* allele.

Therapy is directed at the symptomatic neoplasms, including resection of the cerebellar hemangioblastomas and laser therapy for retinal hemangioblastomas.

3.19 29. The Eye

3.19.1 Orbit

ROBERT FOLBERG

Although this chapter comes at the end of the book, it is not the least important. Vision is a major quality-of-life issue. Before the public awareness of AIDS and Alzheimer disease, the most feared disease among Americans was cancer, and the second most feared disease was blindness. So great is the fear of blindness that even today, people often tell their physicians, “Doctor, I'd rather be dead than be blind!”

In general, diseases that produce loss of vision do not attract as much of our attention as do many of the life-threatening conditions described in this book. For example, age-related macular degeneration (ARMD) is the most common cause of irreversible visual loss in the United States. Most individuals with ARMD do not even suffer from a total loss of vision—an immersion into total darkness. The histopathology is unspectacular: small scars develop in the macula. But consider the effect of these tiny scars perhaps in a retired schoolteacher with ARMD. The small macular scars make it impossible for this person to see anything clearly in the central portion of her or his vision. The faces of spouse or grandchildren are not visible. He or she cannot read a book or newspaper. Once a model of independence, this teacher can no longer drive a car and must be chauffered everywhere. True, his or her life is not threatened by the small scars in the eyes' macula, but the quality of life declines as this person is robbed of the common joys that most of us take for granted until they are lost.

To study the eye, one needs to comprehend all that has come before. For example, the pathology of the eyelids builds on knowledge of dermatopathology (Chapter 25), and the pathology of the retina and optic nerve extends what was learned in Chapter 28 about the brain and central nervous system. However, the study of ocular pathology does not merely repeat what has been presented thus far. The eye provides the only site in which a physician can easily visualize a variety of pathophysiologic disturbances in the microcirculation ranging from arteriosclerosis to angiogenesis in a clinical setting. Although there are conditions that are unique to the eye (such as cataract and glaucoma), many ocular conditions share similarities with disease processes elsewhere in the body that are modified by the unique structure and function of the eye (Fig. 29-1). Moreover, the eye has much to teach us about important mechanisms of disease that extend far beyond the visual system. For example, the tumor suppressor gene, *RB*, was described in retinoblastoma,[1] a quite uncommon ocular tumor of infants and very young children, but the discovery of *RB* opened an important pathway to the understanding of the regulation of cellular replication.

This chapter is organized on the basis of ocular anatomy. The discussion of each region of the eye begins with anatomic and functional considerations, and their impact on the understanding of ocular diseases.

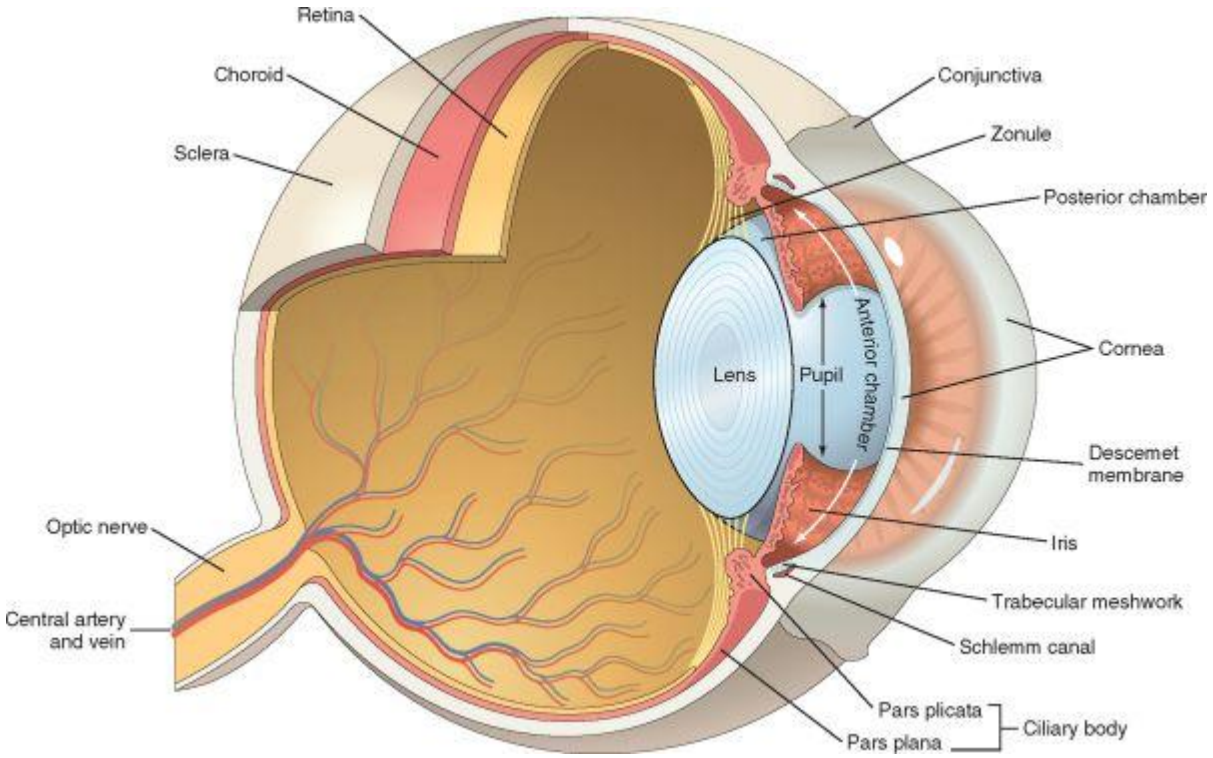

FIGURE 29-1 Anatomy of the eye.

Orbit

FUNCTIONAL ANATOMY AND PROPTOSIS

The orbit is a compartment that is closed medially, laterally, and posteriorly. Diseases that increase orbital contents therefore displace the eye forward, a condition known as *proptosis*. Aside from the obvious cosmetic concerns, the proptotic eye might not be covered completely by the eyelids, and the tear film might not be distributed evenly across the cornea. Corneal exposure is painful and can predispose to corneal ulceration and infection. Proptosis may be axial (directly forward) or positional. For example, any enlargement of the lacrimal gland from inflammation (e.g., *sarcoidosis*) or neoplasm (e.g., *lymphoma, pleomorphic adenoma*, or *adenoid cystic carcinoma*) produces a proptosis that displaces the eye inferiorly and medially, because the lacrimal gland is positioned superotemporally within the orbit.

Masses contained within the cone formed by the horizontal rectus muscles generate axial proptosis: the eye bulges straight forward. The two most common primary tumors of the optic nerve (a tract of the central nervous system and not a peripheral nerve), *glioma* and *meningioma*, produce axial proptosis because the optic nerve is positioned within the muscle cone. The orbital contents are subject to the same disease processes that affect other tissues. Representative inflammatory conditions and neoplasms of the orbit are discussed briefly next.

THYROID OPHTHALMOPATHY (GRAVES DISEASE)

In the chapter on endocrine disorders (Chapter 24) it was noted that axial proptosis is an important clinical manifestation of Graves disease. Proptosis is caused by the accumulation of extracellular matrix

proteins and variable degrees of fibrosis in the rectus muscles (Fig. 29-2). The development of thyroid ophthalmopathy may be independent of the status of thyroid function.[2]

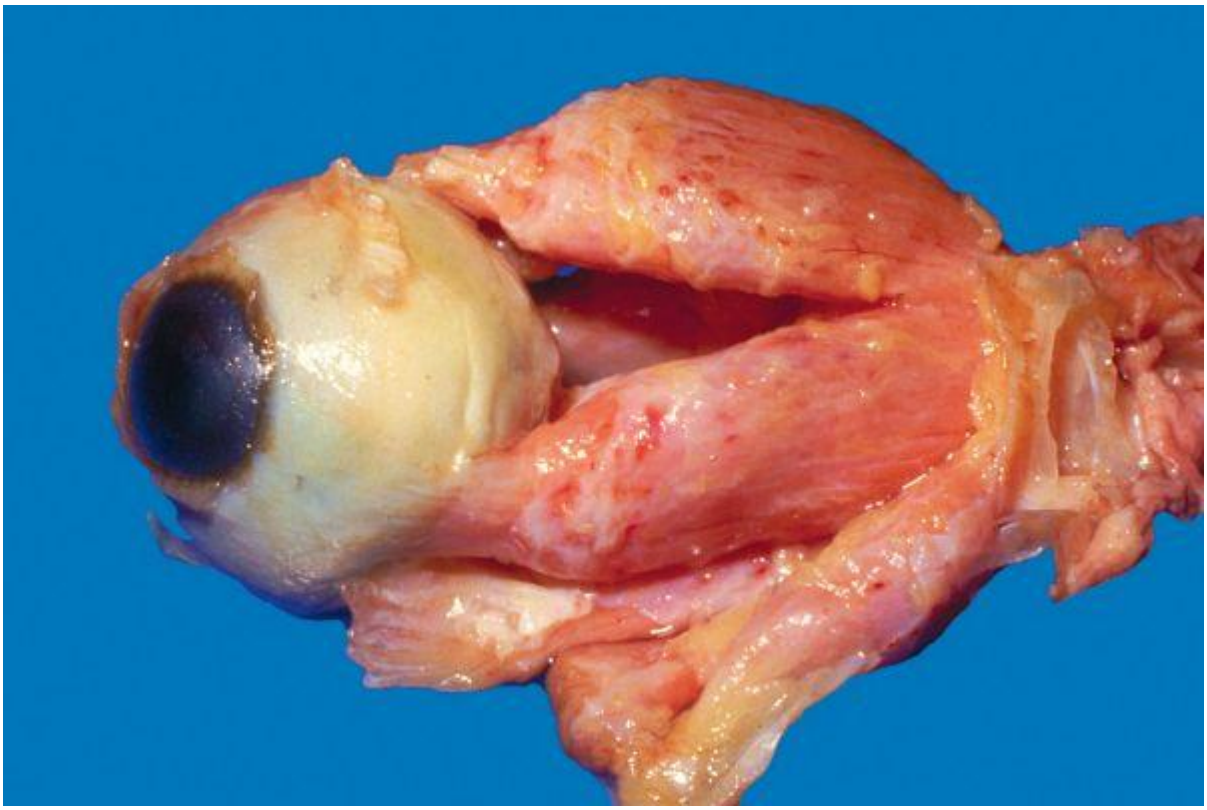

FIGURE 29-2 The extra-ocular muscles are greatly distended in this postmortem dissection of tissues from a patient with thyroid (Graves) ophthalmopathy. Note that the tendons of the muscles are spared involvement. *(Courtesy of Dr. Ralph C. Eagle, Jr., Wills Eye Hospital, Philadelphia, PA.)*

OTHER ORBITAL INFLAMMATORY CONDITIONS

The floor of the orbit is the roof of the maxillary sinus, and the medial wall of the orbit—the lamina papyracea—separates the orbit from the ethmoidal sinuses. Thus, uncontrolled sinus infection may spread to the orbit either as an acute infection (orbital *cellulitis*) or as a component of a fungal infection *(mucormycosis)* in immunosuppressed individuals, in patients with diabetic ketoacidosis, or, rarely, in persons without any predisposition. Systemic conditions such as *Wegener granulomatosis* (Chapter 11) may present first in the orbit and may be confined there for prolonged periods of time,[3] or alternatively, it may involve the orbit secondarily by extension from the sinuses.

Idiopathic orbital inflammation, also known as orbital inflammatory pseudotumor (Fig. 29-3), is another inflammatory condition affecting the orbit. This condition may be unilateral or bilateral, and may affect all orbital tissue elements or may be confined to the lacrimal gland *(sclerosing dacryoadenitis)*, the extra-ocular muscles *(orbital myositis)*, or the Tenon's capsule, the fascial layer that wraps around the eye *(posterior scleritis)*. In long-term follow-up a subset of individuals with idiopathic orbital inflammation may show evidence of systemic vasculitis or other forms of connective tissue diseases.

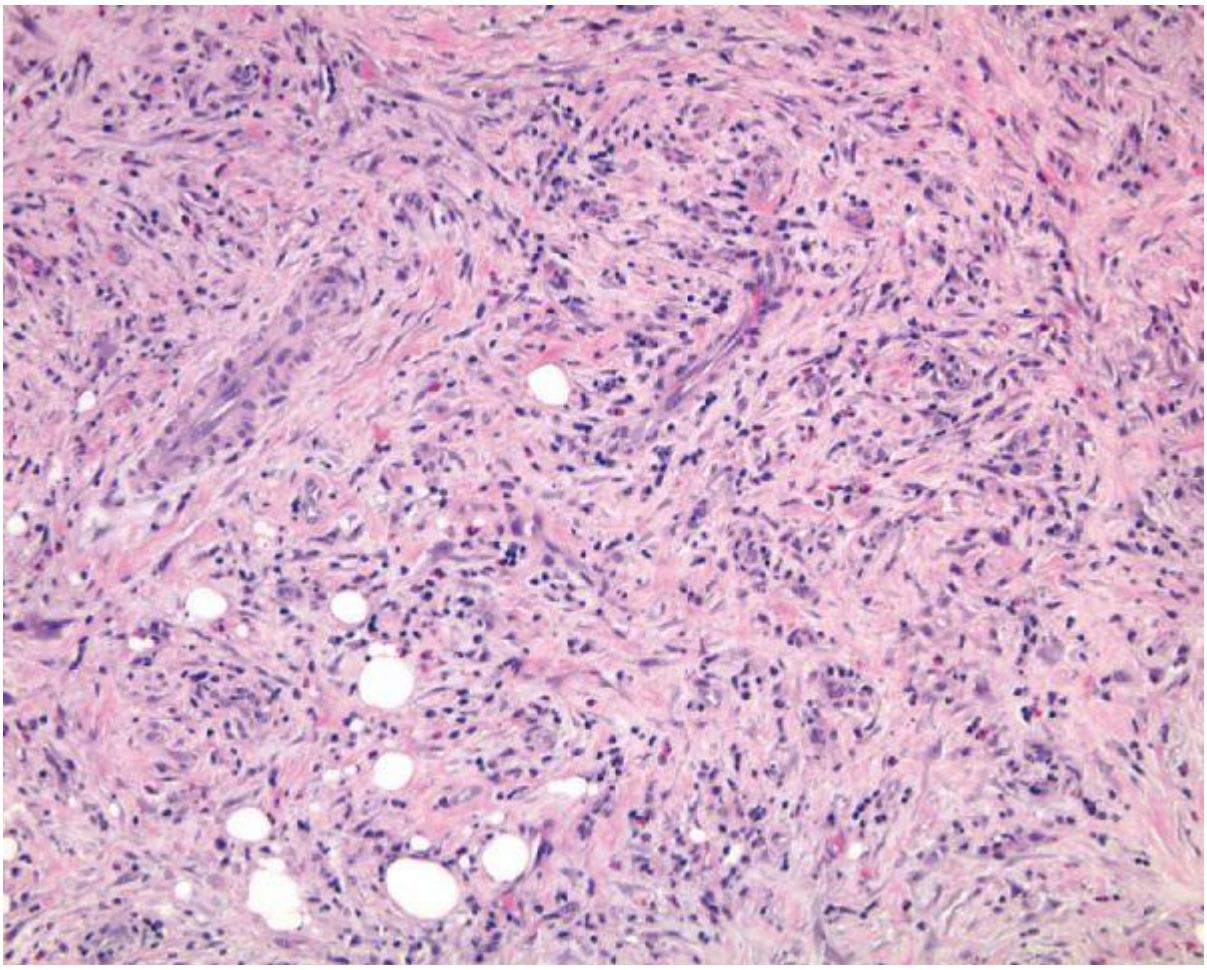

FIGURE 29-3 In idiopathic orbital inflammation (orbital inflammatory pseudotumor) the orbital fat is replaced by fibrosis. Note the chronic inflammation, accompanied in this case by eosinophils.

Morphology. Idiopathic orbital inflammation is characterized histologically by chronic inflammation and variable degrees of fibrosis. The inflammatory infiltrate typically includes lymphocytes and plasma cells and occasionally eosinophils. Germinal centers, when present, raise the suspicion of a reactive lymphoid hyperplasia. Vasculitis may be present, suggesting an underlying systemic condition. The presence of necrotic collagen along with vasculitis should raise the suspicion of Wegener granulomatosis. Idiopathic orbital inflammation is typically confined to the orbit but may develop concomitantly with sclerosing inflammation in the retroperitoneum, the mediastinum, and the thyroid.

NEOPLASMS

The most frequently encountered primary neoplasms of the orbit are vascular in origin: the capillary hemangioma of infancy and early childhood and the lymphangioma (both of which are unencapsulated) and the encapsulated cavernous hemangioma found typically in adults. These are described in other chapters. Only a handful of orbital masses are encapsulated (e.g., pleomorphic adenoma of the lacrimal gland, dermoid cyst, neurilemmoma), and the recognition of encapsulation on imaging studies allows the surgeon to anticipate pathologic findings.

Non-Hodgkin lymphoma, like idiopathic orbital inflammation, can affect the entire orbit or can be confined to compartments of the orbit such as the lacrimal gland. Orbital lymphomas are classified according to the WHO classification system (Chapter 13).

Primary orbital malignancies may arise from any of the orbital tissues and are classified according to the scheme used for the parent tissue. For example, the lacrimal gland may be considered a minor salivary gland, and tumors of the lacrimal gland are classified as salivary gland tumors are classified.

Metastases to the orbit may present with distinctive signs and symptoms that point to the origin of the tumor. For example, metastatic prostatic carcinoma may present clinically like idiopathic orbital inflammation; metastatic neuroblastoma and Wilms tumor—richly vascular neoplasms—may produce characteristic periocular ecchymoses. Neoplasms may also invade from the sinuses into the orbit.

3.19.2 Eyelid

FUNCTIONAL ANATOMY

The eyelid is composed of skin externally and mucosa (the conjunctiva) on the surface apposed to the eye (Fig. 29-4). In addition to covering and protecting the eye, elements within the eyelid generate critical components of the tear film. If the drainage system of the sebaceous glands is obstructed by chronic inflammation at the eyelid margin *(blepharitis)* or, less commonly, by neoplasm, then lipid may extravasate into surrounding tissue and provoke a granulomatous response producing a lipogranuloma, or *chalazion*.

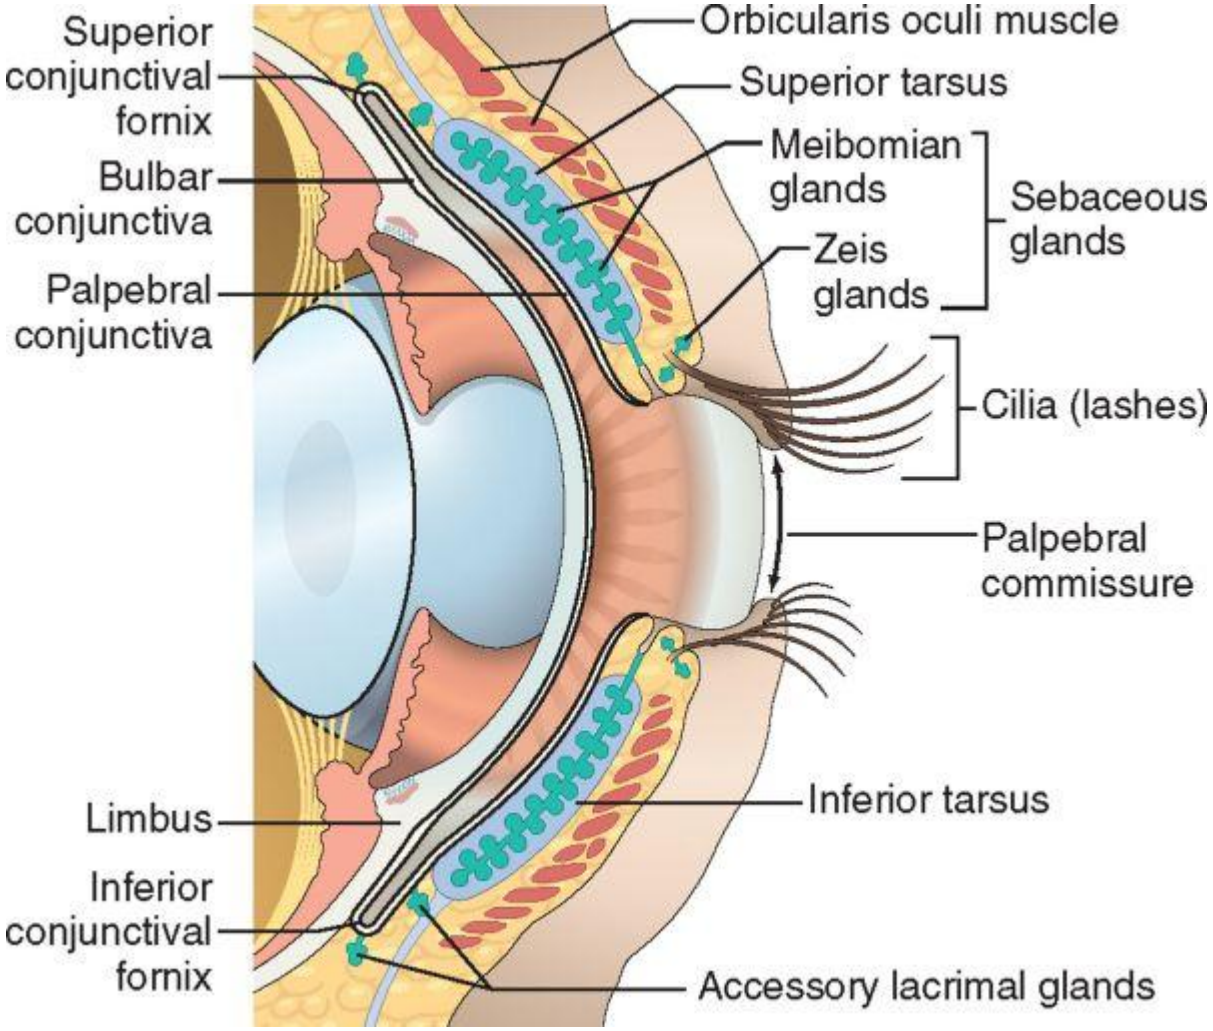

FIGURE 29-4 Anatomy of the conjunctiva and eyelids.

NEOPLASMS

The most common malignancy of the eyelid is basal cell carcinoma. The second most common malignancy is sebaceous carcinoma, followed by squamous cell carcinoma. Surprisingly, primary melanomas of the eyelid skin are extremely rare. Regardless of histogenesis, eyelid neoplasms may distort tissue and prevent the eyelids from closing completely. Exposure of the cornea is not only painful but predisposes the individual to corneal ulceration. Therefore, prompt treatment of locally invasive basal cell carcinomas, which are typically not a threat to the affected individual's life, is imperative to preserve vision. *Basal cell carcinoma has a distinct predilection for the lower eyelid and the medial canthus*.

Sebaceous carcinoma may form a local mass that mimics *chalazion* or may diffusely thicken the eyelid. This neoplasm may also resemble inflammatory processes such as blepharitis or *ocular cicatricial pemphigoid* because of intraepithelial spread as occurs in Paget disease of the nipple (Chapter 23) or vulva. Sebaceous carcinoma tends to spread first to the parotid and submandibular nodes. The overall mortality rate can be as high as 22%.[4]

Morphology. In moderately differentiated or welldifferentiated sebaceous carcinoma, vacuolization of the cytoplasm is present and helps in the diagnosis. This cancer may, however, resemble a variety of other malignancies histologically, including basal cell carcinoma, and establishing the correct diagnosis can be difficult. Pagetoid spread (Fig. 29-5) may mimic Bowenoid actinic keratosis in the eyelid and carcinoma in situ in the conjunctiva. Sebaceous carcinoma may spread through the conjunctival epithelium and the epidermis to the lacrimal drainage system and the nasopharynx. It may also extend into the lacrimal gland ductules and thereby into the main lacrimal gland.

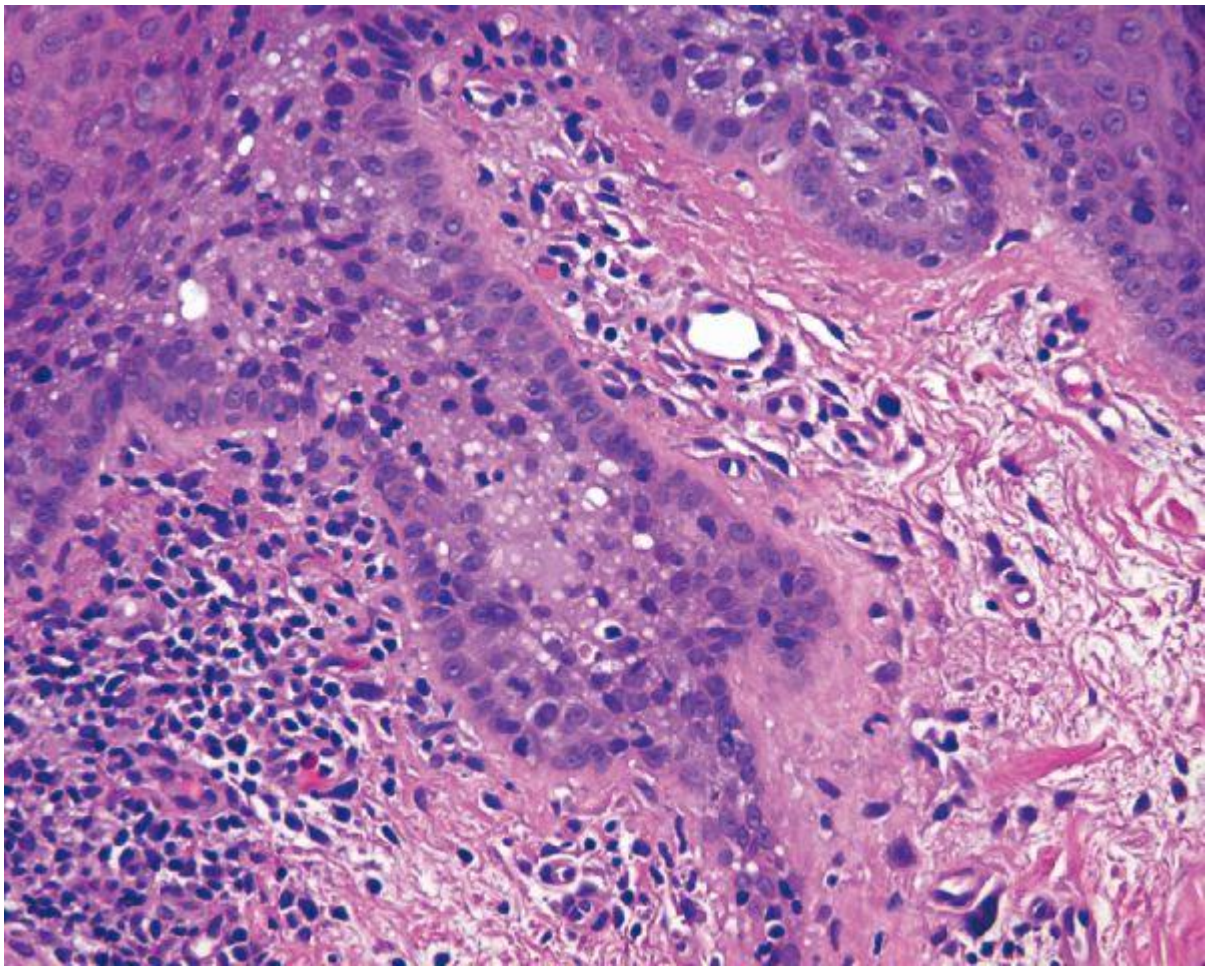

FIGURE 29-5 Pagetoid spread of sebaceous carcinoma. Neoplastic cells with foamy cytoplasm are detected within the epidermis. Invasive sebaceous carcinoma was identified elsewhere in this biopsy sample.

In individuals with AIDS, *Kaposi sarcoma* may develop in either the eyelid or the conjunctiva. In the eyelid the lesion may appear clinically to have a purple hue because the vascular lesion is embedded in the dermis, but in the thin mucous membrane of the conjunctiva, Kaposi sarcoma appears bright red and may be confused clinically with a subconjunctival hemorrhage.

3.19.3 Conjunctiva

FUNCTIONAL ANATOMY

The conjunctiva is divided into zones (see Fig. 29-4), each with distinctive histologic features and responses to disease. The conjunctiva lining the interior of the eyelid, the *palpebral conjunctiva*, is tightly tethered to the tarsus and may respond to inflammation by being thrown into minute papillary folds as may occur in allergic conjunctivitis and bacterial conjunctivitis. The conjunctiva in the *fornix* is a pseudostratified columnar epithelium rich in goblet cells. The fornix also contains accessory lacrimal tissue, and the ductules of the main lacrimal gland pierce through the conjunctiva in the fornix superiorly and laterally. The lymphoid population of the conjunctiva is most noticeable in the fornix, and *in viral conjunctivitis, lymphoid follicles may enlarge sufficiently to be visualized clinically* by slit-lamp examination. *Granulomas* associated with systemic sarcoidosis may be detected in the

conjunctival fornix, and the yield of granulomas from a nondirected conjunctival biopsy in individuals suspected of having sarcoid may be as high as 50%.[5] Primary lymphoma of the conjunctiva (typically indolent marginal zone B-cell lymphoma) is most likely to develop in the fornix. The *bulbar conjunctiva*—the conjunctiva that covers the surface of the eye—is a nonkeratinizing stratified squamous epithelium.

The conjunctiva, like the eyelid, is richly invested with lymphatic channels. Malignant neoplasms arising in the eyelid and conjunctiva tend to spread to regional lymph nodes (parotid and submandibular node groups).

CONJUNCTIVAL SCARRING

Many cases of bacterial or viral conjunctivitis cause redness and itching, but most heal without sequelae. However, infection with *Chlamydia trachomatis (trachoma)* may produce significant conjunctival scarring. Conjunctival scarring is also seen after exposure of the ocular surface to caustic alkalis or as a sequela to ocular cicatricial *pemphigoid* (Chapter 25). A reduction in the number of goblet cells due to conjunctival scarring leads to a decrease in surface mucin, which is essential for the adherence of the aqueous component of tears to the corneal epithelium. Thus, even if the aqueous component of the tear film is adequate, the affected individual will suffer from a dry eye, a condition that, when severe, can be painful and can predispose to corneal opacification and ulceration. More commonly, however, dry eye results from a deficiency in the aqueous component of the tear film generated by the accessory lacrimal glands embedded within the eyelid and fornix.

The conjunctiva may be scarred iatrogenically through reaction to drugs or as a consequence of surgery. In other parts of the body, cancer surgery requires excision of the lesion with a margin of normal tissue to ensure complete removal. However, extensive surgical excision of even diseased conjunctiva can remove a large number of goblet cells or compromise lacrimal gland ductules that traverse the conjunctiva. Thus, removal of a conjunctival neoplasm or a precursor lesion may leave the affected individual with a painful dry eye that can compromise vision. Therefore, surgeons often remove only the invasive components of conjunctival neoplasms, and treat the intraepithelial components with tissue-sparing modalities such as cryotherapy or topical chemotherapy delivered as eyedrops.

PINGUECULA AND PTERYGIUM

Both pinguecula and pterygium appear as submucosal elevations on the conjunctiva. They result from actinic damage and are therefore located in the sun-exposed regions of the conjunctiva (i.e., in the fissure between both the upper and lower eyelids—the interpalpebral fissure). Pterygium typically originates in the conjunctiva astride the limbus. It is formed by a submucosal growth *of fibrovascular connective tissue that migrates onto the cornea*, dissecting into the plane occupied normally by the Bowman layer. Pterygium does not cross the pupillary axis and, aside from the possible induction of mild astigmatism, does not pose a threat to vision. Although most pterygia are entirely benign, it is worthwhile submitting the excised tissue for pathologic examination because, on occasion, precursors of actinic-induced neoplasms—squamous cell carcinoma and melanoma—are detected in these lesions.

Pinguecula, which, like pterygium, appears astride the limbus, is a small, yellowish submucosal elevation. Although the *pinguecula does not invade the cornea as pterygium* does, the presence of a focal conjunctival elevation near the limbus can result in an uneven distribution of the tear film over the adjacent cornea. As a consequence of focal dehydration, a saucer-like depression in the corneal tissue—a *dellen*—may develop.

NEOPLASMS

Both squamous neoplasms and melanocytic neoplasms and their precursors tend to develop at the limbus. Conjunctival squamous cell carcinoma may be preceded by intraepithelial neoplastic changes analogous to those seen in the evolution of cervical squamous cell carcinoma. In the conjunctiva the spectrum of changes from mild dysplasia through carcinoma in situ is designated as *conjunctival intraepithelial neoplasia*. Squamous papillomas and conjunctival intraepithelial neoplasia may be associated with the presence of human papillomavirus types 16 and 18.[6] Although conjunctival squamous cell carcinoma tends to follow an indolent course, *mucoepidermoid carcinoma* of the conjunctiva (reflecting the ability of conjunctival stem cells to differentiate into squamous epithelium and goblet cells) follows a much more aggressive course.

Conjunctival nevi are encountered commonly in clinical practice but seldom invade the cornea or appear in the fornix or over the palpebral conjunctiva.[7] Pigmented lesions in these zones of the conjunctiva most likely represent melanomas or melanoma precursors. Compound nevi of the conjunctiva characteristically contain subepithelial cysts lined by surface epithelium (Fig. 29-6A, B). In late childhood or adolescence, conjunctival nevi may acquire an inflammatory component rich in lymphocytes, plasma cells, and eosinophils. The resultant *inflamed juvenile nevus* is completely benign and not associated with vitiligo or halo nevus.

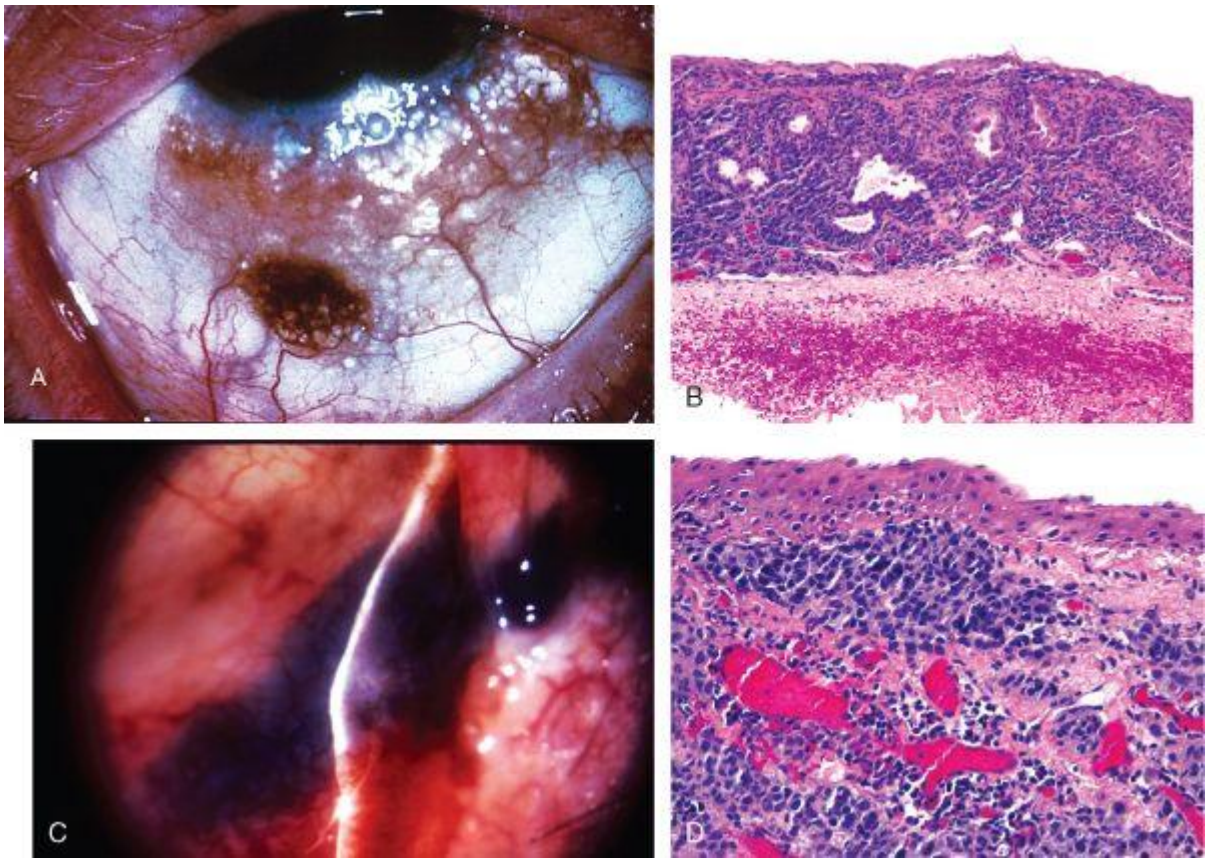

FIGURE 29-6 A, B, Cystic compound nevus of the conjunctiva. **C, D**, Conjunctival malignant melanoma. In **C**, note the deflection of the beam of the slit lamp over the surface of the lesion, indicative of invasion. ***(A, B**, From Folberg R et al.: Benign conjunctival melanocytic lesions: clinicopathologic features. Ophthalmology 96:436, 1989.)*

Conjunctival melanomas are unilateral neoplasms, typically affecting fair-complexioned individuals in middle age[8] (Fig. 29-6C, D). Most cases of conjunctival melanoma develop through a phase of intraepithelial growth termed *primary acquired melanosis with atypia*, which is roughly analogous to *melanoma in situ* but does not correspond neatly to the radial growth phase of cutaneous melanoma. Between 50% and 90% of individuals with incompletely treated primary acquired melanosis with atypia will develop conjunctival melanoma; the best treatment of conjunctival melanoma is its prevention through extirpation of its precursor lesion. The lesions tend to spread first to the parotid or submandibular lymph nodes. The mortality for conjunctival melanoma is 25%.

3.19.4 Sclera

The sclera consists mainly of collagen and contains few blood vessels and fibroblasts; hence, wounds and surgical incisions tend to heal poorly. Immune complex deposits within the sclera, such as in *rheumatoid arthritis*, may produce a necrotizing *scleritis*.

The sclera may appear "blue" in a variety of conditions. It may become thin following episodes of scleritis, and the normally brown color of the uvea may appear blue clinically because of the optical Tyndall effect. Sclera may also be thinned in eyes with exceptionally high intraocular pressure and because this zone of scleral ectasia is lined by uveal tissue, the resulting lesion, known as a *staphyloma*, also appears blue. The sclera may appear blue in osteogenesis imperfecta. Finally, the sclera may appear blue because of a heavily pigmented congenital nevus of the underlying uvea, a condition known as *congenital melanosis oculi*. When accompanied by periocular cutaneous pigmentation, this condition is known as *nevus of Ota*.

3.19.5 Cornea

FUNCTIONAL ANATOMY

The cornea and its overlying tear film—not the lens—make up the major refractive surface of the eye (Fig. 29-7). Parenthetically, myopia typically develops because the eye is too long for its refractive power, and hyperopia results from an eye that is too short. The popularity of procedures such as laser-assisted in situ keratomileusis (LASIK) to sculpt the cornea and change its refractive properties attests to the importance of corneal shape in contributing to the refractive power of the eye.

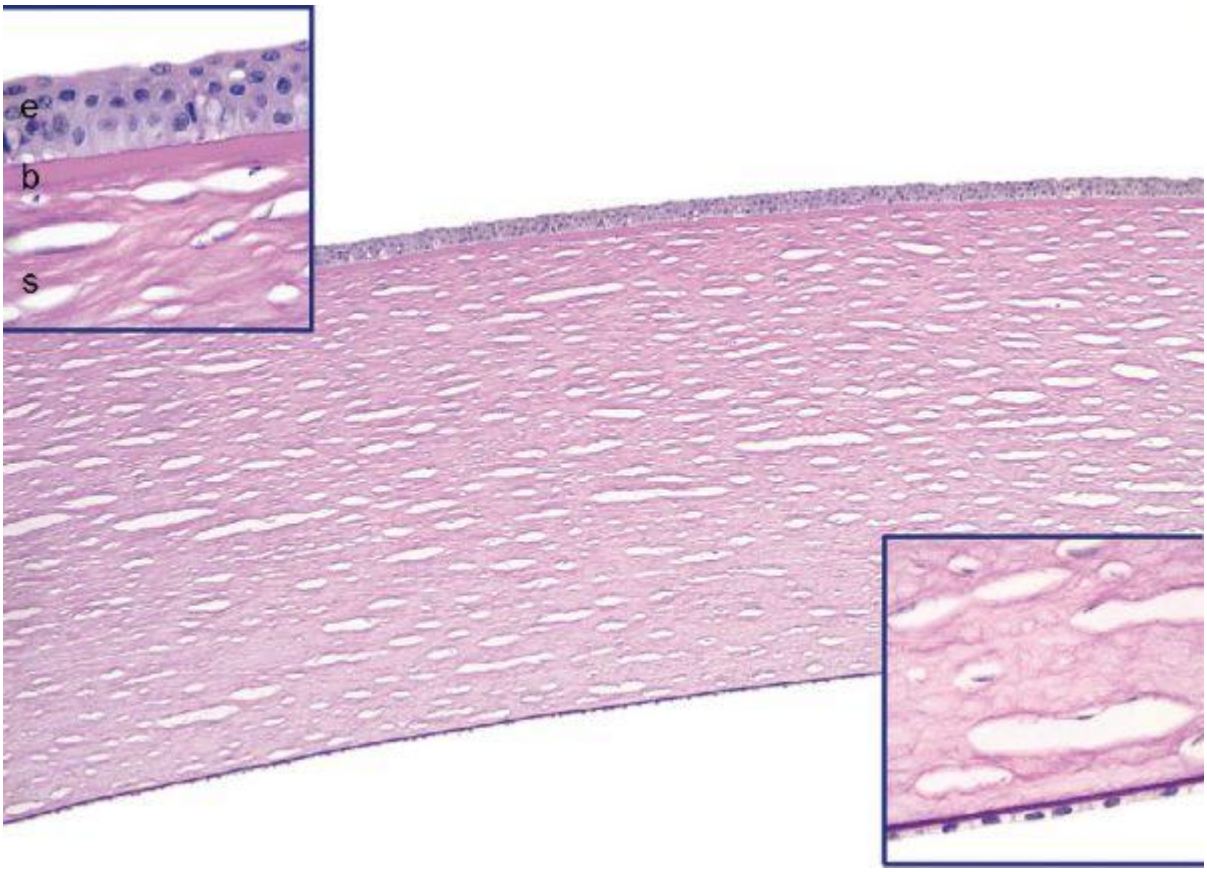

FIGURE 29-7 Normal corneal microarchitecture. The corneal tissue is stained by periodic acid–Schiff (PAS) to highlight basement membranes. The inset at the upper left is a high magnification of the anterior layers of the cornea: the epithelium *(e)*, Bowman layer *(b)*, and the stroma *(s)*. A very thin PAS-positive basement membrane separates the epithelium from the Bowman layer. Note that the Bowman layer is acellular. The *inset* at the *lower right* is a high magnification of the PAS-positive Descemet membrane and the corneal endothelium. The "holes" in the stroma are artifactitious spaces between parallel collagenous stromal lamellae.

Anteriorly, the cornea is covered by *epithelium* that rests on a basement membrane. The *Bowman layer*, situated just beneath the epithelial basement membrane, is acellular and forms an efficient barrier against the penetration of malignant cells from the epithelium into the underlying stroma.

The *corneal stroma* lacks blood vessels and lymphatics, a feature that contributes not only to the transparency of the cornea, but also to high rate of success of corneal transplantation. Indeed, non-immunological graft failure (associated with loss of endothelial cells and subsequent corneal edema) is seen more commonly than is immunological graft rejection. The risk of corneal graft rejection increases with stromal vascularization and inflammation. A precise alignment of collagen in the corneal stroma also contributes to transparency. Scarring and edema both disrupt the spatial alignment of stromal collagen and contribute to corneal opacification. Scars may result from trauma or inflammation. Normally, the corneal stroma is in a state of relative deturgescence (dehydration), maintained in large part by active pumping of fluid from the stroma back into the anterior chamber by the corneal endothelium.

The corneal *endothelium* is derived from neural crest and is not related to vascular endothelium. It rests on its basement membrane, Descemet membrane. A decrease in endothelial cells or a malfunction of endothelium results in stromal edema, which may be complicated by bullous separation of the

epithelium *(bullous keratopathy)*. *Descemet membrane* increases in thickness with age. It is the site of copper deposition in the Kayser-Fleischer ring of Wilson disease (Chapter 18).

KERATITIS AND ULCERS

Various pathogens—bacterial, fungal, viral (especially herpes simplex and herpes zoster), and protozoal (*Acanthamoeba*)—can cause corneal ulceration. In all forms of keratitis, dissolution of the corneal stroma may be accelerated by activation of collagenases within corneal epithelium and stromal fibroblasts (also known as keratocytes). Exudate and cells leaking from iris and ciliary body vessels into the anterior chamber may be visible by slit-lamp examination and may accumulate in sufficient quantity to become visible even by a penlight examination *(hypopyon)*. Although the corneal ulcer may be infectious, the hypopyon seldom contains organisms and is an example par excellence of the vascular response to acute inflammation. The specific forms of keratitis may have certain distinctive features. For example, chronic herpes simplex keratitis may be associated with a granulomatous reaction involving the Descemet membrane (Fig. 29-8).

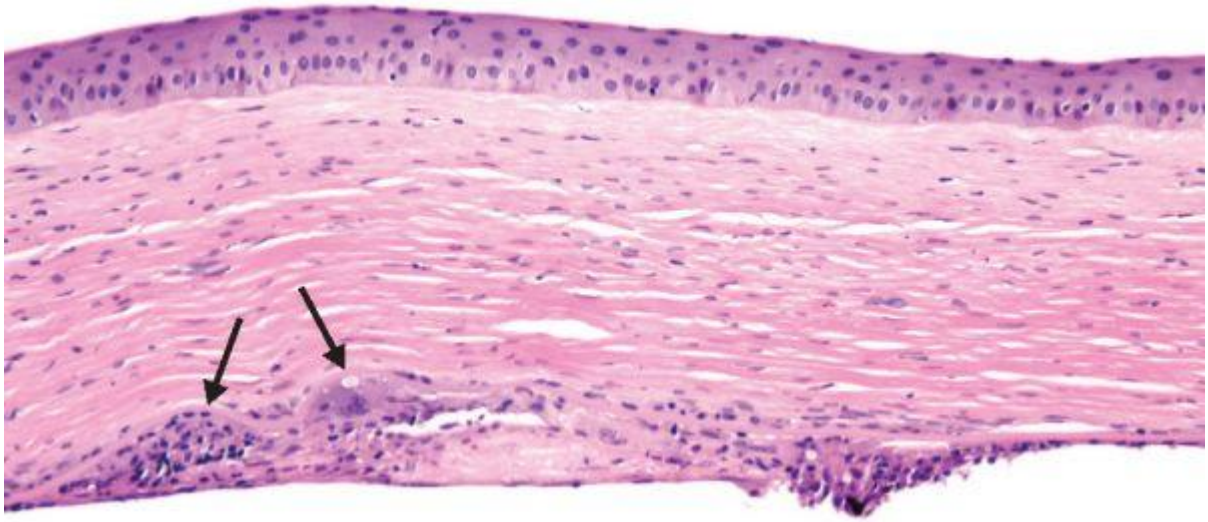

FIGURE 29-8 Chronic herpes simplex keratitis. The cornea is thin and scarred (note the increased number of fibroblast nuclei). Granulomatous reaction in the Descemet membrane, illustrated in this photomicrograph *(arrows)*, is a histologic hallmark of chronic herpes simplex keratitis.

CORNEAL DEGENERATIONS AND DYSTROPHIES

Ophthalmologists have traditionally divided many corneal disorders into degenerations and dystrophies. Corneal degenerations may be either unilateral or bilateral and are typically nonfamilial. By contrast, corneal dystrophies are typically bilateral and are hereditary. Corneal dystrophies may affect selective corneal layers (e.g., *Reis-Bückler dystrophy* affects Bowman layer, and *posterior polymorphous dystrophy* affects the endothelium), or the changes may be distributed throughout multiple layers.

Band Keratopathies

Two types of band keratopathy serve as examples of corneal degenerations. *Calcific band keratopathy* is characterized by deposition of calcium in the Bowman layer. This condition may complicate chronic uveitis, especially in individuals with chronic juvenile rheumatoid arthritis. *Actinic band keratopathy* develops in individuals who are exposed chronically to high levels of ultraviolet light. In this condition,

extensive solar elastosis develops in the superficial layers of corneal collagen in the sun-exposed interpalpebral fissure, hence the horizontally distributed band of pathology. Similar to pinguecula, the sun-damaged collagen of the cornea appears clinically to be yellow to the point that this condition is sometimes erroneously called “oil-droplet keratopathy.”

Keratoconus

With an incidence of 1 in 2000, *keratoconus* is a fairly common disorder characterized by progressive thinning and ectasia of the cornea without evidence of inflammation or vascularization. Such thinning results in a cornea that has a conical rather than spherical shape. This abnormal shape generates irregular astigmatism that is difficult to correct with spectacles. Rigid contact lenses generate a smooth, spherical surface to the cornea and may provide refractive relief for individuals with keratoconus. Patients whose vision cannot be corrected with spectacles or contact lenses are excellent candidates for corneal transplantation, which has a high degree of success in this condition. The etiology of keratoconus is unknown. Unlike many degenerations, it is typically bilateral. There is an association between keratoconus, Down syndrome, and Marfan syndrome, as well as with atopic disorders. Activation of collagenases, gelatinases, and matrix metalloproteinases has been implicated in the pathogenesis of this condition.

Morphology. Thinning of the cornea with breaks in the Bowman layer are the histologic hallmarks of keratoconus (Fig. 29-9). In some patients the Descemet membrane may rupture precipitously, allowing the aqueous humor in the anterior chamber to gain access to the corneal stroma. The sudden effusion of aqueous humor through a gap in the Descemet membrane—corneal **hydrops**—may also cause vision to worsen suddenly. An episode of hydrops may be followed by corneal scarring that can also contribute to visual loss. Acute corneal hydrops can complicate Descemet membrane ruptures that develop secondary to extraordinary elevations of intraocular pressure in **infantile glaucoma (Haab's striae)** or following the now uncommon obstetric forceps injury to the eye.

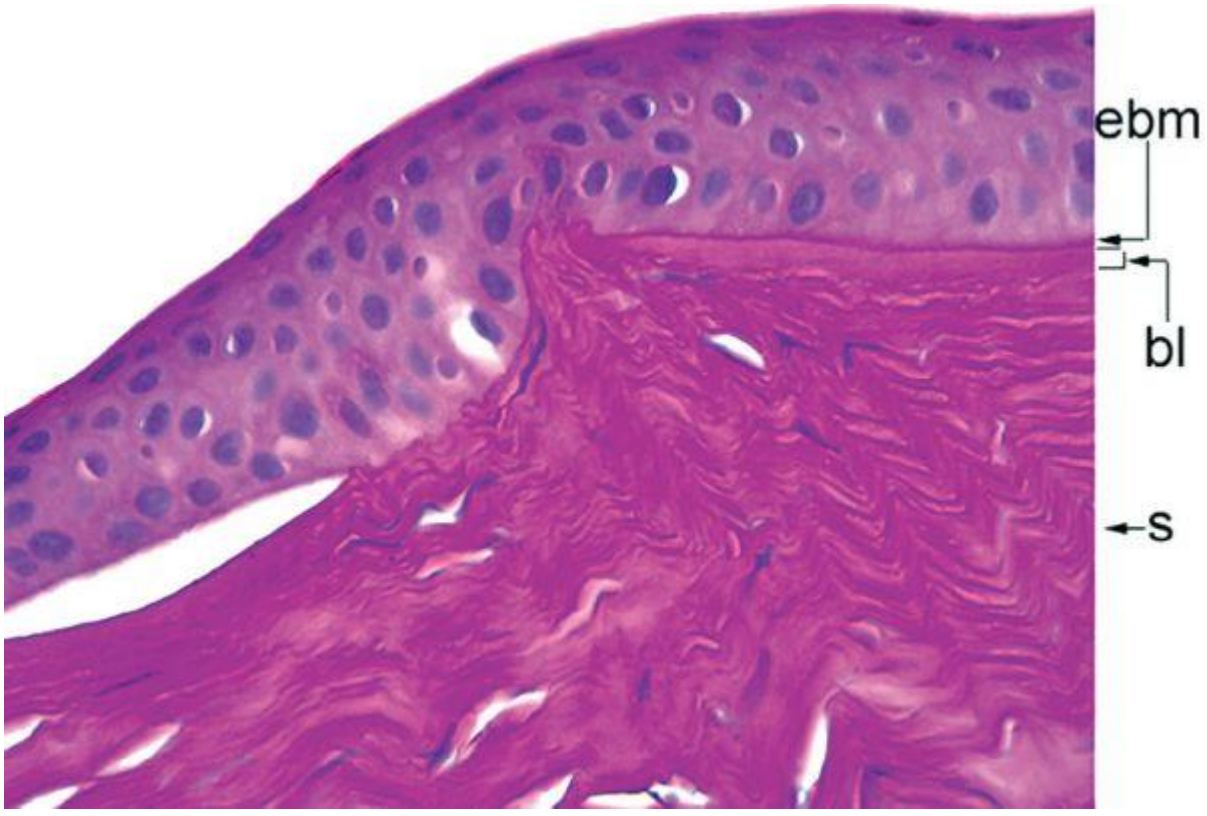

FIGURE 29-9 Keratoconus. The tissue section is stained by PAS to highlight the epithelial basement membrane (ebm), which is intact, the Bowman layer (bl), situated between the epithelial basement membrane, and the stroma (s). Following the Bowman layer from the *right side* of the photomicrograph toward the *center*, there is a discontinuity, diagnostic of keratoconus. The epithelial separation just to the *left* of the Bowman layer discontinuity resulted from an episode of corneal hydrops, caused by a break in the Descemet membrane (not shown).

Fuchs Endothelial Dystrophy

This condition, one of several dystrophies affecting the endothelium, is one of the principal indications for corneal transplantation in the United States. The two major clinical manifestations of Fuchs endothelial dystrophy—*stromal edema and bullous keratopathy*—are both related to a primary loss of endothelial cells. Early in the course of the disease endothelial cells produce droplike deposits of abnormal basement membrane material *(guttata)* that resemble the fetal component of the Descemet membrane ultrastructurally. Guttata can be visualized clinically by slit-lamp examination. With disease progression, there is a decrease in the total number of endothelial cells, and the residual cells are incapable of maintaining stromal deturgescence. Consequently the stroma becomes edematous and thickens; it acquires a ground-glass appearance clinically, and vision is blurred (Fig. 29-10). Because of chronic edema, the stroma may eventually become vascularized. On occasion the number of endothelial cells may decrease following cataract surgery even in individuals who do not have early forms of Fuchs dystrophy, and the condition is then known as *pseudophakic bullous keratopathy*.

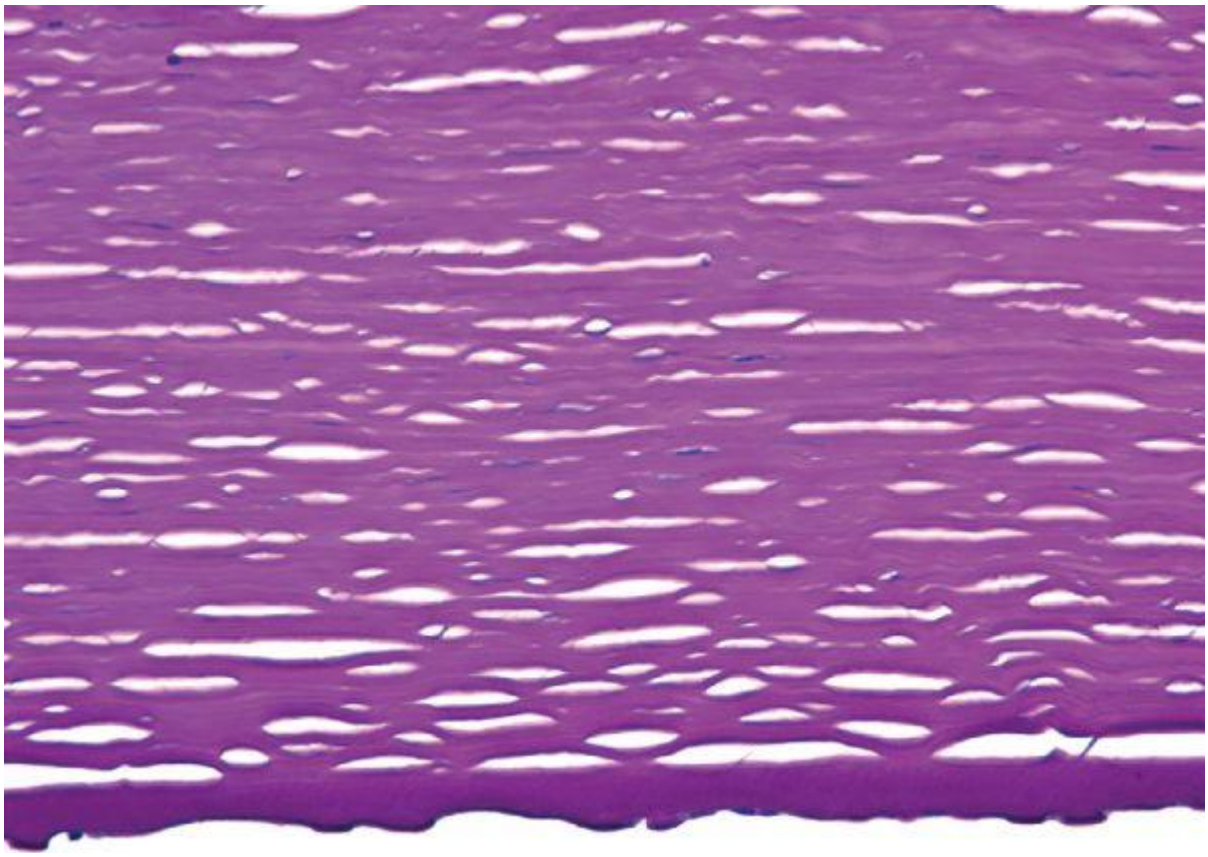

FIGURE 29-10 Fuchs dystrophy. This tissue section is stained by PAS to highlight the Descemet membrane, which is thick. Numerous droplike excrescences—guttata—protrude downward from the Descemet membrane. Endothelial cell nuclei are not seen. Epithelial bullae, not

shown in this micrograph, were present, reflecting corneal edema.

With increasing stromal edema, the epithelium undergoes hydropic change, and the detachment of the epithelium from the Bowman layer produces epithelial bullae that may eventually rupture. Fibrous connective tissue may be deposited between the epithelium and Bowman layer *(degenerative pannus)* either by ingrowth from the limbus or perhaps through fibrous metaplasia of the corneal epithelium.

Stromal Dystrophies

In these conditions the *stromal deposits generate discrete opacities in the cornea* may eventually compromise vision. Deposits in the vicinity of the epithelium, its basement membrane, and Bowman layer may result in painful epithelial erosions. Scarring in the vicinity of Bowman layer may generate an irregular corneal surface, further compromising vision. *Macular corneal dystrophy* is so named because early in the disease, small nummular (macular) deposits of keratan sulfate develop in the corneal stroma. Later in the course of this autosomal recessive dystrophy, keratan sulfate is distributed diffusely throughout the stroma and may affect the endothelium.

The identification of specific mutations responsible for various stromal dystrophies is generating a new molecular classification of these disorders.[9] One example involves an autosomal dominant form of stromal dystrophy associated with mutations in the *TGFB1* gene, which encodes an extracellular matrix protein called *keratoepithelin*. Diverse mutations in *TGFB1* disrupt the folding of keratoepithelin, and depending on the exact mutation, lead to the deposition of various types of proteinaceous deposits in the cornea. These include needle-shaped deposits of amyloid (*lattice dystrophy*); chunky deposits of hyalin (*granular dystrophy*); and combinations of these opacities in the same person (*Avelino dystrophy*, named for the location of the first families with this condition).

3.19.6 Anterior Segment

FUNCTIONAL ANATOMY

The anterior chamber is bounded anteriorly by the cornea, laterally by the trabecular meshwork, and posteriorly by the iris (Fig. 29-11). Aqueous humor, formed by the pars plicata of the ciliary body, enters the posterior chamber, bathes the lens, and circulates through the pupil to gain access to the anterior chamber.

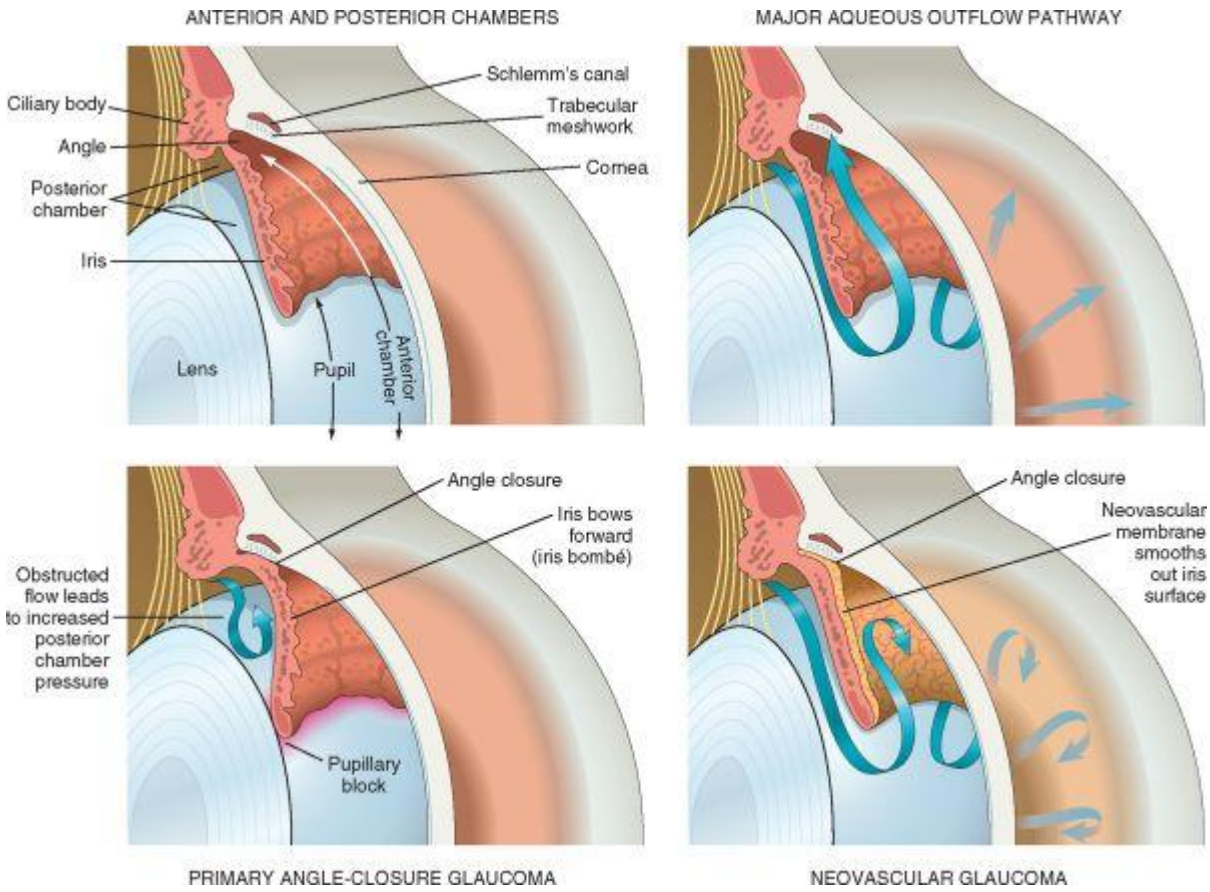

FIGURE 29-11 *Upper left*, The normal eye. Note that the surface of the iris is highly textured with crypts and folds. *Upper right*, The normal flow of aqueous humor. Aqueous humor, produced in the posterior chamber, flows through the pupil into the anterior chamber. The major pathway for the egress of aqueous humor is through the trabecular meshwork, into the Schlemm canal. Minor outflow pathways (uveoscleral and iris, not depicted) contribute to a limited extent to aqueous outflow. *Lower left*, Primary angle-closure glaucoma. In anatomically predisposed eyes, transient apposition of the iris at the pupillary margin to the lens blocks the passage of aqueous humor from the posterior chamber to the anterior chamber. Pressure builds in the posterior chamber, bowing the iris forward (iris bombé) and occluding the trabecular meshwork. *Lower right*, A neovascular membrane has grown over the surface of the iris, smoothing the iris folds and crypts. Myofibroblasts within the neovascular membrane cause the membrane to contract and to become apposed to the trabecular meshwork (peripheral anterior synechiae). Outflow of aqueous humor is blocked, and the intra-ocular pressure becomes elevated.

The lens is a closed epithelial system; the basement membrane of the lens epithelium (known as the lens capsule) totally envelops the lens. Thus, the lens epithelium does not exfoliate like the epidermis or a mucosal epithelium. Instead, the lens epithelium and its derivative fibers accumulate within the confines of the lens capsule, thus "infoliating." With aging, therefore, the size of the lens increases. Neoplasms of the lens have not been described.

CATARACT

The term *cataract* describes lenticular opacities that may be congenital or acquired. Systemic diseases (such as galactosemia, diabetes mellitus, Wilson disease, and atopic dermatitis), drugs (especially corticosteroids), radiation, trauma, and many intraocular disorders are associated with cataract. Age-related cataract typically results from opacification of the lens nucleus *(nuclear sclerosis)*. The accumulation of urochrome pigment may render the lens nucleus brown, thus distorting the individual's perception of blue color (the predominance of yellow hues in Rembrandt's paintings later in life might have been a consequence of nuclear sclerotic cataracts). Other physical changes in the lens may

generate opacities. For example, the lens cortex may liquefy. Migration of the lens epithelium posterior to the lens equator may result in *posterior subcapsular cataract* secondary to enlargement of abnormally positioned lens epithelium. The technique that is most commonly used to remove opacified lenses extracts the lens contents, leaving the lens capsule intact (extracapsular cataract extraction). A prosthetic intra-ocular lens may be inserted into the eye. Residual lens epithelial cells may migrate over the lens capsule, contributing to opacification of the capsule and reduction in vision after surgery.

Inflammatory reactions to lens material may develop following exposure of the intact lens cortex caused by rupture of the capsule due to trauma or as a result of cataract extraction. It has been suggested that antigen-antibody complexes containing lens cortical material develop especially in the presence of *Propionibacterium acnes* (which acts as an adjuvant), generating a *lens-induced uveitis*.

Occasionally, the lens cortex may liquefy nearly entirely, a condition known as hypermature or *morgagnian cataract*. High-molecular-weight proteins from liquefied lens cortex may leak through the lens capsule *(phacolysis)*. This phacolytic protein—either free or contained within macrophages—may clog the trabecular meshwork and contribute to elevation in intra-ocular pressure and optic nerve damage; phacolytic glaucoma is an example of secondary open-angle glaucoma.

THE ANTERIOR SEGMENT AND GLAUCOMA

The term *glaucoma* refers to a collection of diseases characterized by distinctive changes in the visual field and in the cup of the optic nerve. Most of the glaucomas are associated with elevated intra-ocular pressure, although some individuals with normal intra-ocular pressure may develop characteristic optic nerve and visual field changes (*normal* or *low-tension glaucoma*). The relationship between intra-ocular pressure and optic nerve damage is discussed later under “Optic Nerve.”

To understand the *pathophysiology of glaucoma* it is useful to consider the formation and drainage of aqueous humor. As Figure 29-11 illustrates, aqueous humor is produced in the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber. Although there are multiple pathways for the egress of fluid from the anterior chamber, most of the aqueous humor drains through the trabecular meshwork, situated in the angle formed by the intersection between the corneal periphery and the anterior surface of the iris. With this background, glaucoma can be classified into two major categories. In *open-angle glaucoma* the aqueous humor has complete physical access to the trabecular meshwork, and the elevation in intra-ocular pressure results from an increased resistance to aqueous outflow in the open angle. In *angle-closure glaucoma* the peripheral zone of the iris adheres to the trabecular meshwork and physically impedes the egress of aqueous humor from the eye. Both open-angle and angle-closure glaucoma can be subclassified into *primary* and *secondary* types.

In *primary open-angle glaucoma*, the most common form of glaucoma, the angle is open, and few changes are apparent structurally. Mutations in the *MYOC* gene have been associated with a subset of individuals with juvenile and adult primary open-angle glaucoma. The function of the gene product, myocilin, is unclear. *MYOC* is present in the tracetabular meshwork, in other anterior segment tissues, and in the optic nerve. The pathogenesis of primary open-angle glaucoma may be related to several genes, but the genes identified thus far account for a small percentage of affected individuals with this condition.[10] The role of these genes in the pathogenesis of glaucoma is not clear.

There are multiple causes of *secondary open-angle glaucoma*. Particulate material such as high-molecular-weight lens proteins produced by phacolysis, senescent red cells after trauma *(ghost cell glaucoma)*, iris epithelial pigment granules *(pigmentary glaucoma)*, fragments of oxytalan fibers *(exfoliation glaucoma)*, and necrotic tumors *(melanomalytic glaucoma)* can clog the trabecular meshwork in the presence of an open angle. Elevations in the pressure on the surface of the eye (episcleral venous pressure) in the presence of an open angle also contributes to secondary open-angle

glaucoma. This type of glaucoma is associated with surface ocular vascular malformations seen in *Sturge-Weber syndrome* or as a consequence of arterialization of the episcleral veins following a spontaneous or traumatic carotid-cavernous fistula.

Primary angle-closure glaucoma typically develops in eyes with shallow anterior chambers, often found in individuals with hyperopia. Transient apposition of the pupillary margin of the iris to the anterior surface of the lens may result in obstruction to the flow of aqueous humor through the pupillary aperture *(pupillary block)*. Continued production of aqueous humor by the ciliary body thus elevates pressure in the posterior chamber and may bow the iris periphery forward *(iris bombé)*, apposing it to the trabecular meshwork. These anatomic changes provoke a marked elevation in intra-ocular pressure (see Fig. 29-11). Since the crystalline lens is avascular and the lens epithelium receives its nutrition from the aqueous humor, unremitting elevation in intra-ocular pressure in primary angle-closure glaucoma can damage the lens epithelium. This leads to minute anterior subcapsular opacities that are visible by slit-lamp examination *(glaukomflecken)*. Although the affected individual might have a normal complement of healthy corneal endothelial cells, sustained elevated intra-ocular pressure can produce corneal edema and bullous keratopathy.

There are many causes of *secondary angle-closure glaucoma*. Contraction of various types of pathologic membranes that form over the surface of the iris can draw the iris over the trabecular meshwork, occluding aqueous outflow. For example, chronic retinal ischemia is associated with the up-regulation of VEGF and other pro-angiogenic factors. The appearance of VEGF in the aqueous humor is thought to induce the development of thin, clinically transparent fibrovascular membranes over the surface of the iris. Contraction of myofibroblastic elements in these membranes leads to occlusion of the trabecular meshwork by the iris: *neovascular glaucoma* (see Fig. 29-11). Necrotic tumors, especially retinoblastomas, can also induce iris neovascularization and glaucoma. Secondary angle-closure glaucoma may be caused by other mechanisms as well; for example, tumors in the ciliary body can mechanically compress the iris onto the trabecular meshwork, closing off the major pathway of aqueous outflow.

ENDOPHTHALMITIS AND PANOPHTHALMITIS

In intra-ocular inflammation, vessels in the ciliary body and iris become leaky, allowing cells and exudate to accumulate in the anterior chamber. These changes can be visualized with a slit lamp; at times the inflammatory cells may adhere to the corneal endothelium, forming clinically visible *keratic precipitates*. The size and shape of these precipitates can provide clues to the underlying cause of the inflammation. For example, aggregates of macrophages on the endothelium in sarcoid produce characteristic “mutton-fat” keratic precipitates.

Just as pleural exudate in acute bronchopneumonia can lead to adhesions between the visceral and parietal pleura, the presence of exudate in the anterior chamber can facilitate the formation of adhesions between the iris and the trabecular meshwork or cornea *(anterior synechiae)* or between the iris and anterior surface of the lens *(posterior synechiae)*. Anterior synechiae can lead to elevation in intra-ocular pressure, which may lead to optic nerve damage. Prolonged contact between the iris and the anterior surface of the lens can deprive lens epithelium of contact with aqueous humor and can induce fibrous metaplasia of the lens epithelium: *anterior subcapsular cataract* (Fig. 29-12). The pharmacologic induction of pupillary dilation and cycloplegia in individuals with intra-ocular inflammation is intended in part to prevent the formation of synechiae and their sequelae.

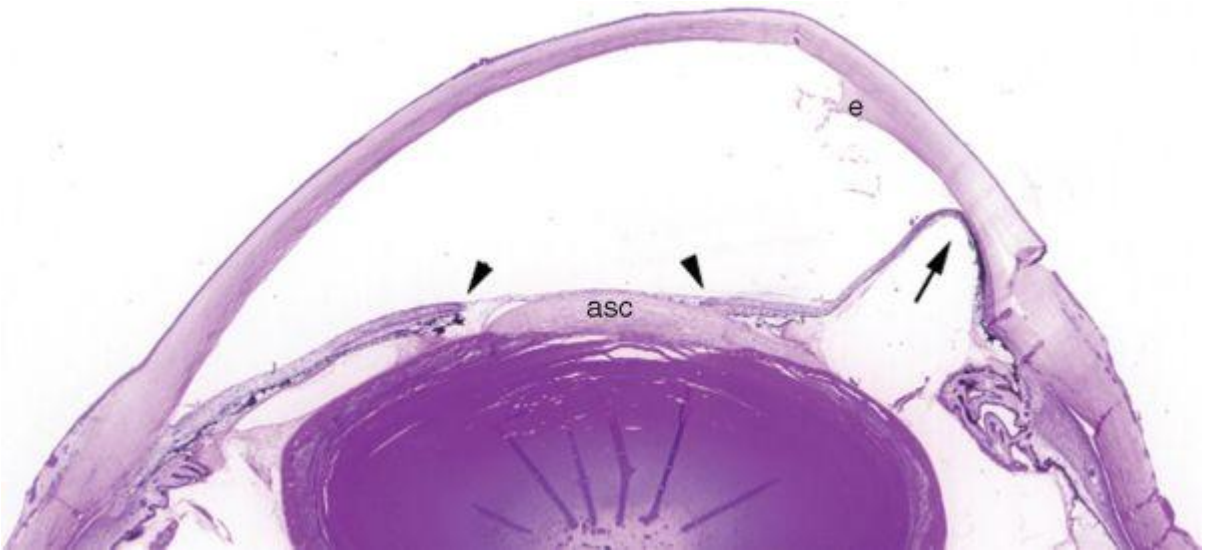

FIGURE 29-12 Sequelae of anterior segment inflammation. This eye was removed for complications of chronic corneal inflammation (not visible at this magnification). The exudate (e) present in the anterior chamber would have been visualized with a slit lamp as an optical "flare." The iris is adherent focally to the cornea, obstructing the trabecular meshwork (anterior synechia, *arrow*), and to the lens (posterior synechiae, *arrowheads*). An anterior subcapsular cataract (asc) has formed. The radial folds in the lens are artifacts.

Although inflammation confined to the anterior segment is technically intra-ocular inflammation, the term *endophthalmitis* is not applied clinically unless there is inflammation within the vitreous humor. The retina lines the vitreous cavity, and suppurative inflammation in the vitreous humor (endophthalmitis) is poorly tolerated by the retina; after only a few hours of exposure to acute inflammation, the retina may be irreversibly damaged. Endophthalmitis is classified as *exogenous* (originating in the environment and gaining access to the interior of the eye through a wound) or *endogenous* (delivered to the eye hematogenously). The term *panophthalmitis* is applied to inflammation within the eye that involves the retina, choroid, and sclera and extends into the orbit (Fig. 29-13).

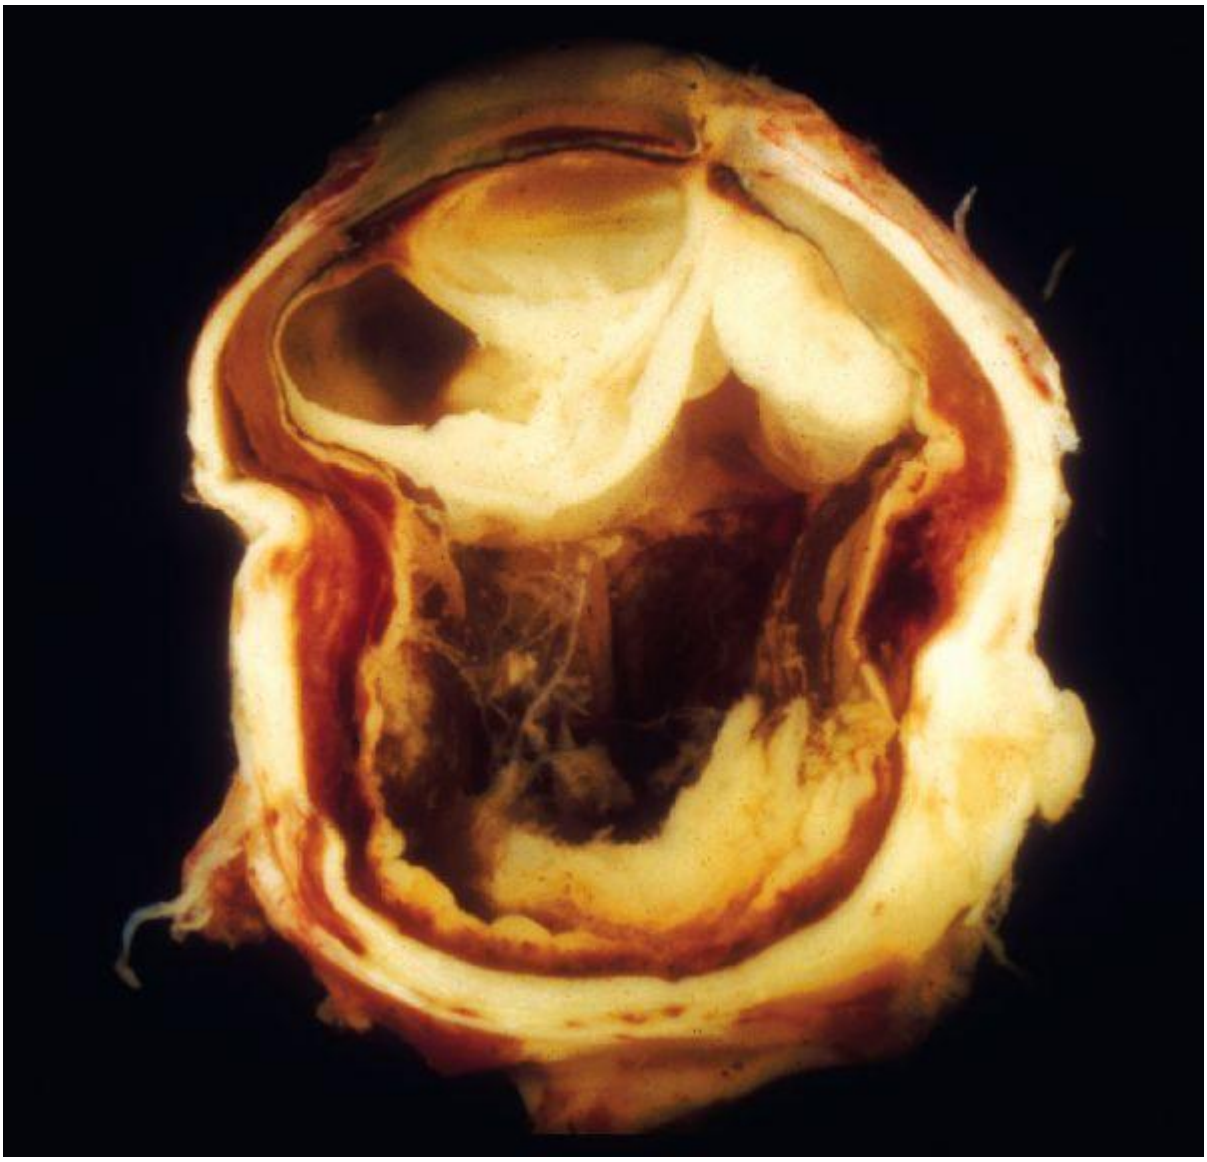

FIGURE 29-13 Exogenous panophthalmitis. This eye was removed after a foreign body injury. Note the suppurative inflammation behind the lens that is drawn up to the right of the lens to the cornea, the site of the wound. The central portion of the vitreous humor was extracted surgically (by vitrectomy). Note the adhesions to the surface of the eye at the eight o'clock position, indicating that the intra-ocular inflammation has spread through the sclera into the orbit: panophthalmitis. *(From Folberg R: The eye. In Spencer WH (ed): Ophthalmic Pathology—An Atlas and Textbook, 4th ed. Philadelphia, WB Saunders, 1985.)*

3.19.7 Uvea

Together with the iris, the choroid and ciliary body constitute the uvea. The choroid is among the most richly vascularized sites in the body. As in the retina, there are no lymphatics within the uvea.

UVEITIS

The term *uveitis* can be applied to any type of inflammation in one or more of the tissues that compose the uvea. Thus, the iritis that develops after blunt trauma to the eye or that accompanies a corneal ulcer is technically a form of uveitis. However, in clinical practice the term *uveitis* is restricted to a diverse group of chronic diseases that may be either components of a systemic process or localized to the eye. Uveal inflammation may be manifest principally in the anterior segment (e.g., in *juvenile rheumatoid*

arthritis) or may affect both the anterior and posterior segments. The complications of chronic anterior segment inflammation were discussed earlier; the remainder of this discussion therefore focuses on the effects of uveal inflammation on the posterior segment of the eye. As will be described briefly, uveitis is frequently accompanied by retinal pathology. Uveitis may be caused by infectious agents (e.g., *Pneumocystis carinii*), may be idiopathic (e.g., sarcoidosis), or may be autoimmune in origin (sympathetic ophthalmia). Some examples are described below.

Granulomatous uveitis is a common complication of sarcoidosis (Chapter 15). In the anterior segment it gives rise to an exudate that evolves into "mutton-fat" keratic precipitates described earlier. In the posterior segment, sarcoid may involve the choroid and retina. Thus, granulomas may be seen in the choroid. Retinal pathology is characterized by perivascular inflammation; this is responsible for the well-known ophthalmoscopic sign of "candle wax drippings." Conjunctival biopsy can be used to detect granulomatous inflammation and confirm the diagnosis of ocular sarcoid.

Numerous infectious processes can affect the choroid or the retina. Inflammation in one compartment is typically associated with inflammation in the other. Retinal *toxoplasmosis* is usually accompanied by uveitis and even scleritis. Individuals with AIDS may develop cytomegalovirus retinitis and uveal infection such as pneumocystis or mycobacterial choroiditis. [11] [12] [13]

Sympathetic ophthalmia is an example of noninfectious uveitis limited to the eye. This condition is characterized by bilateral granulomatous inflammation typically affecting all components of the uvea: a panuveitis. Sympathetic ophthalmia, which blinded young Louis Braille, may complicate a penetrating injury of the eye. In the injured eye, retinal antigens sequestered from the immune system may gain access to lymphatics in the conjunctiva and thus set up a delayed hypersensitivity reaction that affects not only the injured eye but also the contralateral, noninjured eye.[14] The condition may develop from 2 weeks to many years after injury. Enucleation of a blind eye (which can be the sympathizing eye rather than the directly injured eye) may yield diagnostic findings. Sympathetic ophthalmia is treated by the administration of systemic immunosuppressive agents. It is characterized by diffuse granulomatous inflammation of the uvea (choroid, ciliary body, and iris). Plasma cells are typically absent, but eosinophils may be identified in the infiltrate (Fig. 29-14).

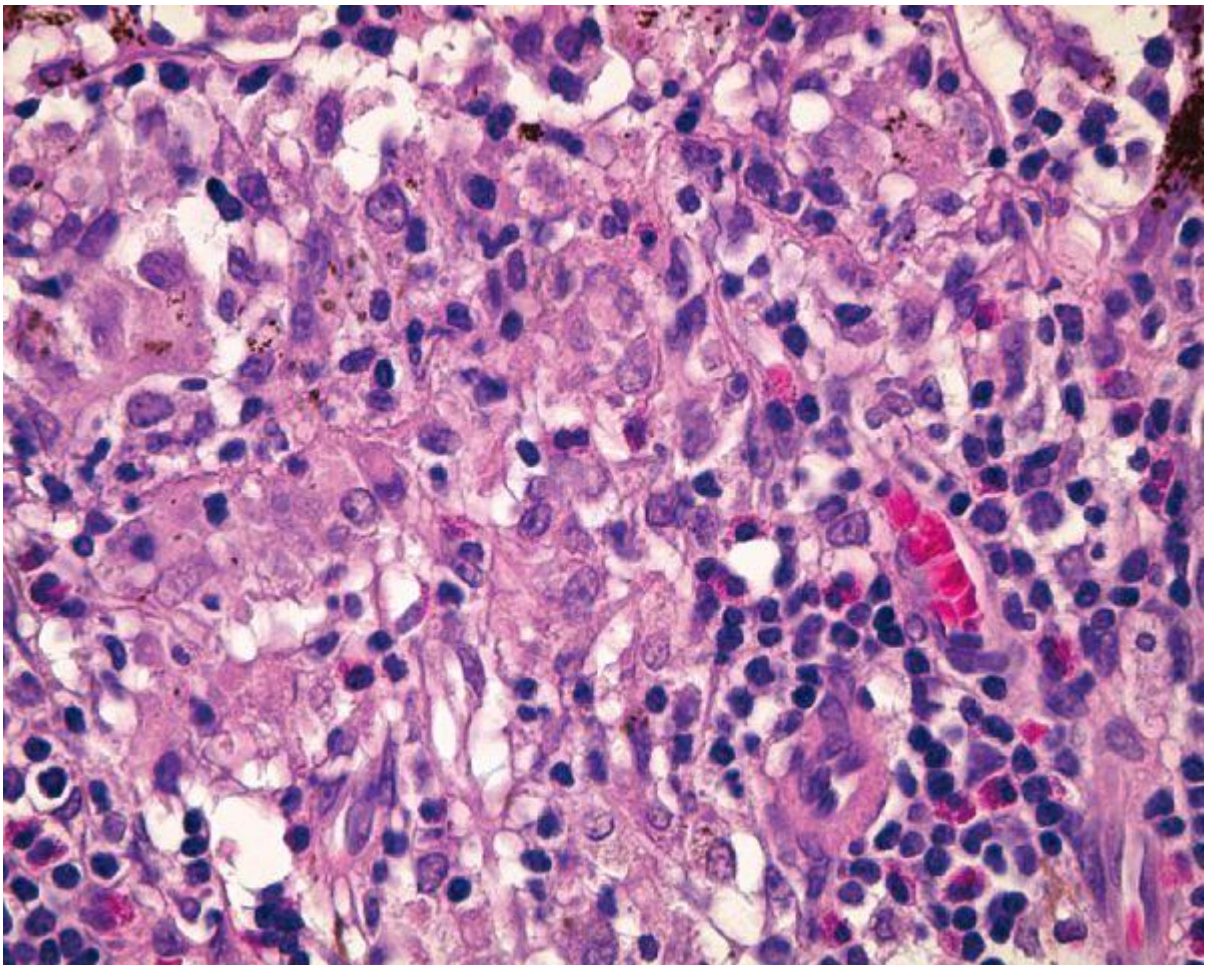

FIGURE 29-14 Sympathetic ophthalmia. The granulomatous inflammation depicted here was identified diffusely throughout the uvea. The uveal granulomas may contain melanin pigment and may be accompanied by eosinophils.

NEOPLASMS

The most common intra-ocular malignancy of adults is metastasis to the uvea, typically to the choroid. The occurrence of metastases to the eye is associated with an extremely short survival, and treatment of ocular metastases, usually by radiotherapy, is palliative.

Uveal Nevi and Melanomas

Uveal melanoma is the most common primary intra-ocular malignancy of adults. Although it was formerly thought to be rare (7 per million per year), the incidence of this tumor increases with age, and by the seventh decade the incidence is more than 20 per million per year. Unlike cutaneous melanoma, the occurrence of uveal melanoma has remained stable over many years.[15] Although excessive childhood exposure to ultraviolet radiation has been implicated, the link between ultraviolet light and uveal melanoma is not nearly as clear as it is for cutaneous melanoma. Therefore the etiology of uveal melanoma is still unresolved at this time. Uveal nevi, especially choroidal nevi, are rather common, affecting an estimated 10% of the Caucasian population but their progression to melanoma is exceptionally uncommon.

There are no lymphatics within the eye; hence, uveal melanomas, with very rare exception, spread exclusively by a hematogenous route (the only exception being the rare case of melanoma that spreads through the sclera and invades the conjunctiva, thereby gaining access to conjunctival lymphatics). Most uveal melanomas spread first to the liver, thereby providing an excellent example of organ-specific metastasis. Although the 5-year survival rate is approximately 80%,[16] the cumulative melanoma mortality rate is 40% at 10 years, increasing 1% per year thereafter.[17] Examples of metastases appearing many years after treatment are well known, making uveal melanoma a prime candidate for the investigation of tumor dormancy.

Morphology. Histologically, uveal melanomas may contain two types of cells, spindle and epithelioid, in various proportions (Fig. 29-15). Spindle cells are fusiform in shape and have little atypia, whereas epithelioid cells are spherical and have greater cytologic atypicality. Melanomas situated exclusively in the iris tend to follow a relatively indolent course, whereas melanomas of the ciliary body and choroid are more aggressive. The prognosis of choroidal and ciliary body melanomas is related to (1) size (in contrast to cutaneous melanoma, the lateral extent of the tumor rather than tumor depth is the size dimension related to adverse outcome); (2) cell type (tumors containing epithelioid cells have a worse prognosis than do those containing exclusively spindle cells); (3) and proliferative index. In contrast to cutaneous melanomas, large numbers of tumor-infiltrating lymphocytes are associated with an adverse outcome.[18] Extra-ocular extension is related to poor prognosis. Other features associated with poor prognosis include monosomy 3 and trisomy 8, and the presence of looping patterns rich in laminin that surround packets of tumor cells.[19] These “spaces” (which are not blood vessels) connect to blood vessels and serve as extravascular conduits for the transport of plasma and possibly blood.[20] In vitro studies and examination of human tissues suggest that these patterns are formed by aggressive tumor cells in a process termed vasculogenic mimicry.[21,][22]

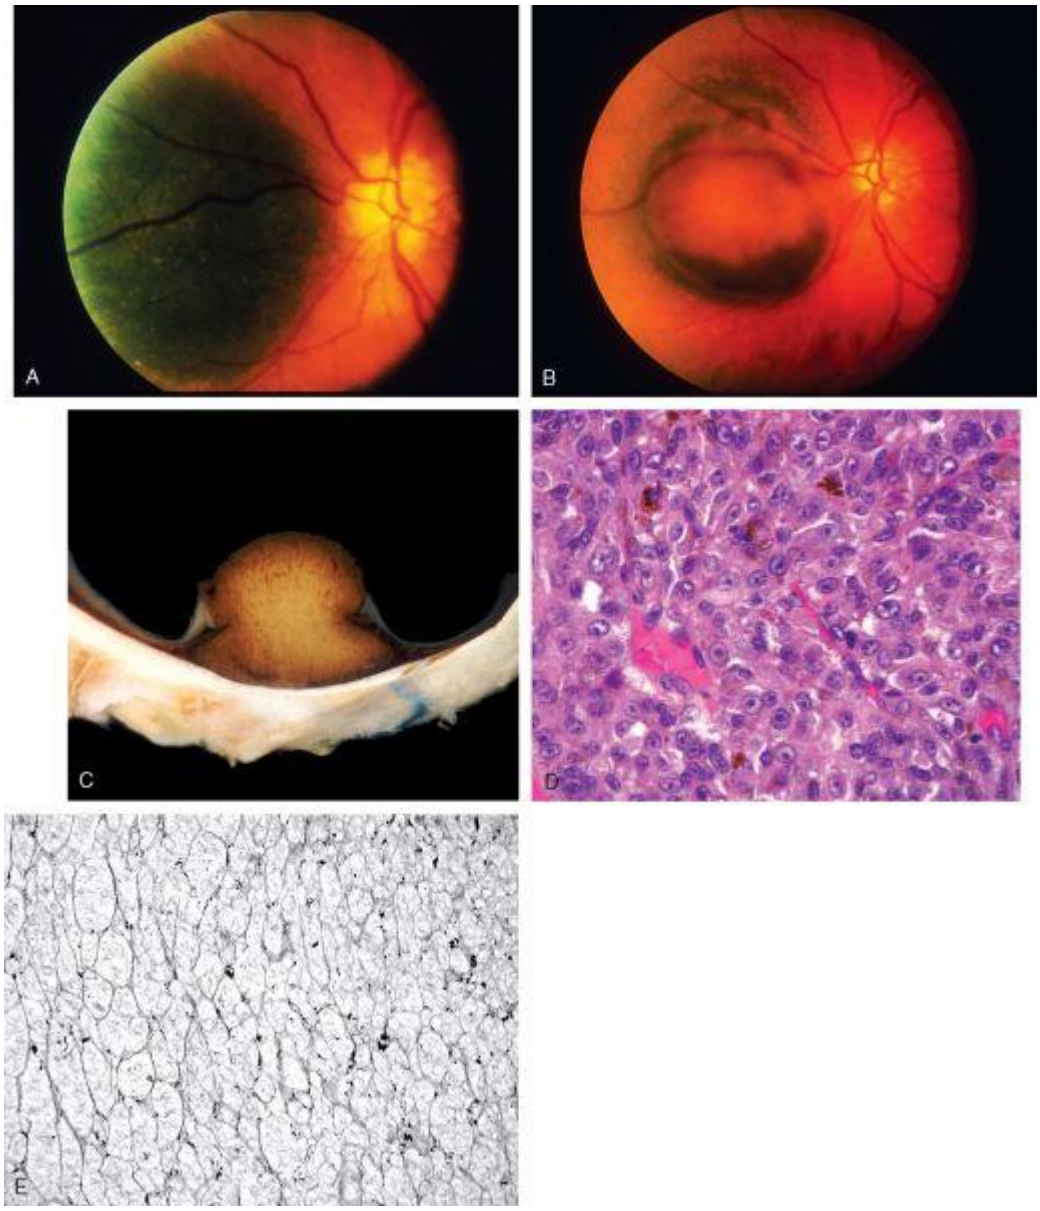

FIGURE 29-15 Uveal melanoma. **A**, Fundus photograph from an individual with a relatively flat pigmented lesion of the choroid near the optic disc. **B**, Fundus photograph of the same individual several years later; the tumor has grown and has ruptured through the Bruch membrane. **C**, Gross photograph of a choroidal melanoma that has ruptured the Bruch membrane. The overlying retina is detached. **D**, Epithelioid melanoma cells associated with an adverse outcome. **E**, Patterns rich in laminin (PAS positive) surround aggregates of melanoma cells; these patterns form a "fluid-conducting meshwork" in uveal melanoma and are associated with an adverse outcome. *(**A** to **C**, From Folberg R: Pathology of the Eye—an Interactive CD-ROM Program. Philadelphia, Mosby, 1996; **E**, from Maniotis AJ et al.: Control of melanoma morphogenesis, endothelial survival, and perfusion by extracellular matrix. Lab Invest 82:1031, 2002.)*

Uveal melanomas can have an adverse effect on vision, producing changes ranging from retinal detachment to glaucoma. There seems to be no difference in survival between tumors treated by removal of the eye (enucleation) and those treated by radiation treatment. It should be noted that patients treated by radiation and other vision-sparing modalities are diagnosed clinically without tissue removal for pathological examination. There is currently no effective treatment for metastatic uveal melanoma.

FUNCTIONAL ANATOMY

The neurosensory retina, like the optic nerve, is an embryologic derivative of the diencephalon. The retina therefore responds to injury by means of gliosis. As in the brain, there are no lymphatics. The architecture of the retina explains the ophthalmoscopic appearance of a variety of ocular disorders. Hemorrhages in the nerve fiber layer of the retina are oriented horizontally and appear as streaks or "flames;" the external retinal layers are oriented perpendicular to the retinal surface, and hemorrhages in these outer layers appear as dots (cross-sections of cylinders). Exudates tend to accumulate in the outer plexiform layer of the retina, especially in the macula (Fig. 29-16).

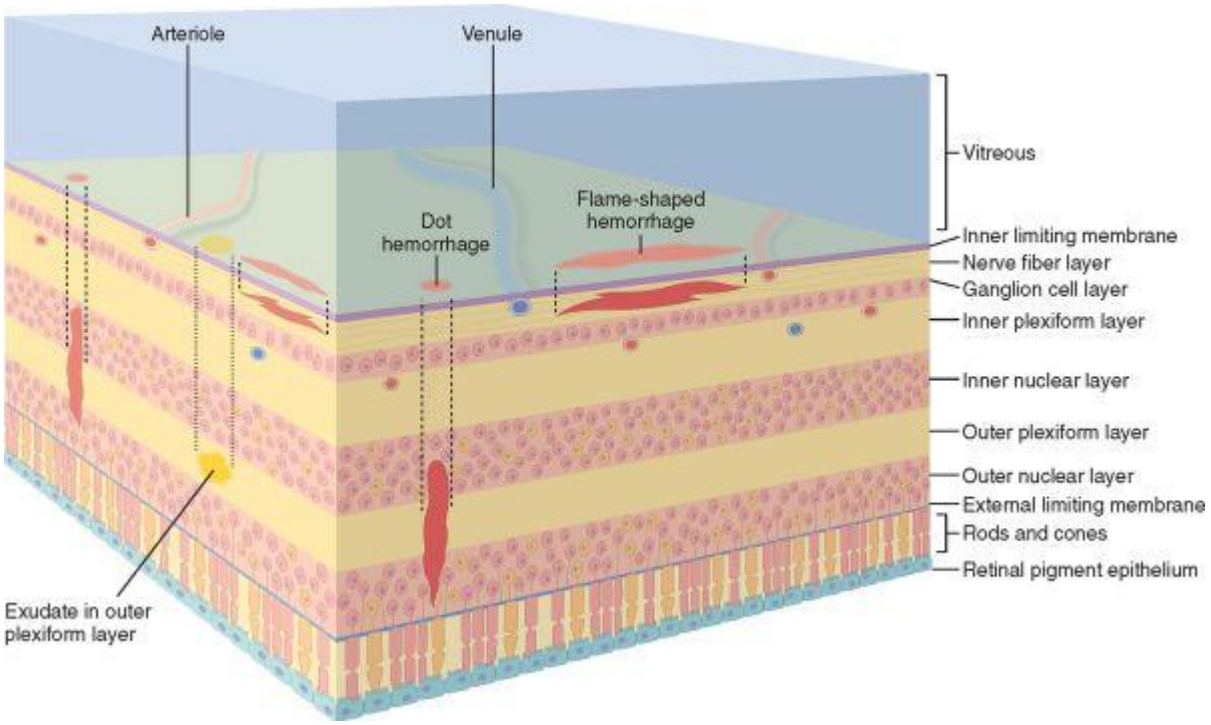

FIGURE 29-16 Clinicopathologic correlations of retinal hemorrhages and exudates. The location of the hemorrhage within the retina determines its appearance by ophthalmoscopy. The retinal nerve fiber layer is oriented parallel to the internal limiting membrane, and hemorrhages of this layer appear to be flame-shaped ophthalmoscopically. The deeper retinal layers are oriented perpendicular to the internal limiting membrane and hemorrhages in this location appear as cross-sections of a cylinder or "dot" hemorrhages. Exudates that originate from leaky retinal vessels accumulate in the outer plexiform layer.

The retinal pigment epithelium (RPE), like the retina, is derived embryologically from the primary optic vesicle, an outpouching of the brain. Separation of the neurosensory retina from the RPE defines a *retinal detachment*. The RPE has an important role physiologically in the maintenance of the outer segments of the photoreceptors. Disturbances in the RPE-photoreceptor interface may play important roles in hereditary retinal degenerations such as *retinitis pigmentosa*.

The adult vitreous humor is avascular. Incomplete regression of fetal vasculature running through the vitreous humor can produce significant pathology as a retrolental mass *(persistent hyperplastic primary vitreous)*. The vitreous humor can be opacified by hemorrhage from trauma or retinal neovascularization. With age the vitreous humor may liquefy and collapse, creating the visual sensation of "floaters." Also, with aging, the posterior face of the vitreous humor—the posterior hyaloid—may

separate from the neurosensory retina *(posterior vitreous detachment)*. The relationship between the posterior hyaloid and the neurosensory retina has a key role in the pathogenesis of retinal neovascularization and in some forms of retinal detachment.

RETINAL DETACHMENT

Retinal detachment (separation of the neurosensory retina from the RPE) is broadly classified by etiology based on the presence or absence of a break in the retina. *Rhegmatogenous retinal detachment is associated with a full-thickness retinal defect*. Retinal tears may develop after the vitreous collapses structurally, and the posterior hyaloid exerts traction on points of abnormally strong adhesion to the retinal internal limiting membrane. Liquefied vitreous humor then seeps through the tear and gains access to the potential space between the neurosensory retina and the RPE (Fig. 29-17). Re-attachment of the retina to the RPE generally requires relief of vitreous traction through indenting of the sclera by surgical procedures. This can be accomplished by the application of strips of silicon to the surface of the eye (scleral buckling) and possibly by removal of vitreous material (vitrectomy). Rhegmatogenous retinal detachment may be complicated by *proliferative vitreoretinopathy*, the formation of epiretinal or subretinal membranes by retinal glial cells (Müller cells) or RPE cells.

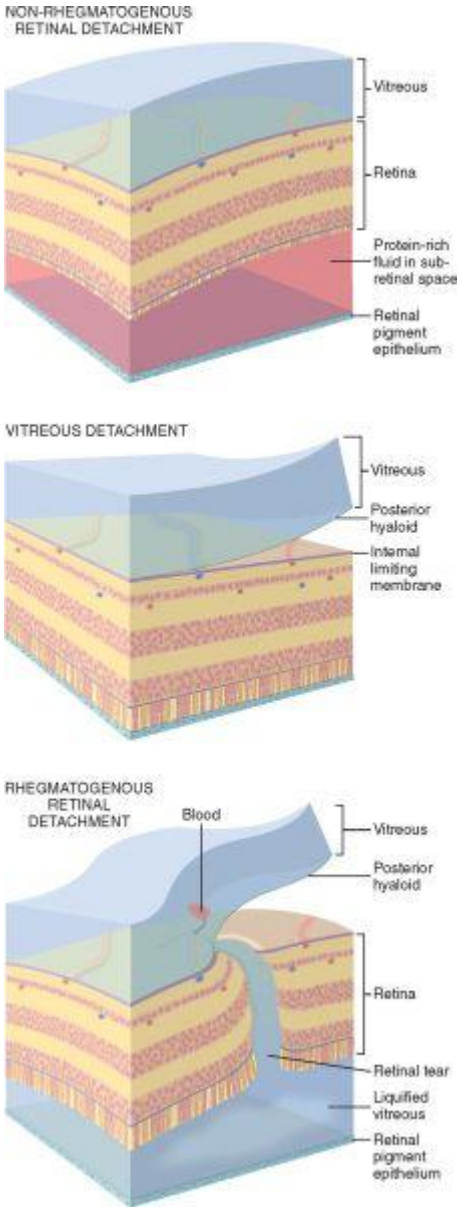

FIGURE 29-17 Retinal detachment is defined as the separation of the neurosensory retina from the RPE. Retinal detachments are classified broadly into non-rhegmatogenous (without a retinal break) and rhegmatogenous (with a retinal break) types. *Top*, In non-rhegmatogenous retinal detachment the subretinal space is filled with protein-rich exudate. Note that the outer segments of the photoreceptors are missing (see Fig. 29-16 for orientation of layers). This indicates a chronic retinal detachment, a finding that can be seen in both non-rhegmatogenous and rhegmatogenous detachments. *Middle*, Posterior vitreous detachment involves the separation of the posterior hyaloid from the internal limiting membrane of the retina and is a normal occurrence in the aging eye. *Bottom*, If, during a posterior vitreous detachment, the posterior hyaloid does not separate cleanly from the internal limiting membrane of the retina, the vitreous humor will exert traction on the retina, which will be torn at this point. Liquefied vitreous humor seeps through the retinal defect, and the retina is separated from the RPE. The photoreceptor outer segments are intact, illustrating an acute detachment.

Non-rhegmatogenous retinal detachment (retinal detach-ment without retinal break) may complicate retinal vascular disorders associated with significant exudation and any condition that damages the RPE and permits fluid to leak from the choroidal circulation under the retina. Retinal detachments associated with choroidal tumors and malignant hypertension are examples of non-rhegmatogenous retinal detachment.

RETINAL VASCULAR DISEASE

Hypertension

Normally, the thin walls of retinal arterioles permit a direct visualization of the circulating blood by ophthalmoscopy. In retinal arteriolosclerosis the thickened arteriolar wall changes the ophthalmic perception of circulating blood: vessels may appear narrowed, and the color of the blood column may change from bright red to copper and to silver depending on the degree of vascular wall thickness (Fig. 29-18A). Retinal arterioles and veins share a common adventitial sheath. Therefore, in pronounced retinal arteriolosclerosis the arteriole may compress the vein at points where both vessels cross (Fig. 29-18B). Venous stasis distal to arteriolar-venous crossing may precipitate occlusions of the retinal vein branches.

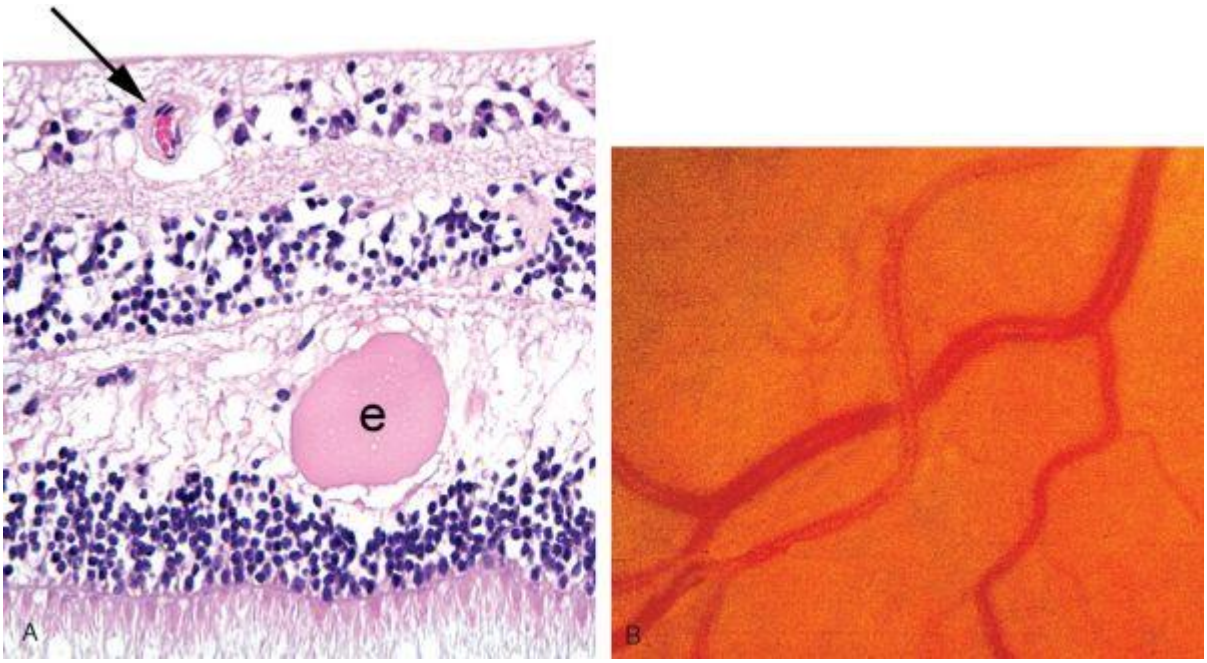

FIGURE 29-18 The retina in hypertension. **A**, The wall of the retinal arteriole *(arrow)* is thick. Note the exudate (e) in the retinal outer plexiform layer. **B**, The fundus in hypertension. The diameter of the arterioles is reduced, and the color of the blood column appears to be less

saturated (copper wire–like). If the wall of the vessel were thicker still, the degree of red color would diminish such that the vessels might appear clinically to have a "silver-wire" appearance. In this fundus photograph, note that the vein is compressed where the sclerotic arteriole crosses over it. ***(B**, Courtesy of Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, IA.)*

In malignant hypertension vessels in the retina and choroid may be damaged. Damage to choroidal vessels may produce focal choroidal infarcts, seen clinically as *Elschnig pearls*. Damage to the choriocapillaris, the internal layer of the choroidal vasculature, may, in turn, damage the overlying RPE and permit the exudate to accumulate in the potential space between the neurosensory retina and the RPE, thereby producing a retinal detachment. Exudate from damaged retinal arterioles typically accumulates in the outer plexiform layer of the retina (see Fig. 29-18A). The ophthalmoscopic finding of a macular star—a spokelike arrangement of exudate in the macula in malignant hypertension—results from exudate accumulating in the outer plexiform layer of the macula that is oriented obliquely instead of perpendicular to the retinal surface.

Occlusion of retinal arterioles may produce infarcts of the nerve fiber layer of the retina (axons of the retinal ganglion cell layer populate the nerve fiber layer). Axoplasmic transport in the nerve fiber layer is interrupted at the point of axonal damage, and accumulation of mitochondria at the swollen ends of damaged axons creates the histologic illusion of cells *(cytoid bodies)*. Collections of cytoid bodies populate the nerve fiber layer infarct, seen ophthalmoscopically as "cotton-wool spots" (Fig. 29-19). Although nerve fiber layer infarcts are described here in the context of hypertension, they may be detected in a variety of retinal occlusive vasculopathies. For example, retinal nerve fiber layer infarcts may develop in individuals with AIDS due to a retinal vasculopathy that is similar to the brain vasculopathy that may develop in this condition.

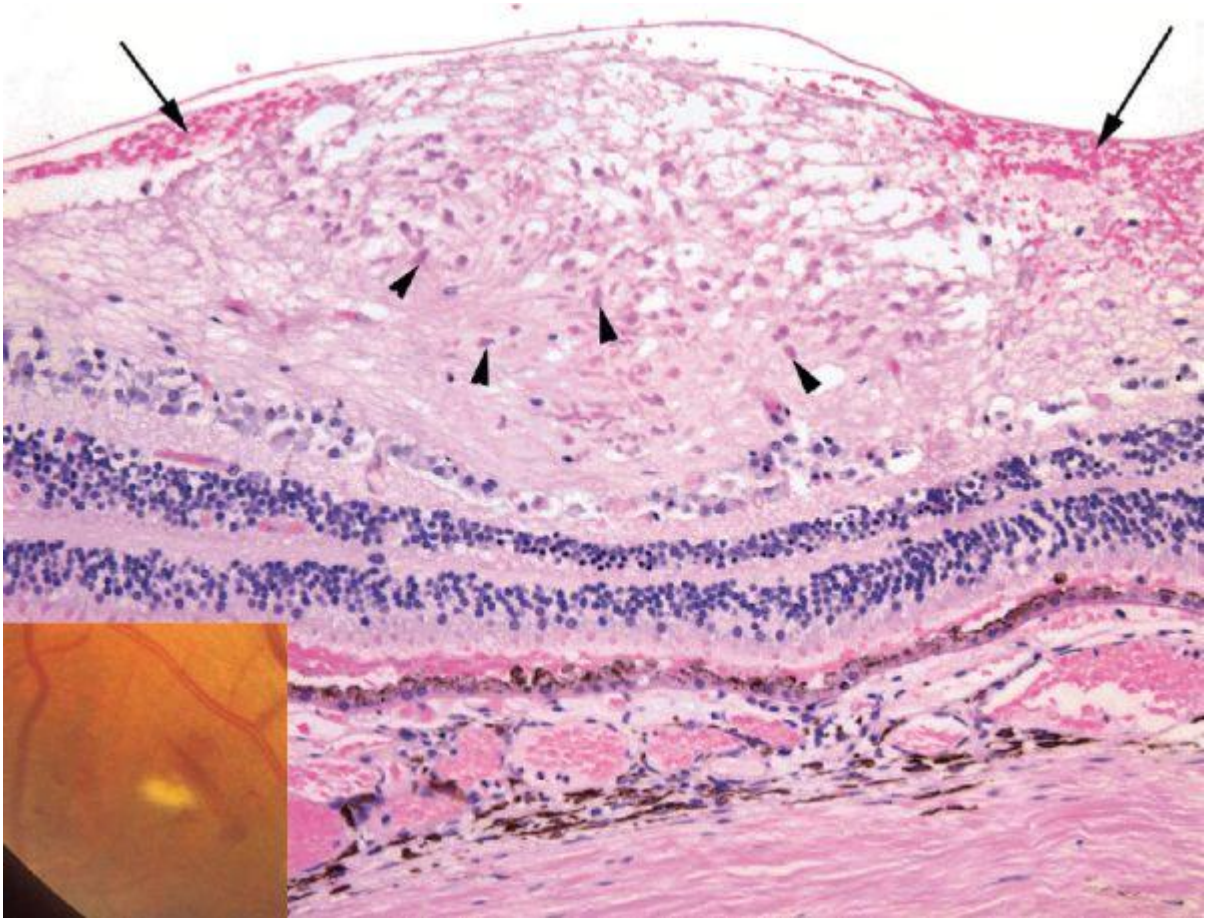

FIGURE 29-19 Nerve fiber layer infarct. A "cotton-wool spot" is illustrated in the *inset*, adjacent to a flame-shaped (nerve fiber layer) hemorrhage. The histology of a cotton-wool spot—an infarct of the nerve fiber layer of the retina—is illustrated in the photomicrograph. A focal swelling of the nerve fiber layer is occupied by numerous red to pink cytoid bodies *(arrowheads)*, bulbous ends of severed axons. Hemorrhage *(arrows)* surrounding the nerve fiber layer infarct as illustrated here is a variable and inconsistent finding. *(Fundus photograph, Courtesy of Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, IA.)*

Diabetes Mellitus

The eye is profoundly affected by diabetes mellitus. The effects of hyperglycemia on the lens and iris have already been mentioned. Thickening of the basement membrane of the epithelium of the pars plicata of the ciliary body is a reliable histologic marker of diabetes mellitus in the eye (Fig. 29-20) and is reminiscent of similar changes in the glomerular mesangium. This discussion focuses on the retinal microangiopathy associated with diabetes mellitus, a prototype for the consideration of other retinal microangiopathies.

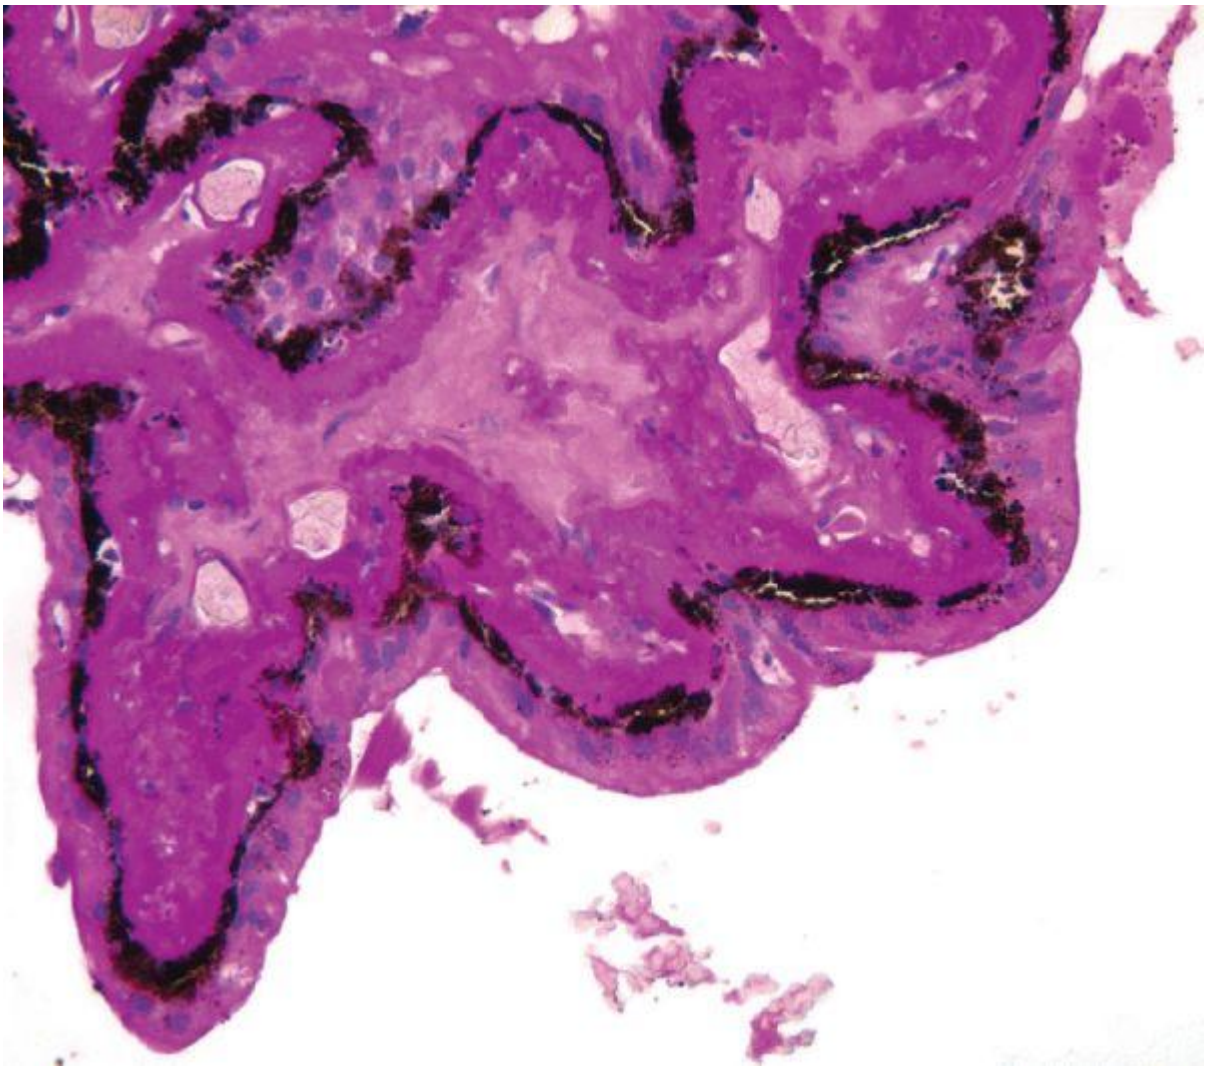

FIGURE 29-20 The ciliary body in chronic diabetes mellitus, PAS stain. Note the massive thickening of the basement membrane of the ciliary body epithelia, reminiscent of changes in the mesangium of the renal glomerulus.

The retinal vasculopathy of diabetes mellitus can be classified into *background (preproliferative) diabetic retinopathy* and *proliferative diabetic retinopathy*.[23]

Background (preproliferative) diabetic retinopathy includes a spectrum of changes ranging from structural and functional abnormalities of angiogenesis located within the retina (i.e., confined beneath the internal limiting membrane of the retina). As with diabetic microangiopathy in general, the *basement membrane of retinal blood vessels is thickened*. In addition, the number of pericytes relative to endothelial cells diminishes. *Microaneurysms* are an important manifestation of diabetic microangiopathy. They are typically smaller than the resolution of direct ophthalmoscopes, and findings customarily described as microaneurysms by ophthalmoscopy may in fact be retinal microhemorrhages. Structural changes in the retinal microcirculation have been associated with a physiologic breakdown in the blood-retinal barrier. Thus, the retinal microcirculation in diabetics may be exceptionally leaky, giving rise to *macular edema*, a common cause of visual loss in these patients. The vascular changes may also produce *exudates* that accumulate in the outer plexiform layer. Although the retinal microcirculation is often hyperpermeable, it is also subject to the effects of micro-occlusion. Both

vascular incompetence and vascular micro-occlusions can be visualized clinically after intravenous injection of fluorescein.

Nonperfusion of the retina due to the microcirculatory change described above is associated with up-regulation of VEGF and retinal angiogenesis.[24] The development of intraretinal angiogenesis—new vessels confined within the retina beneath the internal limiting membrane—can be included with lesions termed *intraretinal microangiopathy*.

Clinically, *proliferative diabetic retinopathy* is defined by the appearance of new vessels that sprout from existing vessels—angiogenic vessels—on the surface of either the optic nerve head, which is termed *neovascularization of the disc*, or the surface of the retina, which is designated by the nebulous term *neovascularization elsewhere*. It is worth emphasizing that the term *retinal neovascularization* is not applied either clinically or pathologically unless the newly formed vessels breach the internal limiting membrane of the retina. The quantity and location of retinal neovascularization guide the ophthalmologist in the treatment of proliferative diabetic retinopathy. The web of newly formed vessels is called a *neovascular membrane* both clinically and histopathologically. It is composed of angiogenic vessels with or without a substantial supportive fibrous or glial stroma (Fig. 29-21).

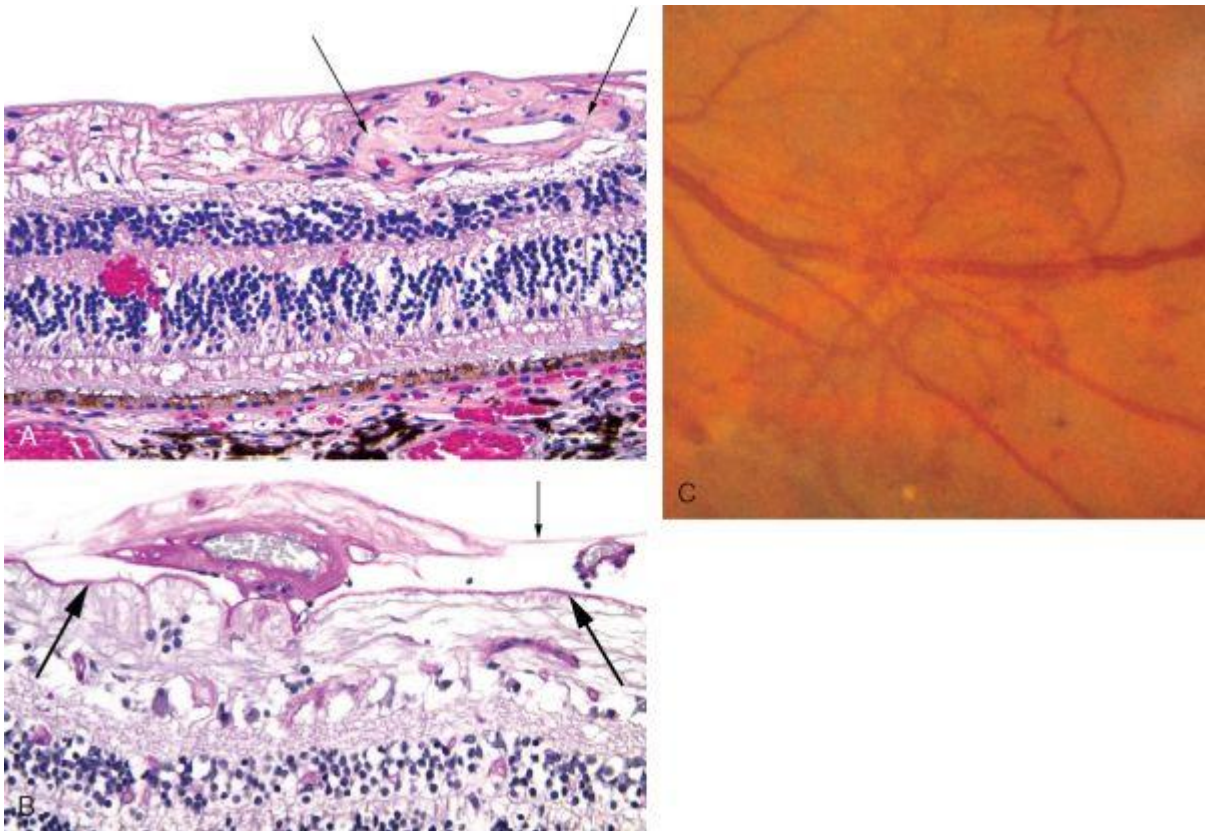

FIGURE 29-21 The retina in diabetes mellitus (see Fig. 29-16 for a schematic of retinal structure). **A**, A tangle of abnormal vessels lies just beneath the internal limiting membrane of the retina on the right half of the photomicrograph *(between arrows)*. This is an example of intraretinal angiogenesis known as intraretinal microangiopathy (IRMA). Note the retinal hemorrhage in the outer plexiform layer in the *left half*. The ganglion cell layer and the nerve fiber layer—the axons of the ganglion cells—are absent. The rarefied space beneath internal limiting membrane to the *left* of the focus of IRMA consists largely of elements of retinal glial (Müller) cells. Absence of the ganglion cell and nerve fiber layers is a hallmark of glaucoma. The chronic diabetes mellitus in this individual was complicated by iris neovascularization and secondary angle-closure glaucoma (neovascular glaucoma). **B**, In this section stained by PAS, the internal limiting membrane is indicated by the *thick arrows* and the posterior hyaloid of the vitreous by the *thin arrow*. In the potential space between these two landmarks, the vessels to the left of the *thin arrow* are invested with a fibrous-glial stroma and would appear ophthalmoscopically as a white neovascular membrane. The thin-walled vessel to the right of the *thin arrow* is not invested with connective tissue. A posterior vitreous detachment in an eye such as this might exert traction on these new vessels and precipitate a massive vitreous hemorrhage. **C**, Ophthalmoscopic view of retinal neovascularization (known clinically as neovascularization "elsewhere" in contrast with neovascularization of the optic disc) creating a

neovascular membrane.

If the vitreous humor has not detached and the posterior hyaloid is intact, neovascular membranes extend along the potential plane between the retinal internal limiting membrane and the posterior hyaloid. Thus, the separation of the vitreous humor from the internal limiting membrane of the retina *(posterior vitreous detachment)* after retinal neovascularization may precipitate massive hemorrhage from the disrupted neovascular membrane. Organization of the retinal neovascular membrane may wrinkle the retina, disrupting the orientation of retinal photoreceptors and producing visual distortion, and may exert traction on the retina, separating it from the RPE (retinal detachment). *Traction retinal detachment* may begin as a non-rhegmatogenous detachment, but severe traction may tear the retina, producing a traction rhegmatogenous detachment.

Retinal neovascularization may be accompanied by the development of a neovascular membrane on the iris surface, presumably secondary to increased levels of VEGF in the aqueous humor.[25] Contraction of the iris neovascular membrane may lead to adhesions between the iris and trabecular meshwork (anterior synechiae), thus occluding a major pathway for aqueous outflow and thereby contributing to elevation of the intra-ocular pressure *(neovascular glaucoma).* Ablating nonperfused retina by laser photocoagulation or cryopexy triggers regression of both retinal and iris neovascularization.

Retinopathy of Prematurity (Retrolental Fibroplasia)

At term, the nasal (medial) aspect of the retina is vascularized, but the temporal (lateral) aspect of the retinal periphery is incompletely vascularized. In premature or low-birth-weight infants treated with oxygen, the immature retinal vessels in the temporal retinal periphery can constrict, rendering the retinal tissue distal to this zone ischemic. Retinal ischemia can result in up-regulation of pro-angiogenic factors such as VEGF and lead to retinal angiogenesis.[26] Contraction of a peripheral retinal neovascular membrane may result in “dragging” of the temporal aspect of the retina toward the temporal peripheral zone such that the macula (situated temporal to the optic nerve) is displaced laterally. With significant contraction the retina can detach.

Sickle Retinopathy, Retinal Vasculitis, Radiation Retinopathy

Retinopathy affecting individuals with sickle hemoglobinopathies (Chapter 14) has been divided into two types that roughly parallel those used for diabetic retinopathy: nonproliferative (intraretinal angiopathic changes) and proliferative (retinal neovascularization). The final common pathway in both types is vascular occlusion.[27] Low oxygen tension within the blood vessels in the retinal periphery results in sickling and red cell deformation causing microvascular occlusions. In the nonproliferative form (which occurs in individuals with SS, and SC hemoglobins), *vascular occlusions* are thought to contribute to preretinal, intraretinal, and subretinal hemorrhages. The resolution of these hemorrhages may give rise to a variety of ophthalmoscopically visible changes, known as *salmon patches, iridescent spots,* and *black sunburst lesions*. Organization of pre-retinal hemorrhage may result in retinal traction and *retinal detachment*. Vascular occlusions may also contribute to angiogenesis secondary to up-regulation of both VEGF and basic fibroblast growth factor.[28] This can give rise to florid zones of retinal neovascularization in the periphery, described clinically as “sea-fans.”

Neovascularization also occurs in a variety of other clinical settings such as peripheral retinal vasculitis, and in irradiation used to treat intra-ocular tumors. The feature common to these conditions is damage to retinal vessels, producing zones of retinal ischemia that drive retinal angiogenesis and its complications, hemorrhage and traction.

Retinal Artery and Vein Occlusions

The central retinal artery or its branches can be occluded by disorders that affect the vessels in general. For example, the lumen of the central retinal artery can be narrowed significantly by atherosclerosis, thus predisposing to thrombosis. Emboli to the central retinal artery can originate from thrombi in the heart or on ulcerated atheromatous plaques in the carotid arteries. Fragments of atherosclerotic plaques can lodge within the retinal circulation *(Hollenhorst plaques)*. Total occlusion of a branch retinal artery can produce a segmental infarct of the retina. With sudden cessation of blood supply, the retina (an embryologic derivative of brain tissue) swells acutely and becomes optically opaque. By ophthalmoscopy the fundus in the affected area appears white instead of red or orange, because the retinal opacity blocks the view of the richly vascular choroid.

Total occlusion of the central retinal artery can produce a *diffuse infarct* of the retina. Following an acute occlusion, the retina appears relatively opaque by ophthalmoscopy. The fovea and foveola are physiologically thin; therefore, the normal orange-red of the choroid is not only visible but highlighted by the surrounding opaque retina—the origin of the *cherry-red spot* of the central retinal artery occlusion. The cherry-red spots seen in rare storage diseases such as *Tay-Sachs* and *Niemann-Pick* diseases also have their basis in the anatomic variations of the macula. The storage material accumulates in retinal ganglion cells: the ganglion cell layer of the macula surrounding the fovea is thick, but there are no ganglion cells in the center of the macula, the fovea. Thus, the fovea is relatively transparent to the underlying choroidal vasculature but is rimmed by relatively opaque retina, the result of storage material accumulating in the perifoveal macular ganglion cells (Fig. 29-22).

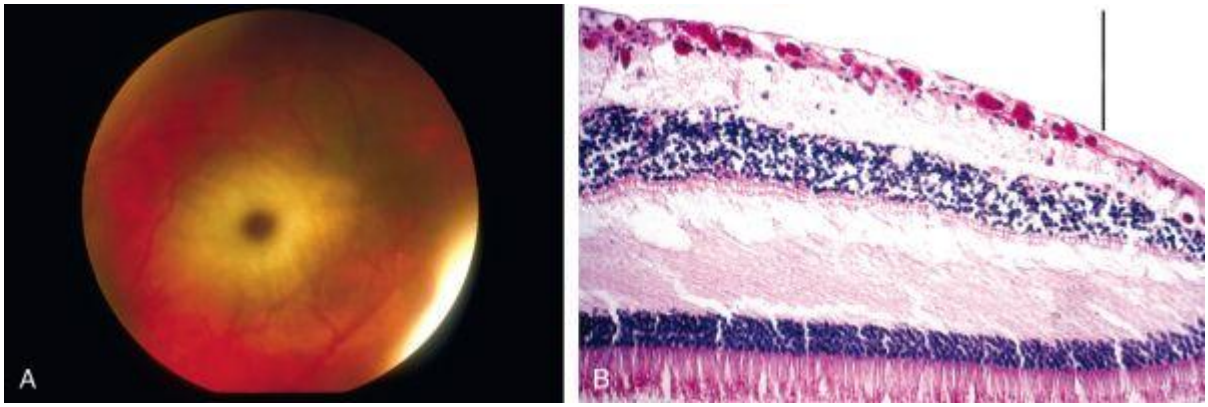

FIGURE 29-22 The cherry-red spot in Tay-Sachs disease. **A**, Fundus photograph of the cherry-red spot in Tay-Sachs disease. **B**, Photomicrograph of the macula in an individual with Tay-Sachs disease, stained with PAS to highlight the accumulation of ganglioside material in the retinal ganglion cells. The presence of ganglion cells filled with gangliosides outside the fovea blocks the transmission of the normal orange-red color of the choroid, but absence of ganglion cells within the fovea (to the right of the *vertical bar*) permits the normal orange-red color to be visualized, accounting for the so-called cherry-red spot. *(**A**, Courtesy of Dr. Thomas A. Weingeist, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, IA; **B**, from the teaching collection of the Armed Forces Institute of Pathology.)*

Retinal arterial occlusions are typically sudden events; therefore, they are not often complicated by prolonged ischemia to allow for up-regulation of pro-angiogenic factors. Hence, retinal arterial occlusions are seldom complicated by either retinal or iris neovascularization.

Retinal vein occlusion may occur with or without ischemia.[29] In ischemic retinal vein occlusion, VEGF and other proangiogenic factors are up-regulated in the retina, leading to neovascularization of the retina

and surface of the optic nerve head as well as neovascularization of the iris and subsequent angle-closure glaucoma.[30] Non-ischemic retinal vein occlusion may be complicated by hemorrhages, exudates, and macular edema but is seldom complicated by retinal or iris neovascularization.

AGE-RELATED MACULAR DEGENERATION

From the name of this disorder, it is clear that advancing age is a risk factor. The cumulative incidence of age-related macular degeneration (ARMD) in individuals 75 years of age and older is 8%, and with increasing longevity ARMD is becoming a major health problem.[31]

Nearly 71% of cases are estimated to be heritable, but the identification of genetic risk factors has not yet contributed to therapeutic strategies that modulate the clinical course.[32] Attention is now focused on the roles of several genes, especially *CFH* (complement factor H) in the pathogenesis of this condition.[33] Individuals with the *CFH* CC genotype who have smoked at least 10 pack-years (i.e., at least 20 cigarettes per day for 10 years) have a 144-fold increase in developing the neovascular form of ARMD than individuals with this genotype who have smoked for fewer than 10 pack-years.[34]

To understand the pathogenesis of ARMD it is important to appreciate the existence of a structural and functional unit composed of the retinal pigment epithelium (RPE), Bruch membrane (which contains the basement membrane of the RPE), and the innermost layer of the choroidal vasculature, the choriocapillaris. Disturbance in any component of this "unit" affects the health of the overlying photoreceptors, producing visual loss.

It is commonplace to describe ARMD as either nonneovascular (atrophic or dry) or neovascular (exudative or wet). Non-neovascular ARMD is identified ophthalmoscopically by diffuse or discrete deposits in the Bruch membrane (drusen) and geographic atrophy of the RPE. Approximately 10% to 20% of individuals with *non-neovascular* ARMD develop choroidal neovascular membranes. Loss of vision is substantially more severe in these individuals.

Choroidal neovascularization is defined by the presence of angiogenic vessels that presumably originate from the choriocapillaris and penetrate through the Bruch membrane beneath the RPE (Fig. 29-23). This neovascular membrane may also penetrate the RPE and become situated directly beneath the neurosensory retina. The vessels in this membrane may leak, and the exuded blood may be organized by RPE cells into macular scars. Occasionally, hemorrhage from these neovascular membranes can be massive, leading to the localized suffusion of blood that may be mistaken clinically for an intra-ocular neoplasm, or may produce diffuse vitreous hemorrhage. Currently the mainstay of treatment for neovascular ARMD is the injection of VEGF antagonists into the vitreous of the affected eye.[35]

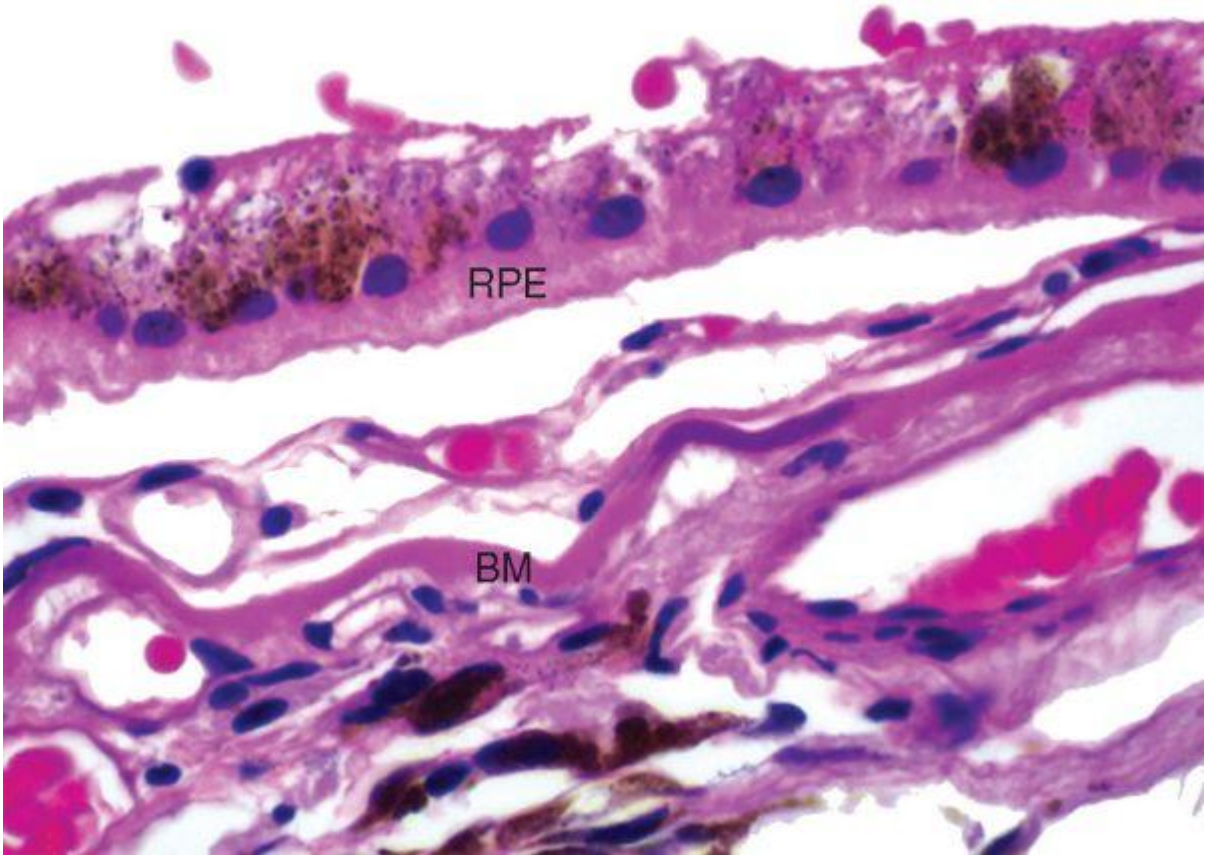

FIGURE 29-23 Age-related macular degeneration. A neovascular membrane is positioned between the RPE and Bruch membrane (BM). Note the blue discoloration of Bruch membrane to the right of the label, indicating focal calcification.

Choroidal neovascular membranes can develop in conditions that are unrelated to age, such as pathologic myopia (Fuchs spot), following traumatic disruption of the Bruch membrane, angioid streaks, or an immunological response to systemic histoplasmosis (presumed ocular histoplasmosis syndrome).

OTHER RETINAL DEGENERATIONS

Retinitis Pigmentosa

The term *"retinitis" pigmentosa* is an unfortunate relic that is used to describe a collection of inherited retinal disorders that were formerly incorrectly presumed to be inflammatory. The conditions that are grouped under the rubric of retinitis pigmentosa are fairly common and have an incidence of 1 in 3600. They may be inherited as X-linked recessive, autosomal recessive, or autosomal dominant (the age of onset correlates with the inheritance pattern, with autosomal dominant retinitis pigmentosa appearing later in life). Retinitis pigmentosa may be part of a syndrome such as *Refsum disease* or may develop in isolation (nonsystemic retinitis pigmentosa).

Retinitis pigmentosa is linked to mutations in genes that regulate the functions of either the photoreceptor cells or the RPE. These include genes that regulate the visual cascade and visual cycle, structural genes (transpanins), transcription factors, retinal catabolic pathways, and mitochondrial metabolism.[36] *Typically, both rods and cones are lost to apoptosis*, though in varying proportions. Loss of rods may lead to early *night blindness* and constricted visual fields. As cones are lost, *central visual acuity* may be affected. Clinically, retinal atrophy is accompanied by constriction of retinal vessels and

optic nerve head atrophy (“waxy pallor” of the optic disk) and the accumulation of retinal pigment around blood vessels, thus accounting for the “pigmentosa” in the disease's name. The electroretinogram reveals abnormalities characteristic of this disease.

RETINITIS

A variety of pathogens can contribute to the development of infectious retinitis. For example, *Candida* may disseminate to the retina hematogenously, especially in the setting of intravenous drug abuse or in systemic candidemia from other causes. Hematogenous dissemination of pathogens to the retina typically results in multiple retinal abscesses. As was mentioned previously, cytomegalovirus retinitis is an important cause of visual morbidity in immunocompromised individuals, especially those with AIDS.

RETINAL NEOPLASMS

Retinoblastoma

Retinoblastoma is the most common primary intra-ocular malignancy of children. The molecular genetics of retinoblastoma has been discussed in detail (Chapter 7). Although the name *retinoblastoma* might suggest origin from a primitive retinal cell that is capable of differentiation into both glial and neuronal cells, it is now clear that the cell of origin of retinoblastoma is neuronal. Recall that in approximately 40% of cases, retinoblastoma occurs in individuals who inherit a germline mutation of one *RB* allele. Retinoblastomas arising in the context of germline mutations not only may be bilateral but also may be associated with pinealoblastoma (“trilateral” retinoblastoma), which is associated with a dismal outcome.[37]

Morphology. The pathology of retinoblastoma, both hereditary and sporadic types, is identical. Tumors may contain both undifferentiated and differentiated elements. The former appear as collections of small, round cells with hyperchromatic nuclei. In well-differentiated tumors there are FlexnerWintersteiner rosettes and fleurettes reflecting photoreceptor differentiation. It should be noted, however, that the degree of tumor differentiation does not appear to be associated with the prognosis. As seen in Figure 29-24 , viable tumor cells are found encircling tumor blood vessels with zones of necrosis typically found in relatively avascular areas, illustrating the dependence of retinoblastoma on its blood supply. Focal zones of dystrophic calcification are characteristic of retinoblastoma.

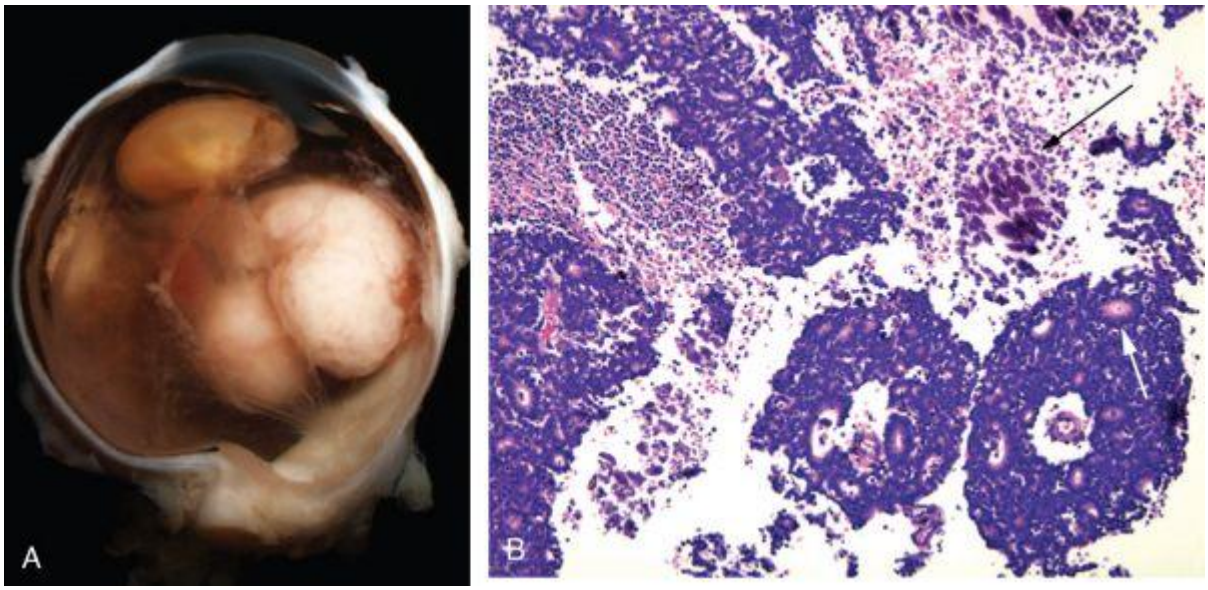

FIGURE 29-24 Retinoblastoma. **A**, Gross photograph of retinoblastoma. **B**, Tumor cells appear viable when in proximity to blood vessels, but necrosis is seen as the distance from the vessel increases. Dystrophic calcification *(dark arrow)* is present in the zones of tumor necrosis. Flexner-Wintersteiner rosettes—arrangements of a single layer of tumor cells around an apparent "lumen"—are seen throughout the tumor, and one such rosette is indicated by the *white arrow*.

In an effort to preserve vision and eradicate the tumor, many ophthalmic oncologists now attempt to reduce tumor burden by administration of chemotherapy; after chemoreduction, tumors may be obliterated by laser treatment or cryopexy. Retinoblastoma tends to spread to the brain and bone marrow and seldom disseminates to the lungs. Prognosis is adversely affected by extra-ocular extension and invasion along the optic nerve, and by choroidal invasion. A variant of retinoblastoma—retinocytoma or retinoma—has been reported and appears to be a pre-malignant lesion.[38] The appearance of retinoblastoma in one eye and retinocytoma in the other eye is characteristic of heritable retinoblastoma.

Retinal Lymphoma

Primary retinal lymphoma is analogous to primary large-cell lymphoma of the brain; therefore, it involves the two retinal layers derived from brain: the neurosensory retina and the RPE. The underlying choroid is typically filled with a cytologically benign lymphoid infiltrate. Primary intra-ocular lymphoma tends to occur in older individuals and may mimic uveitis clinically. The diagnosis depends on a demonstration of lymphoma cells in vitreous aspirates.[39]

3.19.9 Optic Nerve

As a sensory tract of the central nervous system, the optic nerve is surrounded by meninges, and cerebrospinal fluid circulates around the nerve. The pathology of the optic nerve is similar to the pathology of the brain. For example, the most common primary neoplasms of the optic nerve are glioma (typically *pilocytic astrocytomas*) and meningioma.

ANTERIOR ISCHEMIC OPTIC NEUROPATHY

There are striking similarities between stroke and a condition known in ophthalmic terminology as *anterior ischemic optic neuropathy* (AION).[40] As used clinically, the term *AION* includes a spectrum of injuries to the optic nerve varying from ischemia to infarction. Thus, transient partial interruptions in blood flow to the optic nerve can produce episodes of transient loss of vision, whereas total interruption in blood flow can produce an optic nerve infarct, either segmental or total. Zones of relative ischemia may surround segmental infarcts of the optic nerve. Optic nerve function in these poorly perfused but not infarcted zones may recover. The optic nerve does not regenerate, and visual loss from infarction is permanent.

Interruption in the blood supply to the optic nerve can result from inflammation of the vessels that supply the optic nerve, known as *arteritic AION*, or from embolic or thrombotic events, known as *non-arteritic AION*. Bilateral total infarcts of the optic nerve resulting in total blindness have been reported in temporal arteritis (arteritic AION), adding urgency to the treatment of this condition with high doses of corticosteroids.

PAPILLEDEMA

Edema of the head of the optic nerve may develop as a consequence of compression of the nerve (as in a primary neoplasm of the optic nerve) or from elevations of cerebrospinal fluid pressure surrounding the nerve. The concentric increase in pressure encircling the nerve contributes to venous stasis both at the nerve head and in axoplasmic transport, leading to nerve head swelling. Swelling of the optic nerve head in elevated intra-cranial pressure is typically bilateral (unless the affected individual has experienced previous unilateral optic atrophy) and is commonly termed *papilledema*. Typically, acute papilledema from increased intra-cranial pressure is not associated with visual loss. Ophthalmoscopically, the optic nerve head is swollen and hyperemic; by contrast, the optic nerve head in the relatively acute phases of anterior ischemic optic neuropathy appears swollen and pale because of decreased nerve perfusion (Fig. 29-25). In papilledema secondary to increased intra-cranial pressure, the optic nerve may remain congested for a prolonged period of time.

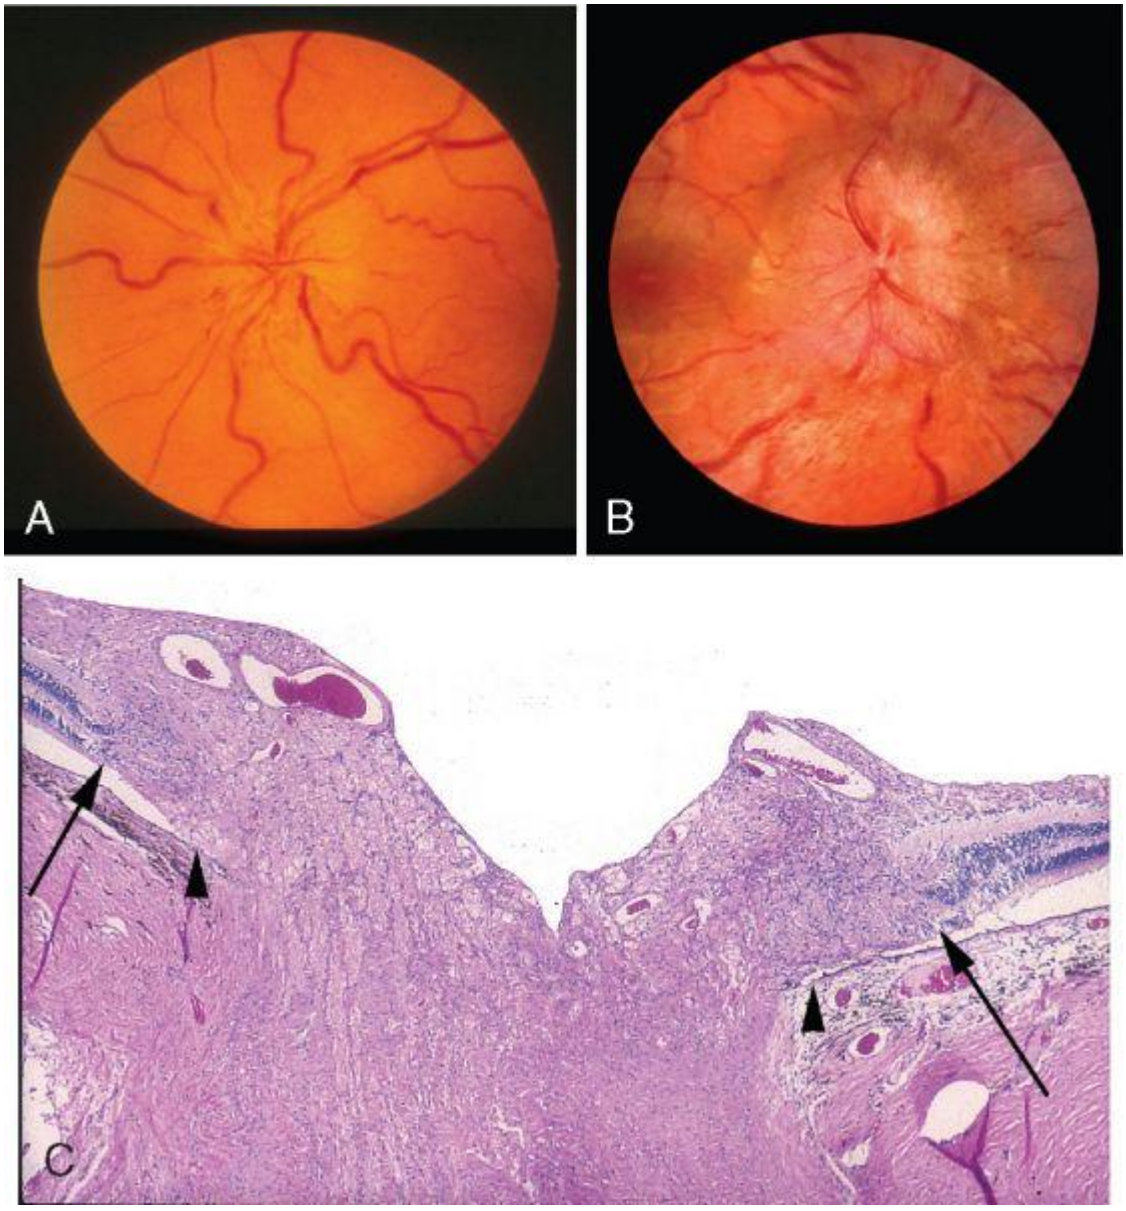

FIGURE 29-25 The optic nerve in anterior ischemic optic neuropathy (AION) and papilledema. **A**, In the acute phases of AION the optic nerve may be swollen, but it is relatively pale because of decreased perfusion. **B**, In papilledema secondary to increased intra-cranial pressure, the optic nerve is typically swollen and hyperemic. **C**, Normally, the termination of Bruch membrane *(arrowhead)* is aligned with the beginning of the neurosensory retina, as indicated by the presence of stratified nuclei *(arrow)*, but in papilledema the optic nerve is swollen, and the retina is displaced laterally. This is the histologic explanation for the blurred margins of the optic nerve head seen clinically in this

condition. *(**A** and **B**, Courtesy of Dr. Sohan S. Hayreh, Department of Ophthalmology and Visual Science, University of Iowa, Iowa City, IA; **C**, from the teaching collection of the Armed Forces Institute of Pathology.)*

GLAUCOMATOUS OPTIC NERVE DAMAGE

As discussed already, the majority of individuals with glaucoma have elevated intra-ocular pressure. However, there is a small group that develops the visual field and optic nerve changes typical of glaucoma with normal intra-ocular pressure: so-called *normal-tension glaucoma*. Interestingly, mutations in the optineurin gene are seen in individuals with normal-tension glaucoma but are not seen in individuals with primary open-angle glaucoma, in which pressure is elevated chronically.[41] Conversely, some individuals with elevated intra-ocular pressure who are followed over long periods of time never develop visual field changes or optic nerve cupping. Therefore, it is clear that whatever the mechanism of damage to the retinal ganglion cell—the axons of which populate the optic nerve—there is a spectrum of neuronal susceptibility to the effects of elevated intra-ocular pressure. Therefore, considerable research is now directed toward understanding mechanisms by which the optic nerve axons may be protected from injury.[42]

Morphology. Characteristically, there is a diffuse loss of ganglion cells and thinning of the retinal nerve fiber layer (Fig. 29-26), which can be measured by optical coherence tomography. In advanced cases, the optic nerve is both cupped and atrophic, a combination unique to glaucoma. Elevated intra-ocular pressure in infants and children can lead to diffuse enlargement of the eye **(buphthalmos)** or enlargement of the cornea **(megalocornea)**. Several mutations have been associated with the development of infantile glaucoma, but the mechanisms by which these genes produce glaucoma is unclear. After the eye reaches its adult size, prolonged elevation of intra-ocular pressure can lead to focal thinning of the sclera, and uveal tissue may line ectatic sclera **(staphyloma)**.

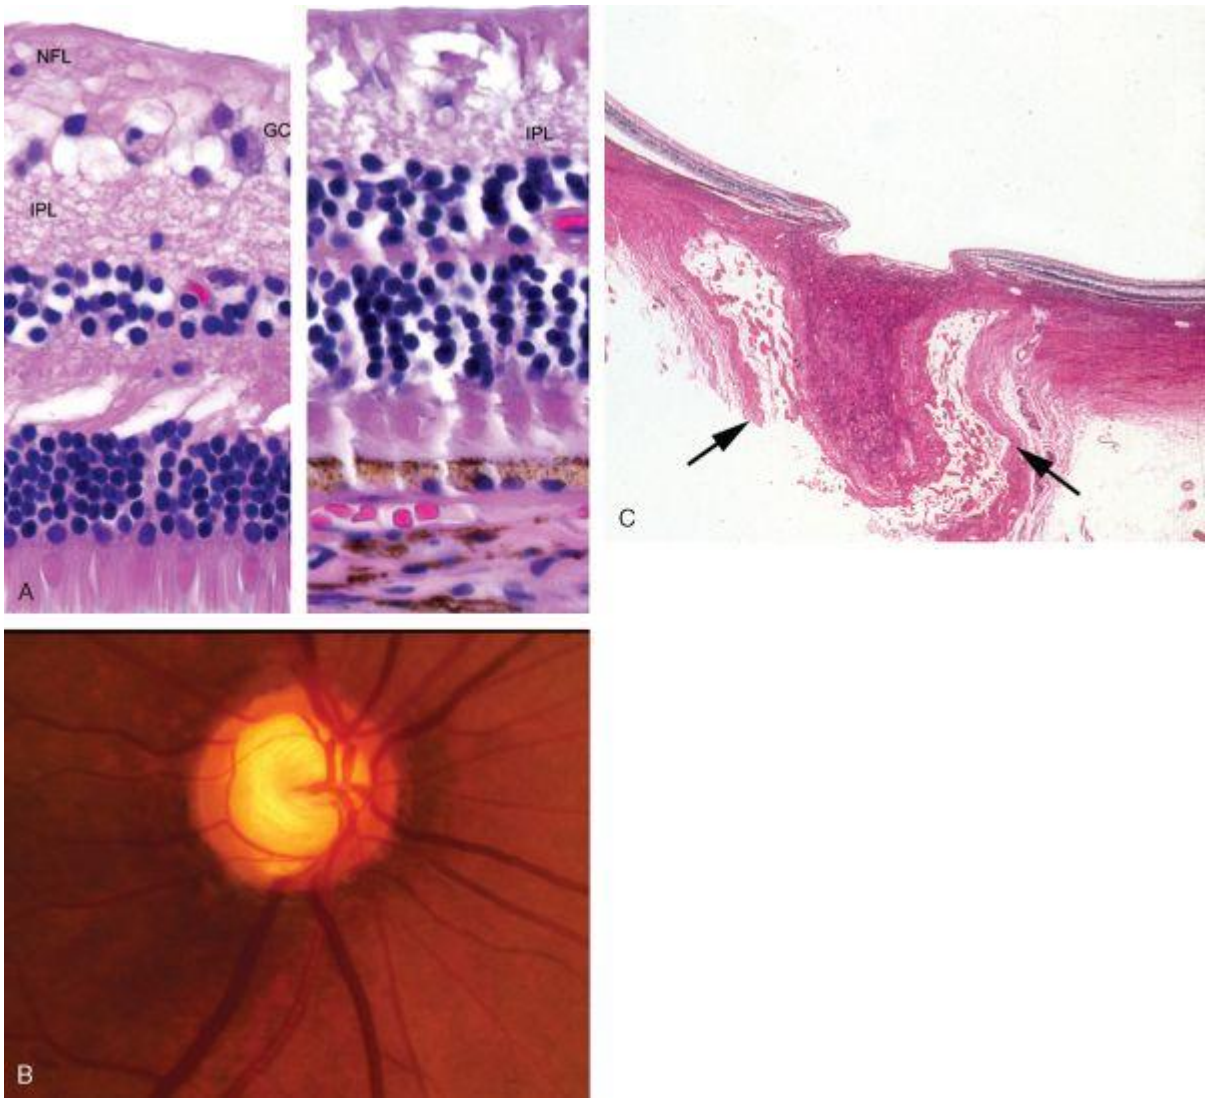

FIGURE 29-26 The retina and optic nerve in glaucoma. **A**, *Left panel*, normal retina; *right panel*, the retina in long-standing glaucoma (same magnification). The full thickness of the glaucomatous retina is captured *(right)*, a reflection of the thinning of the retina in glaucoma. In the glaucomatous retina, the areas corresponding to the nerve fiber layer (NFL) and ganglion cell layer (GC) are atrophic; the inner plexiform layer (IPL) is labeled for reference. Note also that the outer nuclear layer of the glaucomatous retina is aligned with the inner nuclear layer of the normal retina due to the thinning of the retina in glaucoma. See Figure 29-16 for orientation. **B**, Glaucomatous optic nerve cupping results in part from loss of retinal ganglion cells, the axons of which populate the optic nerve. **C**, The *arrows* point to the dura of the optic nerve. Notice the wide subdural space, a result of atrophy of the optic nerve. There is a striking degree of cupping on the surface of the nerve as a consequence of long-standing glaucoma.

OTHER OPTIC NEUROPATHIES

Optic neuropathy may be inherited (as in Leber hereditary optic neuropathy) or may be secondary to nutritional deficiencies (as in so-called tobacco-alcohol amblyopia) or toxins such as methanol. Individuals may experience a severe visual disability if fibers in the optic nerve degenerate, especially if the central visual acuity is lost as a result of degeneration of the nerve fibers that originate from the macula.

The predilection for Leber hereditary optic neuropathy to develop in young men is explained by inheritance of mitochondrial gene mutations (Chapter 5). It is possible that these mutations provide for

a genetic susceptibility to a variety of environmental exposures that constitute the final trigger for optic nerve degeneration.[43] Since neuronal health is dependent on axoplasmic transport of mitochondria, mitochondrial dysfunctions give rise to neurologic disorders including optic neuropathy.[44]

OPTIC NEURITIS

Many unrelated conditions have historically been grouped under the heading of optic neuritis. Unfortunately, the term itself suggests optic nerve inflammation, which might not accurately describe the pathophysiologic changes. In common clinical usage the term *optic neuritis* is used to describe a loss of vision secondary to demyelinization of the optic nerve. One of the most important causes of optic neuritis is multiple sclerosis (Chapter 28). Indeed, optic neuritis may be the first manifestation of this disease. The 10-year risk of developing multiple sclerosis after the first attack of optic neuritis increases if the affected person has concomitant evidence of brain lesions as detected by magnetic resonance imaging. However, even when brain lesions are detectable, the risk of progression to multiple sclerosis is only 40%.[45] Individuals with a single episode of optic nerve demyelinization may recover vision and remain disease free.

3.19.10 The End-Stage Eye: Phthisis Bulbi

Trauma, intra-ocular inflammation, chronic retinal detachment, and many other conditions can give rise to an eye that is both small (atrophic) and internally disorganized: *phthisis bulbi*. Congenitally small eyes—hypoplastic or *microphthalmic* eyes—are generally not disorganized internally. Phthisical eyes typically feature the following changes: the presence of exudate or blood between the ciliary body and sclera and the choroid and sclera *(ciliochoroidal effusion)*; the presence of a membrane extending across the eye from one aspect of the ciliary body to the other *(cyclitic membrane)*; chronic retinal detachment; optic nerve atrophy; the presence of intra-ocular bone, which is thought by many to originate from *osseous metaplasia* of the RPE; and a thickened sclera, especially posteriorly. Ciliochoroidal effusion is typically associated with the physiologic state of low intra-ocular pressure *(hypotony)*. The normal pull of the extra-ocular muscles on a hypotonous eye may render the appearance of the eye as square rather than round.
